Preface

This textbook aims to review the current state of biological psychiatry, a field that has expanded tremendously over the past few decades. The book is aimed at clinical, postgraduate and research audiences, within psychiatry, neurology, psychopharmacology, and psychology.

After a few introductory chapters dealing with conceptual and measurement issues in biological psychiatry, the first part of the book deals with basic principles relating to animal models, transmitter systems (aminergic, amino acid, peptidergic), neuroendocrinology, neuroimmunology, psychophysiology, neuropsychology, brain imaging, neurogenetics, gene-environment interactions, and gender issues. These chapters are intended to provide the necessary basic information that would enable the reader unfamiliar with each of the fields addressed to understand the later chapters applying this knowledge to specific psychiatric disorders.

Although it has frequently been argued that the diagnostic categories of the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders — IVth edition (DSM-IV) are not immediately relevant to biological psychiatric insights, we have used the DSM-IV classification as an organizing principle, for didactic reasons.

Thus, the second part deals with most of the major diagnostic categories of DSM-IV: cognitive disorders, substance-related disorders, schizophrenia, mood disorders, anxiety disorders, somatoform disorders, dissociative disorders, sexual and gender identity disorders, eating disorders, sleep disorders, impulse control disorders, and personality disorders.

With the exception of four comprehensive chapters on "the psychobiology of" somatoform disorders, dissociative disorders, sexual and gender identity disorders, and impulse control disorders, all other sections (cognitive disorders, substance-related disorders. . . .) aim to recapitulate each of the topics introduced in part 1 of the book, as well as including for each disorder, a chapter on the current therapeutic armamentarium.

Although the editors are European, authors from all over the world, indeed from almost all continents, have participated in this endeavour. In editing the book, we have tried as much as possible to avoid overlap between chapters, but the autonomy of each chapter had precedence. Nevertheless, we have found the contributing authors extremely receptive to our editorial suggestions, and take the opportunity to acknowledge their collaboration.

It has also been a real pleasure working with the staff from Wiley, who from the beginning has supported this undertaking. More particularly so, the cooperation with Charlotte Brabants and her assistant Layla Paggetti has been fruitful, encouraging, stimulating and exceptionally pleasant.

Everyday, new biological psychiatric insights in psychopathological disorders are to be found in the professional literature. It is inherent to the requirements of a book such as this, for some time to elapse between the delivery of a manuscript and the publication of the book. All those concerned have made a great effort to limit this interval as much as reasonably possible.

The editors express the hope that the information gathered in this book will provide a basic reference source upon which further knowledge can be built.

Part A

BASIC PRINCIPLES

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

I

Conceptual Issues

German E. Berrios and Ivana S. Marková

Born as a by-product of the nineteenth-century movement to organize society on a scientific basis, psychiatry was charged with the construction and enactment of normative views of madness. (Literature on social and clinical history of psychiatry is large; for scholarly papers on both, see the journal *History of Psychiatry* (started 1990).) Under the protection of medicine and the economic practices following the Industrial Revolution, psychiatrists developed representations of mental disease together with the professional and institutional apparatus to enjoin them.[1] Since its construction, the modalities of psychiatry have been many. For example, there is the group called biological psychiatry,[2] organic psychiatry, neuropsychiatry and behavioural neurology, which seem to share the foundational claims (FCcs) that: (1) mental disorder is a disorder of the brain; (2) reasons are not good enough as causes of mental disorder; and (3) biological psychiatry and its congeners have the patrimony of scientific truth. These four congeners are man-made and there is nothing in nature to suggest real differences between them; indeed, any differences that might be suggested are bound to be historical in origin. To avoid confusion, the term 'biological psychiatry' will be used in this chapter as a proxy for the other three congeners. Since the seventeenth century, versions of what might be called biological psychiatry have come in and out of fashion;[3] the reasons for these cycles are unclear.[4]

FOUNDATIONAL CLAIMS AND THE 'TECHNOLOGY ALIBI'

FCs are unproven and unprovable propositions used to start off the narrative of science. Chosen by 'experts', FCs escape audit and are unchallengeable. The view that mental disorders are 'caused' by changes in the physical conformation of the brain is a typical foundational claim; that 'reasons' cannot constitute efficient causes for the generation of mental disorder is another.

Since the nineteenth century, and every time it has failed to deliver, biological psychiatry has used the excuse that ongoing technologies are not sensitive enough to identify the organic causes of all mental disorders and reassured the expecting public that future techniques will do so: we call this the 'technology alibi'.

Foundational Claim 1: Mental Disorders as Brain Disorders

Meanings for this FC range from the broad assertion that all psychological activity must have brain representation to the narrow assertion that specific brain lesion *l* is a necessary and sufficient cause for presence of specific mental disorder *m* (more on this later). Similar claims were made during the middle of the seventeenth century, e.g. by Thomas Willis in 1685 (see Vinchon and Vie, 1928).[5]

The claims that the body (brain) houses the human soul (or mind) and that changes (lesions) in the conformation or constitution of the body (brain) cause mental disorder (i.e. FC 1) are historically independent, and their relationship is asymmetrical; indeed, the

[1] A representation is an image, model, view, concept or other definitional form that helps someone to think of something. Control includes social practices, such as therapy, prophylaxis, support, management, rehabilitation, policing, punishment, incarceration and the death penalty. A social practice is a rule-governed form of social behaviour that runs on habit, is passed from generation to generation, and contributes to the stability of society; the stability of the concept has been questioned (Turner, 1994).

[2] At this stage, a clarification needs to be made. In this chapter, we distinguish clearly between (1) biological psychiatry as a methodology and research *doctrine* and (2) the *clinical* practice of those who call themselves 'biological psychiatrists'. This is because it is highly likely that they will, like non-biological psychiatrists, talk, understand, support, counsel, and resort to whatever psychological therapies are needed to help their patients. This chapter is entirely about the limitations affecting the *doctrine* and *methodology* of biological psychiatry. Indeed, given its narrowness, we believe that it would be very difficult, even for rigid biological psychiatrists, to guide their clinical practice by doctrine alone. On the other hand, it would be wrong to invoke the flexibility and variety of approaches that biological psychiatrists have to use in their clinical practice as *evidence* that the *doctrine* itself is flexible and comprehensive, for it is not. For earlier work from our group on the methodology of biological psychiatry, see Berrios, 1995; Berrios and Dening, 1990.

[3] Neither cross-culturally nor trans-historically can biological psychiatry be considered as a *unitary* activity: according to social and economic need, different types and practices predominate in different contexts. For example, biological psychiatry during the second half of the nineteenth century was characterized by very specific definitions of disease, internecine disputes concerning the professionalization of neurologists and alienists, an increasing use of the light microscope, and early studies of brain chemistry. Differences were, on occasions, exaggerated by international rivalries and jingoism; for example, this is the case during and after both the Franco-Prussian War, and the Great War, when even writers like Chaslin and Kraepelin made silly remarks about 'enemy' countries. (On the history of biological psychiatry, see Berrios and Marková, 2002a.)

[4] An interesting issue here concerns the relationship between the historical versions of biological psychiatry. Are they manifestations of an ongoing idea existing *sub specie aeternitatis*? Is their similarity skin deep and not worth bothering about? When Thomas Willis stated that mental illness is a 'disorder of the brain', was he being a precursor of similar current claims?

[5] These claims are intelligible to us only because they were made within the new epistemological frame (dualism) created by Descartes. Similar-sounding claims made in earlier periods (e.g. by Galen) are much harder to understand. In pre-Cartesian times, explaining the *existence* of a form of behaviour (e.g. madness) in terms of a *link* to the soma (whether heart, hypochondrium or brain) made little sense because there was no differentiation between anatomy and function in the way that we understand it today. In this sense, it is anachronistic to believe that the history of biological psychiatry starts with the Greeks. Indeed, current concepts, meanings and categories in psychiatry were constructed during the nineteenth century (see Berrios, 1996).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

belief that brain disease causes mind disease is not logically dependent on the belief that the mind resides in the brain (because the former could be plausibly held without the second being true).[6]

The claim that the body (brain) must house the human soul (or mind) follows from the materialist assumption that at the time the world came into being, there was only matter (Lange, 1957). Thinkers of this persuasion need to explain, however, where 'mind phenomena' come from, particularly if a highly configured model of the latter is entertained. Materialist thinkers make use of two types of matter: *Plain* matter is constituted by homogeneous units of analysis (atoms, fields, strings) and cannot explain mind configurations; these then are assumed to come from outside (cultural context). *Baroque* matter may be constituted by atoms of different shapes and sizes moving at different rates, or may include dynamic and hidden qualities (Cappelletti, 1979). For example, Cabanis (1802) (although overtly a materialist) held a baroque view of matter and hence was able to account for complex aspects of the mind without resorting to any external agencies.

Foundational Claim 2: Causes and Reasons

Causes and reasons are forms of accounting for the existence and/or origin of objects, tokens, episodes, processes and behaviours. Although etymologically different, they have overlapping semantic fields (i.e. are used as synonyms) and similar epistemic power (capacity to explain actions). Causes are used in the natural sciences; reasons are used in the social sciences (which, in the past, included psychology). What about psychiatry?[7]

Causes

What we have said above suggests that to ask for the cause of a mental disorder is already to opt for a particular model of explanation (Berrios, 2000a), as equally cogent would be to ask for a reason, based on the view that people may do things, including 'talking and behaving crazy', for reasons better known to themselves. Reason in this sense needs not be construed in material or mechanical terms but may remain expressed in the language of folk psychology. Even more radically, it could be said that mental disorders are not *effects* at all, that they do not follow either causes or reasons, and that they are just 'givens', i.e. they have been there from the beginning of time. In a world keen on looking for the causes of all things, this latter view may sound strange, but it is not unintelligible and it simply reflects the ontology of preformationism, a view of biology predominant in the eighteenth century.

It could be argued that reasons are just a subtype of cause. This claim muddles the issue further. It is true that the Latin *causa* meant reason, motive, inducement, but it also meant occasion and opportunity. It translated the Greek *aitia* and *aition* (stems of the medical term aetiology), which meant origin and ground but also the occasion of something bad. In practical terms, cause has been used mostly as a *relational* concept, i.e. as one without which another thing (effect) cannot be. Based on his own model of the Universe, Aristotle (1991; p. 1600) defined it thus:

> We call a cause (1) that from which (as immanent material) a thing comes into being, e.g. the bronze of the statue and the silver of the saucer, and the classes which include these. (2) The form or pattern, i.e. the formula of the essence, and the classes which include this (e.g. the ratio 2 : 1 and numbers in general are causes of the octave) and the parts of the formula. (3) That from which the change or the freedom from change first begins, e.g. the man who has deliberated is a cause, and the father a cause of the child, and in general the maker a cause of the thing made and the change-producing of the change. (4) The end, i.e. that for the sake of which a thing is, e.g. health is the cause of walking. For why does one walk? We say 'in order that one may be healthy', and in speaking thus we think we have given the cause. The same is true of all the means that intervene before the end, when something else has put the process in motion (as e.g. thinning or purging or drugs or instruments intervene before health is reached); for all these are for the sake of the end, though they differ from one another in that some are instruments and others are actions ...

Of the four Aristotelian types of cause (material, formal, efficient and final), only the efficient one has survived in our day.[8] In the first half of the seventeenth century, Galileo interpreted efficient as resulting from general physical laws. During the second half of that century, Newton redefined cause in terms of a physical metaphor ('collision between two objects, such as billiard balls') (Doney, 1968). This made the concept of cause quantifiable, predicting and reversible but excluded human agency and rendered it soulless.[9] In spite of Hume's opposition to the Newtonian model of cause, the nineteenth century accepted the Newtonian view and soon enough this was incorporated into medicine and alienism.

Since the time of Georget (1820), biological psychiatry has hung on to the thin hope that the demonstration of a brain lesion in a patient with mental illness may be sufficient to generate a cause–effect inference that can be applied to all. During the nineteenth century, the existence of such a link was liberally assumed; for example, post-mortem lesions were considered, *simpliciter*, to be the cause of a disease, irrespective of the nature and age of the lesion and of the period in the patient's life when the disease occurred; that is, the need for contemporaneity was not acknowledged. In current biological psychiatry, this principle of guilty by association is still present. It is unclear what type of contemporaneity is required by the ascertainment of reasons (e.g. discursive accounts of behaviour) and of causes (e.g. statistical correlation) (for the latter, see p. 18).

Reasons

Although in common parlance it is accepted widely that reasons provide adequate accounts for a range of human behaviours, the semantic engine that makes these explanations possible is unclear. Cicero used *ratio* to translate the Greek for account,

[6] For example, at the beginning of the nineteenth century there was a debate as to whether the mind or soul was located in the cerebrospinal fluid or the cortex (Hagner, 1992). Likewise, the view was popular in the same century that because the soul (mind) was a marker of the divine, it could become neither divided or diseased. Its putative location on the cortex also caused difficulties in regard to its functional (or phrenological) parcelling (e.g. Jackson; see p. 8). The issue of whether organs other than the brain might contribute to the formatting of the mind and its diseases was discussed up to the nineteenth century; prime candidates remained the heart (Willis, 1685), hypochondrium (Whytt, 1768) and stomach (Broussais, 1828).

[7] Biological psychiatry has not yet taken on board the importance of the distinction between reasons and causes. This may be due to the fact that explaining human action or symptoms by means of reasons does not fit into the rather crude mechanistic and deterministic frame of neurobiology.

[8] From Greek times, the concept of cause has been used to refer to both aspects of human agency (as per Aristotle) and the belief that effects result from the action of universal laws (as per Plato) (Berrios, 2000a).

[9] This came back to haunt the studies of man during the nineteenth and twentieth centuries when the human sciences tried to ape the natural sciences and abandoned hermeneutics. Without a machinery to deal with meaning, reasons, subjectivity, and the understanding of the individual, the human sciences (and psychiatry with them) became vacuous. The Freudian movement attempted unsuccessfully to provide nineteenth-century psychiatry with a semantic model.

calculations, etc., and soon enough, it also translated the Greek for cognition, thinking, discourse, understanding, etc. This combination of meanings has plagued the term ever since. In most European vernacular languages, reason refers to the *illative* rather than the creative or imaginative aspects of the intellect. Since ancient times, reasons have been used to justify actions (*post facto*) or explain their origin. To say that I did x because of y remains a good way of accounting for my behaviour as long as: (1) there is a cultural or semantic frame within which y mostly leads to x; and (2) there is no reason to believe that I am cheating.

To some, however, accounts of behaviour by means of reasons are considered as after the event and hence do not constitute proper causal accounts. Two factors (*inter alia*) can explain this disenfranchisement: (1) causality is currently understood in terms of general laws (not idiosyncratic explanations); and (2) the neurobiology of reasons remains obscure, and hence there is no material or organic handle with which to convert reasons into real physical causes. There is also the question of whether reasons (as it is mostly believed in medicine, jurisprudence and moral theory) entail intentionality[10] and conscious awareness; in other words, whether in order for person P to claim that he had reason x for behaviour y, he must have been aware *pre facto* of x and then taken a decision that y is the best course of action. This view is considered by others as narrow; for example, according to psychoanalysis, it would be sensical to claim that John gives so many presents to Mary because he is in love with her although he is not aware of it (and also sensical for John to say likewise *post facto* as an explanation for his generous behaviour).

The application of the language of reasons to psychopathology makes things complex. However, a claim by a clinician that a patient has a reason to report 'I am hearing voices when there is no one around' should not be dismissed *tout court*: at a superficial level, it may mean that the patient is believed to be 'entertaining an image' (i.e. experiencing something in terms of the old, passive recipient model), or it may mean that the clinician believes that the patient is actually participating (consciously or unconsciously) in the construction of his experience and that this participation is far more important to the fact that he is having such an experience than whatever signal might be flashing in his brain. This claim by the clinician would be based on a model of symptom formation in which formatting codes are essential to the constitution of the experience itself and its report. Let us say that a patient experiences an inchoate bundle of sensations (elsewhere called 'primordial soup' by us) (Berrios *et al.*, 1995). In order to experience it, handle it cognitively, remember it, and talk about it, he/she needs to configure the primordial soup. He/she does this by means of formats (personal, familiar, cultural) and in negotiation with the clinician (all these factors are extrinsic to the primordial soup). Once this process has been completed, the formatted product will be reported as a voice, a strange belief, sadness, anxiety, a physical sensation, etc. It follows that the fact that the primordial soup is always the result of a brain signal (related to a lesion or dysfunction) is not sufficient (and on occasions not necessary) to explain the utterance. This is because the utterance is about not the primordial soup as such (or it is, but in the remotest of ways) but a final product that is the result of a formatting cascade integrated by many reasons and decisions. In other words, the conceptual distance between brain signal, primordial soup and (reported) mental symptom is so wide that to say that the brain signal is the cause of the mental symptom (for it might correlate with it) has little explanatory meaning.

This claim about the depth of the formatting process must not be confused with the conventional view (which most biological psychiatrists would be happy to accept) that the form of the symptom is determined by the brain site from which it originates (e.g. symptoms related to the occipital cortex are visual, or those related to Broca's area are linguistic). The model of symptom formation explicated above states that not only the content but also the form of the mental symptom is determined by the formatting process. (There is no space in this chapter to discuss the confused and confusing distinction between form and content in relation to mental symptoms.) This has interesting consequences, for if the formatting process can override the influence of the site of origin, then correlations between blood flow (as a proxy for site) and mental symptoms have little meaning.

To recapitulate: (1) brain site and lesion can provide only a jejune and nonspecific causality; (2) the fact that a proxy marker of a brain state (e.g. change in blood flow) correlates with a mental symptom cannot be considered as meaningful; (3) the formatting (i.e. construction) of the mental symptom (i.e. the cause of its form and content) has been governed by reasons; (4) personal factors seem essential to the formation of mental symptoms; and (5) what makes tokens of symptoms (say, hallucinations as reported by different patients) the same symptom is not that all those hallucinations originate from the same location in the brain but that the patients in question have formatted a variety of primordial soups (probably originating in different parts of the brain) by means of the same formatting routines.[11]

The Technology Alibi

As far as we know, the first person to use the technology alibi was Georget (1820) to explain the failure of biological psychiatry to find any sustainable and replicable connections between brain and madness. Then, as now, it was only a 'matter of months' before the pathology and genetics of dementia praecox were sorted out; then, as now, the expectation was kept alive by the release of premature data; and then, as now, there was never the scientific honesty of publishing a denial saying that what had been claimed earlier was nonsense.

As popular now as it was a century ago, the technology alibi is not a hypothesis but the tail end of a foundational syllogism: the mind is represented in the brain → the mind is tantamount to a set of behaviours → hence, all behaviours are represented in the brain → abnormal behaviours are still behaviours → hence, all abnormal behaviours have brain representation → hence, the fact that no brain representation can yet be found for mental disorders must be due to faulty techniques. It is important to realize, however, that finding something in the brain that might be related to the disorder under investigation would not prove the truth of the foundational claim placed at the beginning of the syllogism (i.e. of the antecedent). To believe that it does is to commit the fallacy of affirmation of the consequent, because reasons other than the foundational claim can account for the same finding. Indeed, the same fallacy is committed by biological psychiatrists who believe that rejecting the null hypothesis actually proves that their own explanation is correct.

General Conceptual Issues in Biological Psychiatry: First Pass

The relationship between neuronal activity and mental symptoms can be examined from three perspectives, namely (1) the nature

[10] Intentionality has at least two meanings. According to the psychological one, as per Brentano (1973), all mental acts, *ex definitione*, have a content and are addressed at something. According to the causal (narrower meaning), intention to initiate (or inhibit) action is a requisite component of the very definition of behaviour (some may want to include here unconscious behaviour).

[11] Biological psychiatry has dealt with this by creating a mosaic model of specialized brain sites according to which the form of mental symptoms is determined by its putative site of origin. Evidence for this is surprisingly lacking as current methodology seems tautological.

of the mental symptoms or syndromes, (2) the nature of the neurological dysfunction/lesion, and (3) the empirical determination of the relationship between mental and neurological dysfunction. The division here is simply for ease of analysis and is not meant to imply any actual conceptual separation between the different aspects of the psychiatric/neurological relationship. Thus, attempting to clarify the issues around the empirical determination of the mental/neurological relationship is crucially dependent on some understanding of the conceptual problems, assumptions and constraints affecting the nature of the variables on either side of the relationship. Here, we are concentrating primarily on the mental symptom/syndrome side for it is here that the main conceptual problems and lack of clarity arise.

Before addressing some of the specific points in relation to the mental/neurological relationship, and that will be the main focus of this chapter, it is necessary to raise, at least briefly, a few general issues. Exploration of the above relationship, i.e. between psychiatry and neurology, is dependent on defining the conceptual framework within which such work takes place. In turn, such a conceptual framework is underpinned by not only different sorts and levels of concepts but also assumptions relating to the degree to which such concepts can be understood and held valid. Here, three levels or perspectives are raised in order to highlight the difficulties that need to be acknowledged and the assumptions that must be made in attempting such work.

The Mind–Body Problem

The first, and perhaps most obvious, issue relates to the mind–body problem. In other words, the issue here revolves around the conceptualization of mind and body as distinct categories of substances (various forms of dualism) or conceptualization of them as belonging to a single substance (various forms of monism). Depending on the sort of view one has, different sorts of conceptions will be held in relation to 'psychiatric' and 'neurological' events and the relationship between them.

Taking a position vis-á-vis the mind–body problem is relevant to the biological psychiatrist from both the conceptual and historical perspectives. Historically, it makes him/her aware of the fact that in regard to FCs 1 and 2, there are fundamental differences in meaning between pre- and post-Cartesian writers, and that for current thinkers it is almost impossible to get into the mindset that must have been natural to pre-Cartesian thinkers. Indeed, half-seriously it could be said that the solution to the mind–body problem is to return to a pre-Cartesian time when man was conceived as a substantial unity. Conceptually, the biological psychiatrist must try to become aware of the views he/she really holds in regards to the mind–body problem. Saying 'I am an empirical researcher and hence these philosophical issues are irrelevant to me' is not an option, for it is the case that the very language of neurobiology is soaked in foundational claims. Furthermore, a significant statistical correlation between a mental event (e.g. hallucination) and a brain event (e.g. change in blood flow as per neuroimaging) cannot be understood unless it is given at some level some sort of metaphysical interpretation, i.e. unless some sort of ontological allocation is given to each — and this means taking a position in regards to Cartesian dualism. (On the conceptual basis of correlation, see p. 16.)

Mental Events and Brain Events

Second, we must consider the relationship between 'normal' mental events and brain events. This refers back to the old question of localization of mental states to brain states. The issue is not one of whether mental states are realized in brain states — most would agree that mental states are necessarily determined by brain neuronal activity. The issue concerns the level of *specificity* that can be assumed. In other words, questions have to be asked whether, firstly, mental states can be localized to specific brain systems (and, if so, on what basis), and secondly, at what level or specificity can (a) mental states (moods, thoughts, fears, urges, etc.) and (b) brain states (molar/molecular, etc.) thus be considered.

For example, if it is argued that mental states such as moods, fears and intentions can, in theory, be localized to specific brain states (e.g. particular brain sites or neuronal systems), then by extension it will make sense to look for dysfunction in such areas or systems in relation to abnormal mental states, such as pathological fears, abnormal moods, etc.[12] It needs to be understood, however, that the above claim is, itself, dependent on assumptions. Foremost amongst these is the assumption that our conventional taxonomy of mental states actually corresponds to the brain/neuronal taxonomy. In other words, is it the case that the sorts of mental states or functions as constructed, identified and differentiated by man actually reflect the sorts of divisions operating through neuronal systems? Is there evidence that thoughts, perceptions, intentions, moods, etc. as individuated by language are individuated in a similar fashion by the brain? Evidence would seem to be stronger in relation to some mental functions (e.g. perception, memory) than others (e.g. moods, worries, intentions).

Similarly, considering the level or degree of specificity assumed in relation to both mental states and brain states demands questions that remain to be answered. For example, in regards to mental states, can worries be differentiated from thoughts, memories from daydreams, etc.? And what level of neuronal activity can be expected then to 'account' for preoccupations as opposed to fleeting thoughts, or beliefs as opposed to judgements, etc.? Again, this carries implications for pathological states, for example trying to localize delusions, hallucinations, etc. Furthermore, the level of specificity can go further. What about the content of thoughts, moods, beliefs, etc.? Will fear of dying be localized elsewhere or represented differently than fear of a spider, for example?

Role of Language

Third, from a slightly different perspective is consideration of the role of language in the psychiatry/neurology relationship. Language is used to describe both mental states and brain states, but the issue here is that the language used in relation to each concept has a different epistemic value. In other words, the sort of information captured in relation to mental states (moods, fears, preoccupations, etc.) is different from the sort of information captured in relation to brain states (temporal lobe lesion, cerebral atrophy, demyelination plaque, etc.). Crudely, language of the mind is not equivalent to language of the brain, and this carries implications for the hermeneutics of data (see p. 10).

THE HISTORY OF BIOLOGICAL PSYCHIATRY

The conceptual problems of biological psychiatry can only be understood from a historical perspective; unfortunately, the definitional blurredness of biological psychiatry gets in the way. In other words, is its history like that of a *real object* (horse, orchid, chair, Rosetta stone), a *purview* (aesthetics, ethics), a *disease* (dementia,

[12] The issue of whether emotions can be related to brain sites depends on definition. The passions, an older name for the phenomenon, were conceived of as manifestations of the animal part of man; this view was temporalized by Darwinian evolutionism. Because of their relationship to old brain structures and omnipresence in the brain, emotions are likely to modulate perception, movement plans, memory and cognition. This was also Descartes' view; hence, the idea that he left emotions out of the picture by 'error' is both historically and conceptually nonsense.

anxiety disorder); a *social practice* (priesthood, cobblery, medicine, palmistry), an *ideology* (realism, idealism), or a *construct* (French Revolution, guilt, prostitution)? For the purpose of this chapter, biological psychiatry will be defined as a package of changing ideas and social practices seeking to explain and manage[13] deviant human behaviours in terms of a neurobiological discourse. This enables the historian to ask why biological psychiatry has been successful, what social needs it meets, its best selling point, and how it reconstitutes itself.[14]

Before the Nineteenth Century

A version of the foundational claim (central to biological psychiatry) that mental disorders have a somatic origin can be found in the work of Thomas Hobbes (1588–1679) for whom the causes of madness were 'motions of the blood and animal spirits as they variously expand and contract; the causes of these motions are phantasms concerning good and evil excited in the mind by objects' (Hobbes, 1991). As efficient cause, Hobbes (1968) considered both external images of evil and physical causes:

> ... and to have stronger, and more vehement Passions for any thing, than is ordinarily seen in others, is that which men call MADNESSE. Whereof there be almost as many kinds, as of the Passions themselves. Sometimes the extraordinary and extravagant Passion, proceedeth from the evill constitution of the organs of the body, or harme done them ...

As Gert (1996; p. 165) has noticed, this dual aetiological view helped Hobbes to remain consistent with his materialistic stance: 'Hobbes can be taken to say that sometimes a defective bodily part produces unusual motions, and sometimes the unusual motions of the passion injure the bodily part.'

Historians of medicine consider Thomas Willis (1621–75) to be the main English sponsor of the iatrochemical theory of disease: 'All diseases [are] perversions of natural fermentations in which the sulphurous and spirituous particles in the sanguineous mass were set in too great a motion, and the blood therefore became overheated' (Frank, 1980; p. 167) Brain diseases were explained in the same way (italics in original; Wills, 1685; p. 462):

> ... that we may deliver the *formal nature* and *causes of melancholy*, we may opine, that the liquor distilled from the blood into the brain (which filling and irrigating all the pores and passages of the brain, and its nervous appendix is both the vehicle and vinculum of the animal spirits) has degenerated from its mild, benign, and *subtle* nature, into an acetuos and corrosive disposition ...

Willis also believed that these changes could be shown if careful post-mortem studies of the brain were to be carried out (Conry, 1982). By the middle of the eighteenth century, G.B. Morgagni (1682–1771) found little of interest in such work:

> If you join these six dissections of mine [of patients with a variety of mental disorders] with that which I described to you in the first letter (h) and compared them all with those you have in the *Sepulchretum*,[15] or other books, you will immediately perceive, that among those things which others have observed, *some of them have been never found by me* ...

(our italics; Morgagni, 1769; p. 156). Indeed, Morgagni makes the point that similar forms of madness may show lesions in different parts of the brain; this caused some embarrassment to the 'specificity' claim hinted at earlier on by Willis.

Pierre Cabanis (1757–1808) will be known forever as the man who said that the 'brain secretes thought as the liver does bile'. (Taken out of context, this quotation was used by anti-materialist writers to discredit Cabanis (Chazaud, 1993).) Closer reading, however, shows the complexity of his thought. Cabanis (1802) started with a baroque definition of matter, which, as Moravia (1981; p. xxiii) remarked, 'comprised a full array of forces and properties from whose physico-chemical combination even the most complex living organisms may emerge'. Cabanis' matter could thus give rise to a complex mind (and complex mental disorders) (see p. 3). 'Body' meant brain, heart, stomach, genitalia, etc., and for Cabanis all these organs generated complex patterns of feelings and meanings; it would be anachronistic, however, to consider this view as an anticipation of James and Lange. Biological psychiatrists interested in somatizations and unexplained medical symptoms could study Cabanis with advantage as his ideas are at the basis of the concept of cœnæsthesis and 'cœnæsthopathy' (Berrios, 2001b).

The Nineteenth Century and After

Georget and Bayle

Based on Bichat's vitalism,[16] E. Georget (1795–1828) proposed an organic aetiology of mental disorder (and introduced the technology alibi). His views seemed confirmed by A.J. Bayle (1799–1858), who 'showed' that dementia, other forms of mental disorder, and general paralysis might be related. This has been hailed as the *fons et origo* of biological psychiatry, but it is historically and conceptually wrong (Berrios, 1985). Quétel (1990; p. 161) is correct in claiming:

> General paralysis thus defined might have done no more than figure in psychiatry nosography (though difficult to situate in the nosography of Pinel and Esquirol) had it not fitted in so well with the arguments of those who believed that the aetiology of madness was necessarily organic ... For the first time, then, something had been discovered in the brains of the insane! Moreover, these anatomo-pathological lesions were not only to make general paralysis the model of organic mental disease, they were also to swing the psychogenetic conception of madness.

Griesinger

The quotation that 'all mental diseases are diseases of the brain' has been attributed to Wilhelm Griesinger (1817–68). A physician (the concept of psychiatrist did not exist at the time) interested in mental disorders, his contribution to 'psychiatry' is limited to

[13] Explaining and managing are forms of accounting that can be felicitous, unsuccessful, etc. but of which cannot be said that they are 'true' or 'false' because there is no way to ascertain it.

[14] The process of self-reconstitution can only be understood if the history of terms, concepts and behaviours is considered independently. For example, the fact that the word melancholia has lasted for more than 2000 years has led some to believe that the current condition called melancholia is, in fact, the same as that known by the same word 2000 years ago. This is an anachronism based on the ontological view of disease. The same error has led some to express surprise about the fact that schizophrenia was not reported before the eighteenth century. The explanation regarding melancholia is that all that survived was the word as an empty shell. In the case of schizophrenia, the condition was not reported simply because it did not exist: it was only constructed during the late nineteenth century (see Berrios, 2000b).

[15] *Sepulchretum Sive Anatomica Practica* (Bonetus, 1679) included almost 3000 post-mortem reports; Morgagni set out to check many of its findings.

[16] Vitalism is a doctrine according to which the phenomenon of life results from a principle different from the physical and chemical principles that sustain matter in general. Bichat reacted against metaphysical vitalism, i.e. the idea that the vital principle was part of nature. For Bichat, such a principle can be understood only if it is incorporated into each tissue as sensitivity and contractibility (see Haigh, 1984; Pickstone, 1976).

a textbook, a few papers, and the foundation of the *Archiv für Psychiatrie und Nervenkrankheiten*. His views were grounded on materialist biologism, the new physiology, vitalism and romanticism (Arens, 1996). When Griesinger wrote the first edition of his *Textbook of Mental Pathology and Therapeutics*, he was 28, had little psychiatric experience, and had to borrow most of his clinical illustrations from French and German sources (Griesinger, 1861). Like Jaspers' *General Psychopathology* , published seven decades later, the book is important not so much because of its clinical content but because of its philosophical maturity and imaginative proposals. Griesinger's view that official clinical categories are (and always will be) arbitrary but that their 'elementary' units of analysis (mental symptoms) are ontologically sturdy and stable has provided the basis for descriptive psychopathology (Berrios, 1996).

Put back into its context, and corrected by what the words meant in the 1840s, the claim that 'all mental disorders are disorders of the brain' loses its perspicuity. Griesinger had reacted against German materialism (Gregory, 1977) and was keen on the new physiology of Wunderlich, Roser and Müller; his concept of lesion, therefore, was not anatomical but physiological. It was in the new (and ambiguous) space of the new physiology (Schiller, 1968) where Griesinger located mental disorders. On account of this, and due to the crude ontology to which twenty-first-century biological psychiatry has returned, it is not easy to translate Griesinger's concepts into current categories; for example, although he called mental symptoms 'organic' or 'biological' in nature, he did not expect them (necessarily) to leave an imprint on the brain (Berrios, 1984). His concept of physiological lesion led in the fullness of time to that of psychological lesion.

Meynert

Influenced by Darwinian evolution and the new physiology, Meynert (1833–92) sought to correlate development, function and form. Associationism, localizationism, top-to-bottom inhibition, regional cerebrovascular variations, and the nutritional status of neurons were the pillars upon which he based his speculations on the nature and localization of mental illness. Influenced by the representational ideas of Herbart, he believed that in the network of projection and association fibres, there inhabited a functional ego. The first volume of his *Psychiatrie* (Meynert, 1885), the only one published, is a textbook of neuroanatomy with minor references to psychological concepts (Marx, 1970). Physiological and pathological states (such as obsessions, hallucinations, mania and melancholia) Meynert explained by changes in cerebral blood supply. Nutritional changes at cellular level, resulting from hæmodynamic changes or from congenital defect he considered as the ultimate causal mechanism.

The contribution of Meynert to the aetiology of mental illness is not easy to assess (Lévy-Friesacher, 1983 and Pappenheim, 1975). He has been portrayed as a 'brain mythologizer', but this accusation neglects the fact that on occasions he seemed to be speaking metaphorically (he was also a poet), even in matters medical. He believed that brain activity depended on brain nutrition; the latter was controlled by vasomotor activity, thus, circulatory disturbance could cause mental disorder.

Wernicke

A disciple of Meynert, Karl Wernicke (1848–1905) is considered to be one of the most important psychiatrists of the late nineteenth century (Lanczik, 1988). From the perspective of biological psychiatry, three are his important contributions: (1) a model to encompass all brain-related diseases (whether so-called psychiatric or neurological); (2) the development of a pathophysiological model to mediate between the brain and behaviour, a model that had, until then, been absent from psychiatry; and (3) the introduction of the first neuropsychological approach to mental symptoms.

Central to Wernicke's model was Meynert's idea that the brain of man was endowed with a system of projection and (transcortical) association fibres, and that the latter was the organ of consciousness and high intellectual functions (Wernicke, 1906). Focal lesions to the projection system caused neurological disease; damage of the association system generated mental illness. Using modern jargon, Wernicke was more a connectionist (Stein and Ludik, 1998) than a localizationist.

Neglected Models of Biological Psychiatry

It is an interesting question as to why men like Hughlings Jackson, Von Monakow, Goldstein and Guiraud (*inter alia*) have not had more impact on biological psychiatry. Their ideas are paid lip service but somehow have not been taken up.[17] On account of lack of space, only the ideas of Jackson and Von Monakow will be mentioned here.

Jackson

J.H. Jackson (1834–1911) (Critchley and Critchley, 1998; López Piñero, 1973) spent most of his clinical life giving opinions on the nature of mental disorder. In 1894, he published the 'The factors of insanities'; a paper of relevance to biological psychiatry (Jackson, 1894).[18] Jackson proposed a hierarchical model of the nervous system, with the upper layers inhibiting the bottom ones. Evolution made brain function more complex but less stable; dissolution (Smith, 1982a and 1982b) did the opposite.[19] He defined insanity as a departure from ordinary mentation, which included physiological states such as sleep, chronic brain diseases, and temporary toxic states.[20]

Jackson proposed that insanity originated from the action of four factors. Factor 1 concerned the depth of dissolution; factor

[17] In general, the history of medicine (and psychiatry) remains a chronology of socially successful views that are presented as truthful. This type of history does not seek to understand and explain but to congratulate. It is of the 'whom to worship' variety. It assumes that diseases are like plants waiting for a discoverer. The alternative view is to see all clinical categories as constructs, and discoverers as those sponsoring views that became a social or financial success. The advantage of this view is that it also lends attention to the losers for their work, which in fact, may be far more important from the point of view of coherence, rationality, humanity and predictability than that of the victors.

[18] Why Jackson has had so little influence on British (and later) Anglo-Saxon psychiatry (compared with neurology) is an interesting and understudied question (Berrios, 1977; Dewhurst, 1982). Even the unsuccessful classification of the symptoms of schizophrenia into positive and negative has been based not on Jackson but Reynolds, although its sponsors believed it to be Jacksonian (Berrios, 1985). This was not a trivial error: the Jacksonian model demands an interaction between positive and negative symptoms that has never been shown in schizophrenia (Berrios, 1992).

[19] Jackson's conceptual model was not meant to be mapped on to the real central nervous system, and he said so. However, efforts have been made to find analogical links (e.g. Kennard and Swash, 1989; Dubrovsky, 1993).

[20] He seems to have advocated a continuity (rather than a categorical) view of mental disease, which in practice stretches from physiological states to all gradations of insanity. In this regard, he introduced the concept of mental diplopia, by which he meant definitions of the same behaviour that led to clashes and contradictions, such as using insanity for proper madness and also for a mild degree of drunkenness. Jackson wondered why post-epileptic coma (which he called acute temporary dementia) was not considered as an example of insanity by alienists while post-epileptic mania was. Jackson's concept of insanity or dissolution is only meaningful when compared against a standard, and he used the state of the same person before the disease.

2 the person who has undergone dissolution;[21] factor 3 the rate of dissolution, i.e. how slow or fast the removal of control was; and factor 4 personal variables, providing lists of putative elements and themes around which positive mental symptoms may concrescence. Factors 2 and 4 feed meaning (i.e. information about individuals) into Jackson's model (Berrios, 2001a). Interaction of the four factors gives rise to positive and negative symptoms (Berrios, 1985). The model cannot explain the generation of different types of mental symptoms (e.g. hallucinations, delusions, etc.).

Because of his dualism à outrance,[22] Jackson's stance vis-à-vis FC 1 is equivocal. It is true that he believed that all insanities were related to the brain, but his concept of insanity is so different that it is difficult to link the two.[23] Put together, his views do not tally well. Given his dualism, his concept of mind should have been ontologically independent enough to provide a platform for mental disorders; but it does not. Although not a religious man (Critchley and Critchley, 1998), at some level Jackson seems to have harboured the (nineteenth-century) belief that the mind (or soul) was indivisible and intangible and beyond the reach of disease.

Von Monakow

Constantin von Monakow (1853–1930) authored three books, founded three journals, and mentored great biological psychiatrists (Mourgue, 1931). Together with R. Mourgue, a French psychiatrist and historian of science, he also wrote one of the most important (and neglected) books on biological psychiatry in the twentieth century (von Monakow and Mourgue, 1928). Central to this work is the notion of *Horme*, i.e. the tendency of all living beings to develop all their genetic potential. In each individual, the Horme is governed by *Syneidesis*, i.e. a principle that regulates and balances all instincts in the interest of the given individual. These principles govern both function and structure, hence von Monakow and Mourgue develop a neuropsychiatric model of the type that Guiraud (1950; p. 165) called 'dynamo-morphological'.

Based on the assumption that biological psychiatry was a subfield of biology, the authors imported into it the notion of chronogenetic localization. This concept required that the variable time was built as a parameter into all neuropsychiatric phenomena. Functions (e.g. movement) are processes that, like music, unfold in time and according to a specific kinetic melody. Hence, it would be a mistake to attempt to localize processes (i.e. brain functions) in terms of specific brain sites (i.e. space alone). Now, since most mental symptoms are considered to result from disordered brain function, it follows that it would be equally erroneous to try to localize symptoms on specific brain addresses. Influenced by Jackson, von Monakow and Mourgue believed that chronogenetic localization was a late acquisition in evolutionary time, and hence regarded it as a complex but unstable mechanism.

One of the implications of the concept of chronogenetic localization is that both cross-sectional studies and conventional longitudinal studies (as collections of cross-sectional snapshots) are inadequate for the capture of neuropsychiatric symptoms. The latter, von Monakow and Mourgue insisted, have to be observed as they unfold in time according to their own kinetic melody; for example, a hallucination is understood fully only when an entire token or hallucinatory episode, which may last minutes or hours, has been studied. In addition to its conventional cross-sectional features, such an episode includes real longitudinal information, such as, for example, modulations in intensity and changes in imagery, and accompanying emotions can make sense only when integrated along a time dimension. From an aetiological viewpoint, knowledge of these longitudinal variables may in fact provide more information on the brain localization of the symptom than traditional static snapshots.

THE DEFICITS OF BIOLOGICAL PSYCHIATRY

The empirical credibility of biological psychiatry is threatened by not only its weak foundational claims and equivocal history but also the suspicious validity of its data (capture), of its descriptive and analytical methods (data processing and interpreting), and of the rhetoric of its data reporting. There is no space in this chapter to discuss all these problems in depth; to render the points clear, however, one or two examples will be discussed in each section.

Data Capture in Biological Psychiatry

In the context of biological psychiatry, and the psychiatric-neurological relationship in particular, data fall into two groups, namely psychiatric data (psychopathology — symptoms, signs, behaviours) and neurological data (neurology symptoms, signs, neuroimaging lesions, etc.). The focus in this section will be on psychiatric data, but even on superficial examination, it becomes apparent that there is a mismatch between the way in which the 'mind' or psychiatric data are captured and the way in which the 'brain' or neurological data are captured. With respect to the latter, it is evident that ever-more sophisticated tools are being developed and finer discrimination being sought in terms of visualizing brain structure (e.g. computerized tomography (CT) scanning, magnetic resonance imaging (MRI), etc.) and brain processing (e.g. single positron emission tomography (SPECT), positron emission tomography (PET), functional resonance imaging (fMRI), etc.). Pathology is described at molecular, neurotransmitter, amino acid, etc. levels. In contrast, the level of capture of 'psychiatric' data remains much the same as it was in the nineteenth century when such descriptions were developed (Berrios, 1996). In fact, in many ways descriptions of psychopathology have become narrower and less rich than they were then, constrained perhaps by the classification systems of current times. Thus, the problems with respect to psychiatric data capture in the context of biological psychiatry can be divided into two main areas: general issues pertaining to data capture in psychiatry as a whole, and specific issues relating to data capture in relation to biological psychiatry.

[21] Twenty years earlier, Jackson (1874) had described factor 2 as 'the kind of *brain* in which reduction occurs'. This rephrasing reflects maturity of thinking and a mellowing attitude towards the mentally ill. Jackson believed that variables pertaining to the individual and genetics influenced the form of the insanity but says little else. Personal factors such as age, intelligence and education showed best in states of minor dissolution; 'genetic' factors concerned not the inheritance of specific mental disorders but a tendency to 'give out' to dissolution.

[22] Jackson's views on mind, matter, their relationship, and FC 1 are difficult to map in a coherent way. He was so much of a dualist that he borrowed Clifford's concept of concomitance (Berrios, 2000c) to explain how mind and matter might interact. Jackson (see Taylor, 1931) wrote: 'The doctrine I hold is: first that states of consciousness (or, synonymously, states of mind) are utterly different from nervous states; secondly, that the two things occur together — that for every mental state there is a correlative nervous state; third, that, although the two things occur in parallelism, there is no interference of one with the other. This may be called the doctrine of Concomitance.'

[23] For Jackson, insanity was on a continuum with other states, such as drunkenness or dreaming (hence, he called them states of 'temporal insanity'); only its negative symptoms actually reflected pathology (i.e. lesions or dissolution of the higher, human, inhibiting layers of the brain); positive symptoms were the expression of evolution, of *normal* activity produced by the release of *normal* tissue.

General Problems

Some of the general problems facing data capture in biological psychiatry need to be mentioned. First of all, what sorts of data are being captured? Are psychiatric data different from other sorts of data? What kind of differences are we dealing with? How might this affect the informational value we can obtain from such data? What are the implications for use of such data as variables in correlational studies, etc.?

To answer such questions, we need first of all to define the particular psychiatric data. Broadly, these can be divided into four types: (1) subjective complaints of patients (e.g. feeling depressed, anxious, hearing voices, etc.), (2) signs and behaviours elicited by clinicians (e.g. thought disorder, psychomotor retardation, disinhibition, etc.), (3) psychiatric diagnoses (Diagnostic and statistical manual (DSM) IV categories) (APA, 1994), and (4) scores on various rating scales (e.g. Beck Depression Inventory (BDI), Hospital Anxiety and Depression Scale (HADS), Hamilton Depression (HAM-D), etc.).

Subjective Complaints as Data

The Subjective complaints made by patients (given spontaneously or elicited by questioning) form part of the data captured by clinicians and used to determine the presence of a particular psychiatric symptom, syndrome and/or disorder. It is, however, the nature of such symptoms as 'data' that raises the problems: problems that relate to the sort and quality of information that can be inferred from such data. In other words, questions have to be asked concerning the validity and reliability of subjective complaints as data. Such questions must relate to not only how validity and reliability might be determined but also the epistemological justification for the validity and reliability of the data.

By definition, subjective complaints consist of individual interpretations of some sort of perceived dysfunction or change — whether this is experienced bodily or mentally. Where, then, and what are the origins and constituents of such complaints, and how do they develop into symptoms? These are the crucial questions, since understanding the validity and epistemic value behind subjective symptoms as 'data' depends on the answers. If it is assumed that, irrespective of aetiology (brain lesion, neurological dysfunction, external event, etc.), there is a change in the internal state of an individual, then how does that particular change become transformed and translated into subjective complaints? And can it really be assumed that the 'same' (and this particular assumption carries many problems that cannot be addressed here) internal state will result in its equivalent interpretation and equivalent description by different individuals? In other words, can it be assumed that the data obtained from individual reports of internal states are of similar type to the data obtained from reports of, for example, objects in the public domain, such as sightings of trees, or, more relevantly, fracture on an X-ray, pulse rate, lesion location on CT scan or hot spot on PET? One problem here is that there is not the same system of verification in regard to internal states as there is in relation to external events. How can we know that the internal state as described by an individual is actually that particular experienced state that is matched by the description (i.e. does the description match the experience accurately — assumption of validity)?[24] Secondly, even if the match is assumed to be accurate, how do we know that that particular experience is the same as the one described by someone else (i.e. assumption of reliability)? Furthermore, there is no good model of symptom formation that might help us answer such things (for a précis of our model, see p. 4). Nevertheless, it is difficult to conceive of the process of interpreting a particular internal state and subsequently articulating this in a particular way, as a uniform one, unaffected by individual and sociocultural factors at any stage. Far more plausible would be the possibility that changes in internal states are going to be interpreted in different ways by individuals. For example, it is conceivable that a particular unpleasant internal state change might be read or interpreted as depressed mood in one individual (or at a particular time) while the 'same' or similar internal state might be interpreted by another individual (or at another time) as anxiety or irritability or pain or tiredness, and so on. The factors that might be important in determining a specific interpretation (e.g. past individual experience, cultural biases, contextual issues, language limitations, contribution from the eliciting clinician, etc.) are not the issue here. The point, however, is that it is more than likely that making sense of changes in internal states, and interpreting such changes, is going to be affected by many factors. This means that it is equally unlikely that there will then be a direct relationship between whatever the neurobiological 'signal' manifesting the internal change is and its outward manifestation as a subjective complaint. In other words, there will be a marked degree of formatting going on (noise from various sources), which will change (distort) the original signal to variable extents.

Further complications arise from the fact that subjective complaints themselves cannot be considered a homogeneous class of data. Such symptoms vary in form (moods, fears, perceptions, etc.) and content (anxiety, irritability, elation, hopelessness, grandiosity, voices, images, etc.), and the heterogeneity is likely to be reflected also in the ways in which such symptoms develop and their overall structures (Marková and Berrios, 1995a). In other words, the formatting by other factors is likely to be different in relation to different subjective symptoms. Complaints of depressed mood, for example, may involve types of interpreting factors other than complaints of hearing voices, which one could envisage as perhaps more directly representing the original signal. And when it comes to more complex symptoms or judgements made by patients, e.g. insight into their mental experiences or illness, then the sort of distortion produced by the very many different factors contributing to the construction of such a meta-concept is likely to be much greater (Marková and Berrios, 1995b).

So, what will all this mean for the validity and reliability of subjective complaints as data for biological psychiatry? Given that at present there is little evidence to indicate that a particular description of an internal state actually reflects in a direct way a specific signal or dysfunction, then we have little to justify the validity of such data. Evidence for validity can only start to be gathered when the factors important in distorting the original signal can be identified and teased out in some way. Similarly, reliability will also depend, in part, on the factors determining validity. In addition, however, the issue of whether a particular signal/dysfunction is going to be experienced (leaving aside the issue of interpretation) in the same way in different individuals is open to question. Or perhaps the question here might more usefully relate to there being sufficient similarity in internal state experiences for the state to warrant similar descriptions (again leaving aside the issue of interpretation). What is evident, however, even on this superficial analysis, is that epistemological justification for subjective data in terms of their validity and reliability remains poor. That is not to say, of course, that such data are not useful in themselves. Individuals do have to communicate about not only external objects and events but also internal states, and in general, degrees of understanding can be achieved between individuals (though clearly to various extents), which would argue for some

[24] Aspects of this debate (particularly a criticism of the epistemic value of data obtained by introspection) were first rehearsed during the second half of the nineteenth century in the nascent field of 'scientific' psychology. It was then argued by experimentalists that the quality and reliability of information obtained in the laboratory was superior to that obtained by introspection (Boring, 1953). Those who took this seriously started to train subjects into being good and attentive reporters. This created a 'professional' class of experimental, which no doubt biased findings further.

level of concordance. Thus, subjective symptoms as data used, for example, in clinical management, in terms of making some sort of sense of what and why a patient might be experiencing a particular state is likely to be of practical importance. The essential issue here, however, is not to confuse the practical validity with the epistemic validity of such data. This is of crucial importance in the context of biological psychiatry and any research exploring the psychiatric-neurological relationship, particularly in terms of inferences drawn from correlational research (see Section 3.2), where the data on either side of the correlation may not be epistemologically comparable.

Objective Signs and Behaviours as Data

Psychiatric data are also collected as signs and behaviours identified by the clinician during clinical assessment. Thus, based on a patient's presentation, behaviour, speech and responses, clinicians will determine the presence of, for example, disinhibition, psychomotor retardation, thought disorder, blunted affect, etc. These types of data are thus dependent on the clinician's interpretation of speech and behaviours manifested in the patients. The validity of such data in turn depends on (1) whether the clinician is actually identifying changes that are, in fact, present in the patient, and (2) whether such changes are correctly described and named by the clinician. (In addition, of course, there is the issue of whether the signs and behaviours that are identified by the clinician are in fact the relevant ones out of many possibilities.) Reliability, on the other hand, relates to the extent to which clinicians will agree on the nature of the data presented.

Once again, the questions here, then, are how can validity and reliability be determined, and what are their epistemological justifications? Examining the types of data in this case, it is evident that the data elicited must be dependent not only on whatever dysfunction is manifest in the patient but also on the clinician's interpretation of the patient's presentation. In turn, this will again depend on a number of factors, including clinical experience, knowledge, individual biases, context of subjective complaints, etc. For example, whether a clinician identifies a sign such as affective blunting might depend not only on the explicitness with which it was present but also on the clinician's past experience in seeing this feature, his knowledge and consequent readiness to identify this, his own concurrent mental state, e.g. level of concentration, and whether the patient was denying, for example, depression and anxiety. It can be argued, however, that given the more direct elicitation of such data, in terms of observation of particular outward manifestations, there is more objective determination of the phenomena and hence less likelihood of distortion by the individual factors related to the clinicians.[25] Thus, validity and reliability may, in this sense, be greater in relation to these types of psychiatric data than in relation to the subjective complaints as data. This may well be the case, but the issue remains that interpretation of signs and behaviours must still occur (although perhaps to a lesser extent) so that the potential for distortion is still there and there is so far little known about the factors important in the development of such 'noise'. Similarly, the issue of heterogeneity is again a factor to consider in the capture of these data. It is likely that some signs and behaviours may be more direct manifestations of dysfunction than others and thus less prone to distortion by clinician factors.

Once more, then, the question must be asked: what does all this mean in relation to the epistemic justification of signs and behaviours as data? Such data are clearly once again very different from the sort of data collected in, for example physical science, electrocardiogram (ECG) readings, measurements of height and weight, etc. The latter are, of course, subject to interpretation as well as are any external perceptions. However, the degree of interpretation involved in the elicitation of signs and behaviours, fluctuating in character, themselves dependent on often unclear or abstract theories, must be of a different and greater extent. Identifying changes in patients and naming them correctly (whatever that may mean) is dependent on more than actual dysfunction or lesion. This, together with the fact that little is known about the specific relevance of the identified in relation to the non-identified signs and behaviours, indicates again that epistemological validity is weak.

Psychiatric Diagnoses as Data

Again, in the context of biological psychiatry and the search to explain or clarify the psychiatric-neurological relationship, psychiatric diagnoses are frequently used as data against which brain abnormalities or dysfunction are assessed. In general, issues surrounding validity and reliability of such data have tended to be addressed by the use of lists of diagnostic criteria and diagnostic categories from established classification systems such as ICD-10 (WHO, 1992) or DSM-IV (APA, 1994). The question arising here, though, is what does this actually mean in relation to the use of diagnostic categories as data in biological psychiatry? Reliability here refers to the extent to which clinicians will agree on a specific diagnostic category as applying to a particular patient. Thus, reliability will depend on clinicians agreeing that a certain clinical state fulfils a number of set criteria. And, insofar as levels of agreement are reached, then the classification systems can be said to be relatively successful. But the issue is that whilst this refers to the general facility with which clinical descriptions can be applied, it does not refer to the nature of the data themselves. In other words, it is again the validity of these data that needs to be questioned. The validity of psychiatric diagnoses refers to the extent to which the diagnostic categories actually reflect specific diseases or conditions. Looking more closely at this brings the epistemological problems to the surface. Making a diagnosis will depend, in theory at least (and arguments have been forward against this assumption; see Berrios and Chen, 1993), on identifying and eliciting the primary psychiatric data, namely history, symptoms, signs and behaviours. These will then need to be checked against the list of diagnostic criteria to determine the best fit and hence the most probable diagnosis. It is apparent, therefore, that the informational value of diagnoses (assuming that these are second-order data made on the basis of primary data [signs, symptoms, etc.]) will be affected, in the first place, by the same factors discussed above in relation to subjective complaints and signs and behaviours. In other words, the epistemic value of such data cannot be greater than that underlying the original constituent data. In addition, there is another problem here as far as validity is concerned. This concerns the actual grouping of the primary data into the diagnostic categories and the question of how far such groupings represent true disease process. And, given the so far lack of knowledge concerning aetiology of psychiatric disorders, it has to be accepted that the current groupings are determined by more arbitrary factors, with face validity based on consensus of opinions, but not by information concerning disease states themselves. Furthermore, epistemic justification of diagnostic categories as data will also be affected by heterogeneity in diagnostic categories. For example, criteria set out for the diagnosis of bipolar affective disorder are likely to have an epistemic basis of

[25] Aspects of this issue relate to the old nineteenth-century debate, inspired by the first positivist philosophy, on whether signs were more informative, stable or objective than symptoms. By the end of the century, the success of neurology over alienism seemed to confirm that this was the case (Berrios and Porter, 1995). As far as these authors know, and even within the semiological revolution that took place during this period, there has never been an adequate debate on the epistemic value of signs and symptoms and on the fact that they name continuous rather than discontinuous phenomena (Berrios, 2001c).

a different sort to the criteria set out for diagnosis of, for example, neurasthenia or dissociative disorder.

It is important to emphasize again the point applying to all these types of psychiatric data, i.e. that the issue of epistemic validity should not be confused with their practical utility. It is the former that is weak, and the limitations need acknowledging in research.

The use of specified diagnostic categories, by virtue of their specified criteria, may give rise to assumptions about their validity as data, which may be unjustified since these categories mask the actual lack of epistemic validity underpinning primary psychiatric data.

Data from Rating Scales as Data

To measure is to map in numbers features of objects or processes so that operations on the numbers might obtain patterns of relationships assumed to exist in the objects themselves.[26] As a praxis, measuring is likely to have started very early in the history of mankind, particularly in the fields of bartering, commerce, building and engineering, and astronomy. Cubit, foot, fathom, grain, etc. attest to the fact that *ab initio* parts of the human body and/or ordinary objects were used as measures. Since very early, standardization was required to prevent disagreements and cheating; the former process has not yet been completed.

The stage at which measuring changed from being a praxis to becoming an epistemological tool, i.e. a process considered as important in the acquisition of knowledge about the world, is difficult to say. Neither Plato nor Aristotle seems to have felt that measuring added to the rational analysis of reality. By the high Renaissance, however, a theoretical shift towards quantification is clearly noticeable (it is applied to painting and drawing, map making, and even the deployment of soldiers in the battlefield) culminating with the epistemological redefinition of the new seventeenth-century sciences as 'quantitative' (Crosby, 1997). This was a reflection of the belief that nature itself had a numerical structure, and hence that knowledge of such codes would make man a master of reality. Thus spoke Galileo: 'Philosophy is written in this grand book, the universe, which stands continually open to our gaze, but the book cannot be understood unless one first learns to comprehend the language and read the letters in which it is composed. It is written in the language of mathematics ...' Newton shared this view.

By the late eighteenth century, the rational, discursive analysis of quality and individuality had been abandoned by the natural sciences and had to be taken over by a small group of inchoate disciplines; a century later, these became the great group of 'sciences of the spirit', which, in the hands of Dilthey and others, developed their own epistemological structure, set 'understanding' (Verstehen) as their objective, 'Erlebnis' as their subject matter, 'hermeneutics' as their tool, and shunned quantification altogether. For a while, psychology was considered to be part of the *Geisteswissenschaften* (e.g. by Dilthey), which may explain why efforts to introduce measurement into psychology met resistance at first. In the event, Weber, Fechner, Donders and Ebbinghaus encouraged the unilateral independence of psychology, redefined concepts, and set the process of its 'naturalization' going (Boring, 1942; Boring, 1950; Boring, 1961).[27]

In the shape of rating scales, graphic representations and statistical analysis, measurement did reach psychopathology and psychiatry after the Second World War. Rating scales and graphic representations had been in use in psychology since the turn of the century, and statistical analysis had become available since before the Great War but was not used in medicine or psychiatry. Although momentous, these events have been neglected by historians.[28] All we know is that rating scales arrived furtively, sometime during the late 1950s, hidden in the Trojan horse of the incipient drug industry of the day. Early scales (such as the Hamilton Depression Scale) were designed exclusively for the evaluation of drug trials (Berrios and Bulbena, 1990). After some resistance, rating scales become popular for they seem the ideal response to the *cri de coeur* for objectivity and reliability so characteristic of biological psychiatry, and because they yield the scores required by statistical manipulation.

Given the hybrid nature of psychiatry (a discipline whose subject matter requires both the natural and human sciences), it is extraordinary that at the time (and since) it occurred to no one that the introduction of quantification needed to be justified epistemologically.[29] Of the three topics listed above, only rating scales will be treated in this section. We will mention statistical analysis later. There is no space to deal with the numerical, aesthetic, rhetoric and heuristic aspects of graph representations.

Rating Scales

Under the aegis of the first mental tests — such as the Ebbinghaus word lists to evaluate memory (Ebbinghaus, 1964), questionnaires appeared towards the end of the nineteenth century purporting to capture other phenomena such as hallucinations (Parish, 1897). (Lest it is concluded that this is the beginning of measurement in psychiatry, the point must be made that Parish and others were amateur gentlemen wanting to test beliefs in the parapsychological and psychical fields.) Encouraged by eugenics, educational policies and the war effort, 'proper' tests were first developed to measure intelligence and personality. The development of psychometry and factor analysis was, in turn, spurred on by the need to standardize and process such instruments.

When rating scales arrived in psychiatry in the 1950s, the view that mental symptoms were immeasurable was still common, and not only amongst those of a psychodynamic persuasion.[30] However, the need to measure outcome in drug trials encouraged the construction of rating instruments based on items believed to be susceptible to rapid change (in days or weeks), their incomplete item coverage making them unsuitable for diagnosis (e.g. the

[26] These may range from comparative orderings (larger than, equal to, etc.) to complex pattern-recognition techniques said to be able to extricate from data sheets meaningful numerical configurations. In either case, the assumption is that numbers are mapping configurations that exist in nature.

[27] That is, the view that because the mind is a product of natural evolution, then its study should also fall within the purview of the natural sciences. The narrower view that meaning and individuality are irrelevant to scientific psychology is based on additional assumptions adopted happily during the behaviourist era. Current 'cognitivism', particularly the one based on information technology, has not been able to regain any of the old semantic and symbolic approach to human behaviour.

[28] The arrival of quantification in psychiatry needs analysis. The historian is interested to know about the social conjuncture that allowed its adoption, particularly the groups that benefited from it.

[29] The issue here is not whether measurement should be adopted by psychiatry. The issues are: (1) what types of information or forms of meaning included in the psychiatric discourse are susceptible to measurement? and (2) how much of the semantics of qualia is lost after it is translated into the items of a rating scale? These questions cannot be answered by empirical research.

[30] Personal communication by the late Professor Max Hamilton. The immeasurability hypothesis must be taken seriously. It is based on the view that mental symptoms are semantic events, and that mensuration of features external to meaning or imposed upon their structure (such as dimensions, intensity and localization) missed out on the only element relevant to the understanding and management of mental symptoms. A claim of immeasurability can also be grounded on technical argument, such as the unreliability and low epistemic value of proxying (see p. 16).

Hamilton Depression Scale) (Berrios and Bulbena, 1990; Berrios and Marková, 2002b).

The numerical and semantic meaning of the resulting global score has also caused confusion amongst biological psychiatrists. It does not take long to realize that such a score masquerades as a continuous number. In fact, it is just a totted summary of qualitative (ordinal scale) decisions taken at item level. In the case of the Hamilton Depression Scale, for example, not all items are captured by scales of the same size. The reasons why some researchers believe that a continuous number can issue out of the arithmetic addition of qualitative decisions is one of the mysteries of psychiatric psychometry. There are, however, hundreds of papers where the Hamilton global score has been entered into statistical analyses that are known to demand numerical and parametric features of the figures involved which the global scores cannot hope to meet.[31] The curious thing here is that biological psychiatrists, in general demanding of reliability and objectivity, are happy to accept global scores as numerical proxies of that kind. In fact, the best approach is to understand global scores as summary narratives, as forms of mapping a phenomenon by means of the capture of its features (items).

Something must be said on the noble and mysterious concept of 'item', the 'unit of analysis' of psychiatric scales. Items are claimed to stand as semantic and mathematical proxies for attributes, dimensions or expressions of a phenomenon under measurement (see *The semantic mediator of rating scales* below). The content of items ranges from questions meant to capture the presence of the phenomenon (the question 'hallucinations present/absent' is an instrument with one item; indeed, it generates the global score 1/0, which is ordinarily entered into statistical calculations), to scalar anchor points (nominal, ordinal, interval, ratio and, very rarely, absolute forms of measurement), to visual analogues. All these contents are made to yield a number. Through its content, each item is also made to fulfil a proxy function, and the success of any scale depends on the quality of the proxying. So-called standardization methods (including those addressed at evaluating reliability, validity and internal coherence such as Alpha Cronbach) do not, indeed cannot, evaluate the proxying function of each items (on the complex problem of proxying, see Section 3.2.1). In a way, the relationship of a rated psychiatric instrument to its items is (on the model of DSM-IV) like that of a made diagnosis to the mental symptoms or criteria it is based on. Much fuss has been made about the reliability of psychiatric instruments and of DSM-IV diagnostic categories, but all this work is vacuous without having a clear idea of the proxying function of individual items and the way in which mental symptoms themselves (criteria) are actually recognized.

The Semantic Mediator of Rating Scales

Whether depression, thought disorder, apathy, anxiety, alexithymia or whatever, rating instruments do not measure *directly* the target clinical state, trait or condition. They measure it indirectly, i.e. they are always mediated by a construct. A construct is a notion (such as the concept of virtue or disease) or image (painting) purporting to map or represent something else. Schizophrenia, obsessional disorder, Cotard syndrome, autism, theory of mind, etc. are not objects like stones, horses or stars; they are all 'constructs'.[32] They are semantic grids that format opaque and formless behavioural phenomena and allow their capture. On occasions, the phenomenon may be linguistic or semantic and hence devoid of neurobiology (the co-varying 'something' that is captured by neuroimaging is not necessarily the phenomenon but resources used to express the phenomenon, e.g. linguistic activity). This should not worry us, however, for as far as the patient is concerned, the phenomenon is still a bother, irrespective of whether it has representation in his/her own brain.

Constructs are thus semantic structures that select, circumscribe, impose coherence upon, interpret and create a narrative about mental symptoms. Rating scales hang off these constructs and proxy for them. Hence they have no direct contact with the phenomenon underneath, whether neurobiological or not. Constructs are used to: (1) set the boundaries and interpret the raw phenomenon in question; (2) break it up into features, attributes, dimensions and latent traits (in which latter case it will need to include probes or handles to get at them), thereby creating a 'featural pool'; (3) translate the featural pool into a language that can be understood by the average person; (4) select from the pool attributes according to criteria (pathognomonic, representative, convenient, fashionable, interesting, susceptible to change, susceptible to measurement, etc.); and (5) convert the attributes into items by tethering them to specific response categories.

At each step, distortions and biases of a hermeneutic or semantic nature are introduced into the representation that cannot be eliminated by the statistical evaluation of the scale. Calculating a reliability index (e.g. alpha Cronbach) can only ascertain whether the attributes selected cohere or relate to each other and converge on to a unitary construct; they cannot help to decide on the relationship between the construct and the behaviour. The little there is left of semantic information after a scale has been constructed is to be found in the instructions and in the history of the scale. And yet the latter two are rarely consulted and pondered over, for there is the magical belief that once treated statistically, rating instruments become autonomous entities that do not need to have a past. This is wrong, for all scales belong in cultural and clinical niches and hence wear off, loose reliability through time or mismeasure when applied to phenomena or contexts not specified by their instructions or semantic history.[33] Researchers in biological psychiatry do not seem to bother much about such semantic information; this explains why, for example, they continue using the Hamilton scale (which is, in fact, losing sharpness as the surface symptomatology of depression changes) to measure 'depression' in frontal lobe stroke (and other neurological conditions) in spite of the fact that Max Hamilton instructed specifically that patients suffering from such disorders fell outside the semantic purview of the scale (Berrios and Bulbena, 1990).

The Informational Capacity of Rating Scales

Rating scales are believed to be objective. The denotation of this term is valid and reliable; its connotation is scientific, good, above board, not subjective, sellable, better than other approaches, etc. Hence, rating scales are considered to be a form of assessment superior to the happy chat or the clinical interview. Evidence for such a notion is surprisingly limited, but it survives as a

[31] Except in the case of rating instruments based on absolute measurement, global scores cannot be considered as absolute, i.e. as numbers starting from true 0. For example, a 0 score on the Beck Depressive Inventory cannot be interpreted as absence of depression; nor can someone scoring 40 be said to be twice as depressed as someone scoring 20.

[32] Resistance to the idea that the categories of psychiatry are constructs may issue out of fear that such a view will undermine their ontology (and consequently threaten their localizability, neuroimaging and management by medication). This fear may in turn result from the (wrong) belief that constructs are not part of nature but artefacts of language or fictions. This, in fact, is not the case.

[33] This is a well-known aspect of psychometry. For example, the original Wechsler scale was found to have lost calibration because it was standardized in pre-war samples that are now believed to have been less 'bright' than post-war samples. This principle has not yet been applied to psychiatric rating scales in spite of the fact that there is evidence that the expression of mental disorders has changed on account of both neurobiological and social reasons.

counterpart to the (wrong) view that interviews are subjective. Rating scales have benefited much from comparing them with rulers and other measuring instruments. In fact, the conceptual distance between a stick and the ruler is much shorter than that between a mental symptom and its scale. By conceptual distance, we mean here the number of semantic interventions required to convert a phenomenon into an item. The more interventions, the more the loss and/or distortion of information. As long as scales are taken to be short-hand, semantic devices, or summary narratives, such distortions matter little. They cause needless fatalities, however, when rating instruments are considered to be mirrors of nature and powerful generators of knowledge, and their global scores to be true measurements (and entered into correlations).

In general, there is nothing magic about meters or scales or the other devices created by man to allocate numbers to objects and qualities. All measurements (including the simplest ones) are mediated by concepts and are dependent on aids taken from anatomical (cubit, inch, fathom) or common objects (grain, stones) that have since become abstracted and standardized. Measurements in earlier days were comparative and relational. Reliability (that users meant more or less the same by each unit of measurement) was in those early days more important than accuracy (the concept of validity is not important in a world of comparisons).

Specific Problems

So far, we have concentrated on problems associated with psychiatric data capture in general. Emphasis has been placed on the issue that psychiatric data are of a different sort to other types of data that are used in research and other situations (e.g. height measurements, pulse rate, number of plaques on MRI, etc.). Whilst some differences in validity and reliability can be identified between subgroups of psychiatric data, as a group psychiatric data are marked by weak epistemological support and hence poor epistemic validity. This carries implications for correlational research in biological psychiatry where such data are treated as hard variables (see p. 18).

In addition to conceptual problems applying to psychiatric data capture in general, there are issues specific to psychiatric data capture in biological psychiatry that need to be considered. The specificity of these issues is, to some extent, defined by the presumed neuropsychiatric relationship. This relationship is generally taken to encompass several possible perspectives. Limiting things here to a situation where a patient has a neurological condition and associated psychiatric problems, then these perspectives can include views that: (1) the neurological lesion might be causing directly the psychiatric manifestations (directly in the sense of specific brain sites or neuronal systems damaged); (2) the neurological lesion might be causing indirectly the psychiatric problems in that the latter may reflect the response of the patient to the consequences of the neurological condition/disability; (3) the neurological lesion might be both the direct and indirect cause of the psychiatric problems; and (4) the neurological lesion and psychiatric problems might be occurring independently and hence coincidentally. These perspectives, whether or not stated explicitly, seem to underpin a number of the conceptual and empirical problems facing data capture. The problems are various, and again it is not possible to cover all in this chapter.

Behavioural Phenocopies

One such problem concerns the nature of psychiatric data in the context of neurological disease and relates to the question of whether such data can be considered similar or different to those manifested in conventional psychiatric disorders. This problem is raised in a number of ways. For example, in the case of organic depression (e.g. depression in the context of stroke), questions remain as to whether this might be, in fact, the same sort of condition (i.e. same sort of structure, symptom pattern, behaviour, response to treatment, etc.) as depressive disorder occurring without a neurological condition. ICD-10 classifies organic affective disorders in a separate diagnostic category from affective disorders, but uses 'presumed organic aetiology' as the only discriminator between the two. Some evidence suggests that phenomenologically there may be differences between the two depressions, and that some types of organic depression may be behavioural phenocopies in that although appearing similar, they have different symptom profiles.

For example, a cluster of affective complaints can mimic depression, only to disintegrate after a few days of observation. It could, of course, be the case that the depression has resolved rapidly and spontaneously, but often enough what the observer has noticed is a behavioural phenocopy of depression (Berrios and Samuel, 1987). Such clusters carry implications in relation to the neuropsychiatric relationship perspective in that they may also be mediated by the neurological dysfunction either specifically or as a general response. Another example raising the issue of similarities and differences between mental states in the context of biological psychiatry is that of dementia and so-called 'pseudodementia' (or whatever other name one wants to use to name the behavioural phenocopies of dementia). Thus, dementia-like syndromes can be manifested, in terms of both symptoms and the disease, by other functional and neurological disorders (Berrios and Marková, 2001).

The question, then, is how does this problem of similarities and differences affect the psychiatric data or rather the epistemic validity of such data in this context? Again, in order to tease out some of the possible factors involved, various possibilities need to be considered. First, the psychiatric data in the context of neurological disease may, in fact, be of the same nature and structure as those manifested in conventional psychiatric disorders. In other words, the same sort of psychiatric symptoms, signs, behaviours and diagnoses would occur, and the specific neurological lesion would not be adding anything different or new to the possible psychiatric picture. In this case, the epistemic validity of the data is limited by the same factors discussed earlier in relation to psychiatric data in general.

Second, some of the psychiatric data in the context of neurological disease may appear and actually be different in nature and in structure, from those found in conventional psychiatric disorder. Patients might express different sorts of complaints, talk about strange experiences, and exhibit odd signs and behaviours, all of which might not necessarily fit current lists of conventional symptoms and diagnoses. In the context of the neuropsychiatric relationship, such differences may arise directly as a result of the neurological lesion (relating to the site and/or neuronal system affected) or be mediated by any ensuing brain damage (e.g. dysphasia interfering with abilities to articulate experiences, personality changes colouring behavioural manifestations, etc.). The problems in this situation, as far as data capture are concerned, would relate to the identification, the capture and the naming or classification of such data. For example, where 'new' and odd experiences are complained about, i.e. those not fitting into conventional categories, then it might be more difficult to identify these as data; often, such complaints are then ignored (or forced into the nearest category available). Similarly, were such experiences to be completely new to the patient, it might be particularly difficult to articulate, for they may not have the language to do the experience justice. Again, this may result in ignoring the experience or fitting it into a known category of description, thus causing difficulties in capturing the data. Both such difficulties carry implications for the 'correct' naming of data.

Third, some of the psychiatric data in the context of neurological disease may only appear to be similar to those found in conventional psychiatric disorder. This is the issue raised in relation to mimics and behavioural phenocopies. The question then follows: what does 'similar' mean? The analysis of similarity is complex, but here

we shall use a simple definition: 'two symptoms are similar when they have many but not all properties in common.' A property, in turn, is an 'attribute or quality belonging to a thing or person: in earlier use sometimes, an essential, special, or distinctive quality, a peculiarity; in later use often, a quality or characteristic in general (without reference to its essentialness or distinctiveness)' (Oxford University Press, 1992). Properties can be essential and accidental. For example, 'being related to vision' is an essential property of the current definition of a visual hallucination, and 'forgetting' is an essential feature of a memory deficit. On the other hand, properties that can change without affecting the class of symptoms involved (e.g. content) are called 'accidental'. Both types of properties can generate similarity. Following previous definitions (Berrios and Marková, 2001), the term 'mimic' is used here to refer to a clinical state that shows partial similarity to another. In the case of dementia, it may consist of one predominant symptom (e.g. disorientation). The term 'behavioural phenocopy', on the other hand, is used to refer to a mental state that resembles more completely the full clinical picture of a particular condition. For example, organic depression could be considered to be a behavioural phenocopy of depressive episode, and depressive pseudodementia might be said to be a behavioural phenocopy of dementia (Berrios and Hodges, 2000). In addition, behavioural phenocopies are met with in clinical practice that remain unnamed and hence unrecognized because they are fleeting, clinically uninteresting, or cause little subjective distress; all three, however, are still temporary coincidences of symptoms (each originating from a different mechanism) that create the impression of being something else.

The question of whether all similarities engender mimics remains to be answered. Nor is it clear whether essential or accidental properties are more likely to give the impression of similarity. For example, in a patient with psychomotor retardation and memory deficits, the presence of delusions with a content of poverty (an accidental property) will be more likely to create a copy of depression than a delusion with another content. On the other hand, in a patient with confusion and memory deficits, the presence of visual hallucinations (an essential property), regardless of content, may create a copy of Lewy body disease (Perry *et al.*, 1996).

Similarity can be predicated of both symptoms and diseases. In regards to the latter, patients are said to have a similar disease x, regardless of whether they share all the same symptoms pertaining to x. For example, if x is constituted by symptoms x_1 to x_{10}, in an extreme case one patient could suffer x_1 to x_5 and another suffer x_6 to x_{10} and they would still be considered as having the same disease in spite of their phenomenology being different. In practice, however, not all symptoms x_s have the same weight (e.g. some may be considered as pathognomonic, sine qua non) and hence decisions taken concerning similarity depend on more complex judgements relating to patterns and selection of symptoms presented. Alternatively, both patients might have x_1 to x_5 and would thus show very similar presentations of the disease.

The issue of similarity, or mimics and behavioural phenocopies, is clearly important, but what are the implications for psychiatric data capture? One way to answer this and to examine the epistemic problems around the psychiatric data capture in this context is to separate out where such similarity might occur. In other words, the question first is at what level might the similarity be generated? Following the previous line of analysis, broadly three levels can be distinguished here: (1) the level at which the actual dysfunction is being *experienced* (ontological level); (2) the level at which the internal changes are being *interpreted* and/or manifested; and (3) the level at which the psychiatric symptoms and signs (data) are being *captured* by the clinician and hence identified and named. The level at which similarity might be generated carries different implications for the epistemic value of the resultant psychiatric data, and it is useful to briefly examine each of these in turn.

Experiential Origin

Similarity may be generated at the level at which a particular dysfunction is experienced. This would mean that different sorts of lesions or dysfunctions would result in similar internal experiences. For example, similar feelings of low mood, fatigue, amotivation, etc. may be produced in response to a brain tumour, stroke, multiple sclerosis, dementia or major depression. Whether it is individual symptoms or whole clinical syndromes that are experienced as similar matters little at this point. The issue is, however, that similar experiences may be produced as a result of quite different brain insults. To make better sense of this, the notion of similarity here demands deeper analysis. The latter, however, is complex and well beyond the remit of this chapter, since we are dealing here with an ontological issue, itself dependent on the exploration of underlying problematical concepts such as identity and localization. Here, the only point to highlight is that at the level of symptom origin, internal changes might be experienced as similar and hence give rise to similar clinical pictures. This issue relating to the specificity or non-specificity of mental symptoms in relation to different brain insults is not new. During the late nineteenth century, there was a debate as to whether the phenomenology of the organic mental disorders (also called exogenous psychoses) always carried information or a mark that betrayed its underlying aetiology. For example, did the symptomatology of exogenous psychoses produced by hypothyroidism, brain tumours, toxins, meningitis and brain injury differ from each other in any way? Again, there is little space here to expand on this, which was but a remnant of the old medieval theory of 'signatures'. Kraepelin (1899) believed that, in principle, such subtle marks were embedded in the phenomenology of most exogenous psychoses but that not enough research had yet been done to identify them in all cases. By the early twentieth century, however, and mainly under the influence of evolutionary theory, views began to change. In the event, Bonhoeffer's proposal was accepted that the brain had only a limited number of stereotyped responses to insult and injury (confusion, delirium, stupor, cognitive disorganization, etc.), which were triggered by whatever aetiology. Subsequent questions asked by Bonhoeffer (1910), Redlich (1912) and others referred to whether some aetiologies preferentially chose particular stereotyped responses.

What, though, are the implications for the epistemic validity of the psychiatric data, in the context of biological psychiatry (the neuropsychiatric relationship), if similarity were to be generated at this level? If very similar internal states are being generated, irrespective of the specific cause, then any determinable clinical differences will depend not on the original signalling but on the nonspecific (in relation to the brain or other trigger) individual interpretation (formatting) of the internal change. Such interpretation would, however, represent the 'noise' in the system rather than reflect specifically the original signal. Thus, mimics or behavioural phenocopies arising at this level may have similar core structures but different subjective colouring and different aetiologies.

Epistemic justification of such psychiatric data in this situation will therefore be weakened on two main grounds. Firstly, the factors important in the interpretation of internal states, as discussed in the general section, remain to be established. Secondly, and specifically concerning the similarities issue, as far as the relationship to the neurological lesion/dysfunction is concerned, then the informational value of the psychiatric data will be limited primarily by the level at which original signals can cause different internal changes. In turn, this depends on understanding at a deeper (and as yet unknown) level the mechanisms underlying brain changes and their mental manifestations. In practical terms, clearly similarity occurring at this level would mean that attempts to develop finer clinical or phenomenological discriminators would not help to differentiate between 'true' psychiatric

states (e.g. depression, psychosis, etc.) and different mimics or behavioural phenocopies.

Interpretative Origin

Similarity, postulated to arise at the level of interpretation of an internal change, carries different implications for the nature of psychiatric data. Here, the idea is that different brain events or lesions produce different internal experiences, but similarity is generated through a commonality of interpretation. In turn, this implies that there may be limits to the way in which internal states are interpreted and named by individuals. Such limits are different from those mentioned above, since they are imposed not by the signals themselves but by the capacity of an individual to describe and discriminate between different internal states. For example, it could be envisaged that different states of sadness, emptiness, gloominess, tension, irritability, etc. could all be interpreted as feelings of depression associated perhaps with loss of interest and enjoyment. In turn, these could lead clinicians to infer the presence of depressive disorders. Nevertheless, it may be that these differences and other qualitative differences in internal states may, in fact, be real differences, in the sense that they represent different (and significant) internal changes. Similarities are thus invoked on account of the way in which such changes are interpreted and articulated. In terms of epistemic justification for the validity of psychiatric data in this situation, there are, therefore, the same general problems as mentioned before in that the factors important in determining such interpretation and articulation will need to be understood. Firstly, it may be that differences may exist between individuals in terms of sensitivity to changes in internal states. Some individuals may be able to discriminate between more subtle differences than others. Secondly, even if all could discriminate to the same level, then limits to interpretation may be imposed by language itself and the linguistic categories available to the individual. Again, it is only by determining and clarifying such factors that the validity of the psychiatric data and the neuropsychiatric relationship itself can be improved.

Observational Origin

Similarity can also be generated at the level at which psychiatric data are being elicited and captured by the clinician. In other words, there may be differences in clinical symptoms, signs and behaviours that are simply not being determined by the clinician. For example, patients may be manifesting and/or expressing symptoms and behaviours that are suggestive of a depressive disorder and hence interpreted as such by the clinician, whereas in fact the clinical states are similar only superficially. Epistemic validity of psychiatric data here is dependent not only on the previously discussed problems of validity and reliability in general but on the specific factors determining similarity. The latter were raised earlier in the discussion concerning the notion of properties both essential and accidental and will not be explored further. The main point, however, is that, as elsewhere, such factors remain largely unresolved and hence again contribute to the weakness of the validity of the psychiatric data. Practical implications follow from this since, in theory, developing finer phenomenological discriminators would help to distinguish between mimics and behavioural phenocopies arising at this level. Thus, in the example above, applying finer discriminators to the patient with a behavioural phenocopy of depression might help distinguish those clinical states likely to benefit from antidepressant medication from those needing other forms of management.

In summary, psychiatric symptoms, signs and behaviours are data of a different sort to those captured in the physical/biological sciences and, as such, present specific problems in terms of their epistemic validity that carry important implications for both the clinical and research aspects of neuropsychiatry. Given the increasing technical sophistication of techniques designed to capture infinitesimal neurological lesions or brain dysfunction, the aim in this section has been to focus on the other aspect of neuropsychiatric data collection, namely psychiatric data. It is evident that the latter, in comparison, remain relatively neglected as objects of research, and only some issues relating to their epistemic justification as data have been raised here. Nevertheless, in the context of biological psychiatry, and the neuropsychiatric relationship in particular, further work on such issues relating to psychiatric data will be crucial.

Data Processing in Biological Psychiatry

The section on data capture dealt with threats to the validity of the information on which biological psychiatry bases its conclusions. This section deals with problems affecting data processing. The availability of canned statistical packages has changed the way in which biological psychiatrists conceive (or rather do not conceive) of the meaning and conceptual basis of statistical analysis. The old art of preparatory thinking (calculations in the pre-computer age were labour intensive[34]) has been replaced by a high-speed, magical processing that in milliseconds flashes on the screen more data than the operator can ever handle. Far from releasing time for the understanding of the concepts and limitations of statistical data processing, computers have just created a mirage of objectivity. The conceptual complexities of biological psychiatry require this bewitchment to be broken. The best research starts at the level of concepts.

The slowness of progress in biological psychiatry research can be attributed to difficult subject matter, bad or inappropriate technology, lack of ideas, and excessive reliance on the epistemic power of statistical analysis. This section will focus on the latter.

The best way to understand issues concerning epistemic power (here, 'epistemic' means capacity to gain, construct, generate knowledge) is through an example: is there any epistemic difference between the claim by a biological psychiatrist that hallucinatory voice x correlates with a hot spot z in Broca's area and the claim by a physical anthropologist that in humans, there is a correlation between size and weight? Unpacking this question should illuminate the (epistemic) problems confronted by biological psychiatry. Before doing so, three issues need to be discussed: representativeness and proxying (as in proxy variables); correlations (as in statistical correlation); and generalizability (as in whether statistical techniques can be used in fields other than those in which they were originally created).

Representativeness and Proxying

It is a common assumption that the world is a complete and stable system populated by fixed objects, facts and events all regulated by the same laws of nature, and that only experimental science can identify and harness these facts for the good of humanity. The furniture of the world is organized in sets sharing similar essential and accidental features (natural kinds) that can be represented (without residuum) and measured by man-chosen variables. Members of a natural kind are so similar (except for some accidental features) that to know them all it is enough to measure some. It is, however, important that the sample selected

[34] For example, when done by hand calculator, each factor analysis might take up to one hour. This encouraged reflection on its appropriateness to the project in hand, on the variables to be included, on the type of rotation, etc. It is unclear whether similar thinking goes on in the computer age.

is representative of the group, i.e. within respective value ranges, sample and universe should share essential features.

In real life, things are not as cosy as this. There is little evidence that the world is a stable system, or that its furniture is fixed, or that the laws of nature apply in all instances. The same probabilistic notions that encouraged the development of statistics also influenced twentieth-century physics, and natural laws (and later biology) are now understood as statements of probability (Gigerenzer *et al.*, 1989). To biological psychiatrists working in the no man's land between the organic and the psychological, these new views are of importance; hence, their main worry is not sample representativeness (as there are conventional techniques to resolve such) but what we call here 'object representativeness'.[35] This refers to the nature of the relationship between the object and its qualities, and can be divided into ontological and conceptual representativeness and proxying. It should be remembered that representativeness (of whatever type) becomes an issue only when phenomena are studied scientifically with the intention of drawing generalizable conclusions.

Ontological Representativeness

This refers to the nature of the relationship between the object of inquiry and its features (essential and accidental). Whether a diamond, a dog, a virtue or a mental disorder, features must contribute to the ontology (existence) of the objects they characterize. The issue of whether an object is just the collection of its features or a substance from which all features hang is not relevant to ontological representativeness. For when it comes to diamonds or dogs (and exemplars of other natural kinds), essential features must still contribute to the objects' ontology, ideally without leaving a residuum (unless there are unreported features); the point being that the object's total ontology would be diminished if one feature were to be taken away. It remains unknown whether features are aliquots, i.e. contribute the same amount of ontology.

Things become interesting when the same question is asked of objects such as a virtue (justice, prudence, temperance, etc.) or a mental disorder (say, schizophrenia) that are not natural kinds but constructs, i.e. their ontology is dependent fully on a bet (prediction) made by a person in times past (say, Kraepelin or Bleuler) that features x_1 to x_n (which was all that was available to them and is available now) define an object s as a firm candidate for being a natural kind. In this regard, pathognomonic would name features that contribute the most to the ontology of their object. Given the way mental symptoms and disorders have been constructed historically, it is unlikely that even the pathognomonic features themselves are ontologically or informationally homogeneous (i.e. aliquots).[36]

But then who decides for how long can the bet be allowed to go on? Should that be a scientific, social or economic decision? At what stage should it be said that the people who placed it have lost in that all they produced was an empty construct, a mirage? This does not mean to say that the complaints of the many people who have been told they suffer from schizophrenia are the less real or devastating. It means that those who put together the earlier cluster of features wrongly selected, ontologically privileged, interpreted and explained some of the complaints (features) uttered by those patients. In doing, so they created a malformed concept,[37] a concept that nature, after a century of persistent interrogation, knows nothing about.[38]

It could be argued that it is nonsense to claim that schizophrenia is like a diamond or a dog or a virtue in that the very definition of disease entails that it is always expressed through someone's body and/or mind. The problem of ontological representativeness becomes more complicated in this case, for now we have object x and its x_n features (i.e. schizophrenia as an abstract disease) and object y and y_n features and object z and z_n features (y and z are, in fact, two people suffering from schizophrenia). The question here is whether the way in which the disease expresses itself through the brain resources of Messrs Y and Z will distort the distribution or pattern of ontological representativeness suggested by the abstract definition. The answer is that it should, for in each individual, personalized formatting activity will take place that would cause major distortions in the expected patterns, particularly in relation to symptoms that are (1) idiosyncratic re-elaboration and reformatting of primary experiences (which makes them escape the control of whatever lesion underlies the disease), and (2) symptoms that are atavic behaviours written into the brain by evolution and hence nonspecific, and (if we are to believe Hughlings Jackson) are regularly 'released' by the lesion to the point that some believe that they are caused by it.[39] It can be concluded that disease features relate to bearers in different ways (have different ontological representativeness), and hence the choice of a feature or features to establish correlations with other variables poses interesting problems. These cannot be handled statistically, for the values for ontological representativeness are unknown.

[35] It is important to distinguish between sample, design (ecological) and object representativeness. *Sample representativeness* refers to the assumption that the objects selected for study (the sample) show the same distribution of qualities as the parent universe. Generalizability is warranted by the degree of sameness. *Design* or *ecological representativeness* concerns the view that sampling theory must also be applied to the objects or, more generally, the stimulus or input or environmental conditions of experiments. Because subjects live in a probabilistic world, their responses to tests and stimuli will be tentative in the sense that they never have enough information or training to respond in the deterministic way that the theory dominant in a particular area will predict. In consequence, responses will also be probabilistic and often biased by cultural learning. Design representativeness relates to ecological validity. *Object representativeness* concerns the issue discussed in this section, namely how well the variable represents the object under study.

[36] We have studied symptom heterogeneity elsewhere, but for the needs of this chapter suffice it to say that mental symptoms are constructs exhibiting different inner structure, semantic load, and relationship to the brain signal that putatively originates them. These dissimilarities result from the fact that they are constructed by different mechanisms that provide them with their specific form and content. Structurally, there is very little similarity between a hallucination, delusion, sadness, fear, etc. The real difference is determined not by content or brain site but by the formatting imposed upon the symptom at the moment of its formation (Marková and Berrios, 1995a).

[37] Conceptual malformation results from semantic underspecification, poor biological anchoring, negative definition, conceptual parasitism, over-contextualization, porous boundaries, anomalous linguistic practice, etc. Malformed concepts can be identified, understood and corrected only by historical analysis (not empirical research). There is nothing terrible about psychiatry creating malformed concepts. It is in the nature of the descriptive and explanatory enterprise that this happens. What is bad is that biological psychiatry is not aware of malformed concepts and hence has no mechanism to deal with them.

[38] The problem is that since no real neurobiological marker has ever been discovered, samples of schizophrenic cases are selected in terms of conventional feature arrays, which seriously distorts the interrogation of nature exercise, e.g. if pancreatic weight were to be an important marker, how could that be discovered if that information is not collected in the first place? For a full discussion of these issues in relation to schizophrenia, see Berrios, 1995; Berrios, 2000b.

[39] If frequent (say, like auditory hallucinations), dormant features may be taken to be pathognomonic in spite of the fact that they are related to the disease neither structurally nor aetiologically. The fact that they often they show a high correlation with diagnosis is a good example of the unreliability of correlations.

Conceptual Representativeness

Given that we do not know about the ontological import of symptoms (features) in relation to specific bearers, choosing those with adequate representativeness (say, for the creation of a rating instrument or a diagnostic tick list) becomes difficult. Conceptual representativeness refers to the relationship between the chosen features and the expression of the disease (i.e. how a subset of features co-varies with a vectorial representation of the disease).[40]

Now, a statistical solution (such as 'random' selection) will not do, for disease features are structurally and empirically different from one another.[41] This is certainly the case intra-individually and some may want to argue that the same holds across individuals. For example, let us say that disease d as specified by DSM-IV consists of criteria c_1 to c_5. Although criteria are often made to include more than one feature of the disease, we shall assume that there is a $1:1$ correspondence between criterion and feature. As a rule, c_1 to c_5 are considered as different from each other in all respects (phenomenology and structure), but the manual does not specify their representational or epistemic validity. Previously, this notion was also conveyed by categories such as primary/secondary, pathognomonic/accidental, etc., but for some reason symptom hierarchies have gone out of fashion.

However, it is dangerous to assume that all criteria (features) have the same representational validity (vis-à-vis the disease) since little is known about the structure of the concept of mental disorder in general and of schizophrenia (or any other disorder) in particular. Indeed, it is even unclear whether it makes sense to claim that all mental disorders share a similar structure or, as in the case of mental symptoms, each group (psychoses, neuroses, personality disorders, etc.) will have its own internal structure, which would have different implications for the way in which features relate to each disease. At the moment, features are chosen in terms of criteria, such as ease to measure, availability, saliency, etc., but not in terms of their conceptual representativeness.

Proxying

Proxying is a form of conceptual representativeness. A proxy variable is defined as 'a variable[42] used as an *indirect measure* of another variable when that second variable is difficult to measure or to directly observe. For example, the frequency of abuse of street drugs is difficult to measure but it can be studied through the proxy variable of hospitalizations for drug overdose' (Reber, 1995). Proxying is often used in biological psychiatry, and hence it is important to know how it works.

The practice of proxying is based on the assumptions that: (1) variables can represent other variables (where 'represent' seems to mean co-vary) and (2) sensible or plausible proxy variable selection is possible. The first claim can be understood as meaning that variable p (proxy) co-varies with variable x (proxied), or that p and x co-vary with variable z (although not necessarily with each other). In order for proxying to be made to work, the biological psychiatrist needs a model that embraces p, x and z (otherwise the exercise become nonsensical). The assumption that sensible or plausible proxy variable selection is possible leads to the same conclusion, namely that selection can be justified only on the basis of a model. Only on the basis of the latter could finding a significant co-variance be reasonably taken to be a form of ascertainment.

Ex definitione, a proxy variable is further removed from the object of inquiry than the proxied one. This means that it is less under its ontological and epistemological control and that is more exposed to extraneous factors than the proxied variable. Because in most cases the distance between object and proxy variable is unknown, the latter is chosen on the basis not of science but of expediency. For example, the choice of the proxy variable 'hospitalizations for drug overdoses' to measure levels of street drug use or of using 'changes in blood flow' for changes in brain activity (and thereby subjectivity) may not sound extremely plausible, but it is all the biological psychiatrist has. However, in terms of verification (empirical ascertainableness), there is a difference between the two examples. Impractical as it may be, it should be possible to carry out a large epidemiological study to measure street drug usage and its co-variance with hospitalizations. However, no amount of empirical research will be able to ascertain the real nature of the co-variance between blood flow and subjective mental activity.[43] Unfortunately, there is no space in this chapter to develop our own model of proxying.

Correlation

One of the assumptions built into earlier metaphysical accounts of reality was that everything in the world was connected with everything else; hence the qualitative or philosophical concept of association (a mode of correlation) can be considered as ancient. The Newtonian and probabilistic revolutions introduced a new metaphor, to wit, that the book of nature is written in the code of mathematics, and that knowledge about objects and their laws and relationships has to be ascertained piecemeal.

The modern concept of correlation appeared in the biological thinking of the eighteenth century as a general explanation for observed (size) co-variations between organs in living beings. Such co-variance could be *physiological*, i.e. organs worked towards a common purpose (e.g. stomach, guts, liver, etc. in relation to digestion); *developmental*, i.e. organs grew in a synchronized fashion (e.g. secondary sexual organs) when serving a specific function; and *featural*, i.e. somatic characters developed in connection with each other. These three aspects of organ co-variance were conceptualized in terms of the old laws of association.[44] During the nineteenth century, featural co-variance became incorporated into evolutionary theory, for it was characters or traits (anatomical and physiological) that were believed to be the substratum for spontaneous variation and the target for selection.

Up to the 1870s (including the work of Darwin), the description of variation was qualitative, but Francis Galton (Darwin's cousin), Weldon, Edgeworth, Karl Pearson (Stigler, 1986) and others developed quantitative descriptions, which, in the event, became the

[40] Since biological psychiatrists believe that all mental disorders have a seat in the brain, then the presumption must be that such a feature will also correlate with a vectorial representation of a putative lesion.

[41] All diseases are constructs locked in a particular space and time. The small sample on the basis of which the original description was made tends to be fixed as prototypical. Ideology, opportunity and luck determine the success of the construct: constructors are always guided by expectations and anticipatory concepts, are opportunistic, and must have a modicum of luck.

[42] A variable is a mathematical symbol for a quantity that can take any value from a set of values called the range. A variable that can take any value between two given values is called continuous; otherwise it is discrete. A quantity that can take only one value is called a constant. This definition does not deal with the issue of how that quantity in question relates to its source, how it is measured, and how it is represented.

[43] The term qualia (singular = quale) has become standard amongst philosophers of mind to refer to properties of mental states and events that determine what it is like to have them, i.e. to subjective, experiential aspects. It is a synonym of phenomenal properties or qualitative features.

[44] According to associationism, certain principles of thought encourage human beings to assume a relationship between objects, e.g. when they are close together (contiguity), look the same (similarity) or are the opposite (contrast). This form of cognition and prediction is likely to have had its origin in the simple observation that members of the same genus have a family resemblance and march together. First formalized by Aristotle, the principles of association were to become psychological laws in Western thinking (Warren, 1921; Rapaport, 1974).

current concept of correlation. Pursuant to his overwhelming interest in eugenics, Galton wanted to show that 'good' features ran in 'good' (English) families and used for this purpose 'error theory' (originally developed to correct measurement errors in astronomy). He reintroduced the term 'correlation' to name a new idea, a numerical association (coefficient r) that was supposed to measure the strength of co-variances between objects or their properties.[45]

What data are needed to calculate r, say, between objects or features a and b? One measure of each will not do, for r needs profiles of variance, i.e. it needs to be based on a data series, i.e. a number of magnitudes, degrees of some attribute, or the like, viewed as capable of being enumerated in some sort of order. Series of pairs of data points can be obtained from either a group of people (cross-sectionally) or one individual (longitudinally). The former are single measures (from many individuals) of properties a and b at a given moment in time; the latter are repeated measures (from one individual) taken on a time series. The statistical treatment of both series may be very similar, but the conceptual treatment should be different as they are ontologically dissimilar. As far as the authors know, no mechanisms seem to exist to carry the ontological differences to the interpretation of r.

To make possible their inferences and generalizations, biological psychiatrists must make (often implicitly) a number of assumptions: (1) that if features a and b co-vary, they do so in the same way regardless of the source of the data; (2) that a and b change with time; (3) that the changes will be the same whether spontaneous or provoked by the researcher; (4) that when a and b change, they do so in a synchronized way such that the pattern of their relationship is preserved; (5) that r (as a quantity) holds a relationship of sorts with whatever is happening in the ontological substratum or natural phenomenon (this relationship has been called reflection, picture, mapping, etc.); and (6) that a very low r means that there is a weak or no relationship, and a very high r means that is a very strong relationship. All these are ontological assumptions for they pertain to the reality that the correlation is numerically meant to portray. At the moment, they remain implicit and often contradict each other. We hold that they must be connected with the scientific hypothesis that the researcher is trying to test.

In order to achieve this connection, an ontological model needs to be specified. Is the co-variance pattern the same when a and b: (1) hold a cause–effect relationship (the type of relationship that biological psychiatrists long for but that is, in fact, rarely available as the ontological basis for a correlation); (2) depend on a third factor (this type of ontological account is ambiguous as it can be interpreted as coincidental (trivial) or meaningful); (3) hold a pre-established harmony (this type of co-variance may give rise to a significant r but is empty of meaning); and (4) are truly coincidental?[46] Is the co-variance pattern the same if the changes in a and b are spontaneous or if they are provoked by the researcher?

Correlations are one of the most common forms of statistical analysis used by biological psychiatrists as they search for cause–effect relationships. Since all the number crunching is now undertaken by canned computer programs, many are no longer aware of the operations performed on the data series (or of the data themselves). This can be excused as division of labour between man and computer; less excusable, however, is ignorance of the issues discussed in this section, namely that correlations are patterns of thought based on forms of reality (ontological models) assumed to behave according to specific assumptions. These patterns must dovetail with the general model controlling the area of research in hand (whether depression, brain receptors, PET scan of verbal hallucinations, neuropathology of schizophrenia, etc.). In other words, this knowledge is essential to the biological psychiatrist both in the context of discovery (hypothesis making) and in the context of justification (relating 'evidence' to the logic of the model). Without this knowledge, the scientist is creating empty narratives, just like writing a bad novel guided by a recipe.

Generalizability

Does the fact that statistical techniques were developed to resolve problems generated by particular object arrays affect their applicability to the field of biological psychiatry constituted by different object arrays? For example, does the fact that R.A. Fisher[47] developed analysis of variance specifically to measure the effect of variable additivity on seed growth (*static* objects) mean that it should not be applied to *dynamic* arrays such as are obtained from the longitudinal measurement of human behaviour? Lest there is confusion, this problem is not about the normality of distribution of variables (and the remedial application of so-called parametric and nonparametric statistical techniques); it is about the relationship between the mapping capacities of mathematical models and the ontological features of an object array on the basis of which they were first developed. In the case of analysis of variance this means object array (seeds) → representations and concepts (choice of variables, definitions, measurements specific to seeds) → algorithms for analysis (analysis of variance). Has the original reality (seeds, static object) formatted the algorithm to the point that the latter cannot be used in object arrays other than the original or very similar one? The stock answer is that the whole point about algorithms is that they are formal and abstract and transferable and hence can be applied to any realm of reality.

To recapitulate, analysis of variance was developed to deal with static arrays of objects (seeds in bags) where simultaneity between variables data points (size, weight, etc.) was guaranteed. The question is whether analysis of variance can work equally well (here, 'work' means able to generate valid results rather than formally applied) when applied to data whose simultaneity cannot be guaranteed. Simultaneity cannot be guaranteed in much of the data collected in biological psychiatry. For example, patients may be tired, thus neuropsychological assessment needs to be undertaken on more than one occasion. (However, when data are entered in a two-dimensional matrix, the assumption is made that data are at least contemporaneous.) Surprisingly, there has been little work on the (temporal) definition of contemporaneity. Without good accounts (backed up by empirical data) of why correlations of variables measured a year apart are epistemically weaker than correlations of variables measured contemporaneously, it is difficult to carry out research in biological psychiatry.

Biological psychiatrists seem to take a common-sense view of this problem. In some situations, say PET scanning of

[45] Two objects or features are said to co-vary when changes in one 'map' changes in the other, so that the overall pattern of their relationship remains unchanged. Co-variation may be linear or sigmoid. In the former case, both variables change more or less at the same rate along the range of measurement; in the latter, they may change at a different rate. Correlations may be positive (both magnitudes increment at the unison) or negative (increases in one correspond to decreases in the either). Co-variation is a dynamic and relative concept that must be interpreted. This is done in terms of an ontology model; without the latter, correlations are empty.

[46] Claims that a coincidence has taken place (i.e. a concurrence of events or circumstances having no apparent causal connection) are meaningful only if made within a specific domain. For example, the claim 'Within this particular theory of schizophrenia, a significant correlation between intensity of formal thought disorder and length of left toe must be considered as coincidental' is intelligible; the same claim made in general about schizophrenia becomes nonsensical.

[47] When Fisher arrived at the agricultural station of Rothamsted, he found years of raw data waiting for analysis, mostly seed collections that had been cultivated in different environmental conditions (Box, 1978).

hallucinatory experiences, researchers are likely to want to define contemporaneity as simultaneity (i.e. require a time overlap between image capture and subjective experience). However, in many other studies, say analysis of association between plaque density and cognitive deficits in multiple sclerosis, researchers worry less about contemporaneity, i.e. about the event (memory impairment) occurring within a reasonable time of the development of certain other events (plaques) (Berrios and Quemada, 1990). Little is known about what 'reasonable' means in this context or about the way in which simultaneity and contemporaneity affect statistical significance, and the interpretation of results (on interpretation, see p. 20).

All this suggests that when applying statistical techniques to data in biological psychiatry, the researcher must take into account what could be called 'hermeneutics of analysis', namely the relationship between ecological time, semantics (pertaining to the data), and the way in which 'statistical significance' is interpreted. A biological psychiatrist genuinely keen to understand their subject matter should spend more time solving this crucial problem than worrying about formally meeting journal conventions.

Epistemic Value

Now to the question asked earlier as to whether there is any epistemic difference between the claim by a biological psychiatrist that hallucinatory voice x correlates with a hot spot z in Broca's area and the claim by a physical anthropologist that in humans there is a correlation between size and weight. The anthropologist's claim is redolent of the old eighteenth-century debate on correlations between physical features in biological entities; as we have seen above, the question first was given an ontological answer and later a probabilistic one. This happened because in the intervening century, probability and evolution theory had developed sufficiently to change the definitions of species and variability. The former concept reconstructed the idea of biological natural kind; the latter offered the substratum upon which evolution would operate its selection process. The epistemic value of the physical anthropologist's claim depends on three conditions: (1) compliance with representativeness and other sampling requirements; (2) theoretical warrant for their ontological claims; and (3) a factor x, namely a combination of acceptability by peer group, fashionableness and luck.[48] The anthropologist's claim seems to have met all three conditions.

Although it seems to have the same form as the anthropologist's, the claim by the biological psychiatrist differs in terms of epistemology and ontology. This means far more than the trite claim that all variables differ from all other variables. Therefore, its epistemic value depends on the resolution of these differences. The claim is very different for it reports a correlation between two *sui generis* concepts, hallucination and change in blood flow (deeply different from size and weight). Auditory hallucination is a construct based on the utterance by a subject that they are hearing voices when there is no one around. The issue is not whether the experience and phenomenon are real but that all the researcher has to go by is (1) an utterance and (2) two assumptions: that utterances always report images and that the quality of the reporting is not impaired by the presence of an acute psychotic state.

Although the two claims above are formally similar, only the hallucination/Broca's area claim is trapped in an unresolvable ambiguity for there is no way of telling whether the subject reports an auditory image or the belief that he is having one. From a therapeutic perspective, this may not matter, as the same treatment is offered. It is, however, crucially important to neuroimaging studies purporting to correlate the utterance with a marker of brain activity. The discourse of science may or may not be about truth, but it certainly is about coherence and reduction of ambiguity, and the one reported above cannot be overlooked for it affects all neuroimaging studies of mental symptoms. In practice, this means that it drastically reduces their epistemic value.

[48] In fashionable areas of research, e.g. neuroimaging, statistical rules may be violated on the excuse that it is early days, and that the mathematics will be sorted out eventually. Manuscripts violating statistical rules (e.g. with no correction for $>150\,000$ t tests) may therefore be published and their results accepted by the throng; this constitutes factor X.

Data Interpreting and Reporting in Biological Psychiatry

How does biological psychiatry fare in relation to data interpretation? It is often believed that in modern research, methodological and statistical algorithms can even indicate what conclusions to draw. This may be so superficially; in practice, however, efforts are made by biological psychiatrists to select and interpret. How do they fare? Due to the nature of its research questions and variables, problems that are standard in other fields of inquiry become magnified in biological psychiatry.

Interpretation and Evidence

To interpret means to expound the meaning of (something abstruse or mysterious); to render (words, writings, an author, etc.) clear or explicit; to elucidate and to explain. The sort of data obtained in biological research are of the type that require careful interpretation in all the senses listed above. An interesting feature of interpretations is that they cannot be said to be true, exact or apodictic; they can only be fair, imaginative, beautiful, audacious, speculative or silly.

Evidence

In biological psychiatry, much is made of the claim that clinical narratives and decision making are now based on evidence. Members of the public may rightly wonder as to how medical and psychiatric decisions were made before the concept of evidence was invented in the Oxford of the 1980s. In fact, the concept of evidence (Latin, *evidens*: clear, distinct, plain, visible[49]) is ancient, complex, kaleidoscopic and changeable, and there is no reason to believe that the current (blurred) meaning will last for long.

One problem with the historical analysis of evidence is that its origins go back to conceptual contexts and worlds that are no more. Another problem is that because it is an epistemological notion (one that talks about how we know the world), its study causes tautologies and self-reflexive contortions. The notion of evidence was first conceived in a world in which, in addition to sense perception, humans were believed to acquire knowledge through a variety of other mechanisms. Thus, between the fourth and second centuries BC, *enargeia* was used to mean 'clear, visible, datum of experience, manifest, in the mind's eye, evident, prominent, palpable, in bodily shape, brilliant, distinct, etc.' (Liddell and Scott, 1994). All these terms revolve around the claim that, whether through perception or directly coming into the mind, objects in the

[49] The impact of the term 'evidence', i.e. what moves people in the street when told there is evidence for x, relates to its metaphorical force — "clear, distinct, plain, visible"; to the fact that it relates to something that appears to the eye; to the suggestion that it points at something objective, tangible, visible, above board, public, pure, innocent and uncontaminated. Even when evidence is not made public, the point is to reassure people that it could. The personal vision of at least one witness (seeing is believing) is crucial here: 'Now Thomas (called Didymus), one of the Twelve, was not with the disciples when Jesus came. So the other disciples told him, "We have seen the Lord!" But he said to them, "Unless I see the nail marks in his hands and put my finger where the nails were, and put my hand into his side, I will not believe it"' (John 20 : 25).

world can be known with certainty, and that epistemological feature is called evidence. This also explains the ambiguous purview of the term, namely that it refers to the *feeling* of certainty itself (subjective evidence); to the *objects* that cause the feeling (objective evidence); and to its *inferential force* (epistemological and social authority) (more on this below). When at the end of the seventeenth century John Locke (1959) did away with all methods of knowledge other than experience via perception (fundamentally) and reflection (secondarily), the force of the mechanism of evidence became seriously undermined, particularly in regards to its direct access to the mind (bypassing perception). This attribute of non-perceptual directness survived for a time in the old notion of intuition and also in the later concept of apperception (Lange, 1900) but it died out with them. The legal usage remains fully extant, but it is no more than a generic name for objects or testimonies that can be used as a source of inferences.

Thus set asunder, the concept of evidence has had no safe port of call. Since the Cartesian challenge, perception has been considered as too fallible to provide the epistemological purchase needed by evidence; considering it as a derivative of certainty causes a tautological loop; basing it on the old concept of dictum by authority is not politically correct. The twentieth century cleverly linked evidence to science, and the tautological consequences of this link have been hidden from view: any narrative generated by science is now considered as sufficient epistemological purchase for evidence, and that is the way it has been defined. When someone asks what legitimates the scientific narratives themselves, the answer is that it is evident or that they are what evidence is about. Evidence can work only if it gets its force from somewhere. Originally it came from magic, and the notion then worked at its best; theologians took it over and the divine was a good replacement for magic. Nowadays, it is science. In all cases, it would seem that the concept of evidence fulfils more than a philosophical need, and that is why societies cling to it at all costs.

Evidence as a Social Practice

The claim that certain things are true can be understood in various ways, e.g. true now and ever (static), inching towards the truth (dynamic progressive). Whichever, it needs to be related to, or anchored in, the mind and behaviour of people. People have to be convinced that a is the case before they fully accept a. Evidence is the mechanism whereby this is achieved. In each historical period, those in control (whether religious, political or scientific leaders) have put together cognitive and emotional packages for the rest of us with the form, 'The world is like w and the reasons to believe it is so are contained in evidence e."

Thus, from the perspective of social order, evidence acts as the long arm of the abstract notion of certainty. In this sense, it can be defined as a social practice or mechanism designed to induce in the majority of the collective social an unconditional acceptance (both cognitive and emotional[50]) of certain world views (*Weltanschauungen*). The latter contain 'truths', whether religious, moral or scientific, that are convenient to social order. Evidence is offered as a proxy for truth since there is little choice for the social collective but to accept and internalize as certain a world view that has been chosen for them.[51] Who decides on what counts as evidence, and which world view is more convenient remains a problem. Earlier solutions revolved around authority and the creation of an elite of seers of evidence. However, the type of society that issued out of John Locke's 'democratic individualism' renders the above solutions incorrect, and new solutions had to be found that ideally were based on impersonal authority of statistics and database systems. These are sold as autonomous epistemological devices, untainted by human hand, and hence impartial and objective. By calling them 'the' evidence, these systems benefit from whatever is left of the force of a once magical term.

The Scaffolding of Evidence

Whether in theology, jurisprudence or epistemology, historical analysis shows that the concept of evidence has been shaped by specific metaphors and dichotomies. One distinction concerns the use of the term to refer to (1) facts or objects (e.g. knife, document, etc.) from which some other fact can be inferred, and (2) the testimony of persons as to the existence of facts. In the former case, there is a real object available to the collective; in the latter, there is a claim by a person who has seen or heard something. In the cultures of the West, the concept of evidence was first (fully) used by organized religion. For example, up to the medieval period, there was a debate in the Christian church as to whether the best grounds for believing in god was rationality (what nowadays would be called a cognitive understanding) or faith. Evidence played a role in the buttressing of rationality and was related to the contents of the Bible. Not always perspicuous, part of the latter often were given more than one interpretation. Who was to decide on the correct one became a problem, and one of the solutions was to create a cast of interpreters.[52]

By challenging the legitimacy of these interpreters, Luther created not only the need to redefine interpretation (hermeneutics) and evidence but also to rethink the relationship between god and men (Lohse, 1987). Another challenge to the old person-based concept of evidence came from John Locke at the end of the seventeenth century, particularly in his conception of the individual as a tabula rasa and the democratizing aspects of epistemology (object will reflect identically in the camera obscure of all minds). As against this, the Platonic influence on both Galileo and Newton generated the great hermetic metaphor of the seventeenth century, namely that evidence is encoded in nature, that nature needs to be interrogated or read, and that the code is mathematics. The probabilistic revolution that started at the end of the eighteenth century led in due course to the mathematization and relativization of the concept of scientific truth.

The history of evidence as a relative concept is a consequence of these changes. Evidence-based medicine is part of this social process, whereby the old authoritarian structures have been hidden behind the statistical techniques (such as meta-analysis), which are presented as impersonal cognitive devices able to extract meaningful information (sufficient for decision making) from large masses of data. They have now become the highest tribunal, and the evidence they issue is presented as the truth. Things, however, are not what they seem, for figures need *interpreting*, and this is still done in the way it always was: in smoke-filled rooms by men

[50] The role of emotions in the acceptance of evidence has not been well studied. This may be because, both in science and the law, evidence is made to appear as the *summum bonum* of objectivity and hence as denuded of emotions. In this regard, it is good to remember Wittgenstein's claim: 'Every explanation is indeed a hypothesis. But someone who is disquieted . . . will not find much help in a hypothetical explanation. The latter will not reassure' (Wittgenstein, 1989).

[51] The force of *videre* issues out of the original metaphor, 'Seeing with your own eyes is believing'. The form of the negotiating gambit is therefore, 'You must believe in this because it is based on evidence' (i.e. on something that you see or you could see). Buttressed by evidence, certainty generates authority. The concept of evidence is therefore central to social order and links stable views of the world with social control.

[52] The highest appeal station for the intermediaries was (and is) Rome. The doctrine of Papal Infallibility was confirmed by the First Vatican Council (1869–70). It was the role of the intermediaries that Luther was to challenge, and by doing so he not only redefined the concept of evidence within the confines of religion but created a new way in which man related to evidence and interpretation.

(and now some women) who decide in the end what is and what is not passed on to the throng.[53]

Interpretation

Central to the cognitive and emotional organization of the world is the concept of interpretation (Grondin, 1994). First a noun naming contradictions and options in everyday life, the Greek term was to become a verb to refer to the action of choosing between options. It then entered Aristotle's epistemology as the name for the link between the sign and the mental image or concept (what the Greek philosopher called 'affections of the mind'). Lastly, since choices and decisions were negotiated in words, interpretation became a term that was used mainly in the realm of language. *Hermeneia* and derivatives were rendered into Latin as 'interpretatione'; soon enough, this voice became incorporated into most European vernaculars.

To start with, the practical acts of interpretation (*exegesis*) concerned sacred and legal books; hermeneutics followed as its theoretical discipline. Within Christian philosophy, the problems posed by biblical interpretation were seen as resulting from the distance that existed between man and God; hence a decision had to be made about whether the Bible needed to be interpreted literally, doctrinally, philologically or historically. Luther challenged the Roman Catholic view that interpretations had to be left to the experts. In encouraging a personal reading of the scriptures, and a direct dialogue with the divinity, he opened up the need for a new subjective relationship between man and God and the concept of inner self, as a private space for such encounter emerged from these momentous changes. During the late eighteenth century, J.G. Herder (Pènisson, 1992) introduced the view that problems with understanding could also be due to different cultural purviews. During this period, interpretation is applied to literary works on the assumption that good hermeneutics (which included a study of the worlds, the history of the ideas) should lead to the one final meaning. Although the reader still defers to the author, the view is also introduced that the former may end up knowing more about the work than the latter. Schleiermacher broadens this definition further by making the interpretative task one coextensive with comprehensive psychology, and Dilthey (at the other end of the nineteenth century) sees hermeneutics as the central task of the human sciences (Grondin, 1994). During the twentieth century, the attention of hermeneutics shifts towards the role of the author and in due course conflates it with that of the reader. The idea that texts have only one meaning is surrendered, and the view that hermeneutics is about texts alone is replaced by the view that it is about the study of human communication.

All these changes are of momentous importance to psychiatry and the derivative biological psychiatry. For a time, the natural sciences presented themselves as immune to hermeneutics on the argument that objectivity was about eliminating subjectivity and rendering knowledge impersonal. These claims are groundless and part of the selling rhetoric of science. Like all other discourses, the scientific discourse is also open to interpretation and hermeneutics, and deferring to statistical significance and the results of laboratory experiments is a cop-out. Whilst that stance can be defended in physics or chemistry, it cannot in relation to psychiatry and biological psychiatry. These are best defined as interstitial disciplines, as doings that inhabit the borderlands between the natural and social sciences. Rhetorical reductionisms and naturalizations of the mind do away with the essence of psychiatry, which remains the specific understanding of human beings with a disorganized psychology. If modelling these processes may be tough, that is not an excuse for giving up and skirting around them (Dupré, 1993, 2001).

Interpretation is essential and pervasive in biological psychiatry, and its practitioners interpret away regardless of whether they have been trained to do so. This makes interpretation haphazard and uninformed. Interpretation occurs at the level of the contact with the patient, the level of the organization of the information, and the level of science making (both context of discovery and justification). The old positivistic view of science jars particularly in the context of biological psychiatry. There is little doubt that even neurobiological research would benefit from a hermeneutic approach to biological psychiatry.

Data Reporting: the Leniency of Fashion

According to the needs of the market place, interpretations of the same biological psychiatry data may suffer a different fate. When in fashion (a sure indicator of large investment by the industry), certain topics or techniques are supported by the major academic funding bodies in the land, and the unsaid message is that they are nearer the truth than older or tired approaches. In addition to an understandable rush by the young, there is an unseemly run by even older researchers who pursue money rather than lifelong research programmes. These fits and instabilities seriously affect long-term team approaches in biological psychiatry, and cherished hypotheses are indecently abandoned as soon as the industry withdraws investment. The current surrender of university research to such oscillations is to be regretted. The publishing industry joins in by showing surprising leniency towards fashionable topics, which are given a much easier passage than 'unfashionable' ones. This practice causes distortions in the public definition of biological psychiatry, and it should be asked seriously whether the privileging of certain topics because they are considered as good investment should not be considered as a form of scientific fraud. Biological psychiatrists should be aware of the way in which the vagaries of the market can destroy any chance of pursuing a balanced and coherent line of research.

CONCLUSIONS

Biological psychiatry is one of the incarnations of psychiatry. It is based on the foundational claims that all mental disorders are disorders of the brain, and that they should be explained by causes and not reasons. In various guises, these claims have individually been made since the seventeenth century, and by the nineteenth century they were defended by organized groups. A particularly keen version of biological psychiatry is predominant at the moment, and its success is due less to anything intrinsic or scientific but to the fact that its definition of mental illness fits in well with the ongoing philosophy of globalism. It is clear that if it was to be decided some time in the future that psychological approaches to mental illness are after all cheaper and a good investment, and that biological therapies are causing too much litigation, etc., universities, the government and the industry without any compunction would pull the epistemological rug from under the feet of biological psychiatry. Let us hope that it does not happen and that (a much improved form of) biological psychiatry goes on for a long time.

Predominance and fashion, however, should not make biological psychiatry immune to criticism. Its *sui generis* and interstitial nature, in fact, creates specific problems that sooner or later biological psychiatry will have to resolve by returning to the drawing board. It seems abundantly clear that the naturalization lark is not working. There are serious problems at the level of data

[53] It is not true to say, for example, that quangos like NICE (National Institute of Clinical Excellence, Great Britain) simply transmit to the throng the results of meta-analysis and literature searches. Whether overtly or covertly, they *interpret* evidence in terms of social, political and financial criteria. (NICE is a special health authority in charge of systematically appraising health interventions.)

capture, processing and interpreting, and all threaten its epistemic validity. The extraordinary complexity of mental disorder demands a humbler attitude on the part of everyone and the incorporation of a hermeneutic dimension to its study. The latter should not just be paid lip service, but should be integrated in whatever organic models are going to be pursued in the future. What biological psychiatry requires is a new model of symptom formation and a new language of description (Berrios, 1999). Thus equipped, biological psychiatry will be harder to research and practise, but it will also be far more likely to generate the kind of narrative that may capture the extraordinary phenomenon of mental disorder, and be more helpful to sufferers.

II

Measurement Issues

P. Bech

FROM PSYCHOMETRICS TO CLINIMETRICS

It is generally accepted that psychology became a scientific discipline in Wundt's laboratory in Leipzig at the end of the nineteenth century, where measures such as reaction time were used to evaluate the effect of alcohol or opiates on mental states. These psychometric measurements were made under careful and skilled observations, analogous to biological measurements. However, Kraepelin, the founder of biological psychiatry, realized when working in Wundt's laboratory that these tests were too limited for the measurement of higher mental functions (Hippius *et al.*, 1987).

In his monograph on clinimetrics, Feinstein (1987) has argued that clinical data are distinctly human characteristics that differentiate people from animals, tissues or molecules. He continues:

> If we say that cardiac size became smaller, that cardiac rhythm became normal, and that certain enzyme values were lowered, the description could pertain to a rat, a dog, or a person. But if we say that chest pain disappeared, that the patient was able to return to work, and that the family was pleased, we have given a human account of human feelings and observations ...

Kraepelin used clinimetrics when he discriminated between bipolar disorder and schizophrenia in the clinical course of symptoms, or when he found that delusional depression was the extreme severity of depressive states.

The first psychometrist in this clinimetric sense was, however, Binet. He used the basic psychometric principles when he developed the Metrical Scale for Intelligence from 1902 to 1908. This scale has dominated the assessment of intelligence in the twentieth century. It is not a laboratory test but a bedside scale. The psychometric principle, consisting of internal validity, reliability and external validity, will be outlined in this chapter in correspondence with the work by Binet and his colleagues.

The statistical tests related to the psychometric triangle will then be reviewed. The unique scale of global improvement in clinimetrics will be treated separately. Thereafter, the concordance between the procedural algorithms in DSM-III (American Psychiatric Association, 1980) or DSM-IV (American Psychiatric Association, 1994) and the clinical symptom rating scales will be presented.

DSM-III is the first evidence-based diagnostic system for mental disorders. It has been argued that DSM-III is a revised version of Kraepelin's textbooks in clinical psychiatry in order to improve the interobserver reliability of the psychiatric diagnosis. However, the multiaxial approach in DSM-III and DSM-IV is the clinimetric approach, as outlined by Feinstein (1987), through its inclusion of measures of life events or stressors, personality traits and social functioning.

Among the modern philosophical approaches to psychometrics or clinimetrics on the one hand, and biometrics on the other hand, Davidson (1980, 1991) and Chomsky (see Lyons, 1991) should be mentioned. Thus, Davidson (1980) has emphasized the holistic character of the mental field by including the patient's beliefs and motives. This implies (Davidson, 1991) that psychometrics or clinimetrics have to adhere more closely than biometrics to the psychometric principle of internal validity (coherence), reliability (communication) and external validity (correspondence). Davidson (1980) concludes that because of this anomaly between psychometrics and biometrics, only small correlations between psychological and biological phenomena can emerge.

According to Chomsky, however, in the development of modern science, biometrics has been able, step by step, to expand the biological field to cover anything we understand, so that when ultimately beginning to understand the properties of the mind, we simply extend the concept of biometrics to cover these properties as well (Lyons, 1991). In this chapter, the concept of stress has been used as an example of Chomsky's approach. If cortisol is the most valid measure of chronic stress, then this hormone should be called the chronic distress hormone.

In this Chomsky approach to the problems of body and mind, it is held implicitly, however, that proper knowledge can be obtained only in the biological field. This chapter will show that the psychometric measurement of stressors, distress, disability and quality of life collects important clinimetric knowledge. The use of appropriate statistical tests associated with the psychometric principle is expected to increase the correlation between the clinical phenomena and the biological phenomena in biological psychiatry, as has already been the case in clinical neuropsychopharmacology.

THE PSYCHOMETRIC TRIANGLE

When a field of knowledge becomes understood more clearly, the need for quantification or measurement increases (Kuhn, 1961). When Binet (1902) developed his first intelligence tests, he used the psychometric triangle (Bech, 1996; Davidson, 1991) (Figure II.1), which includes (1) the principle of coherence (internal validity), (2) the principle of interpersonal communication (interobserver reliability), and (3) the principle of correspondence (external validity).

At the end of the nineteenth century, experimental psychology had developed using psychophysical methods, reaction time tests or questionnaires to measure intelligence (Galton, 1883; Wundt, 1888; Ribot, 1896). Binet had been working with these methods but was mostly familiar with Ribot's principle of coherence, pointing at the cumulative approach when measuring higher mental states. Thus, Ribot (1896) found that '... in comparing melancholy (clinical depression) with ordinary sadness, we may follow the cumulative method ...' Updating this statement, major depression contains in

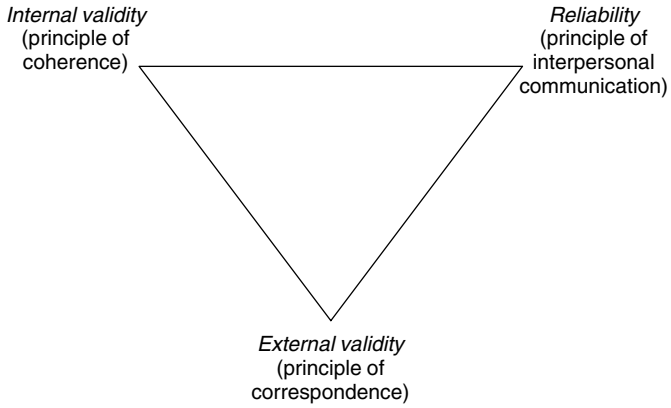

Figure II.1 The psychometric triangle (Bech, 1996)

it minor depression, not unlike the way in which a higher number contains only lower number.

Binet had no exact definition of intelligence, but he considered intelligence to include functions such as reasoning, judgement, comprehension, attention and memory. This was the content validity of intelligence. He then collected tests that reflected these functions. The principle of coherence was applied during his interviews with several children in the pilot studies (Binet and Simon, 1905). If a test did not distinguish between the brighter and the duller children, it was abandoned. In the final version of the Metrical Scale for Intelligence (Binet and Simon, 1905), the tests or subscales were arranged in order of increasing difficulty. The principle of cumulative validity (construct validity) implies that the bright person can solve the easy as well as the difficult tests, while the dull person can solve only the easy tests. Thus, each person passed as many tests or subscales as they were able to until they became too difficult for them to solve. How far the child Binet tested got down the list of subscales could then be compared with how far other children of the same age were able to go.

Each subscale or item in the Metrical Scale for Intelligence was scored dichotomously as a right or wrong response. Thus, the internal validity of Binet's intelligence scale includes both content validity (the components of intelligence) and the cumulative principle of coherence in which the total score is a sufficient statistic (construct validity) (see Figure II.2).

During Binet's pilot studies (Binet, 1902), it became important to take into consideration the bias of the teachers when these classified the children as dull, less dull, rather bright and bright. The same problem was operative for the interviewer when applying the intelligence scale. In psychometric terms, this problem is described as the interobserver reliability of a scale.

The external criteria for validity of the Metrical Scale for Intelligence were the association of the scores with age and school grade as well as with the teacher's assessment on a global scale from dull to bright. Binet assumed that within a single school grade, the eldest children would generally be less bright than the others because they had presumably been held back. Binet and Simon (1908) introduced the concept of mental age, which was determined as being the age at which the tested child would match the performance of the average child. Terman (1916) introduced the intelligence quotient in the Stanford–Binet version of the Metrical Scale for Intelligence.

In 1923, Boring concluded that intelligence is what is measured by intelligence tests such as the Metrical Scale for Intelligence (Boring, 1923). Later, Jensen (1969) concluded that the most important thing we know about intelligence is that it can be measured.

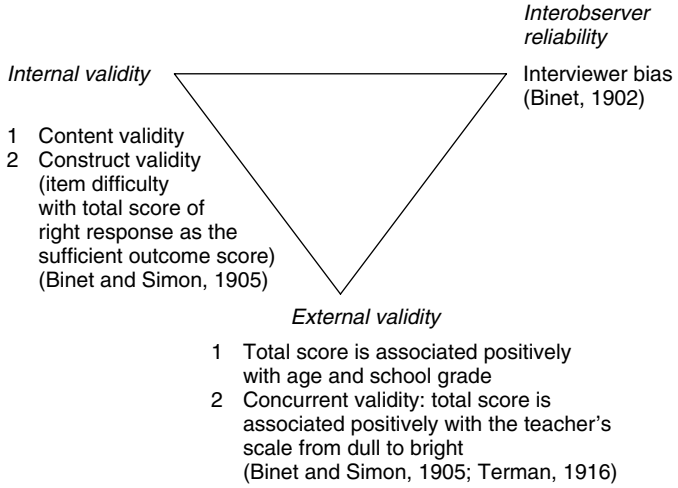

Figure II.2 The psychometric triangle: internal validity, reliability and external validity as used by Binet when constructing the Metrical Scale for Intelligence

STATISTICAL MODELS RELATED TO THE PSYCHOMETRIC TRIANGLE

Internal Validity

In the first major textbook of psychometric methods, Guilford (1936) concluded: '... No single event in the history of mental testing has proved to be of such momentous importance as Spearman's proposal of his famous two-factor theory (Spearman, 1904) ...' Most of the statistical tests in Guilford's first textbook edition of psychometric methods are concerned with correlation coefficients. In his measurement of intelligence, Spearman (1904) used factor analysis. However, it was Binet's psychometric triangle rather than Spearman's correlation analysis that finally emerged as the most valid measurement of intelligence. Thus, a theory of intelligence (content and construct validity) is the first principle of coherence, not a correlation analysis without a theory (explanatory factor analysis). With factor analysis, Spearman (1904, 1927) made valuable contributions to the structure of intelligence but not to its measurement. He identified a general factor that seems common to all types of intellectual activity, and he identified specific factors that seem unique to particular intellectual problems.

In the second edition of his textbook of psychometric methods, Guilford (1954) still considered Spearman's factor analysis (or other types of factor analyses) to be the most important psychometric model for measurements of mental states or activities. However, Mokken (1971) concluded in a comprehensive review of statistical tests in the measuring of mental states that explanatory factor analysis is a method of classification, not of measurement. The use of factor analysis for the classification of target syndromes in clinical psychiatry is described later. In the next section, the confirmatory factor analysis is also mentioned, here as a method of measurement.

Figure II.3 shows the statistical tests found most appropriate by Mokken (1971) for the measurement of the internal validity of a scale. The Guttman scale (Guttman, 1944) can be seen as the Binet approach to measuring the internal validity of intelligence by the cumulative principle. Essentially, as pointed out by Mokken, the Guttman approach is not a statistical approach because Guttman leaves no room for the estimation of errors in his analysis. The Guttman principle is a deterministic approach in which the items should be rank ordered, as in the Binet scale, in accordance with the

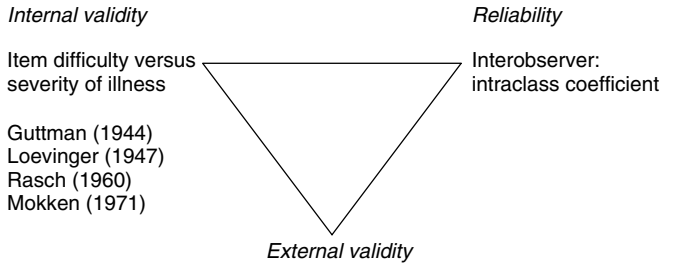

Figure II.3 Statistical models for testing a scale within the psychometric triangle based on the review by Mokken (1971) concerning internal validity

item difficulty (Guttman, 1968). The brightest person will have the right response to both the easiest items and the more difficult items, while the dull person will have a right response to only the least difficult items. Guttman's impact was to apply this scaling principle to other fields of mental states, which was Ribot's original idea.

An example of the Guttman deterministic principle is the scale for post-traumatic anxiety in soldiers who had been under fire (Suchman, 1950). It was found that soldiers with the highest level of post-traumatic anxiety answered yes to 'heart pounding', 'feeling sick at stomach', 'shaking all over', 'losing control of the bowels', and 'feeling of stiffness all over'. Those with mild post-traumatic anxiety experienced only 'heart pounding' and 'feeling sick at stomach'. Thus, the total score of these somatic anxiety items was an appropriate statistic. Suchman concluded that this strong cumulative coherence between the stress symptoms reflects an underlying physiological (hormonal) continuum.

Another example based on the Guttman model is the facet theory, which has been used by Steinmeyer and Möller (1992) for evaluation of the internal validity of the Hamilton Depression Scale. They identified six items as the depressive core items, which were similar to the six items identified by Bech *et al.* (1981) using the Rasch analysis.

Loevinger (1947, 1957) developed an index for errors in the rank order of item difficulty. Mokken (1971) has developed a coefficient of homogeneity for each of the items of a scale. Moreover, the Loevinger coefficient of homogeneity is part of the general Mokken analysis as the Loevinger index can be calculated as the weighted average of the individual Mokken item coefficients.

Figure II.4 shows the basic, cumulative principle in Mokken's coefficient of homogeneity. Mokken uses the term 'monotonous homogeneity' as an expression of the principle of cumulative coherence between items. In Figure II.4, the abscissa indicates the item difficulty (sigma). Four items are shown in Figure II.4: depressed mood, tiredness, guilt feelings and psychomotor retardation. These items are among the core items of major depression. Depressed mood has delta 1, tiredness delta 2, guilt feelings delta 3, and psychomotor retardation delta 4.

The ordinate in Figure II.4 is the probability of a positive score (phi). Hence, phi has a range from 0 (no probability) to 1 (maximal probability). Figure II.4 shows four curves that have the form of item characteristic curves, which is an essential feature of the Rasch analysis (Rasch, 1960) but not necessarily of the Mokken analysis (Mokken and Lewis, 1982). In Figure II.4, it is indicated how the item difficulty (sigma) is measured for phi values of 0.5. The four item curves in Figure II.4 are, thus, rather similar to dose–response curves in pharmacology, in which a phi value of 0.5 equals 50% response. A person who scores positively on psychomotor retardation will also score positively on the other three items. If not, the person has no depression but might have a neurological disorder.

Mokken used the term 'double monotony' to cover the situation in which the curves in Figure II.4 show the probability of a positive item score (phi) as a function that decreases with increasing values of the item difficulty (delta).

The Mokken analysis of a scale is based on the following:

1. The theoretical maximum of phi is 1.
2. The theoretical minimum of phi is 0.
3. It is possible to evaluate a scale as a whole (all items together as the Loevinger coefficient) as well as the scaleability of the individual items (Mokken's coefficient of homogeneity for each item).
4. Confidence intervals of the homogeneity coefficient can be shown.

Mokken has published the following interpretations of the Loevinger coefficients: 0.30 to 0.39 = a weak scale; 0.40 to 0.49 =

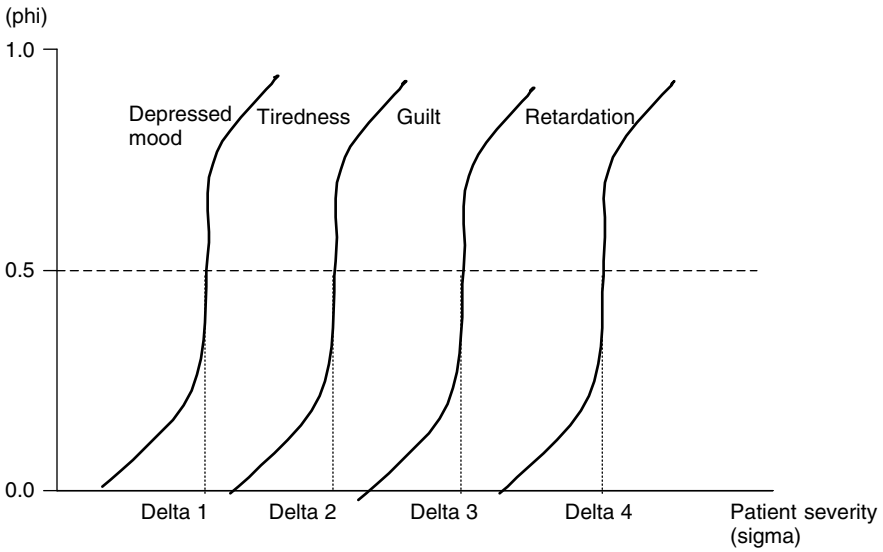

Figure II.4 Probability of positive symptom score on the individual item (phi) of a scale with only four items. The curves are rank ordered in such a way that a patient with scores on retardation also has positive scores on the other items. Sigma signifies the severity of the patient's depression

an acceptable scale; and 0.50 or higher = a strong scale. The most updated programme for the Mokken analysis has been published by Molemaar *et al.* (1994).

The Mokken analysis has been developed with reference to the Rasch analysis. As mentioned already, the Rasch analysis focuses on the item characteristic curves as an essential part of the analysis, in contrast to the Mokken analysis. These curves follow strictly specified S-shaped patterns, as shown in Figure II.4. They are monotonic. According to the Rasch model, the curves for all the items should all have the same shape. The curves are parallel, as are the four curves in Figure II.4, but they are placed as the various points along the abscissa. If the curves shown in Figure II.4 emerge when males are compared with females, younger people with elderly people, etc., then the scale is a measure of the underlying dimension (e.g. major depression). Within the Rasch model, the total score is a sufficient statistic. If a total score is not sufficient, this signifies that two identical scores from two different patients have different clinical meanings in that a very high rating on a few items can yield the same score as a moderate rating on many items.

Thus, compared with the Mokken analysis, the Rasch analysis has the advantage in that the model can be tested empirically by external criteria such as gender and age. The essential importance of the Rasch model compared with the Mokken analysis is that the Rasch analysis is population free, i.e. it is part of the model to evaluate randomly the distribution governing the selection of the population under examination as well as the items of the scale. Mokken also concluded that the superiority of Rasch over his own analysis is that it incorporates an evaluation in respect to the selection of both subjects and items.

Confirmatory factor analysis (Jöreskog, 1990; Jöreskog, 1993) has the advantage over exploratory factor analysis in that it is a direct part of the analysis to test for dimensionality, not just to identify factors. The confirmatory factor analysis, the facet analysis, the Mokken analysis and the Rasch analysis seem to have as a consequence that the higher the homogeneity, the lower the number of items (Bech *et al.*, 1981; European Rating Aggression Group, 1992; Steinmeyer and Möller, 1992; Aish and Wasserman, 2001). Thereby, these analyses converge at the magical number of 7 ± 2, which, as Miller (1956) showed, is the limit of human ratings of psychological dimensions.

In a recent psychometric re-examination of the citalopram dose–effect study by Feighner and Overø (1999), the six-item HAM-D subscale, which in contrast to the full Hamilton Depression Scale (HAM-D; Bech *et al.*, 1981) was shown to fulfil the Rasch analysis, has been found to have a much higher Loevinger coefficient (0.48) than the full HAM-D (Bech *et al.*, 2002). The same pattern was found for the Montgomery Åsberg Depression Scale (MADRS; Montgomery and Åsberg, 1979), in which the six-item subscale had a higher Loevinger coefficient than the full scale. The six MADRS items were 'apparent sadness', 'reported sadness', 'inner tension', 'lassitude', 'inability to feel' and 'pessimistic thoughts'.

Reliability

Another strong criterion in psychometrics is the correlation of a measurement with itself. If we measure body temperature in a healthy person over a few days, the correlation between the results will be close to 1.0. This kind of test–retest reliability is often referred to as the coefficient of stability. For a questionnaire, it is customary to show the coefficient of stability when the scale has been administered over a period of a week. However, in most textbooks on psychometrics, it is the rule to refer to another type of reliability, the split-half reliability coefficient, i.e. the correlation of half of the items with the other half of the items at the same administration (no time lag between two observations). The most frequently used reliability coefficient in this sense is the Cronbach coefficient alpha (Cronbach, 1951), which expresses the mean coefficient of all possible split-half coefficients (Nunnally and Bernstein, 1994). The split-half coefficient correlates the score of half of the items with the score of the other half of the items of a scale, typically odd items versus even items. This procedure is performed on the basis of a single administration of the scale to a sample of subjects.

The Cronbach coefficient alpha is often considered to be a test of internal validity because it seems to refer to the internal consistency of the scale. However, if the coefficient alpha is high, then all the items show the same item difficulty (sigma). In other words, all the items will have one single curve in common, for instance delta 2 in Figure II.4. Moreover, because the number of items is included in the formula resulting in the coefficient alpha, a high coefficient can also be an indicator of the length of a scale. This has been the reason why many scales measuring life events have included many items (Turner and Wheaton, 1995). A high Cronbach coefficient indicates not only that the scale includes many items but also that they can substitute for each other. Thus, the Beck Hopelessness Scale has been found by Beck *et al.* (1974) to have a Cronbach coefficient alpha of 0.93, which has been confirmed by Nimeus *et al.* (1997). However, Aish and Wasserman (2001) have shown by use of confirmatory factor analysis that the 20 items of the Beck Hopelessness Scale can be substituted by one single item: 'My future seems dark to me.' There is no reason to calculate Cronbach's coefficient alpha in order to express the reliability of a questionnaire or to express the internal consistency of a scale. The Rasch analysis and the confirmatory factor analysis are much better statistical analyses of internal validity.

For interview scales (e.g. the HAM-D), the intraclass coefficient is the most correct indicator for interobserver reliability. The intraclass coefficients correspond to degrees of interobserver agreement as: 0.0 to 0.20 = no agreement; 0.21 to 0.40 = very weak agreement; 0.41 to 0.60 = moderate but not acceptable agreement; 0.61 to 0.79 = acceptable agreement; and 0.80 to 1.00 = strong, nearly perfect agreement.

External Validity

There are two major psychometric aspects of external validity: responsiveness and sensitivity. The responsiveness of a scale refers to its ability to measure changes in the individual patient's symptomatology during a treatment period. Clinically, the index of validity in this situation is often the global severity assessment performed by an experienced psychiatrist. When Binet developed his intelligence scale, he used the global intelligence scale assessed by an experienced teacher as the index of validity.

In clinical psychopharmacology, the dose–response effect is often used as an index of responsiveness.

The most frequently used measure for global severity of clinical states is the Clinical Global Impression Scale (CGI) (Guy, 1976). The CGI is scored on a Likert scale from 1 (no clinical symptoms) to 7 (among the most extremely ill patients with the clinical syndrome under examination). In a study on the antimanic effect of a typical antipsychotic in severely manic patients, the Mania Scale (MAS) (Bech *et al.*, 1979) had a higher responsiveness than the CGI (Bech *et al.*, 2001a).

In dose–response studies with tricyclic antidepressants (clomopramine; DUAG, 1999) or serotonin selective reuptake inhibitors (e.g. sertraline; Fabre *et al.*, 1995), it was found that the depression factor of the HAM-D (Bech *et al.*, 1981) had a greater responsiveness than the total HAM-D scale. The HAM-D factor includes six items, which have been found to fulfil the Rasch analysis in contrast to the total HAM-D scale (Bech *et al.*, 1981).

The definition of the term 'sensitivity of a scale' is restricted to the ability of a scale to discriminate between active therapy

and placebo. The different statistical analyses of sensitivity for the meta-analysis of fluoxetine versus placebo have been compared by Bech *et al.* (2000). Among those statistics, the effect size seemed appropriate. This is defined as the difference between the mean of the baseline scores and the mean of the endpoint scores for patients in the active drug group and patients in the placebo group, divided by the pooled standard deviation. It was shown that the effect size for the depression factor of the HAM-D (Bech *et al.*, 1981) was higher than for the total HAM-D (Bech *et al.*, 2000).

In another fluoxetine analysis in which the HAM-D was compared with the MADRS, it was also shown that the HAM-D subscale was superior to the full HAM-D (Faries *et al.*, 2000). When fluoxetine was compared with placebo, the respective effect sizes were 0.32 (subscale) and 0.28 (full scale). A further analysis of Faries' study with the six-item MADRS subscale showed effect sizes of 0.22 (subscale) and 0.20 (full scale).

THE CLINIMETRIC INDEX OF GLOBAL IMPROVEMENT

The clinical global improvement scale is a measure of the overall therapeutic effects of an intervention during the treatment period. In principle, it is a measure of change during treatment in which the therapist makes an assessment of the reversibility of the mental state of the patient when retrospectively recalling the state before treatment and comparing it with the state after treatment. The change in before versus after treatment can be either an improvement or a worsening. However, often only the clinical improvement is measured by a scale in which 0 = unimproved or worse; 1 = improved slightly; 2 = improved much; and 3 = improved very much.

Feinstein (1987) has investigated this global clinical improvement scale in more detail and concludes that this kind of measurement is unique for psychometrics or clinimetrics, as it has no analogue in biometric measurements of change in the laboratory. It is a human rating of human changes of feelings or observations over time.

Cronholm *et al.* (1974) considered the global clinical improvement scale to be an idiographic measurement. Thus, the clinician can weight the individual clinical symptoms differently from patient to patient: '... in a way a new scale is constructed for each patient ...' (Cronholm *et al.*, 1974).

The interobserver reliability of the global clinical improvement scale has been investigated only rarely. It is, however, part of the Cronholm–Ottosson Depression Scale (Ottosson, 1960; Bech, 1991a). In a study by Isaksson *et al.* (1968), the interobserver reliability of the global improvement scale was only 0.56, while the Cronholm–Ottosson Depression Scale obtained a coefficient of 0.72.

However, in the original study by Ottosson, the global improvement scale was administered by experienced psychiatrists. When assessing the ability to discriminate between various dosages of antidepressive therapy, the global improvement scale was found to be superior to the Cronholm–Ottosson Depression Scale (in which the mean scores before and after treatment were used) (Ottosson, 1960). However, a re-examination of Ottosson's data showed that the Cronholm–Ottosson Depression Scale was superior to the global improvement scale when the 50% reduction of before-treatment scores was used (Bech, 1991a).

The use of clinical improvement scales has confirmed that the most commonly accepted analogue to 'much' or 'very much' improvement is a 50% reduction of baseline scores on symptom rating scales such as the HAM-D after around six weeks of antidepressive treatment (Bech, 1989).

When investigating the sensitivity of a modified version of the Cronholm–Ottosson Depression Scale, the MADRS, the global clinical improvement scale was used as the index of validity. The results showed that the MADRS was superior to the HAM-D. However, as pointed out by Faries *et al.* (2000), the treatments used in the Montgomery–Åsberg study were tricyclic antidepressants. In their meta-analysis of tricyclic antidepressants versus placebo trials, Faries *et al.* showed that the effect size was 0.23 for MADRS but only 0.15 for the HAM-D. However, a further analysis of the Faries study showed that the respective effect sizes were 0.25 for the MADRS subscale and 0.23 for the HAM-D subscale.

The most frequently used global improvement scale is the CGI. However, this scale also includes a severity scale, from 1 = not at all ill to 7 = among the most extremely ill patients within the diagnosis under consideration, e.g. depression or mania.

In a recent study of manic patients (Bech *et al.*, 2001b), the MAS (Bech *et al.*, 1979) was compared with Guy's (1976) version of severity in the CGI. In this study on severely manic patients treated with different antipsychotics, it was shown that the MAS was superior to the global severity scale in terms of responsiveness. Thus, after one week of therapy, 53% of the patients had a 50% reduction of baseline scores on the MAS, while only 30% had a 50% reduction of the baseline scores on the CGI. This difference was statistically significant.

PROCEDURAL ALGORITHMS VERSUS RATING SCALES

The first evidence-based diagnostic system for mental disorders was the *Diagnostic and Statistical Manual for Mental Disorders*, Third Edition (DSM-III) (American Psychiatric Association, 1980). The basic principle of the DSM-III, compared with the previous two editions (DSM-I; American Psychiatric Association, 1952; DSM-II; American Psychiatric Association, 1968) was the degree of interobserver reliability. It was demonstrated that in relation to the clinical target syndromes in psychiatry (schizophrenia, mania, depression, anxiety), DSM-III in contrast to DSM-II obtained an acceptable intraclass coefficient (Spitzer and Fleiss, 1974).

The innovations in DSM-III are the use of procedural algorithms when defining the various target syndromes as well as a multiaxial system in which concepts such as stress, stressors, distress and disability can be stipulated compartmentally.

This use of procedural algorithms in the definition of the symptomatic (distress) syndromes of the clinical target syndromes in psychiatry has been responsible for the rather high interobserver reliability. The internal validity of the clinical target syndromes in DSM-III is, however, not based on the cumulative principle. Thus, for the diagnosis of major depression in accordance to DSM-III, any five out of a total of nine symptoms must have been present. In DSM-IV (American Psychiatric Association, 1994), the algorithm has been modified so that at least one of depressed mood and lack of interest should be present. These two symptoms are the ones with the lowest delta number in the HAM-D (Bech *et al.*, 1981). This lack of the cumulative principle implies that the algorithm is resistant to qualification or measurement (Bech, 1991b; Quine, 1963). The algorithm is for the purpose of diagnosis. However, in the ICD-10 (World Health Organization, 1993), different contents of algorithms can categorize depression as mild, moderate or severe.

The items in the DSM-III system were selected according to two principles. On the one hand, they were to reflect the core symptoms based on shared phenomenology over time; on the other hand, they were to have discriminating power for the diagnosis they reflect. In this context, Frances *et al.* (1990), when editing DSM-IV, emphasized that '... unfortunately, items at the core of the definition are sometimes poor at discriminating the disorder, and items that are more discriminating may not be close to the core ...' However, factor analyses of comprehensive rating scales have identified most of the clinical target syndromes. Thus, on the

basis of factor analysis, using rating scales such as the Wittenborn Scale (Wittenborn, 1955), the Lorr Multidimensional Scale (Lorr, 1953), the Lorr Syndromes Scale (Lorr *et al.*, 1963), the Symptom Checklist (SCL; Parloff *et al.*, 1954), Frank (1975) concluded that the target syndromes of schizophrenia, mania, depression and anxiety (including phobia or obsessive–compulsive states) were valid at the symptom level. The same pattern was found by Pietzcker *et al.* (1983) when using the Arbeitsgemeinschaft für Methodik und Dokumentation in der Psychiatric (AMDP) Scale for factor analysis.

	How much of the time ...	All the time	Most of the time	Slightly more than half the time	Slightly less than half the time	Some of the time	At no time

Figure II.5 Major (ICD-10) Depression Inventory

These studies by Frank and Pietzcker *et al.* have demonstrated that factor analysis is a method of classification, as shown by Mokken (1971). The number of items needed to define the various target syndromes has not been established by factor analysis from a measurement point of view. The comprehensive rating scales used by Frank and Pietzcker *et al.* are checklists of symptoms rather than ratings. The number of items in the various target syndromes in DSM-IV is rather limited, following the concept of the magical number of 7 ± 2, as first introduced by Miller (1956).

Rating scales developed to measure the individual target syndromes and found valid according to a Mokken (1971) or Rasch (1960) analysis also have as their number of items 7 ± 2. The basic principle in this analysis of internal validity of measurement is that no single item of the scale in itself is sufficient, but that a limited number of items are sufficient if these items can be rank ordered according to the cumulative principle. It is not unimportant which of the items are used for a rating scale when the total score is a sufficient statistic in contrast to algorithms (Bech, 1991b).

Figure II.5 shows the Major Depression Inventory (Bech *et al.*, 2001c). This questionnaire is based on the DSM-IV symptoms for major depression. In order to include the ICD-10 system, the DSM-IV symptom of guilt feelings has been subdivided into two items covering low self-confidence (an individual item in ICD-10) as well as guilt feelings. Each item is scored in terms of frequency using the DSM-IV and ICD-10 timeframe of the last two weeks.

The Major Depression Inventory can be scored both as a rating scale in which the total score is a sufficient statistic and as a diagnostic scale using, for instance, the procedural algorithm for major depression according to DSM-IV. In both situations, items 8 and 10 are scored so that the highest values of 8a or 8b and 10a or 10b are used.

As a screening tool for DSM-IV major depression, the sensitivity and specificity of the Major Depression Inventory, when using the Schedule for Clinical Assessment in Neuropsychiatry (SCAN; World Health Organization, 1998) as the index of diagnostic validity, were 0.90 and 0.82, respectively (Bech *et al.*, 2001b). As a rating scale to measure the severity of depressive states, the Major Depression Inventory has been shown to fulfil the Rasch analysis, i.e. the total score is a sufficient statistic (Olsen *et al.*, 2002).

The ten items in the Major Depression Inventory seem to have a discriminating power for the diagnosis of major depression and to be close to the core symptoms of depression. Although Kessler and Mroczek (1995) have argued that measuring severity requires a scale that represents more aspects of the domain being measured than a diagnostic scale, empirical studies with such scales as the Major Depression Inventory seem to converge the number of items in severity scales and diagnostic scales (Bech, 1993).

THE MEASUREMENT OF CHRONIC STRESS

The main outcome of DSM-IV has been the procedural algorithms in axis 1, which classify the clinical target syndromes in psychiatry based on symptoms. The psychometric importance of these algorithms is their acceptable interobserver reliability rather than their validity. In DSM-IV, it is assumed that when assessing these target syndromes based on current symptoms, no bias from the other axes should be operating. In this sense, the assessment of the target syndromes of schizophrenia, mania, depression or anxiety should be atheoretical. One of the few syndromes in which a theory of aetiology is operating is the diagnosis of post-traumatic stress. A measurement of the severity of stressors is essential for this syndrome, because the concept of stress is response-based, as emphasized by Selye (1973) when defining chronic stress, which he was the first to do in medical literature.

Post-traumatic stress disorder is an acute stress reaction to a discrete, sudden trauma. Only a small percentage of people with post-traumatic stress disorder will develop a chronic stress reaction as defined by Selye (1973). In chronic stress, the more continuous stressors (e.g. daily hassles) are the ones that should be measured. Axis 4 in DSM-IV provides a measure of stressors in which both acute stressors and chronic stressors are considered.

The relationship between chronic stressors and personality traits has been shown most penetratingly by Eysenck and Eysenck (1976) in their questionnaire measuring neuroticism (or emotional instability) and extraversion (in stress reaction often referred to as Type A behaviour). Thus, the monotony of daily work is perceived as a stressful understimulation by people with high extraversion, while people with high neuroticism have a tendency to catastrophize demands, to get worked up over nothing, and to worry unnecessarily over things that might happen.

From a psychometric point of view, too many life event scales have been constructed with too many items based on the Cronbach coefficient alpha when showing the 'reliability' of the scale (Turner and Wheaton, 1995).

Selye's original model of stress placed stress as the biological response to stressors (Selye, 1936; Selye, 1973). Among the biological reactions, it was the hypothalamic-pituitary-adrenocortical axis (HPA) that Selye found most important, especially the measurement of cortisol. The subjective experience of the high production of cortisol was referred to by Selye as distress. The 'peripherical' experience of distress therefore included sweating, dry mouth, muscle weakness, heart pounding and tension. The 'central' experience was worrying, anxiety and depression.

The first distress scale was constructed by Parloff *et al.* (1954). This scale included 41 distress symptoms (Bech, 1993). The SCL has since been expanded to include 90 symptoms (SCL-90; Lipman, 1986). The SCL-90 questionnaire includes most of the DSM-IV symptoms of psychopathology.

The International Classification of Impairments, Disabilities and Handicaps (World Health Organization, 1980) is an important attempt to expand the Selye concept of chronic stress (Bech, 1998). 'Impairments' refer to the biological disease process in which cortisol should be considered as an important nonspecific response of the body to the demands of a chronic illness. 'Disabilities' refer to the clinical symptoms when measured not as psychopathological (axis 1) syndromes but as their impact on social performance in terms of behavioural restriction. The consequences of the social or behavioural reactions are then measured subjectively in health-related quality of life (Bech, 1998). Figure II.6 summarizes the five axes of DSM-IV when applied to the concept of chronic stress. Axis 3 (somatic or biological conditions) is shown to classify the biological state of stress according to Selye (1973). Axis 1 covers the clinical distress syndromes. Axis 4 covers both the acute and the chronic stressors. Axis 2 covers the most important personality traits, among these the Eysenck dimensions of neuroticism and extraversion. Finally, axis 5 covers the measurement problems of disability and the subjective health-related dimensions, which will be discussed in the next sections.

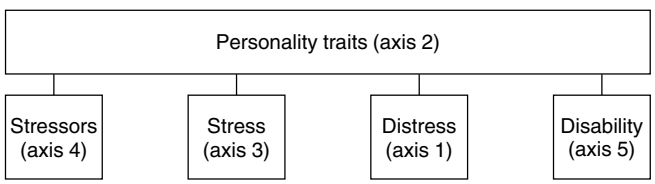

Figure II.6 The measurement of stress with reference to the five axes in DSM-IV

ILLNESS MEASURED IN UNITS OF DISABILITY

The most frequently used questionnaire for the measurement of disability is the Medical Outcomes Study SF-36 (short form, 36 items) questionnaire (Ware, 1996). This is a mixture of disability and subjective quality-of-life items.

Figure II.7 shows the content validity of SF-36. Apart from one item (measuring health transition), the items can be listed to cover eight subscales. The first measures the performance in physical functioning. The second subscale measures the limits in the kind of work or other activities that have been operating as a result of decreased physical health (role — physical). The third subscale measures bodily pain. The fourth measures self-reported health on a five-point scale from excellent to poor. The fifth subscale measures the limits in the kind of work or other activities that have been operating as a result of distress (role — emotional).

From a measurement point of view, the SF-36 has been an experiment of psychometric research when measuring health-related disability or functioning. The specifications of SF-36 in relationship to the psychometric triangle are shown in Figure II.8. Another advantage of SF-36 is the use of a 0-to-100 scale for all eight subscales, as shown in Figure II.9. The Danish norm values of SF-36 for people aged 25 years and 75 years are compared with a group of patients with major depression. As can be seen, only the subscale of emotional health has no age effect. The impact of major depression is pervasive in that this illness has an impact on all eight subscales in SF-36 (Wells *et al.*, 1992).

Finally, the SF-36 has had a major impact on the translation procedures involved when a scale is used outside the language in which it has been developed. Gandek and Ware (1998) have presented the scientific translation procedures for SF-36 when translated from American English into the various European languages.

	Components	
1	Physical functioning	(10 items)
2	Role – physical	(4 items)
3	Bodily pain	(2 items)
4	General health	(5 items)
5	Vitality	(4 items)
6	Social functioning	(2 items)
7	Emotional health	(5 items)
8	Role – emotional	(3 items)
	(Self-evaluated health transition)	(1 item)
	Total	36 items

Figure II.7 Content validity of the Medical Outcomes Study SF-36

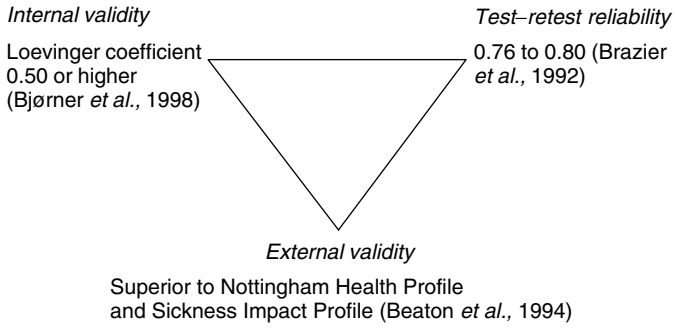

Figure II.8 The psychometric triangle for SF-36

Finally, the last item in SF-36, self-evaluated health transition, measures five levels on which the patients compare their current health with their health a year ago (from 'much better' to 'much worse'). This item is thus a clinimetric index of change. The validity of this item when compared with the General Health Rating Index is very high (Davies and Ware, 1981).

THE SUBJECTIVE QUALITY OF LIFE DIMENSIONS

Figure II.10 shows the eight components of SF-36 in relation to the Psychological General Well-Being (PGWB) questionnaire, which was developed by Dupuy (1984), although the most comprehensive study was made by Ware *et al.* (1979). The purely disability-oriented components of SF-36 are not included in the PGWB. Three of the more quality-of-life-related components (mental health, vitality, general health) are included in the PGWB. The two new components, positive well-being and self-control, are pure quality-of-life components.

In contrast to SF-36, the PGWB is commonly used as a rating scale in which the total score of the 22 items included in the questionnaire is a sufficient statistic. Higher scores mean a better quality of life.

Figure II.11 shows the properties of the PGWB within the psychometric triangle when used as a total score of the 22 items.

Many scales analogous to the PGWB have been constructed, e.g. the Hospital Anxiety Depression Scale (HADS) (Zigmond and Snaith, 1983) or the World Health Organization (WHO) 28 Well-Being Scale (Meadows and Bradley, 1990). Both the HADS and the WHO Well-Being Scale have subscales for anxiety and depression covering the mental health subscale of SF-36. However, these subscales are too crude to afford a valid measure of clinical depression.

Positive well-being is the most important subjective quality-of-life aspect. In the PGWB, a subscale of five items measuring positive well-being analogously to the WHO (five) Well-Being Scale has been extracted from the WHO 28 Well-Being Scale (Bech, 1999; Heun *et al.*, 1999). Like the SF-36 subscales, this scale is scored from 0 (worst thinkable well-being) to 100 (best thinkable well-being). Three of the items are found in the SF-36 mental health subscale. The remaining two items have recently been added to SF-36 in order to incorporate a pure positive well-being subscale. This SF-38 has been used in a Danish health status project in the normal population.

The first evaluation of the WHO (five) Well-Being Scale in patients with mental disorders has shown that the scale discriminates significantly between the five levels of the self-evaluated health item in SF-36 (Folker and Jensen, 2001). The level of 'much better' discriminated an average of 15 points, which is

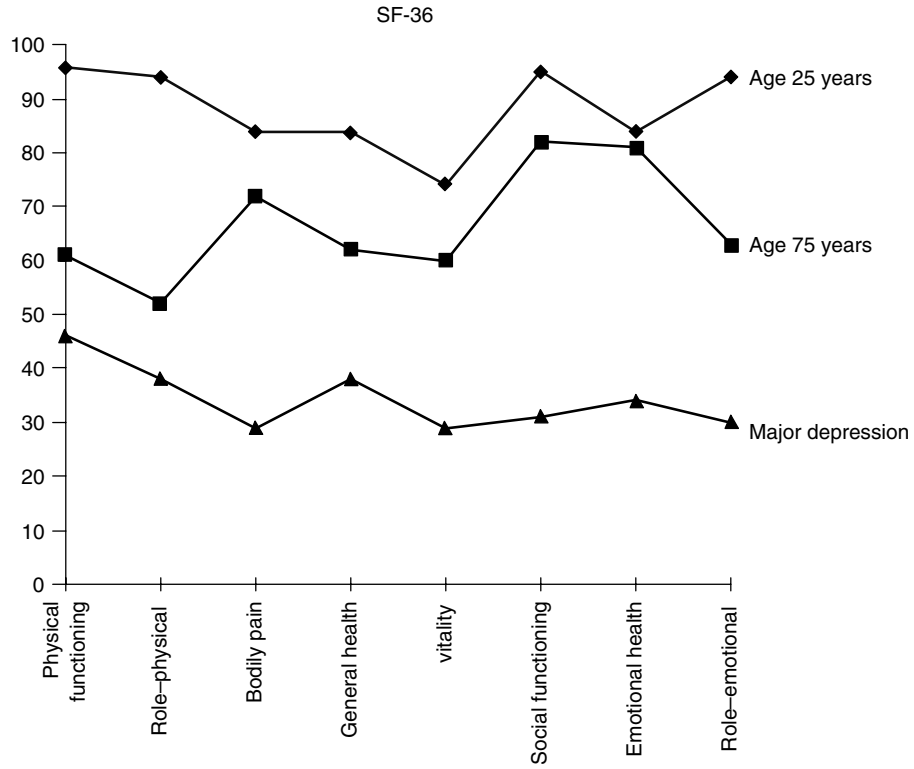

Figure II.9 Standardization of SF-36 in a Danish normal population including only people aged 25 years and 75 years. The profile of a patient with major depression is also included to show the importance of age when using the SF-36 as the goal of treatment

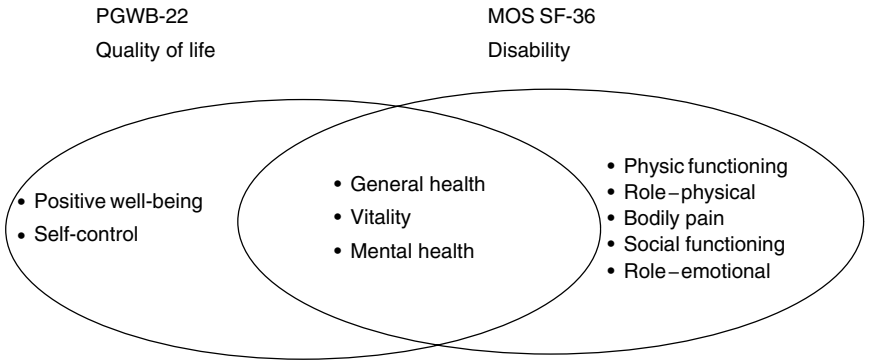

Figure II.10 Comparative content of disability and health-related quality of life scales

comparable to the findings reported by Ware (1996). In terms of WHO (five) Well-Being Scale scores, 'much better' corresponded to 78 and 'much worse' to 30. The level of 'no change' corresponded to a WHO (five) Well-Being Scale score of 45, which equals the average score of patients with major depression before treatment.

CONCLUSION

This chapter has dealt with the basic psychometric triangle of internal validity, reliability and external validity. The clinimetric field has included scales or questionnaires measuring clinical symptoms, life events, distress, disability and quality of life.

The statistical models or tests associated with the psychometric triangle have been described. The test for internal validity of a scale controls for the cumulative coherence among the individual items in the scale. These tests (e.g. Rasch analysis, Mokken analysis, confirmatory factor analysis) have shown that a relatively small number of items (7 ± 2) is often sufficient. Historically, however, the Cronbach coefficient alpha has been misused to imply that many more items are needed.

For questionnaires, the test for reliability is an analysis of test–retest stability as measured with a coefficient of stability. For interviewer-based scales, the intraclass coefficient is the most relevant.

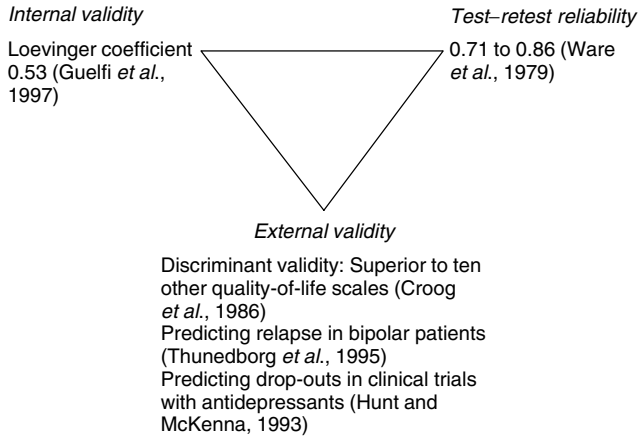

Figure II.11 The psychometric triangle for PGWB

The external validity of a scale is evaluated by responsiveness and sensitivity. While responsiveness refers to the ability of a scale to measure changes in the individual patient's symptomatology over time (analogous to the global clinical improvement scale), sensitivity is restricted to the ability of a scale to discriminate between active therapy and placebo.

The correlation between clinimetrics and biometrics has been discussed with reference to the measurement of stress. The psychometric triangle has also been found to apply when mental disorder or illness is measured in units of disability as well as in subjective quality-of-life units.

Animal Models in Biological Psychiatry

Martin Sarter and John P. Bruno

INTRODUCTION

Historically, animal research has served as a main empirical approach to the development and testing of neuropsychopathological theories (e.g. Suomi *et al.*, 1975). Furthermore, animal models have played a major role in efforts to determine the behavioural and neuronal mechanisms underlying drug effects (e.g. Dews, 1958). Generating the perfect animal model does not represent a separate goal of research in biological psychiatry; rather, the model and its constant evolution represents an integral part of biological psychiatry (McKinney, 2001). Animal models of neuropsychiatric disorders range from attempts to produce complex models that incorporate both the neurobiological and behavioural/cognitive abnormalities underlying a disorder, to animal assay models that typically utilize the effects of relatively simple pharmacological or neuronal manipulations for the detection or screening of potentially effective drugs (see Figure 1 in Chapter XVI-1).

The discussion about the proper evaluation of animal models has been continuing (e.g. Willner, 1991; Geyer and Markou, 1995; Geyer and Markou, 2000; McKinney, 2001). This discussion centres around the relative significance of the different aspects of validity (face, predictive, construct validity). The literature generally, but not universally, agrees concerning the extremely limited significance of phenomenological similarities between the model and the human conditioned model (face validity). Furthermore, the importance of the demonstration of predictive validity, which typically involves the demonstration of effects of drugs on measures generated by the model that mirror and predict their efficacy in patients, is obvious and indisputable (Geyer and Markou, 2000). Approaches to demonstrate construct validity, and the actual meaning of this type of validity, have remained less clear, and often have been confused with other aspects of validity. In most general terms, construct validity refers to a theory-driven, experimental substantiation of the behavioural and/or neuronal components of the model. Similar to the constant development and revision of all theoretical aspects of neuropsychiatric disorders, the demonstration of construct validity represents a continuous task (Geyer and Markou, 2000). This chapter will stress that the demonstration of construct validity, despite its inherent complexities, represents the most important and a necessary component of the development and validation of an animal model in biological psychiatry (see also Willner *et al.*, 1991).

ANIMAL MODELS CONSTITUTE THEORIES ABOUT DISORDERS

The effects of chronic mild stress (CMS) on consummatory behaviour of rodents are postulated to model anhedonia, a core symptom of depression (e.g. Willner, 1997). The behavioural and cognitive effects of systemic muscarinic and nicotinic receptor blockade in humans and animals are claimed to model aspects of senile dementia (e.g. Parrott, 1992; Little *et al.*, 1998). The behavioural and neurochemical effects of repeated psychostimulant exposure are thought to model the positive symptoms of schizophrenia (e.g. Robinson and Becker, 1986). These few examples indicate what animal models really are — they are theories, and in fact complex ones, about the aetiology and neuronal mediation of psychiatric disorders (Willner, 1991). For example, the CMS model reflects a multitude of theories, including the relationship between stress and consummatory behaviour, the role of stress in depression, the reduction in saccharin intake as a symptom of anhedonia, and anhedonia as a core symptom of depression (Willner, 1997). Each aspect of this model involves complex and contested biopsychological questions (see also Hatcher *et al.*, 1997; Hagan and Hatcher, 1997). Likewise, the repeated psychostimulant exposure model theorizes that the neurochemical consequences of repeated psychostimulant exposure, particularly the sensitization of mesolimbic dopaminergic systems, and the associated behavioural effects, such as stereotypy, are related causally. Furthermore, this model is based on the theory that increases in mesolimbic dopaminergic transmission mediate the positive symptoms of schizophrenia, and so forth. Thus, data produced by animal models expand not only the theory of the disorder but also the theory underlying the model.

The recognition of animal models as theories is much more than just a philosophical exercise, as it has substantial implications for the use of animal models in biological psychiatry research and for the interpretation of data generated by animal models. In reality, an animal model often gains acceptance by virtue of its technical ease and its resulting popularity. Such models rapidly acquire the character of laboratory assays. Examples for such assays are the effects of muscarinic receptor antagonists on the performance of rodents in simple one-trial memory tasks as a model of amnesia or even senile dementia (e.g. Iversen, 1997), and the use of a spontaneously hypertensive rat strain as a model of attention deficit hyperactivity disorder (ADHD; e.g. Papa *et al.*, 1998). Obviously, the degree to which data generated by these assays can be interpreted in terms of amnesia or ADHD often involves sobering complexities (e.g. Sarter *et al.*, 1992a; Sarter *et al.*, 1992b; Sagvolden and Sergeant, 1998). Therefore, the typical question 'How good is this animal model?' can be answered only by addressing the soundness of the theory about the disorder and the related theories underlying the model in addition to other, more obvious questions. Likewise, data generated by a model need to be interpreted within the theoretical framework that justifies the model. As will be stressed below, these are the main reasons why construct validity represents the most important criterion among the several criteria available to determine the validity of an animal model.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

DETERMINING THE VALIDITY OF ANIMAL MODELS

The rationale underlying the demonstration of construct, predictive and face validity of animal models in psychiatry has been discussed extensively in the literature and does not need to be repeated here (see Willner, 1991 for a particularly noteworthy chapter; see also Weiss and Kilts, 1998 and Robbins, 1998). Instead, the present discussion will focus on paradigmatic issues and the clarification of the complexities in applying these validation criteria, and on typical pitfalls. Below, the limited significance of face validity, as opposed to construct validity, will be discussed. This will be followed by a paradigmatic analysis of animal models of schizophrenia that attempts to exemplify our main hypothesis that, in developing animal models, the demonstration of construct validity represents the most vital step.

Face Validity Rarely Matters

Face validity represents the most straightforward validation criterion, as it refers to the degree of phenomenological similarity between the model and the disorder to be modelled. It is also the most seductive aspect of validity, as an animal that, for example, does not move much or consumes little palatable food may be readily characterized as being depressed. Likewise, an animal traversing a pool using relatively irregular swimming patterns appears to lack memory for the position of the invisible platform. However, there are two main reasons why face validity represents the weakest of all validation criteria. First, and most obviously, the species-specific behavioural repertoire of laboratory animals, especially rodents, confounds such interpretations. For example, a stressed animal may consume less saccharin because it exhibits a general reduction in fluid intake while in fact maintaining its preference for saccharin (Hatcher *et al.*, 1997). Increased latencies of rats to find the platform in a water maze may reflect not so much loss of memory about its location but the confounding effects of 'amnesic' treatments on sensorimotor skills and exploratory habits (e.g. Whishaw, 1989).

Second, and more importantly, many cardinal symptoms of a psychiatric disorder, such as hallucinations or impairments in verbal recall, cannot be modelled directly in animals. However, core components of the (cognitive) theory describing the mechanisms mediating the development of such symptoms may be modelled. The prime example for this issue is the positive symptoms associated with schizophrenia. While there have been attempts to interpret stimulant-induced behaviour, such as stereotypy and locomotor hyperactivity, in terms of positive symptoms (Segal *et al.*, 1981), it is difficult to substantiate such speculations. Alternatively, contemporary theories concerning the attentional dysfunctions that give rise to positive symptoms provide the basis for animal models that focus on such attentional dysfunctions (e.g. Braff, 1993; Swerdlow and Geyer, 1998; Sarter and Bruno, 1999). The modelling of such attentional dysfunctions in animals may be unrelated phenomenologically to positive symptoms or the attentional impairments in schizophrenic patients. However, such models may represent core cognitive dysfunctions and, depending on the methods used to induce such dysfunctions in animals, may also represent the core neurobiological aspects of the disease that may indeed be sensitive to antipsychotic treatments (Sarter *et al.*, 2001; Sarter and Bruno, 1999). Thus, the importance of face validity in the animal modelling of neuropsychiatric disorders has been overestimated considerably.

The widespread overestimation of the importance of face validity is due in part to the dominating role of nosology in biological psychiatry. As clinicians focus on the classification and categorization of disorders in accordance with symptom clusters, such schemes emerge as important criteria for animal models. For example, current efforts to establish animal models that represent both the positive and negative symptoms of schizophrenia (e.g. Lahti *et al.*, 1999), with attentional impairments often being classified as a negative symptom, are nosology driven but may be less important in light of data and conceptualizations that postulate relationships between different symptom clusters, particularly between the cognitive impairments and psychosis (e.g. Strauss, 1993). The determination of the usefulness of animal models that follow clinical nosology almost by definition is restricted to considerations of face validity.

Lastly, the intermittently expressed demand to focus strictly on species-specific behaviours in animal models is based on the general idea that only naturalistic studies can inform properly about the behavioural or cognitive processes affected by neuronal manipulations (e.g. Gerlai and Clayton, 1999). Obviously, data from studies employing presumably more 'naturalistic' settings that exploit species-specific capabilities (e.g. the use of olfactory stimuli in rodents) do not generalize readily to other species, thus the demonstration of face validity would be very difficult. Although 'natural tasks' may be useful in identifying phenomena of interest, they often preclude the rigorous control and systematic manipulation of variables that are essential for meaningful investigations of behaviour. Consequently, naturalistic studies have only limited potential in identifying specific changes in cognitive or behavioural functions. In fact, animal models that use highly artificial, yet theoretically valid, tasks for the probing of, for example, cognitive functions in laboratory animals may be most effective in generating valid conclusions about the mechanisms mediating performance abnormalities (Sarter and Bernston, 1999). The demonstration of such mechanisms may be more important in terms of the validity of the model than the degree to which the actual behavioural measure shows face validity. Thus, animal models focusing on naturalistic settings and species-specific behaviour *per se* may be the least valid, or at least they are most difficult to validate.

Construct Validity is Necessary

Construct validity refers to a complex, multifaceted approach that in essence aims to map a theory about the biopsychological mechanisms of a human disorder on to a biopsychological theory of a particular animal behaviour. For example, the positive symptoms of schizophrenia are widely accepted to result from a hyperactive mesolimbic dopaminergic input system (see below). If an animal can be created that shows persistent dopaminergic hyperactivity, and if this hyperactivity is demonstrated to produce a particular behaviour, the underlying (cognitive) mechanisms of which can be related to the (cognitive) mechanisms mediating the development of positive symptoms in patients, then construct validity would be established (see below for additional necessary components of such a model).

Another important means to establish construct validity focuses on the effects of variations of theoretically or clinically important factors. If the model is valid, then the main dependent measure(s) of the model would be expected to vary as predicted. For example, the theory of sustained attention predicts that increases in the event rate will result in a steeper decrement in performance over time; if a task designed for the measurement of sustained attention in rodents is valid, then increases in the event rate would be expected to increase the slope of the decline in performance over blocks of trials (e.g. McGaughy and Sarter, 1995). In general, in order to establish construct validity of an animal model of neuropsychiatric disorders, the main neuroscientific, behavioural and cognitive points that constitute a theory of the condition modelled need to be connected with the equivalent points constituting the model.

An animal model may exhibit good face validity and solid predictive validity (e.g. by predicting efficacy of therapeutic agents), and researchers may be inclined to suggest that, in such cases, the demonstration of construct validity may be unnecessary (Geyer and

Markou, 2000). Moreover, it may be assumed that such models do not require an extensive experimental and theoretical analysis of, for example, the role of associational mechanisms mediating shock-induced suppression of spontaneous behavioural responses in animal models of anxiety. Efforts to model complex theoretical relationships between neurobiological and behavioural variables that are a core focus of construct validation have been suggested to not necessarily benefit the scientific usefulness of such a model. After all, one may argue that such a model predicts clinical drug efficacy and thus it does not matter whether it agrees with the relevant neurobiological and behavioural theories of the disorder or the behaviour modelled.

There are several animal models that match the scenario outlined above, and they seem to be favoured in pharmaceutical research settings. Among these models, those used to assess the anxiolytic effects of antianxiety drugs, mostly benzodiazepine receptor (BZR) agonists, represent prominent cases. As discussed by Sanger (1991), the models based on punishment-induced suppression of responses generally have good face validity, and their predictive validity is impressive, specifically concerning BZR agonists. While the degree to which such models assess aspects of pathological anxiety remains unsettled, this absence of construct validity apparently has not been of much concern, as the models 'worked'. With the discovery of non-BZR, clinically effective anxiolytic drugs (particularly buspirone) that have little effect in these traditional animal models, the limitations of using models without construct validity has been impressively revealed (Sanger, 1991; Rodgers, 1997). Thus, this example illustrates that models with face and predictive validity may 'work' but for the 'wrong' or at least largely unknown reasons. Moreover, such models are prone to produce false negatives, as their predictive validity may be limited to the class of compounds that originally supported the usefulness of the model. In any event, such a model *per se* does not provide the basis for the safe prediction that new groups of therapeutic compounds acting via different neuropharmacological and behavioural/cognitive mechanisms will be detected as such. Thus, the demonstration of construct validity does not represent a luxurious experimental activity but, differing with Geyer and Markou's (p. 16, 2000) conclusion that '... predictive validity is the only necessary and scientifically meaningful criterion ...', the focus on construct validity is, in fact, a necessary step for successfully validating an animal model. To this end, more recent efforts to develop new models for research in the field of anxiety have focused on construct validity by attempting to address the cognitive mechanisms mediating the biased processing of fear- and anxiety-related stimuli and contexts (e.g. Bernston *et al.*, 1998; Stowell *et al.*, 2000).

The perspectives discussed above differ quite radically from the conclusions drawn by Weiss and Kilts (1998). They argue that the modelling of symptoms, as opposed to theory-driven analysis, must remain the primary goal of animal modelling. Moreover, they suggest that theoretical validity represents a secondary, and possibly even unnecessary, component. The example discussed above, as well as the various animal assay models used traditionally in the field of schizophrenia (such as the catalepsy test or the conditioned avoidance response; see Weiss and Kilts, 1998), illustrate not only the practical limitations of such a perspective but also that the focus on face and predictive validity in certain fields may, in fact, have contributed to the paucity of theoretical development in those fields. This can be illustrated particularly well in the area of depression. While animal assay models, such as the behavioural despair test or the tail suspension test, have dominated animal research in this area, models that could potentially assist in developing contemporary hypotheses about the neuronal mechanisms mediating depression-associated cognitive processes have remained sparse (Healy, 1998).

A PARADIGMATIC ANALYSIS OF ANIMAL MODELS OF SCHIZOPHRENIA

The present knowledge concerning the aetiology, neurobiology and cognitive dysfunction of schizophrenia suggests that an optimally valid animal model of schizophrenia may incorporate the following perspectives and criteria (discussed below), all but the last of which relate to construct validity. This discussion is designed not to review comprehensively the evidence in support for the various components of the model, but to describe paradigmatically the construction of an animal model of schizophrenia and to exemplify further the relative unimportance of face validity compared with construct validity.

Developmental Dysmorphogenesis

Neuroanatomical and neuropsychological evidence has strongly supported the general hypothesis that abnormal brain development mediates the development of schizophrenia. Although the exact nature of such developmental dysmorphogenesis remains unclear, evidence suggests defective migration of neurons and resulting cytoarchitectural irregularities (e.g. Jones, 1997; Rajkowska *et al.*, 1998), abnormal interneuronal circuitry (Woo *et al.*, 1998), and cortical proapoptotic processes (Jarskog *et al.*, 2000). These abnormalities are generally thought to mediate the childhood neuropsychological precursor symptoms of schizophrenia (e.g. Cannon and Mednick, 1993; Dworkin *et al.*, 1993), and later to yield the mesolimbic dopaminergic hyperactivity hypothesized to be related directly to positive symptomatology (Laruelle, 2000; Lieberman *et al.*, 1997; Grace, 2000).

Although the importance of modelling the developmental component of schizophrenia has been widely appreciated (Weinberger and Lipska, 1995; Lipska and Weinberger, 2000), the range of manipulations and the relatively undeveloped underlying rationales reflect the absence of clear and prevailing hypotheses about the nature of the developmental dysmorphogenesis. As discussed extensively in Lipska and Weinberger (2000), such models investigated the effects of gestational malnutrition, prenatal exposure to influenza virus, Borna disease virus or lymphocytic choriomeningitis virus, prenatal exposure to X-ray irradiation or several toxins, including the antimitotic agent methylazoxymethanol (MAM), post-natal exposure to stress, and the effects of neonatal lesions. Although these manipulations generally disrupt the integrity of neuronal systems to a more global and profound extent than indicated by current neuropathological evidence from the brains of schizophrenic patients, and thus do not show good face validity in this respect, several of these manipulations are capable of producing secondary effects that are key to the disorder, including increased behavioural and neurochemical responsivity to the effects of psychostimulants (see below). Furthermore, some of the behavioural and neurochemical effects of these manipulations are attenuated by antipsychotic treatment. Thus, although the immediate neuronal effects of X-ray exposure or neonatal lesions may not show good face validity in terms of reflecting the dysmorphogenesis observed in the brains of schizophrenia, these manipulations may result in behavioural and neurochemical consequences that model important aspects of the disorder that are sensitive to antipsychotic treatment. Thus, the construct validity of such manipulations may be of sufficient quality to warrant further research using such models, despite their limited face validity.

The Role of Stress

The acute manifestation of the behavioural and cognitive correlates of the developmental dysmorphogenesis in schizophrenia often interacts with, or is even triggered by, stress (e.g. Norman and Malla, 1993). Based on the activation of dopaminergic systems

by stressors (e.g. King *et al.*, 1997; George *et al.*, 2000), stress has been speculated to tax developing prefrontal circuits, thereby revealing deficient prefrontal organization in patients, and thus triggering first episodes of schizophrenic symptoms and, subsequently, relapse (e.g. Weinberger, 1987).

Changes in the reactivity of the behavioural and neurochemical effects of stressors were demonstrated in various models, including neonatal hippocampal and prefrontal lesions. However, it is less clear whether the demonstration of stress-induced increases in nucleus accumbens (NAC) dopamine release in adult animals with neonatal hippocampal lesions depends on the time of the lesion, because the effects of stress in neonatally lesioned animals were rarely compared with those in animals with lesions produced in adulthood (Lillrank *et al.*, 1999; Brake *et al.*, 2000; but see Wood *et al.*, 1997). Furthermore, neonatal hippocampal lesions attenuate the reactivity of NAC dopamine to stress (Brake *et al.*, 1999; Lillrank *et al.*, 1999), while prefrontal lesions increase the effects of stress on NAC dopamine (Brake *et al.*, 2000). Based on the substantiated hypothesis about hyperdopaminergic functions in schizophrenia (see below), the effects of neonatal hippocampal lesions therefore may violate a main component of the construct validity of this model. Alternatively, a more precise determination of the developmental window during which such lesions need to be produced in order to result in increased behavioural and dopaminergic reactivity in adulthood (Wood *et al.*, 1997) may resolve this problem. Such a model, together with evidence from studies on the effects of prefrontal lesions, would support the suggestion that early loss of telencephalic input to the mesolimbic dopaminergic system in general yields increased behavioural and dopaminergic responses to stress and psychostimulants (Saunders *et al.*, 1998; Coutureau *et al.*, 2000).

The Role of Puberty

It is not clear whether puberty merely serves as a marker of the degree of general brain development required to permit the development of schizophrenic symptoms in interaction with the effects of stressors, or whether neuroendocrinological events associated with puberty interact directly and necessarily with the neuronal maturation of defective circuits in schizophrenia (e.g. Clark and Goldman-Rakic, 1989; Frazier *et al.*, 1997). In animals with neonatal hippocampal lesions or prefrontal lesions, sensorimotor gating and other behavioural deficits, and increased behavioural and dopaminergic reactivity to the effects of amphetamine, were demonstrated specifically at postpubescent time points (e.g. Lipska *et al.*, 1995; Wood *et al.*, 1997; LePen *et al.*, 2000; Flores *et al.*, 1996; but see Chambers *et al.*, 1996). At the very least, these findings relate to the typical time of onset of symptoms in patients and thus add face validity to these models. Puberty-associated cognitive maturation enables the perception and experience of stress, and thus puberty may minimally mark a developmental stage necessary for triggering first episodes. Alternatively, the puberty-defining increases in gonadal hormones and the associated increases in tropic hormones and their regulating hypothalamic factors may interact necessarily with the maturation of defective circuits to form the basis for the emergence of schizophrenic symptoms. Substantiation of these hypotheses would add important construct validity to animal models of schizophrenia and, at the same time, would significantly extend current theories of schizophrenia.

Increases in Mesolimbic Dopaminergic Activity

After decades of conflicting scenarios concerning the status of striatal dopaminergic transmission in schizophrenia, the demonstration of enhanced amphetamine-induced decreases in striatal dopamine D2 receptor binding in schizophrenic patients (Laruelle *et al.*, 1999; Breier *et al.*, 1997) has strongly supported the hypothesis that a hyperdopaminergic dysregulation represents a neuronal marker of schizophrenia (see also Grace, 1991; Moore *et al.*, 1999b). Administration of amphetamine to schizophrenics presumably resulted in a greater release of striatal dopamine than in normal subjects, therefore displacing the labelled dopamine receptor ligand from striatal binding sites to a greater degree in schizophrenics than in control subjects. Moreover, the psychostimulant-induced displacement in labelled D2 receptor binding was correlated specifically with the presence of positive symptoms and, importantly, its demonstration did not depend on prior treatment with antipsychotic drugs. These data also support the hypothesis that the dopaminergic system in schizophrenic patients is sensitized (Laruelle and Abi-Dargham, 1999; Lieberman *et al.*, 1997; Laruelle, 2000; Strakowski *et al.*, 1997).

Although the neuropharmacological interpretation of the increased releasability of dopamine in schizophrenic patients is complex (e.g. Seeman and Kapur, 2000), this finding represents a neuronal hallmark of the disease that, if present in an animal model, contributes significantly to its construct validity. (Given the strong evidence in support of hyperdopaminergic activity in patients, increased releasability of dopamine in animal models may increasingly also be considered as supporting face validity.) In fact in the absence of precise hypotheses about the developmental dysmorphogenesis in schizophrenia (see above), any developmental manipulation yielding increased releasability of dopamine may therefore be of interest to explore further the mechanisms mediating the abnormal regulation of mesolimbic dopaminergic transmission.

The evidence in support of an increased releasability of dopamine in schizophrenia has enhanced further the construct validity of animal models based on psychostimulant-induced sensitization of mesolimbic dopaminergic transmission (Robinson and Becker, 1986; Segal and Kuczenski, 1997; Castner *et al.*, 1999). Likewise, the effects of the *N*-methyl-D-aspartate (NMDA) receptor antagonists phencyclidine (PCP) and ketamine have been attributed in part to dysregulation of the mesolimbic dopaminergic system (Jentsch and Roth, 1999; Kegeles *et al.*, 2000). Recent studies have focused on the consequences of repeated psychostimulant administration in forebrain circuits efferent to the mesolimbic regions. For example, repeated amphetamine administration was demonstrated to sensitize robustly cortical acetylcholine release (Nelson *et al.*, 2000). Abnormally high increases in cortical acetylcholine release have been hypothesized to represent an integral component of the abnormal regulation of limbic-telencephalic circuits, and to mediate the impairments in information processing that contribute to, or even determine, the development of positive symptoms (Sarter and Bruno, 1999; see below).

Impairments in Information Processing

Since the original descriptions by Kraepelin and Bleuler, impairments in cognitive functions, specifically in the ability to discriminate between relevant stimuli and associations and those that are irrelevant for the task or cognitive process at hand, have been hypothesized to contribute to, or at least be associated with, the core symptoms of schizophrenia. In the 1960s, the mostly descriptive analyses (Venables, 1964; McGhie and Chapman, 1961; Shakow, 1962) stressed the patient's inability to filter irrelevant sensory stimuli and associations from processing, and the resulting exhaustion of attentional resources for the processing of relevant inputs (e.g. patient 15 in McGhie and Chapman: '. . . if something else is going on somewhere, even just a noise, it interrupts my thoughts and they get lost . . .'; p. 51). More contemporary, cognitive psychology-inspired theories focus on the patient's inability to employ top-down processes to select significant cognitive cues and stimuli as well as rejecting distracting inputs (Braff, 1993; Andreasen *et al.*,

1998; Javitt *et al.*, 2000). Gray's (1998) theory hypothesizes explicitly that the long-term, escalating consequences of such attentional impairments impede the subject's ability to use and update past experiences to interpret and respond properly to current information processing and thus contribute to the development of positive symptoms, particularly delusions.

The precise cognitive features of the attentional impairments in schizophrenia, and their relationships to the main symptom clusters, are complex and poorly understood. However, the results from numerous studies support the notion that attentional capacities are reduced in schizophrenics and exhausted by the processing of task-irrelevant information (e.g. Grillon *et al.*, 1990; Bentall and Slade, 1985; Salo *et al.*, 1996; see also Light and Braff, 2000 and Mar *et al.*, 1996). Moreover, several studies suggested that such attentional impairments are related intrinsically to the neurobiological bases and the positive symptoms of this disorder (e.g. Sperber *et al.*, 1994).

Clinical research that focused on the descriptive classification of symptoms using standard scales (e.g. scales for the assessment of negative/positive symptoms) and the assessment of the patient's attentional impairments using regular psychometric tests (e.g. continuous performance task, CPT) typically has not been designed to test hypotheses about the role of attentional impairments in the development of positive symptoms (Elliott and Sahakian, 1995; Green *et al.*, 2000). In fact, the clinical literature occasionally classified such impairments as negative symptoms, or suggested inconsistent relationships between attentional impairments and positive symptoms (but see Addington *et al.*, 1991 and Brockington, 1992).

The modelling of the cognitive components of schizophrenia clearly has not progressed well (e.g. Moore, 1999) for several reasons. First, the focus on nosology and face validity (see above) has impeded efforts to identify those elementary cognitive dysfunctions that mediate the development of the disorder's cardinal symptoms. The perspective that cognitive impairments are unrelated to positive symptoms, and the associated attempts to model and treat such impairments separately from positive symptoms, represents a logical extension of the nosological perspective and the associated classification of cognitive impairments as negative symptoms (e.g. Tandon and Greden, 1989; see also Ellenbroek and Cools, 2000a).

Clearly, among all attempts to model the core cognitive impairments of schizophrenia, the disruption of pre-pulse inhibition has been developed and validated most extensively (for a comprehensive review, see Swerdlow and Geyer, 1998 and Geyer *et al.*, 2001). Other attempts to model such impairments have focused on the hyperattentional performance of amphetamine-sensitized rats in tasks designed to assess specific attentional functions (Crider *et al.*, 1982; Deller and Sarter, 1998). Furthermore, these impairments were hypothesized to be due to increases in the reactivity of cortical cholinergic inputs (Nelson *et al.*, 2000; Sarter and Bruno, 2000) and associated increases in mesolimbic dopaminergic activity (Moore *et al.*, 1999a). As mentioned previously, despite the obvious limitations in achieving face validity when modelling positive symptoms in animals, models are capable of reproducing the fundamental impairments in information processing that mediate, at least in part, the development of schizophrenic symptoms. Relevant attentional functions can be measured in laboratory animals, including rodents (e.g. Muir, 1996; Bushnell, 1998; McGaughy and Sarter, 1995; Turchi and Sarter, 1997), and thus the attentional effects of psychotogenic manipulations can be assessed. Although historically animal models of schizophrenia did not address cognitive variables, the construct validity of any model remains incomplete without reflecting the cognitive variables of schizophrenia (see also Ellenbroek and Cools, 1990b and Ellenbroek *et al.*, 1996).

Effects of Antipsychotic Drugs

Generally, atypical antipsychotic drugs have been assumed to attenuate more effectively the cognitive symptoms in schizophrenia than conventional antipsychotic D2 receptor antagonists (e.g. Breier, 1999; Kinon and Lieberman, 1996; Remington and Kapur, 2000; Arnt and Skarsfeldt, 1998). Although the clinical evidence in support of this assumption has remained limited (e.g. Goldberg and Weinberger, 1994; but see Green *et al.*, 1997 and Kern *et al.*, 1999), data supporting the differential efficacy of typical and atypical antipsychotic drugs in different animal models (e.g. Morrow *et al.*, 1999) have substantiated the contrasting effects of the two classes of therapeutic drugs. For example, typical antipsychotic drugs were reported to attenuate the effects of psychostimulant sensitization, while atypical antipsychotic treatments in fact augment some of the effects of repeated psychostimulant administration. Conversely, atypical antipsychotic drugs appear to be particularly potent in reversing phencyclidine-induced behavioural and cognitive impairments, while haloperidol exacerbates such impairments (Jentsch and Roth, 1999).

Animal models may also reveal therapeutic mechanisms that go beyond the traditional focus on typical and atypical antipsychotic drugs. For example, treatment with dopamine D2 receptor antagonists *per se* has been hypothesized to result in cognitive impairments via downregulation of D1 receptors. Thus, D1 receptor stimulation has been considered a complementary therapeutic approach for the cognitive symptoms in schizophrenia (Castner *et al.*, 2000; Goldman-Rakic, 1999). Predictive validity represents an obvious component of any animal model of schizophrenia, specifically in light of the necessarily overwhelming focus on models with construct validity (Geyer and Markou, 2000). For such models, the demonstration of beneficial effects of clinically effective drugs represents the main empirical test of their underlying theory.

CONCLUSION

This brief discussion of the main components of an animal model of schizophrenia illustrates the spectrum of developmental, neuroscientific, behavioural, cognitive and pharmacological components that, in combination, need to be addressed to create a model of schizophrenia. As discussed by Tallman (2000), schizophrenia does not represent a more complex disorder than other psychiatric disorders, and thus the requirements for developing an animal model for schizophrenia are not fundamentally different from those for models of, for example, depression or senile dementia (see also Sarter *et al.*, 1992b). The alternative to engaging in the construction of animal models that combine all levels of analysis, and to demonstrating construct validity, is to revert back to animal assay models. Animal assay models may not only generate data with very limited validity but also deprive the researcher from achieving the main goal of research using animal models, i.e. to test and extend a theory about the disorder of interest.

Monoaminergic Transmitter Systems

Torgny H. Svensson and Aleksander A. Mathé

NORADRENALINE

Introduction

Noradrenaline (NA) together with dopamine (DA) and adrenaline (A) are the most important mammal catecholamines. This group of compounds is characterized by a benzene ring with two attached hydroxyl groups (a catechol nucleus) and an opposing side chain of ethylamine or its derivatives. Stimulation of sympathetic nerves leads to release of a substance originally called 'sympathin' (Cannon and Uridil, 1921), subsequently identified as NA by von Euler (von Euler, 1946a, b). A few years later, NA was also identified in the brain (Holtz, 1950) and as its distribution was not following vasculature, it was proposed that NA in fact is a neurotransmitter in the central nervous system (CNS) (Vogt, 1954). Its wide distribution and potential significance in normal CNS function and pathophysiology were established in the early 1950s (Carlsson, 1959; Montagu, 1956; Vogt, 1954). In similarity to DA and A, and also 5-hydroxytryptamine (5-HT), there are considerable species differences in NA distribution as well as receptor types and their localization (Smeets and Gonzáles, 2000).

Biochemistry

L-Tyrosine, an aromatic amino acid derived from food proteins, is the precursor for the catecholamines. Interestingly, catabolism of phenylalanine in the liver by phenylalanine hydroxylase also leads to synthesis of L-tyrosine. A genetic deficiency of that enzyme results in accumulation of phenylalanine and the disorder phenylketonuria with subsequent retardation as the major symptom. Hydroxylation of L-tyrosine by tyrosine hydroxylase (TH) results in L-3,4-dihydroxyphenylalanine (L-DOPA). L-DOPA is decarboxylated by aromatic L-amino acid decarboxylase to DA, the final product in DAergic neurons. In cells that contain DA-β-hydroxylase (DBH), DA is hydroxylated to NA. Lastly, cells that possess phenylethanolamine *N*-methyltransferase (PNMT) methylate NA to A. Only a limited neuronal cell population in hind brain contains PNMT and consequently, in contrast to DA and NA, only very small amounts of A are synthesized in the CNS.

The rate-limiting step in the synthesis of catecholamines is TH since its maximal velocity is less than those of other enzymes in the synthetic pathway. TH activity is acutely regulated in an inhibitory fashion by a pool of catecholamines readily accessible to the enzyme, i.e. end-product inhibition (Masserano *et al.*, 1989), and enhanced following electrical stimulation of neurons, as shown in the early 1970s by Roth and collaborators (Roth *et al.*, 1975), or by phosphorylation mediated by cAMP-dependent protein kinase A, Ca^{2+} calmodulin-dependent protein kinase and protein kinase C (Edelman *et al.*, 1978; Masserano *et al.*, 1989). TH is long-term regulated by increased TH gene expression, which is induced by a variety of stressors increasing the neuronal activity. This trans-synaptic induction results in enhanced synthesis of TH enzyme protein.

Catabolism and turnover of catecholamines were extensively studied and mapped in the 1970s and 1980s and only a few, hopefully representative, papers are cited here (Berry *et al.*, 1994; Butcher *et al.*, 1990; Carlsson, 1975a, b; Costa *et al.*, 1972; Elchisak *et al.*, 1977; Elsworth *et al.*, 1983; Kopin, 1985; Mårdh *et al.*, 1981, 1983; Sharman, 1981; Widerlöv and Lewander, 1978).

Catecholamines are metabolized by two enzymes: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). MAO, both the A and B types, is found throughout the body, and in CNS MAO has been demonstrated in both neurons and the glial cells. In the CNS, particularly in locus coeruleus (LC), the MAO-A form predominates. Deamination by MAO leads to 3,4-dihydroxyphenylglycolaldehyde (DHPGA) and subsequently to 3,4-dihydroxyphenylglycol (DHPG) and 3-metoxy-4-hydroxyglycol (MHPG). Another pathway is conversion of DHPGA to 3,4-dihydromandelic acid (DHMA) and, finally, to vanilylmandelic acid (VMA). COMT catabolizes NA to normetanephrine (NMN), which is converted to 3-metoxy-4-hydroxyphenylglycoaldehyde (MHPGA). MHPGA in turn is catabolized to either VMA or 3-metoxy-4-hydroxyphenylglycol (MHPG). Significant quantitative differences exist between different species; in humans MHPG is the principal metabolite found in the CSF, whereas in plasma and urine VMA predominates. While MHPG concentrations in CSF represent a reasonable measure of central NAergic activity, measurement of only urinary VMA does not adequately reflect the peripheral NAergic state since MHPG is also synthesized peripherally and, moreover, MHPG can be converted to VMA.

NA Nuclei, Pathways and Receptors

The anatomy of NA (nuclei and pathways) in the CNS was originally mapped by Dahlström and Fuxe (1964) and subsequently modified by Lindvall and Björklund (1983). Three main cell groups located in the pons and medulla are recognized: (1) the LC, (2) the lateral tegmental cell system, and (3) the dorsal medullary group. The LC is the most important NA structure, projecting both rostrally and caudally, and innervating essentially all parts of the telencephalon and diencephalon, e.g. all layers of the neocortex, hippocampus, amygdala, thalamus and hypothalamus. Although the number of cells in the LC is small (clearly less than 10 000), due to the extremely high number of axon terminal ramifications (virtually >10 000 axon; Moore and Bloom, 1979). LC exerts a major influence on brain and behavioural responses. In contrast, the lateral tegmental system and the dorsal medullary group provide integration between the central and peripheral NAergic systems, as well as control/modification of the cardiovascular, visceral and autonomic functions. NA is colocalized with neuropeptide Y in

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

some brain regions (Evenitt *et al.*, 1984; Hökfelt *et al.*, 1983; for review see Aoki and Pickel, 1990).

Neurons in the LC with their wide projections to the brain are central to NA release and actions in the CNS. Interestingly, in parallel to the feedback controls between the frontal cortex–nucleus accumbens–A9/A10 areas, LC is subjected to a reciprocal regulation from the prefrontal cortex by glutamatergic input (Jodo *et al.*, 1998). However, there are also two brainstem nuclei that provide major synaptic inputs to the LC: the nucleus paragigantocellular (PGi) and the nucleus prepositus hypoglossi (P_RH; Aston-Jones *et al.*, 1986). The PGi mediates, via glutamatergic and corticotrophin releasing factor (CRF) inputs, the excitatory effects of environmental stimuli and is thus crucial for vigilance, attention and behavioural responses to external stimuli. The P_RH nucleus exerts a primary inhibitory action via GABAergic and encephalinergic inputs. Other structures, such as ventral tegmental area (VTA), raphe nuclei, hypothalamus and paraventricular nucleus (PVN), also provide LC input and thereby modulation of behaviour via effects on NA release in terminal areas. In addition to external stimuli, the LC also responds to noxious stimuli (Elam *et al.*, 1986a) and, moreover, monitors the internal autonomic and vegetative state. Thus, LC responds even to entirely peripheral events, such as a small alteration in blood volume (Svensson and Thorén, 1979), as well as to changes in blood pressure, a regulatory influence that seems largely mediated via vagal afferents from the cardiopulmonary region (Elam *et al.*, 1984, 1985). In addition, the LC responds to hypercapnia and hypoxia (Elam *et al.*, 1981) analogously to the peripheral sympathetic nerves, as well as to entirely visceral stimuli, such as distension of the urinary bladder, the distal colon or even the stomach (Elam *et al.*, 1986b; for extensive review see Svensson, 1987). Generally, the activity of the LC neurons is strongly positively correlated to the waking–sleep cycle, being essentially quiescent during REM sleep. LC cell firing is stimulated by sensory stimuli and is decreased during maintenance/automatic behaviours (Aston-Jones and Bloom, 1981; Foote and Aston-Jones, 1995; Valentino and Aston-Jones, 1995). LC lesion experiments, recordings of neuronal firing, and stimulation and inhibition, respectively, of α_1 and α_2 receptors have demonstrated the significant role LC plays in the function of, for example, cortex, thalamus, hypothalamus, PVN, hippocampus and amygdala, and the corresponding behavioural manifestations such as attention, vigilance, arousal, fear stimulus discrimination, eating behaviour and learning (Aston-Jones *et al.*, 1994; Ressler and Nemeroff, 2000; Wellman, 2000).

The NA and A receptors (adrenergic receptors) all belong to the G-protein-coupled receptor superfamily. The original classification of Ahlquist (Ahlquist, 1948) — based on the response of sympathetically innervated peripheral organs to sympathomimetics and their antagonists — into α and β receptors is still valid. Subsequently, pharmacological studies and the development of molecular biology have enabled receptor cloning and subdivision into α_{1A}, α_{1B} and α_{1D}; α_{2A}, α_{2B}, α_{2C} and α_{2D}; and β_1, β_2 and β_3 (Bylund *et al.*, 1994; Hieble *et al.*, 1995). In this context it is important to keep in mind that adrenergic receptors are found not only pre- and postsynaptically on neurons but also on glial cells, which respond to NA and other agonists and are coupled to the same second messenger systems (Salm and McCarthy, 1992; Stone and Ariano, 1989).

α_1 adrenoceptors are characterized by a high sensitivity to the agonists phenylephrine and metoxamine and to the antagonists phenoxybenzamine, prazosin, and 5-methylurapidil and WB-4101. Both α_{1A} and α_{1B} are postsynaptic and are found throughout the rat CNS although their relative density is different in different brain regions (Morrow and Creese, 1986; Ruffolo *et al.*, 1991, 1993, 1994). α_1 receptors are excitatory. By inhibiting the non-voltage-dependent K^+ current they cause a slow depolarization and thereby increase cell excitability (McCormick, 1991; Nicoll *et al.*, 1990). As regards intracellular effects of α_1 receptor stimulation, G-protein-mediated stimulation of phospholipase C (PLC) leads to phosphoinositolphosphate (PIP_2) breakdown to inositol triphosphate (IP_3) and diacylgycerol (DAG). IP_3 stimulates release of Ca^{2+} from endoplasmic reticulum, while DAG both increases phosphokinase C (PKC) activity and when phosphorylated to phosphatidic acid (PA) acts as Ca^{2+} ionophore. In this context, it should be pointed out that the relationship between the described electrophysiological effects and the effects on Ca^{2+} and PKC have not been fully elucidated.

α_2 adrenoceptors are characterized by activation by α-methyl-NA and clonidine and blockage by yohimbine, idazoxan and rauwolfscine (Bylund *et al.*, 1994; Ruffolo *et al.*, 1993, 1994). According to the original suggestion of Langer, this receptor is presynaptic (Langer, 1974). The α_{2A} and α_{2C} receptors are widely but unevenly, with regard to brain regions and to each other, distributed in the brain. High α_{2A} and α_{2C} receptor densities are found in the LC, amygdala and hippocampus, and all LC neurons contain α_{2A} receptor subtype. On the other hand, α_{2B} is localized mostly in the thalamus (Nicholas *et al.*, 1993b, 1996; Scheinin *et al.*, 1994; Talley *et al.*, 1996; Wamsley *et al.*, 1992).

In contrast to the electrophysiological properties of α_1 receptors, α_2 receptors hyperpolarize the cell membrane as a consequence of activating an inward-rectifying K^+ current and thereby have inhibitory effects. Thus α_2 receptors on NAergic nerve terminals act as autoreceptors inhibiting NA release and the somatodendritic α_2 receptors in LC inhibit the firing of LC neurons (Aghajanian and VanderMaelen, 1982a; Andén *et al.*, 1970; Cedarbaum and Aghajanian, 1977; Langer and Arbilla, 1990; Langer *et al.*, 1971; Starke *et al.*, 1989; Svensson *et al.*, 1975). Interestingly, this K^+ response is the same as the one associated with DA-D_2 and 5-HT_{1A} receptors (McCormick, 1991). With regard to the second messenger system, α_2 receptors are negatively coupled to adenylyl cyclase, through action on Gi, with a subsequent decrease in cAMP synthesis.

The β adrenoceptor subdivision into β_1 and β_2 was originally proposed by Lands *et al.* (1967) based on physiological responses of several tissues to sympathomimetic compounds. Both β_1 and β_2 have been extensively investigated as prototypes for the G-protein-coupled superfamily of receptors and cloned early on (Frielle *et al.*, 1987, 1988; Kobilka *et al.*, 1987; Ostrowski *et al.*, 1992; Shorr *et al.*, 1981, 1982). β_3 receptor, found in the periphery, has been cloned some years later (Emorine *et al.*, 1989). Isoproterenol and salbutamol are classical β receptor agonists, while propranolol and pindolol are non-selective antagonists. Selective antagonists for β_1 and β_2 are atenolol and ICI-118, 551, respectively (Hieble and Ruffolo, 1991).

Radioligand binding studies as well as mRNA studies demonstrate that both β receptors are widely distributed in the brain. Although in many areas the distribution is about even, β_1 predominates in the cerebral cortex, the dentate gyrus, and CA1 and medial dorsal hypothalamic nuclei, while β_2 is more abundant in the cerebellum and reticular, paraventricular and central thalamic nuclei (Nicholas *et al.*, 1993a, 1996; Palacios and Kuhar, 1983; Rainbow *et al.*, 1984). Electrophysiologically, β receptors stimulate Ca^{2+} currents, augment the hyperpolarization–activated cation current and enhance the rate of cell firing under conditions of high excitation (McCormick, 1991; Nicoll *et al.*, 1990). The extensively studied effect of β receptors on the second messenger system is stimulation of adenylyl cyclase via Gs followed by an increase in cAMP (Kobilka, 1992).

Interestingly, the relationship between the electrophysiological and second messenger effects is better understood than that for α_1 and α_2 receptors, since stimulating adenylyl cyclase (for example with forskolin) or using α-bromo-cAMP (a cAMP analogue, not susceptible to breakdown as cAMP) elicits the same electrophysiological responses.

β receptors have been used as a paradigm to study two phenomena: receptor desensitization and receptor downregulation/upregulation. Following exposure to β agonists, β receptors

show a decrease in responsivity within minutes or even seconds. This is caused by the uncoupling of the receptor from Gs and adenylyl cyclase (Kobilka, 1992). The uncoupling is a consequence of phosphorylation of the receptor by PKA and β adrenergic receptor kinase (βARK). Longer (hours) agonist exposure results in loss of receptor binding sites; that is, receptor downregulation. This phenomenon is due to diminished receptor mRNA and increased degradation of receptor protein (Collins, 1993; Collins *et al.*, 1991). Receptor upregulation is opposite to downregulation. In parallel to many other systems, receptor upregulation is a sequelae of decreased agonist availability. Thus 6-OHDA lesion of the catecholaminergic nerve terminals results in increased β_1 and β_2 receptor binding.

Transmitter Release and Physiology of NA Neurons

In the CNS, NA is concentrated and stored in synaptic vesicles by a vesicular transporter. The same transporter protein is found in DAergic, NAergic and 5-HTergic neurons, indicating that these three monoamines are concentrated by the same mechanism. Of historical interest was the finding in the early 1950s that reserpine (derived from the plant *Rauwolfia serpentina*, and used for centuries in India, and in the 1950s in the USA as an antipsychotic) inhibits catecholamine and 5-HT neuronal vesicle transporters. This leads to inhibition of monoamine accumulation with subsequent depletion and profound behavioural depression. A classical early study in the field was conducted by Carlsson and co-workers (Carlsson *et al.*, 1957).

In similarity to other neurotransmitters synaptically released, NA is released by depolarization of the nerve terminals. Depolarization of nerve terminal membrane opens the Ca^{2+} channels with Ca^{2+} entry and fusion and discharge of the vesicle, a process called vesicular exocytosis. This phenomenon has been extensively studied for several decades (Thureson-Klein, 1983; Trifaro *et al.*, 1992). Release of NA is regulated by presynaptic α_2 autoreceptors mostly of the α_{2A} subtype. This was first demonstrated in the periphery by showing that nerve stimulation-induced NA release is enhanced by α_2 receptor antagonists and inhibited by α_2 receptor agonists (Langer and Arbilla, 1990; Langer *et al.*, 1971; Starke, 1971; Starke *et al.*, 1989). The inhibition is probably achieved by a decrease in depolarization-evoked entry of Ca^{2+} into the nerve terminal and also hyperpolarization of nerve terminal by increasing K^+ conductance (Aghajanian *et al.*, 1977; Starke *et al.*, 1989). Release can also be modulated by somatodendritic α_2 autoreceptors found in the LC neurons (Svensson *et al.*, 1975). By increasing K^+ conductance, the neuronal cells are hyperpolarized and the firing rate decreased (Aghajanian *et al.*, 1977; Cedarbaum and Aghajanian, 1977). Although the validity of findings of release autoregulation by presynaptic α_2 receptors is generally accepted, a different hypothesis, namely that agonist inhibitory effects and antagonist enhancing effects occur at two different sites, has also been proposed (Kalsner, 2001). Most of the NA release in the CNS is secondary to neuronal activation of LC.

NA Reuptake

In similarity to 5-HT, NA released into the synaptic cleft is either metabolized or transported back into the neurons by a high-affinity transporter. The transporter is a presynaptically located glycoprotein, and this intraneuronal high-affinity uptake is called uptake 1. NA can also be taken up extraneuronally, by a different mechanism which has lower affinity for and is less selective for NA. This uptake has been termed uptake 2 (Amara and Kuhar, 1993; Brownstein and Hofmann, 1994). Both uptake 1 and uptake 2 accumulate NA against a substantial concentration gradient and require a source of metabolic energy. This energy is provided by the transmembrane Na^+ electrochemical gradient achieved by the Na^+-K^+ ATPase. Many therapeutic drugs and substances of abuse inhibit the uptake of NA. Tricyclic antidepressants have been developed expressly for therapeutic use and inhibit both the NA and 5-HT transporters but in the therapeutic concentrations used have no effect on DA. On the other hand, drugs of abuse such as cocaine, amphetamine and methylphenidate are effective inhibitors of both NA and DA uptake (and to a certain extent also of 5-HT, e.g. cocaine). Reuptake of NA and 5-HT, as one of the mechanisms of action of antidepressants, is dealt with in other chapters of this book.

Functional Role and Clinical Significance of Brain NA Neurons

Although an extensive review of this topic is far beyond the scope of this chapter, the function of the largest central NA system, which originates in the LC and has been extensively studied for several decades, will be briefly discussed. Early studies in awake animals, in particular the monkey, revealed LC activity to be correlated with vigilance, showing phasic activation responses to environmental sensory stimuli, particularly if associated with novelty or fear, but showing low activity in association with behaviours such as grooming, sweet water consumption or sleep (Foote *et al.*, 1983). Thus a role in attentional functioning was confirmed and, in principle, the system may serve as a significance enhancer with respect to salient environmental stimuli. As mentioned above, this function also appears to apply to the internal milieu, and a general role in the so-called defence reaction appears very likely (Svensson, 1987). Subsequent studies over the past two decades have largely confirmed and extended such a biological role of the largest brain NA system (Aston-Jones *et al.*, 1999) and accordingly it is not surprising that brain NA neurons have been found to be involved in the mode of action of both many antidepressant drugs as well as a number of antipsychotics, and drugs affecting wakefulness and attention, such as nicotine (Mitchell, 1993; Svensson and Engberg, 1980). Blockage of central α_2 receptors may be involved in both antidepressant (Linnér *et al.*, 1999; Svensson, 2000a; Svensson and Usdin 1978) and antipsychotic drug effects (Hertel *et al.*, 1999), although the specific roles of the different receptor subtypes in this regard remain to be clarified. It could be added that blockage of brain α_1 adrenoreceptors seems to contribute to the therapeutic effect of a number of antipsychotics (Andersson *et al.*, 1994; Mathé *et al.*, 1996; Svensson *et al.*, 1999; Wadenberg *et al.*, 2000). Thus brain NA neurons represent a highly important target for major groups of psychoactive drugs.

DOPAMINE

Introduction

DA was discovered as an independent neurotransmitter in the brain during the late 1950s (Carlsson, 1959; Carlsson *et al.*, 1957, 1958). Since that time DA has emerged as one of the most important neurotransmitters in brain from a behavioural as well as psychopharmacological perspective, with an established role not only in the pathophysiology and treatment of Parkinson's disease, but also in schizophrenia and the mode of action of antipsychotic drugs, as well as in drug dependence. Indeed, during the past five years alone, more than 16 000 papers on DA have been published. The present review will therefore only briefly outline its biochemistry, anatomy and physiology, with some emphasis on the more recent developments in the field.

Biochemistry

The major processes of synthesis, storage and metabolism of this neurotransmitter have been known for decades. DA is synthesized from the amino acid tyrosine in a two-step enzymatic process. First, tyrosine is converted to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase, which is the rate-limiting enzyme in DA synthesis. Subsequently, L-DOPA is rapidly converted to DA by aromatic L-amino acid decarboxylase. In noradrenergic neurons, DA is further converted by DA β-hydroxylase to NA. DA is stored in vesicles and physiologically released by a calcium-dependent process initiated by nerve impulse activity. Released DA is approximately 80% effectively and rapidly transported back into the nerve terminal by a DA-specific transporter. Extravesicular DA is intracellularly metabolized by the enzyme monoamine oxidase (MAO) to dihydroxyphenylacetic acid (DOPAC). Released, extracellular DA is sequentially degraded by the actions of catechol-*O*-methyltransferase (COMT) and MAO to 3-methoxytyramine (3-MT) and homovanillic acid (HVA). In the rat brain DOPAC is the major DA metabolite. Nevertheless, both DOPAC and HVA, in both sulphate-conjugated and free forms, are found in high concentrations along with small amounts of 3-MT in rat brain. In the human brain, free HVA appears instead as the main metabolite, with only small amounts of DOPAC (Cooper *et al.*, 1996).

DA Nuclei, Pathways and Receptors

The large mesotelencephalic DA systems originate in the midbrain tegmentum, and the distribution of DA cell bodies in this region is restricted largely to two nuclei in the rat, the substantia nigra zona compacta (SN-ZC or A9) and the ventral tegmental area of Tsai (VTA or A10), as revealed by Dahlström and Fuxe (1964). The neurons in the SN-ZC project primarily to the caudate nucleus and putamen, i.e. striatum, and the system was thus called the nigrostriatal DA system (Andén *et al.*, 1964). The VTA exhibits somewhat more diverse projections than the SN-ZC. Thus, the DA neurons in the VTA project to, for example, ventral striatum (VSTR), including the nucleus accumbens (NAC), amygdala, hippocampus and olfactory tubercle as well as several limbic cortical sites, such as medial prefrontal, cingulate and entorhinal cortices (Andén *et al.*, 1966; Björklund and Lindvall, 1984; Ungerstedt, 1971).

In humans, the cortical DA projection is much more widespread than in the rat, corresponding to the relatively larger size of the frontal cortex in humans. These DA pathways are often collectively referred to as the mesolimbocortical DA system. However, cortically projecting DA neurons appear not to innervate subcortical sites, and vice versa (Fallon, 1981; Swanson, 1982). These cortical and subcortical DA projections seem, at least partially, to arise from different anatomical subdivisions of the VTA. The ventrally located paranigral nucleus of the VTA primarily contributes the subcortical, mesolimbic DA projection, e.g. to the NAC and other striatal sites. In contrast, the parabrachial pigmented nucleus of the VTA also contains the somata of DA neurons from which the cortical DA innervation originates (Deniau *et al.*, 1980; Fallon, 1981; Oades and Halliday, 1987; Phillipson, 1989; Simon *et al.*, 1979; Swanson, 1982). In addition, these mesocortical DA neurons exhibit several functional differences from the mesolimbic DA cells; mesocortical DA neurons display a more variable firing pattern, differential coexistence with neuropeptides, as well as altered autoreceptor and heteroreceptor regulation in comparison with the subcortically projecting DA neurons (Grenhoff *et al.*, 1988a; Roth and Ellsworth, 1995). Coexistence and interaction of DA with some neuropeptides, e.g. cholecystokinin (Hökfelt *et al.*, 1980; Schalling *et al.*, 1990) and neurotensin (NT), has been extensively investigated (Bean *et al.*, 1990; Hertel *et al.*, 1996; Lambert *et al.*, 1995; Quirion *et al.*, 1985).

Dopamine Receptors

There are currently five known DA receptor subtypes categorized according to structural, functional and pharmacological characteristics, and divided into two main families (D_1-like and D_2-like) based upon their sequence homology. The D_1-like receptors (D_1 and D_5) activate adenylyl cyclase, whereas the D_2-like receptors (D_2, D_3 and D_4) inhibit adenylyl cyclase. The D_2 receptor was cloned from rat brain based on its homology with the previously cloned β adrenoceptor (Bunzow *et al.*, 1988). The other D_2-like receptors, the D_3 and D_4 receptors, were cloned by low-stringency hybridization using probes derived from the D_2 receptor (Sokoloff *et al.*, 1990; van Tol *et al.*, 1991). These receptors also have been extensively studied *in vivo* and *in vitro* using a variety of methodologies, including behavioural, physiological, neurochemical, pharmacological and, more recently, molecular approaches.

Both the D_1 and D_2 families are found postsynaptically, whereas the presynaptic receptors are regarded to belong to the D_2 family. There appears to be some differential distribution of DA receptor types in various DA terminal regions in the rat. Dense D_1 binding has been found in the dorsolateral striatum and moderate binding has been detected in the neocortex (Boyson *et al.*, 1986). Dense D_5 binding is mainly restricted to thalamic, hypothalamic and hippocampal neurons. High D_2 binding is observed in, for example, dorsolateral striatum, NAC, VTA and SN-ZC (Gehlert and Wamsley, 1985).

Specifically, the D_2 receptor has been found mainly in the striatum, in the olfactory tubercle, and in the core of the NAC (Bouthenet *et al.*, 1991; Jackson *et al.*, 1994). The D_2 receptor is expressed in the core of the NAC by GABAergic neurons coexpressing enkephalins (Le Moine and Bloch, 1995; Le Moine *et al.*, 1990), as well as in the septal pole of the shell of the NAC, where it is expressed by NT-containing neurons (Diaz *et al.*, 1994). D_2 receptor mRNA is also present in the prefrontal, cingulate, temporal and entorhinal cortices, in the septal region, in the amygdala, and in the granule cells of the hippocampal formation (Bouthenet *et al.*, 1991; Jackson *et al.*, 1994). It is furthermore found in the hypothalamus, the substantia nigra pars compacta and the VTA, where it is expressed by dopaminergic neurons (Bouthenet *et al.*, 1991; Meador-Woodruff *et al.*, 1989; Weiner *et al.*, 1991). Immunohistochemical analysis with specific antibodies revealed that D_2 receptors are present in medium spiny neurons of the striatum, where they are more concentrated in spiny dendrites and spine heads than in the somata. D_2 immunoreactive terminals are frequently detectable, forming symmetrical, rather than asymmetrical, synapses (Hersch *et al.*, 1991; Levey *et al.*, 1993). The D_2 receptors are also present in perikarya and dendrites within the substantia nigra pars compacta and are much more concentrated in the external segment of the globus pallidus than in other striatal projections (Levey *et al.*, 1993). D_2 receptor immunoreactivity has also been detected in the glomerular and internal plexiform layers of the olfactory nerve and in the central nucleus of the amygdala (Levey *et al.*, 1993).

The D_3 receptor is largely expressed in forebrain and limbic areas (Sokoloff *et al.*, 1990). In rat brain, the D_3 receptors are mainly expressed in the islands of Calleja, where D_3 receptor mRNA is expressed in granule cells (Bouthenet *et al.*, 1991; Levesque *et al.*, 1992), and in the medium-sized spiny neurons of the rostral and ventromedial shell of the NAC. In contrast to the D_2 receptor, low levels of the D_3 receptor are found in the dorsal striatum. Moreover, D_3 mRNA is also found in the substantia nigra pars compacta, and in the ventral tegmental area, where, compared to the D_2 receptors, it is expressed only in a minority of dopaminergic neurons. D_3 receptors are also found in Purkinje cells and, at low expression levels, in hippocampus, in the septal area, and

in various cortical layers of the medial–temporal lobe (Bouthenet *et al.*, 1991).

The D_4 receptor is predominantly expressed in the frontal cortex (O'Malley *et al.*, 1992), a region that receives dense input from midbrain DA neurons and is associated with cognitive and emotional processes. Low levels of D_4 receptor mRNA have been found also in the basal ganglia. This receptor also appears to be highly expressed in the amygdala, hippocampus, hypothalamus, mesencephalon and retina. Experiments using immunohistochemistry and electron microscopy have revealed that, in both the cerebral cortex and hippocampus, D_4 receptors are present in both pyramidal and non-pyramidal neurons that have been identified as GABAergic (Mrzljak *et al.*, 1996).

In short, the patterns of D_3 and D_4 receptor expression are predominantly restricted to the mesocortical and the mesolimbic systems. Overall, it appears that D_2 receptors are more prominently expressed in areas associated with motor control, while D_3 and D_4 receptors are more exclusively located in areas where the DA system is thought to serve a role in modulating emotion and cognition. Interestingly, the D_3 and D_4 receptors are linked to the heteromodal association neocortex via their expression in the NAC and prefrontal cortex (Ross and Pearlson, 1996; Schwartz *et al.*, 2000). The heteromodal neocortex network includes the dorsolateral prefrontal cortex, Broca's area, planum temporale and the inferior parietal lobule (Ross and Pearlson, 1996). These interconnected association areas are involved in higher integrative functions, such as executive tasks (for example, working memory, motivation and planning), speech and focused attention. Dysfunctions of these brain regions have been implicated in schizophrenia. Indeed, neuropathological abnormalities have also been described in these brain areas of schizophrenic patients (Roberts, 1991).

Before the discovery of the various subtypes of DA receptors, it was generally accepted that the therapeutic effects of antipsychotic drugs could be mainly attributed to blockade of D_2 receptors. The notion of a DA receptor blocking component *per se* in the mode of action of antipsychotics was originally hypothesized by Carlsson and Lindquist (1963), and among the many subsequent studies an apparent tight correlation between the clinical potency of various antipsychotics and their affinity for DA-D_2 receptors was observed (Creese *et al.*, 1976; Seeman *et al.*, 1976). Although this correlation subsequently has been seriously questioned, the fact remains that no drug has yet been identified as an effective antipsychotic agent without any significant affinity for DA-D_2 receptors. For classic antipsychotic drugs (e.g. haloperidol) it has been demonstrated that antipsychotic treatment leads to striatal D_2 occupancies between 60% and 80%, and that occupancies above 80% in most cases are associated with extrapyramidal side effects. On the contrary, the atypical antipsychotic drug clozapine has showed considerably lower D_2 occupancy, i.e. in the range of 20–60% (Farde *et al.*, 1992; Goyer *et al.*, 1996). However, clozapine displays a unique clinical profile and possesses relatively high affinity for many different neurotransmitter receptors, including other DA receptors, several subtypes of 5-HT receptors, α adrenergic receptors, etc., and it has accordingly been proposed that also blockade of non-D_2 receptors must contribute to its therapeutic effect in schizophrenia (Svensson, 2000b). Since it had been suggested that D_3 and D_4 receptors may be of particular significance in schizophrenia and in the mode of actions of antipsychotic drugs (Reynolds, 1996; Seeman *et al.*, 1997), several selective D_3 and D_4 antagonists have subsequently been developed. Compared to typical and atypical antipsychotics, selective D_3 or D_4 receptor antagonists have, however, generally been found rather inactive in animal behavioural tests predictive of antipsychotic or extrapyramidal activity, although at present it is too early to draw any firm conclusions in this regard.

Physiology of DA Neurons and Transmitter Release

DA neurons in the SN-ZC and VTA show spontaneous spike firing which is driven by an endogenous pacemaker conductance (Grace and Bunney, 1983, 1984; Grace and Onn, 1989) and is modulated by afferent inputs. Generally, the discharge of the cells is an important determinant of the DA release process (Keefe *et al.*, 1992; Mathé *et al.*, 1999). The firing pattern of the DA neurons is characterized by two differential modes of firing; single-spike firing and burst firing (Grace and Bunney, 1983, 1984; Wang, 1981). Single-spike firing is a relatively regular, low-frequency firing pattern, i.e. 1–10 Hz. In contrast, burst firing is typically recognized as the transient high-frequency discharge of multiple action potentials. The burst firing mode has been shown to elicit much more efficient release of DA in terminal areas than a regular firing pattern of the same average rate, and burst firing also causes significant activation of postsynaptic neurons as indicated by induction of c-*fos* and NG1-A (Bean and Roth, 1991; Chergui *et al.*, 1996, 1967; Gonon, 1988; Suaud-Chagny *et al.*, 1992). Moreover, this postsynaptic response shows both a spatial and a temporal specificity with respect to brain region, genes activated and cell phenotype (Chergui *et al.*, 1997). Physiologically, the pulse of DA produced by a burst of action potentials is rapidly attenuated by efficient uptake of transmitter from the synaptic cleft (Grace and Bunney, 1984). In addition, bursts seem to specifically facilitate release of colocalized neurotransmitters, such as NT and cholecystokinin (Bean and Roth, 1991). Such transient changes in impulse activity normally occur in relation to basic attentional and motivational processes in response to reward-predicting stimuli, and apparently serve to initiate goal-oriented behaviours (Nishino *et al.*, 1987; Schultz, 1986, 1998; Schultz *et al.*, 1993). In both awake and anaesthetized mammals *in vivo*, DA cells typically display a firing pattern which includes both single-spike and burst firing, with frequent switches between these two modes of firing. In contrast, in DA cells in a midbrain slice preparation, i.e. in cells that have been largely deprived of active neuronal inputs, burst firing is absent and little variability in the firing pattern is observed (Grace and Onn, 1989). Generally, the structure of the firing patterns of midbrain DA neurons *in vivo* has been proposed to reflect the neuronal response to coordinated synaptic inputs emerging from several neuronal circuit interactions (Hoffman *et al.*, 1995).

Regulation by Afferent Inputs

Generally, the midbrain DA neurons receive glutamatergic, GABAergic, cholinergic, serotonergic and noradrenergic inputs.

Glutamate

Spontaneous burst activity of DA neurons *in vivo* appears to be directly dependent upon activation of somatodendritic *N*-methyl-D-aspartate (NMDA) receptors via afferent excitatory amino acid (EAA) inputs, which mainly stem from the prefrontal cortex (PFC), the subthalamic, laterodorsal (LDTg) and pedunculopontine (PPTg) tegmental nuclei. The PFC seems to regulate a subpopulation of DA neurons in the VTA that in turn innervate the PFC, whereas other VTA neurons projecting to the NAC, which are innervated from the PFC, are GABAergic (Carr and Sesack, 2000; Carr *et al.*, 1999; Christie *et al.*, 1985; Sesack *et al.*, 1989). At any rate, the different glutamatergic afferents to the VTA seem to be importantly involved in the overall control of DA release in terminal fields (Charléty *et al.*, 1991, Chergui *et al.*, 1993, Gariano and Groves, 1988; Grenhoff *et al.*, 1988b; Murase *et al.*, 1993; Svensson and Tung, 1989). In addition, the NMDA receptors are involved in the control of the regularity of firing, another functionally important determinant of DA neuronal discharge, which seems critical for the capacity of a neuronal system to adapt to environmental demands

(Grenhoff *et al.*, 1988b; Servan-Schreiber *et al.*, 1990). NMDA-receptor activation mediates a slow excitatory postsynaptic potential (EPSP) in these cells (Mercuri *et al.*, 1996), whereas metabotropic glutamate agonists have been found to depress both excitatory and inhibitory input to the DA neurons (Bonci *et al.*, 1997). In fact, the latter effect seems to be shared by muscarinic receptors, which also depress both excitatory and inhibitory afferents via a presynaptic action (Grillner *et al.*, 1999, 2000). Some biochemical support for differential regulation of VTA DA neuronal subpopulations by EAAs was reported in the late 1980s. Thus, although DA release in the PFC was found to be preferentially modulated by NMDA receptors in the VTA, the DA release in the NAC seemed largely controlled by AMPA and kainate receptors in the VTA (Kalivas *et al.*, 1989; Mathé *et al.*, 1998). Needless to say, by electrical stimulation of afferents in a brain slice preparation, synaptic potentials can be elicited in DA neurons through activation of both AMPA/kainate and NMDA receptors (Johnson and North, 1992b; Mereu *et al.*, 1991). Metabotropic glutamate receptors (mGluRs) have also been shown to mediate both a slow excitatory as well as an inhibitory synaptic potential (Fiorillo and Williams, 1998; Shen and Johnson, 1997). More recently, even the presence of glutamate in the DA neurons themselves has been reported, forming functional glutamatergic synapses, so-called autapses (Sulzer *et al.*, 1998).

The glutamatergic input to the VTA has considerable interest in relation to the putative pathophysiology of schizophrenia, which has been considered as a hypoglutamatergic state (Kim *et al.*, 1980) and, in particular, a reduced activation of the NMDA receptor (Bunney *et al.*, 1995). Several early studies showed that negative symptoms are correlated with decreased capacity to activate the dorsolateral prefrontal cortex, so-called hypofrontality (Ingvar, 1987; Ingvar and Franzén, 1974; Weinberger *et al.*, 1986), a brain region that contributes an excitatory amino acid input to the VTA. Interestingly, experimentally induced 'hypofrontality' — suppressed functional activity of the corresponding brain region in the rat, i.e. the medial prefrontal cortex — as produced by local cooling or direct intracerebral application of lidocaine, was found to cause a selective abolition of the burst firing mode in VTA DA neurons, as well as regularization of their firing pattern (see above), although basal firing rate did not change (Murase *et al.*, 1993; Svensson and Tung, 1989). In other words, a pacemaker-like firing was seen, similar to the firing pattern seen in the deafferented slice preparation or following intracerebral application of kynurenate, a non-selective excitatory amino acid receptor antagonist (Grenhoff *et al.*, 1988b). If also present in humans, such a dysfunction of the VTA neurons, especially those that in turn project to the PFC (see above), might well contribute to explain the decreased capacity to process positive or negative reinforcement signals generally associated with impaired frontal lobe function as well as with schizophrenia (Svensson and Tung, 1989). Significantly, pretreatment with 5-HT_{2A} or 5-$HT_{2A/C}$ receptor antagonists, which clinically have been found to ameliorate dysthymia and negative symptoms in schizophrenia, as well as to improve motivation and drive, was subsequently shown to antagonize the selective reduction in burst firing of VTA neurons in 'hypofrontal' animals (Svensson *et al.*, 1989, 1995).

GABA

The firing of VTA DA cells is also influenced by γ-amino butyric acid (GABA). The GABAergic input originates in the striatum and in the pallidum (Bolam and Smith, 1990; Fonnum *et al.*, 1978; Smith and Bolam, 1990) as well as from intrinsic GABAergic interneurons in the midbrain (Di Chiara *et al.*, 1979; Grofova *et al.*, 1982; Stanford and Lacey, 1996), and mediates inhibition of DA neuronal activity by both GABA-A and GABA-B receptors (Johnson and North, 1992b). GABA may induce a hyperpolarization through both GABA-A and GABA-B receptor activation and thus reduce the average firing rate and attenuate burst firing (Erhardt *et al.*, 2002; Grace and Bunney, 1980; Johnson and North, 1992b).

Cholinergic, Serotonergic and Noradrenergic Inputs

The midbrain DA neurons receive a cholinergic input from the PPTg and the adjacent LDTg (Beninato and Spencer, 1987; Bolam *et al.*, 1991; Clarke *et al.*, 1987). Both muscarinic and nicotinic receptors are present on the dopaminergic cells (Cortès and Palacios, 1986; Schwartz, 1986; Wada *et al.*, 1989) and pharmacological activation of these receptors leads to excitation of the neurons (Calabresi *et al.*, 1989; Lacey *et al.*, 1990). Also the serotonergic raphe nuclei provide a serotonergic afferent input to the DA neurons (Dray *et al.*, 1976; Fibiger and Miller, 1977; Hervé *et al.*, 1987; Phillipson, 1979; Ugedo *et al.*, 1989; van Bockstaele *et al.*, 1994) and a noradrenergic input has been demonstrated as well (Grenhoff and Svensson, 1989; Grenhoff *et al.*, 1993; Phillipson, 1979). Thus, burst activity of VTA DA neurons seems to be modulated by a noradrenergic input from the LC to the VTA and, for example, administration of the α_1 adrenoceptor antagonist prazosin selectively depresses burst firing (Grenhoff and Svensson, 1993). In addition, electrical stimulation of the LC elicits monoamine-mediated short-latency bursts in VTA DA cells, an effect that in turn was specifically antagonized by prazosin administration (Grenhoff *et al.*, 1993). Stimulation of α_1 adrenoceptors seems to increase the excitability of DA cells via inhibition of K^+ efflux (Grenhoff *et al.*, 1995).

Dopamine-Receptor-Mediated Regulation

The general physiological and biochemical activity of DA neurons originating in the midbrain is profoundly regulated by DA receptors. The original experiments by Carlsson and Lindqvist (1963), which studied antipsychotic drug action utilizing biochemical methodology, proposed a feedback regulation of DA neuronal activity by postsynaptic DA receptors. This notion was subsequently confirmed by several electrophysiological studies (Aghajanian and Bunney, 1973, 1977; Bunney and Aghajanian, 1978; Bunney *et al.*, 1973; Einhorn *et al.*, 1988). Moreover, DA activity is also powerfully controlled by so-called autoreceptors, i.e. various DA receptors located along the DA neuron responding to its own neurotransmitter by an inhibition of transmitter synthesis and release, as well as of the firing rate. Conversely, a stimulation of DA activity is observed following administration of DA-D_2 receptor antagonists (Andén *et al.*, 1973; Bunney *et al.*, 1973; Kehr *et al.*, 1972; Roth, 1973; for review see Carlson, 1977; Roth and Elsworth, 1995) and, consequently, the autoreceptors are thought to maintain a certain degree of tonic suppression of DA neuronal activity. At the cellular level, activation of somatodendritic autoreceptors by DA or DA agonists, such as apomorphine, hyperpolarize DA neurons through opening of K^+ channels via pertussis-toxin-sensitive G-protein (Aghajanian and Bunney, 1973; Innis and Aghajanian, 1987; Lacey *et al.*, 1987). Under physiological conditions such an endogenous autoreceptor activation is thought to be maintained by DA released from dendrites of neighbouring DA neurons, rather than by autoinhibition from the releasing neuron itself. Release of DA is also modulated by presynaptic DA autoreceptors located on the nerve terminals, since local or systemic administration of DA agonists has been reported to decrease DA release in the striatum (Kehr *et al.*, 1972; Westerink and de Vries, 1989; Zetterström and Ungerstedt, 1984). Generally such homeostatic regulatory mechanisms may serve a compensatory purpose, serving to antagonize dramatic changes in the functioning of the DA system and thus maintaining its activity within a stable range. However, mesocortical DA neurons appear largely to lack nerve impulse and synthesis-modulating autoreceptors (Chiodo *et al.*, 1984; Roth and Elsworth, 1995) and,

moreover, DA terminals in the deep cortical layers do not seem to be equipped with DA transporters (Sesack *et al.*, 1998). Thus the released transmitter may, especially following burst activity in the neurons, diffuse extrasynaptically, and previous studies indicate that a substantial portion of such DA may be taken up and metabolized in noradrenergic nerve terminals in the region (Gresch *et al.*, 1995). Importantly, the extrasynaptic DA may allow for activation of numerous extrasynaptic D1 receptors in the prefrontal cortex, specifically located on the pyramidal neurons (Smiley *et al.*, 1994), which in turn are thought to regulate the communication between such neuronal ensembles. As a corollary, brain NA uptake inhibitors would be expected to increase the availability of DA in the PFC, by preventing its uptake into noradrenergic terminals, a notion that recently has been confirmed by experimental results (Linnér *et al.*, 2001).

Postsynaptic Effects of DA

The postsynaptic effects of DA in its target areas have been the subject of numerous studies for decades. These actions are manifested both at the level of the individual postsynaptic neuron, with a cascade of intracellular transduction mechanisms being affected (for recent review see Greengard, 2001), and also include presynaptic effects and modulatory effects at the network level, which in addition may vary between different brain regions. This review will focus on some of these postsynaptic actions that may be of particular interest in relation to psychiatric disorders and their pharmacological treatment.

Striatum

Within this much-studied brain region DA has mostly been found to decrease the excitability of neurons in both the dorsal striatum and the NAC by means of D_1 receptor stimulation (Calabresi *et al.*, 1987; O'Donnell and Grace, 1996; White and Wang, 1986), although this notion has been challenged (Gonon, 1997). Here the D_1-mediated inhibition may act synergistically with D_2-receptor-mediated inhibition if agonists are applied at the same time. However, the D_1-induced reduction in excitability can be reversed to facilitation if a D_2 agonist is applied subsequently (Onn *et al.*, 2000). Such a temporal dissociation may have physiological significance. Thus, during burst activation of the DA neurons, e.g. in association with a rewarding stimulus, the ensuing large DA release (see above) would not only activate intrasynaptic D_1 and D_2 receptors, but also probably spill over, out of the synaptic cleft, to stimulate additional extrasynaptic D_1 receptors (Hersch *et al.*, 1995; Jansson *et al.*, 1999). However, with maintained high activity of the DA neurons the continued D_1 receptor activation may serve to attenuate a subsequent D_2 receptor activation, which preferentially is an intrasynaptic event (Onn *et al.*, 2000). Such a mechanism may help to explain the rather rapid attenuation of the response to rewarding stimuli, which is a well-known psychological phenomenon. The cellular mechanisms are different for the D_1- and the D_2-receptor-mediated responses. Thus, whereas D_1 stimulation modulates sodium conductances as well as high-voltage-activated calcium conductances involving PKA-mediated processes (Surmeier *et al.*, 1995), D_2 receptor stimulation modulates voltage-dependent potassium conductances. The D_1 response subsequently involves the phosphorylation of a DA- and cAMP-regulated phosphoprotein, DARPP-32, and this protein is, in turn, a critical component in the whole intracellular cascade of events that mediates D_1-receptor-regulated functions, which include, for example, modulation of glutamatergic transmission (Fienberg *et al.*, 1998; Greengard, 2001). Needless to say, DARPP-32 is by no means exclusively located in D_1 expressing neurons, but is also found in other striatal projection areas and, for example, in enkephalin containing striatal neurons (Langley *et al.*, 1997). D_2 receptor activation may here cause dephosphorylation of DARPP-32 (Nishi *et al.*, 1997). In short, DARPP-32 may generally serve to modulate DA-mediated functions at the striatal outflow level.

Apart from its effects at the cellular level, DA may also influence neuronal functioning in its target areas at the network level, e.g. by modulation of gap junction conductance and the associated interactions between neighbouring neurons, as elegantly demonstrated by Grace and colleagues. Here it appears that whereas D_2 receptor stimulation may cause an increased intercellular coupling, D_1 stimulation seems ineffective. Moreover, the level of coupling *per se* seems to be tonically suppressed by DARPP-32 (Onn *et al.*, 2000).

Finally, DA may modulate the postsynaptic response of striatal neurons to other neurotransmitters as well as the presynaptic regulation of transmitter release. Thus, for example, D_1 receptor activation has been shown to augment NMDA-receptor-mediated currents (Cepeda *et al.*, 1998), i.e. to facilitate glutamatergic transmission, and the D_1-mediated responses have been shown to be preferentially mediated by burst firing of the DA neurons (Chergui *et al.*, 1996, 1997; Gonon, 1997). Other studies show that D_2 receptor stimulation may, at the presynaptic level, decrease release of GABA from intrinsic neurons as well as glutamate release from corticostriatal nerve terminals. Generally, there exists a complex interaction and balance between dopaminergic and glutamatergic neurotransmission in the striatum, where DA may suppress the release of glutamate, whereas glutamate seems to enhance DA release. Overall this arrangement may contribute to maintain a restricted range of activity in striatal neuronal circuits, especially over time, albeit allowing for rapid changes in DA signalling in association with environmental cues. Recent work shows that DA also contributes to synaptic plasticity within the striatum. Thus, following high-frequency stimulation of corticostriatal, glutamatergic afferents, long-term potentiation (LTP) may be obtained, whereas low-frequency stimulation of the same striatal afferents may elicit long-term depression (LTD), and such processes require the presence of the DA afferent input (Centonze *et al.*, 1999). Such phenomena are mostly thought to be related to learning and memory and may thus, in this brain structure, have a bearing on, for example, the learning of various motor behaviours.

Prefrontal Cortex

The role of DA in the PFC has attracted successively increased attention over the years and still remains somewhat controversial, although studies *in vivo* clearly demonstrate an inhibitory effect of DA on PFC neuronal firing. Results *in vitro* have, however, revealed that DA and D_1 agonists may affect the excitability of PFC neurons via several mechanisms, involving both sodium and potassium conductances as well as L-type calcium conductances in the proximal dendrites of the pyramidal neurons (Yang *et al.*, 1999). Generally, the DA input is thought to regulate the glutamatergic input to these cells. The inhibitory effect of DA on pyramidal neurons is, instead, probably related to DA-induced excitation of GABAergic interneurons (Zhou and Hablitz, 1999). To add to the complexity and physiological sophistication of this machinery, studies have shown that the effects of DA on PFC neurons depend on their membrane potential, which normally may vary. Thus D_1 agonists may increase excitability only under certain conditions, i.e. in the depolarized state (Lavin and Grace, 2001).

Mediodorsal Thalamus

Here the dopaminergic input, which originates in the midbrain, may generally contribute to the control of thalamocortical information

processing. Specifically, experiments *in vitro* indicate that DA, acting through D_2 receptors, may facilitate oscillatory activity within the mediodorsal nucleus (Lavin and Grace, 1998).

Basolateral Amygdala

This brain region also receives an innervation from the midbrain DA neurons and here the effects of DA seem to vary between different cell types in a complex way. In addition, DA may serve to control afferent input to these cells from various sources in a differential fashion.

Ventral Pallidum

This DA projection area also receives a dopaminergic innervation from the midbrain DA neurons and, generally, this brain region represents an interface between the limbic and extrapyramidal systems. Therefore, DA in this region may contribute to influence motivated behaviour.

Summary

The effects of DA in its target areas are thus very complex and executed all along the cortico-striato-pallido-thalamocortical loop, which is of prime interest in relation to schizophrenia and its pharmacological treatment. In fact, several loops are interconnected and neurons of the shell region of the NAC not only receive a dopaminergic input from the VTA but also receive inputs from the cerebral cortex (infralimbic, agranular, piriform and insular areas), hippocampus and amygdala. In turn, these neurons project back to the VTA, but also to entorhinal cortex and the PFC, after relaying in the ventral pallidum and mediodorsal thalamus. Thus, the shell of the NAC is involved in a series of feedback and feedforward loops, involving the PFC as well as the VTA. Interestingly, the PFC is included in the heteromodal association neocortex, which in turn comprises other interconnected association areas, such as Broca's area and the inferior parietal cortex. These brain regions are generally involved in highly integrative mental functions, such as speech, learning and memory, and focused attention. The dopaminergic input may in a physiological sense serve to control efficiency in these heteromodal, cortico-ventrostriatal circuits, in analogy with its purported role in motor, cortico-dorsostriatal circuits. DA has been suggested to help maintain stability in such circuits at baseline conditions, but may at the same time serve to enhance or suppress signals, for example related to learning in association with rewarding or non-rewarding stimuli. DA activity may also contribute to direct attention to salient environmental stimuli and cues, and facilitate effective mental and motor strategies. In short, the complex effects of DA in its target areas suggest that this transmitter allows a gating mechanism for selection, acquisition and maintenance of appropriate behavioural programmes.

Behavioural and Clinical Significance of DA Neurons

The DA neurons of the midbrain were in the 1950s found to be implicated in motor tasks related to normal movements, but also, as subsequent studies showed, in motivational and reward-related behaviour as well as cognitive functions (for review see Koob *et al.*, 1998; Le Moal and Simon, 1991; Schultz, 1997, 1998).

The nigrostriatal DA neurons have long been known to be critically involved in the pathophysiology of Parkinson's disease (Carlsson, 1959; Ehringer and Hornykiewicz, 1960), and degeneration of the DA cells in the ventrolateral part of the substantia nigra zona compacta and to a lesser degree also in the VTA is responsible for the typical symptoms of Parkinson's disease, namely bradykinesia, rigidity and tremor. The degeneration of the DA neurons leads to a reduced DA output to neostratium (e.g. caudate-putamen), increasing the activity in the indirect loop to globus pallidus interna and substantia nigra pars reticulata of the basal ganglia, leading to an increased inhibition of motor output from the thalamus (for review see DeLong, 1990). As proposed by Carlsson (1959), the DA precursor L-DOPA was found to provide the first effective treatment for the disease by Birkmayer and Hornykiewicz in 1961, and is still the most effective treatment of Parkinson's disease despite severe side effects affecting up to 75% of the patients after five years of treatment.

The mesolimbocortical DA neurons are profoundly implicated in reward-related behaviour (Robbins and Everitt, 1999), and many drugs of abuse, including cocaine, amphetamine, opiates, ethanol and nicotine, are known to directly or indirectly cause an increased release of DA in terminal areas (Di Chiara, 1995). Moreover, specific lesions of NAC-projecting DA neurons reduce self-administration of nicotine (Corrigall *et al.*, 1992), cocaine and amphetamine (Roberts *et al.*, 1980; Wise and Bozarth, 1987). Rats can also learn to electrically self-stimulate the dopaminergic neurons of the VTA (Corbett and Wise, 1980; Garris *et al.*, 1999; Wise and Rompre, 1989; Wolske *et al.*, 1993). The cholinergic input to the DA neurons has been shown to be implicated in mediating rewarding brain stimulation of the lateral hypothalamus (Yeomans and Baptista, 1997; Yeomans *et al.*, 1985, 1993). In several *in vivo* and *in vitro* studies nicotine has been shown to excite DA neurons (Calabresi *et al.*, 1989; Grenhoff *et al.*, 1986; Picciotto *et al.*, 1998; Pidiplichko *et al.*, 1997), whereas opiates have been shown to inhibit the GABAergic input to these cells, leading to a disinhibition of the DA neurons (Johnson and North, 1992a).

Studies in the monkey (Schultz *et al.*, 1993, 1998) have further analysed the role of the midbrain DA neurons in reward-related tasks and demonstrated that these neurons are, indeed, activated by a primary reward and especially if it is unexpected. If the reward is coupled to a conditioning signal (visual or auditory), the increased firing of the DA neurons will switch from the moment of appearance of the reward to the instant when the conditioning stimulus appears, and not when the actual reward is delivered. Moreover, if the conditioning stimulus is not followed by the expected reward the DA cells decrease their firing. DA neurons can thus detect deviations from the expected reward, so that a positive signal is delivered to the brain if the reward is better than expected, no change if the reward is just as expected, and negative if less than expected. Thus, DA neurons seem to serve two functions: (1) to provide a tonic, generally enabling input on postsynaptic neurons in terminal fields, and (2) to send a phasic, global reinforcement or teaching signal to the brain, which helps to adapt behaviour and motor acts according to the motivational value of environmental stimuli (for review see Redgrave *et al.*, 1999; Schultz, 1997, 1998; Schultz *et al.*, 1997, 1998).

The prefrontal projection of the mesocortical DA neurons in the VTA is considered to modulate the activity of neurons in the PFC related to cognitive functions such as working memory, planning and execution of behaviour, inhibitory response control and maintenance of focused attention (Le Moal and Simon, 1991). Also reward-related stimuli increase dopaminergic activity in this region (Taber and Fibiger, 1997). In particular, D_1 receptor activation has been demonstrated to be required for the adequate performance of working memory tasks (Sawaguchi and Goldman-Rakic, 1994). Indeed, experimental results in both rats and monkeys indicate that not only too little, but also too much D_1 receptor activation may impair cognitive functioning, e.g. working memory (Murphy *et al.*, 1996).

In addition to their implication in reward-related behaviour and cognitive functioning, a putative overactivity of the mesolimbocortical DA system has been considered to be involved in

the symptomatology of schizophrenia (Carlsson, 1988). The 'DA hypothesis of schizophrenia' was based on the fact that: (1) all effective antipsychotic drugs used for treatment of schizophrenia share antidopaminergic activity, in particular through blockade of D_2 receptors, and (2) drugs which directly or indirectly facilitate dopaminergic neurotransmission in brain, e.g. amphetamine or L-DOPA, can precipitate or aggravate psychosis. However, this classical hypothesis was successively challenged by the relative difficulties of finding unequivocal evidence for dopaminergic hyperactivity in the brains of schizophrenic patients, by the relative lack of effect of the typical neuroleptics on negative symptoms, and by the fact that the atypical antipsychotic drug clozapine, despite its lower occupancy of D_2 receptors, has a significantly higher efficacy in refractory patients, as well as an advantageous effect on negative and some cognitive symptoms (Farde *et al.*, 1988, 1992; Kane *et al.*, 1988, Nordström *et al.*, 1995). Clozapine is not only a D_2 receptor antagonist but also has affinity for D_1, D_4 and α_2 adrenergic, 5-HT_{2A}, 5-HT_{2C}, 5-HT_6, 5-HT_7, muscarinic and histaminergic receptors (for review see Roth *et al.*, 1998), and in contrast to classical neuroleptic drugs it increases DA efflux in the prefrontal cortex (Moghaddam and Bunney, 1990; Nomikos *et al.*, 1994). This is of particular interest in view of the role of prefrontal DA in cognitive functioning and may have a bearing on its effectiveness against cognitive and negative symptoms (Hertel *et al.*, 1999). Consequently, the original DA hypothesis of schizophrenia, proposing a global hyperactivity of brain dopaminergic systems, needed to be revised. A differential dysfunctioning of the dopaminergic systems with hyperactivity, or hyperactivity in some areas and hypofunction in others, seemed more likely (Weinberger *et al.*, 1986). Such a dysfunction of brain DA systems might, in turn, rather than involving any particular pathology of the DA neurons themselves, be related to alterations in the input to these neurons (Nauta, 1976, Svensson and Tung, 1989). Indeed, subsequent preclinical results obtained with the so-called phencyclidine model of schizophrenia proposed the notion of a hyperactive subcortical, striatal DA projection concomitant with an impaired prefrontal DA projection in schizophrenia (Jentsch *et al.*, 1997; Svensson *et al.*, 1993, 1995). Significantly, this experimentally derived notion has subsequently been directly borne out by clinical studies in schizophrenic patients (Breier *et al.*, 1997; Egan *et al.*, 2001; Laruelle *et al.*, 1996). Thus, a novel strategy in the development of improved antipsychotic drug treatment emerged, in the sense that rather than simply to attempt to antagonize a presumed generally overactive DA transmission in brain, one should aim for normalization or stabilization of the above hypo- and concomitantly hyperfunctioning different DA projections at the same time (Svensson *et al.*, 1995). Indeed, clozapine and some other atypicals appear to do so (see above), and it appears very likely that their activity at several receptors other than D_2 receptors may contribute to such an effect (for review see Svensson *et al.*, 1999).

5-HYDROXYTRYPTAMINE

Introduction

A serum vasoconstrictor discovered over a century ago (Brodie, 1900), was isolated, characterized, and named serotonin by Rapport and collaborators in 1948 (Rapport *et al.*, 1948). Soon thereafter, Rapport identified serotonin as 5-hydroxytryptamine (5-HT). Enteramine, a smooth muscle contracting substance that had been isolated from the enterochromaffin cells in the gastrointestinal tract (and also contained in a variety of tissues) by Ersparmer and Vialli in the 1930s, was found to be identical with 5-HT by Ersparmer in the early 1950s (Ersparmer, 1966; Ersparmer and Asero, 1952). A few years later, Twarog and Page demonstrated the existence of 5-HT in mammalian brain (rats, rabbits and dogs) (Twarog and Page, 1953).

The widespread and uneven distribution of 5-HT in the brain led to the proposal that it is a neurotransmitter in the CNS (Bogdansky *et al.*, 1956; Brodie and Shore, 1957). Subsequently, Dahlström and Fuxe, using the then newly developed Falck-Hillarp's histochemical fluorescence methods, mapped the serotonergic cell bodies and showed their extensive projections to all brain regions (Dahlström and Fuxe, 1964; Fuxe, 1965).

Phylogenetically, 5-HT belongs to the oldest known neurotransmitters and is ubiquitously found not only in vertebrates and invertebrates, including the most primitive organisms endowed with a nervous system, but also in plants, e.g. vegetables and fruits (Tyce, 1985; Umbriaco *et al.*, 1990).

Biochemistry

5-HT is synthesized from the essential amino acid tryptophan (TRP). TRP is a major building block for protein synthesis and only a small amount of ingested TRP is used to synthesize 5-HT in a variety of cells, but not in platelets. Tryptophan hydroxylase hydroxylates TRP to 5-hydroxytryptophan (5-HTP), which is decarboxylated to 5-HT by aromatic-L-amino acid decarboxylase (AADC) and pyridoxal-5-phosphate (vitamin B6) as coenzyme. The rate-limiting step in 5-HT synthesis is considered to be the availability of 5-HTP, since AADC activity is at least an order of potency higher than that of tryptophan hydroxylase (Kema *et al.*, 2000). Of the total body 5-HT, only 1–2% is found in the brain (Cooper *et al.*, 1995). 5-HT does not cross the blood–brain barrier (BBB) and thus the brain is dependent on its own synthesis of the transmitter. This process, in turn, is determined by concentrations of free plasma TRP and transport across the BBB. TRP competes with other amino acids — isoleucine, leucine, phenylalanine, tyrosine and valine — to be moved across the BBB by the same large neutral amino acid (LNAA) transporter. The fact that TRP transport is dependent on both its concentration and those of five other amino acids constitutes the physiological basis for the rapid tryptophan-depletion (RTD) test. The test has in the past decade been used to assess the serotonergic function in brain, in particular in depression, and the mechanisms of action of antidepressant and prophylactic treatments (Bell *et al.*, 2001; Delgado *et al.*, 1999; Moore *et al.*, 2000; Reilly *et al.*, 1997). The goal of the RTD test is to decrease brain 5-HT synthesis and release by temporarily reducing/eliminating availability of TRP. This is achieved by administering a load of LNAA not containing TRP to the experimental subjects. The procedure stimulates liver protein synthesis, thereby using TRP and secondarily decreasing TRP transport into the brain.

Using positron emission tomography (PET), Nishizawa and coworkers (1997) have shown that in healthy subjects, men had approximately 50% higher rates of 5-HT synthesis than women and that following tryptophan depletion these differences were increased severalfold. These results are of interest in view of the greater prevalence of and vulnerability to depression in women. Other human studies have shown significantly reduced CSF 5-HIAA levels following the RTD test (Carpenter *et al.*, 1998; Williams *et al.*, 1999), while animal experiments have revealed decreased brain 5-HT and 5-HIAA as well as reduced release of 5-HT from serotonergic raphe nucleus following dietary interventions similar to those in humans (Bel and Artigas, 1996; Gartside *et al.*, 1992a, b; Moja *et al.*, 1989). In this context, for the interpretation of the RTD depletion test it might be relevant that TRP is also a constituent of other CNS regulatory proteins, e.g. a variety of enzymes, receptors, ion channels, neuropeptides, etc., and that possible alterations in their synthesis and function have thus far not been elucidated.

The RTD test has contributed to our knowledge of the role of 5-HT in the mechanisms of action of antidepressant treatments and,

to a limited extent, the pathophysiology of depressive disorders. Perhaps the most interesting, albeit also speculative, conclusions are that while a 5-HT dysfunction may play a role in eliciting depression in patients vulnerable to alterations in 5-HT function and that synaptic 5-HT availability is of therapeutic importance in maintaining euthymic mood in patients treated with selective serotonin reuptake inhibitors (SSRI) (but not with predominantly NAergic drugs), the primary determinants of depression are likely to involve compounds and circuits other than 5-HT, but modulated by it.

The major 5-HT metabolic pathway is deamination by monoamine oxidase (MAO), in particular MAO-A. The intermediary MAO product, 5-hydroxyindoleacetaldehyde, is a substrate for two enzymes: aldehydedehydrogenase, resulting in 5-hydroxyindoleacetic acid (5-HIAA), and alcohol dehydrogenase, leading to formation of 5-hydroxytryptophol (5-HTOL). 5-HIAA is by far the major metabolic product of 5-HT and its measurements in human CSF and brain tissue and in awake freely moving animals also in microdialysates from specific brain regions, have been a standard and fruitful tool to assess 5-HT release and metabolism. Determination of 5-HTOL is a useful index to study effects of ethanol on 5-HT. Minor metabolic routes for 5-HT are *N*-acetylation by serotonin-*N*-acetyltransferase and 5-*O*-methylation by hydroxyindole-*O*-methyltransferase leading to synthesis of melatonin (5-*O*-methyl-*N*-acetylserotonin). Lastly, in parallel to other biologically active compounds, elimination also takes place via conjugation with sulphuric and glucuronic acids.

5-HT Nuclei, Pathways and Receptors

5-HT cells are localized in brainstem nuclei called the raphe nuclei. The original classification of Dahlström and Fuxe (1964) into nine cell clusters, B_9-B_1, based on rostral to caudal topography, has generally been superseded by categorizing the cells into the caudal linear nucleus, the dorsal raphe nucleus (DRN), the median raphe nucleus (MRN) and the caudal nuclei. For a more detailed description see, for example, Jacobs and Azmitia (1992). The DRN is the largest nucleus, containing 50% or more of the 5-HT neurons.

Afferent input into the raphe nuclei comes from several brain regions, most notably hypothalamic areas, substantia nigra, LC, ventral tegmental area (VTA), prefrontal cortex, amygdala, NAC, etc., and is mediated by, for example, GABA, excitatory amino acids, NA, substance P, NT and vasointestinal polypeptide (VIP). Notably, the serotonergic neurons in the dorsal raphe neurons receive an excitatory noradrenergic input mediated by postsynaptic α_1 adrenoceptors, and thus inhibition of this input causes inhibition of serotonergic cell firing (Svensson, 2000a; Svensson *et al.*, 1975).

Efferents from the rostral nuclei, mostly the DRN and MRN, project ascendingly to telencephalon and diencephalon. The caudally located nuclei, on the other hand, project downward to the spinal cord and the cerebellum. In contrast to the more circumscribed DA pathways, virtually all brain regions receive 5-HT input (for review see Piñeyro and Blier, 1999) and these 'all encompassing' projections constitute the anatomical/functional basis for the wide array of 5-HT roles in CNS (Heinz *et al.*, 2001; Jacobs and Fornal, 1995; Lanctôt *et al.*, 2001; Shiah and Yatham, 2000; Rajkowska, 2000).

Actions of 5-HT are mediated by a multitude of 5-HT receptors. Although each receptor is activated by 5-HT itself, an array of agonists and antagonists has been synthesized to act more selectively on each subtype. A detailed description of 5-HT receptors is beyond the scope of this chapter and only the most salient points are taken up here. In parallel to classification of other receptors, the amino acid sequence of the receptor protein, the intracellular transduction mechanisms (that is, G-protein-linked or ligand-gated ion channel) and drug-related characteristics (selective agonists and antagonists) have been employed to identify/classify the 5-HT receptor subtypes. The pioneering work of Peroutka and Snyder (1979) using labelled 5-HT, LSD and spiroperidol established the existence of multiple 5-HT receptors. Several reviews on this subject are available (Barnes and Sharp, 1992; Hoyer and Martin, 1996, 1997; Hoyer *et al.*, 1994). The currently recognized receptor families are: 5-HT_1, 5-HT_2, 5-HT_3, 5-HT_4, 5-HT_5, 5-HT_6 and 5-HT_7. 5-HT_1 receptors are further subdivided into A, B, D, E and F; 5-HT_2 into A, B and C; and 5-HT_5 into A and B. Anatomical distribution is wide and most brain regions possess multiple receptor subtypes. Thus, in the limbic structures such as hippocampus, septum and amygdala there are 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, 5-HT_{1F}, 5-HT_{2A}, 5-HT_{2B}, 5-HT_3, 5-HT_4, 5-HT_{5A}, 5-HT_{5B} and 5-HT_6 receptors; in striatum 5-HT_{1B}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2B}, 5-HT_4 and 5-HT_6 receptors; in raphe nuclei 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2C}, 5-HT_3, 5-HT_{5B}, and 5-HT_7 receptors; in cortex 5-HT_{1B}, 5-HT_{1E}, 5-HT_{1F}, 5-HT_{2A}, 5-HT_{2B} and 5-HT_3 receptors; in hypothalamus 5-HT_{2B}, 5-HT_{2C}, and 5-HT_{5A} receptor; in choroid plexus 5-HT_{2C} receptor. The abundant and widespread localization of 5-HT receptors in the limbic system, raphe nuclei, mesolimbic pathways and choroid plexus gives an indication of the role 5-HT plays in regulation of affect, its own release, modulation of DA function and cerebrospinal fluid characteristics, respectively (Blier, 2001; Kilpatrick *et al.*, 1996; Piñeyro and Blier, 1999).

Transduction mechanisms involve the G-protein-coupled superfamily. Thus, all five 5-HT_1 receptors induce membrane hyperpolarization and are negatively linked to adenylyl cyclase; 5-HT_4, 5-HT_5, 5-HT_6 and 5-HT_7 are positively coupled to adenylyl cyclase with generation of cAMP; activation of the three 5-HT_2 subtypes induces depolarization and these receptors transduce via activation of phospholipase C and effects on phosphoinositides with generation of two second messengers, inositol triphosphate and diacylglycerol. In contrast, the 5-HT_3 receptor belongs to the ligand-gated ion channel family (analogous to, for example, glycine receptors, $GABA_A$). This is unique not only for the 5-HT receptors but also among other monoamine and diamine neurotransmitter receptors (Hoyer and Martin, 1996; Hoyer *et al.*, 1994). Last but not least, effects of a given transmitter are determined not only by its receptor subtypes and their regional distribution, but also by pre- and/or postsynaptic localization and whether they exert inhibitory or facilitatory actions. The 5-HT_{1A}, 5-HT_{1B} and 5-HT_{1D}, and also 5-HT_3 are both pre- and postsynaptic, while 5-HT_{1E} and 5-HT_{1F} are postsynaptic. The three types of 5-HT_2 receptor are postsynaptic (although 5-HT_{2C} may also be presynaptic). The 5-HT_4, 5-HT_5, 5-HT_6 and 5-HT_7 are postsynaptic. The role of 5-HT pre- and postsynaptic receptors in 5-HT synthesis and release is reviewed in a subsequent section.

Transmitter Release and Activity of 5-HT Neurons

In neurons, 5-HT is stored in vesicles and released by exocytosis, a process by which synaptic vesicle fuses with the cell membrane. Exocytosis, the main mechanism for release of transmitters, is triggered by depolarization (classically induced by K^+) and involves membrane proteins, for example synapsin I. A second release mechanism is carrier-mediated (Levi and Raiteri, 1993); 5-HT from the cytoplasmic pool is released by that kind of mechanism. The carrier-mediated release is not modulated by presynaptic receptors and is blocked by serotonin transporter (SERT) inhibitors (Levi and Raiteri, 1993). SERT mediates the 5-HT release evoked by drugs of abuse such as PCP, MDA and 'ecstasy' (MDMA) (Berger *et al.*, 1992; Bonanno *et al.*, 1994).

5-HT release from the neuronal cell body is regulated by somatodendritic 5-HT_{1A} autoreceptors which exert feedback control on neuronal firing. In addition, release is controlled by terminal 5-$HT_{1B/1D}$ autoreceptors, in e.g. cortex and hippocampus.

In contrast to release via 5-HT_{1A} receptors, this release can be modulated without changing the firing activity of 5-HT neuron (Crespi *et al.*, 1990). Experiments in rodents indicate that 5-HT_{1B} and 5-HT_{1D} receptors negatively regulate 5-HT release from MRN (Piñeyro and Blier, 1999; Piñeyro *et al.*, 1995, 1996). The release in cortex and hippocampus is negatively regulated by activation of 5-HT_{1B} terminal autoreceptors (Middlemiss and Hutson, 1990).

Heteroregulation of release in DRN and MRN occurs via GABA and GABA agonists that exhibit inhibitory effects (Becquet *et al.*, 1990) while substance P and direct and indirect DA agonists have facilitatory effects (Ferré *et al.*, 1994; Reisine *et al.*, 1982). As regards heteroregulation in the terminal projection areas, α_2 adrenoceptors appear to play an important regulatory role. Available evidence indicates that hetero- and auto-α_2 adrenoceptors regulating release of 5-HT and NA, respectively, have different properties (Blier *et al.*, 1993; Martire *et al.*, 1989; Mongeau *et al.*, 1993; Raiteri *et al.*, 1990). Acetylcholine increases 5-HT release in forebrain by nicotinic receptor activation, while histamine inhibits it, most likely acting via the H_3 heteroreceptor (Fink *et al.*, 1990; Summers and Giacobini, 1995).

SSRIs are highly efficient in increasing extracellular concentrations of 5-HT. Thus, acute administration of a high dose (e.g. $10\,mg\,kg^{-1}$) of any of the typical SSRIs, such as citalopram, sertraline or fluoxetine, will cause increased 5-HT levels in microdialysates from serotonergic terminal areas, such as striatum, cortex and diencephalon (Dailey *et al.*, 1992; Fuller, 1994; Invernizzi *et al.*, 1994; Rutter and Auerbach, 1993). Administration of lower doses of SSRIs (e.g. $1\,mg\,kg^{-1}$) does not elevate 5-HT in microdialysates from the projection areas but has a significant effect on 5-HT in the raphe nuclei. In turn, this increase in somatodendritic extracellular 5-HT leads to activation of inhibitory 5-HT_{1A} autoreceptor located on the soma and dendrites of 5-HT neurons (Bel and Artigas, 1992, 1993; Invernizzi *et al.*, 1994).

The immediate consequence is decreased serotonergic cell firing and, consequently, inhibition of 5-HT release in the terminal projection areas. The long-term sequelae are 5-HT_{1A} autoreceptor desensitization (Arborelius *et al.*, 1995; Svensson 1978) and a rebound of release (Arborelius *et al.*, 1996). Elucidation of these mechanisms has led to animal studies and clinical augmentation trials with 5-HT_{1A} antagonists (Bordet *et al.*, 1998; Maes *et al.*, 1996; Zanardi *et al.*, 1998). This topic, including the usage of pindolol, an agonist/weak antagonist of 5-HT_{1A} somatodendritic receptors (Arborelius *et al.*, 2000; Cremers *et al.*, 2001), is further reviewed in subsequent sections. Interestingly, in animal experiments, prolonged administration of SSRIs, such as paroxetine ($10\,mg\,kg^{-1}$) or fluoxetine ($5\,mg\,kg^{-1}$), was found also to diminish the effects of 5-$HT_{1B/1D}$ receptor inhibition of electrically induced 5-HT release (El Mansari and Blier, 1996; Piñeyro and Blier, 1999).

In similarity to SSRIs, acute administration of MAO inhibitors (MAOI) decreases 5-HT neuronal firing. Long-term treatment with MAOI also produces a recovery of 5-HT cell firing and increases the release of 5-HT. However, the mechanisms involved appear to be different from those following SSRIs since the terminal 5-HT_{1B} autoreceptor sensitivity appears not to be altered. A likely explanation is desensitization of α_2 adrenergic heteroceptors as proposed by Blier and co-workers (Blier and Bouchard, 1994; Blier *et al.*, 1986a, b). Interestingly, mianserin and mirtazapine (two antidepressants that antagonize α_2 adrenoceptors) also desensitize α_2 adrenergic heteroceptors on 5-HT neurons (Haddjeri *et al.*, 1997). Lastly, clinically used 5-HT_{1A} agonists, e.g. buspirone, also require a few weeks for their antidepressive/anxiolytic effects to develop. This delay in onset is apparently due to the recovery of the initial inhibitory 5-HT_{1A} autoreceptor effects with concomitant stimulation of the postsynaptic receptors (Haddjeri *et al.*, 1998).

The activity is both auto- and hetero-regulated. 5-HT decreases the firing rate of 5-HT neurons (Aghajanian *et al.*, 1972). This effect is mediated via somatodendritic 5-HT_{1A} receptors, as shown by the effects of 5-HT_{1A} agonists; 8-OH-DPAT is perhaps the one most extensively studied; other compounds explored *in vivo* are LSD, buspirone, (S)-UH-301 and (+)-WAY100135 (Aghajanian *et al.*, 1972, 1987; Arborelius *et al.*, 1994, 1995, 1996; Blier and Montigny 1994; Fornal *et al.*, 1994). α_1-Adrenoceptor antagonists also suppress the firing activity of 5-HT neurons (Baraban and Aghajanian, 1980; Haddjeri *et al.*, 1996). Importantly, administration of SSRIs and MAOIs results in a rapid 5-HT increase in extracellular concentrations at the somatodendritic level (Artigas, 1993; Sharp and Hjorth, 1990) and, as a consequence, activation of the 5-HT_{1A} autoreceptors and decreased 5-HT release. However, chronic administration of tricyclic antidepressants as well as SSRIs, 5-HT_{1A} agonists and MAOIs results in desensitization of somatodendritic 5-HT_{1A} autoreceptors. In turn, this leads to a greater 5-HT activity in terminal areas compared to the initial effects of antidepressants on 5-HT (Arborelius *et al.*, 1995, 1996; Blier and de Montigny, 1983, 1985; Blier *et al.*, 1986a, b; Svensson, 1978). Indeed, such a mechanism may well, at least partly, account for the typical delay in onset of the drugs' effects, as originally proposed by Svensson (1978).

Manipulation of 5-HT neuronal firing has accordingly been tried to shorten the time for onset of the therapeutic effects of antidepressant drugs. Artigas and co-workers gave pindolol to depressed patients treated with SSRIs and obtained a rapid improvement in their clinical condition (Artigas *et al.*, 1994). The results were initially attributed to pindolol's blockade of somatodendritic 5-HT_{1A} autoreceptors and thereby antagonism of the feedback inhibition of 5-HT neuronal firing caused by SSRIs. In a recent study, acute (−)pindolol reduced the firing rate of the 5-HT neurons. However, it did not abolish the inhibition of the 5-HT neuronal activity caused by citalopram but, in fact, further decreased the firing rate. The results were interpreted as showing that pindolol is both an agonist and a weak antagonist of the 5-HT_{1A} somatodendritic receptors (Arborelius *et al.*, 2000).

Pindolol is also a partial β adrenoceptor agonist, with significantly higher affinity for the β adrenoceptor than the 5-HT_{1A} receptor (Hoffman and Lefkowitz, 1990; Sánchez *et al.*, 1996). In view of this fact, Cremers and co-workers (Cremers *et al.*, 2001) hypothesized that its beneficial effects might be due to the action on β adrenoceptor and not the 5-HT_{1A} autoreceptor. This hypothesis was tested in guinea-pigs. In microdialysis studies of the ventral hippocampus, systemic administration of paroxetine augmented, as expected, the extracellular levels of 5-HT. Pretreatment with pindolol in doses resulting in brain levels $>600\,nmol\,l^{-1}$ were required to augment the 5-HT increases elicited by systemic paroxetine, while concentrations of only $3\,nmol\,l^{-1}$ were needed to antagonize the β adrenoceptor-agonist-induced increases in brain cAMP. Considering that approximately 100-fold higher plasma pindolol concentrations compared to the clinical plasma levels are necessary to enhance SSRI effects, it was hypothesized that SSRI augmentation is not secondary to blockade of somatodendritic 5-HT_{1A} autoreceptors.

In summary, the experiments reviewed above demonstrate the plasticity of the 5-HT receptor system and that the net result of the autoreceptor transmission changes is an increased release of 5-HT.

5-HT Reuptake

In parallel to DA and NA, following release into the synaptic cleft 5-HT is either metabolized or actively transported back into the neuron by a high-affinity transporter, SERT. SERT is a membrane polypeptide located presynaptically. Intracellular 5-HT is subsequently carried by a vesicular transporter into secretory vesicles, where it is stored. SERT has been solubilized, purified and reconstituted after purification from a variety of sources, e.g. rat

brain and platelets, human CNS and platelets (Biessen *et al.*, 1990; Ramamoorthy *et al.*, 1993a). Moreover, it was found to be encoded by a single gene on chromosome 17 and has also been cloned (Blakely *et al.*, 1991; Lesch *et al.*, 1993; Ramamoorthy *et al.*, 1993b). SERT is expressed both in neuronal and non-neuronal cells. Early binding studies were carried out with 3H-imipramine (Langer *et al.*, 1980), and subsequently with SSRIs, e.g. ^{3}H-paroxetine and ^{3}H-citalopram (D'Amato *et al.*, 1987; Descarries *et al.*, 1990; Habert *et al.*, 1985). Imipramine binding shows a significantly higher density than binding of SSRIs, a phenomenon explained by the fact that it binds to a high- and a low-affinity site. SSRIs, on the other hand, bind only to the high-affinity site, the site that appears to be related to uptake of 5-HT. SERT has been successfully studied in human subjects *in vivo* using PET. SERT was clearly identified in several brain regions, such as the frontal cortex, occipital cortex, hypothalamus and brainstem (Kuikka *et al.*, 1995). As for cellular localization of SERT, its presence in neurons has been demonstrated by immunocytochemistry. In contrast, in glial cells, depending on the antibody used SERT has been found by some (Anderson *et al.*, 1992; Lawrence *et al.*, 1995) but not by other research groups (Piñeyro and Blier, 1999; Qian *et al.*, 1995). SERT mRNA is found in neurons of the raphe nuclei coinciding with the localization of 5-HT cell bodies (Austin *et al.*, 1994; Fujita *et al.*, 1993). SERT mRNA has also been identified in the hippocampus, neostriatum and the frontal cortex, although the levels are substantially lower (Lesch *et al.*, 1993).

The mechanisms of uptake have been investigated for almost three decades, originally in platelets and following SERT cloning in different expression systems (Blakely *et al.*, 1991; Corey *et al.*, 1994; Demchyshyn *et al.*, 1994; Ramamoorthy *et al.*, 1993a, c; Rudnick, 1977). 5-HT is the specific substrate for SERT. However, 5-HT derivatives as well as PCP, amphetamine and cocaine are also substrates, although substances of abuse, e.g. cocaine, exert most of their effects by antagonizing DA uptake. In contrast, TRP, 5-HTP, 5-HIAA, and also NA and DA (in concentrations up to 10 μM) do not bind significantly (Corey *et al.*, 1994; Barker and Blakeley, 1995; Ramamoorthy *et al.*, 1993a, b; Wölfel and Graefe, 1992). 5-HT is taken up as cation and the process is dependent on the extracellular Na^+ and Cl^- and intracellular K^+ fluxes. The Na^+ gradient is the driving force for the 5-HT uptake, and Na^+ and 5-HT fluxes are directly coupled by SERT. Obviously, tricyclic antidepressants and SSRIs have SERT as their primary target. The question of the number of binding sites has been a subject of extensive exploration. Binding studies of labelled 5-HT, imipramine, paroxetine; chemical modification of SERT; and using antibodies directed against different parts of SERT (Langer and Schoemaker 1988; Langer *et al.*, 1980, 1987; Marcusson *et al.*, 1992; Tarrant and Williams, 1995) indicate that there are two separate but overlapping recognition sites for 5-HT, tricyclic antidepressants and non-tricyclic antidepressants. Important in this context is the fact that in addition to SERT, tricyclic antidepressants also bind at the NA reuptake transporter. Consequently, the relative potency of binding at those two sites constitutes, in part, the biological basis for the different clinical profiles of some classical tricyclics; for examples, chlomipramine and imipramine have more potent effects on 5-HT, while desipramine and nortriptyline primarily affect NA.

Behavioural and Clinical Significance

In the late 1960s Aghajanian and collaborators described the electrophysiological characteristics of presumed 5-HT neurons within the midbrain raphe nuclei in the anaesthetized rat. The cells were found to display a rather regular and slow firing pattern (Aghajanian *et al.*, 1968). Later they definitely established that the neurons were indeed serotonergic by combining single-cell recording with an intracellular double-labelling method (Aghajanian and VanderMaelen 1982b), and subsequent studies in awake animals, e.g. by Jacobs and collaborators, further documented the physiological characteristics of these neurons (see below).

Interestingly, the serotonergic neurons in the DRN seem to be subjected to a tonic excitatory input from noradrenergic neurons, at least as judged by experiments in anaesthetized animals. Thus, when the noradrenergic input is inhibited after administration of either clonidine, which suppresses the activity of NA cells, or by blocking α_1 adrenoceptors, which are located on the serotonergic neurons, the activity of midbrain 5-HT neurons is inhibited (Baraban and Aghajanian, 1980; Svensson *et al.*, 1975). *In vitro*, the majority of serotonergic cells in the DRN are silent, probably due to interruption of the noradrenergic input, but they can be activated by adding NA or the α_1 adrenoceptor agonist phenylephrine into the medium (Aghajanian *et al.*, 1987).

The activity of 5-HT cells in the DRN has been found to change in relation to the sleep–wake–arousal cycle (Jakobs and Azmitia, 1992). Thus, the activity is at its highest during active waking, but becomes slower and more regular during quiet waking. When an animal is entering slow-wave sleep (SWS) the 5-HT cell activity becomes even slower and also irregular, whereas during REM sleep the 5-HT neurons in the DRN are completely silent. These changes in activity of 5-HT cells in the DRN have been found to be associated with corresponding changes in the extracellular concentration of 5-HT in the DRN (Portas and McCarley, 1994). Thus, the concentrations of 5-HT appear to be highest during waking, to decrease during SWS and to become even further reduced during REM sleep. However, the light–dark cycle does not appear to influence the activity of these neurons, at least not in the cat. In several studies Jacobs and co-workers have studied the activity of 5-HT cells in the DRN in behaving cats. They found that the activity of the 5-HT neurons was not altered by a wide range of physiological challenges, e.g. changes in body temperature, blood pressure, environmental stimuli, such as confronting the animal with a natural enemy, or by exposure to painful stimuli. However, studies in cats have also shown that during some types of repetitive motor activities, i.e. running or chewing and biting, the activity of a subgroup of DRN 5-HT neurons is increased, whereas during orienting behaviours the activity of some 5-HT neurons is suppressed. It was hypothesized that a high 5-HT neuronal activity, associated with repetitive motor behaviours, might function to suppress sensory inputs. However, the reduced 5-HT activity, found in association with orienting behaviour, might instead serve to facilitate sensory functions (for review see Jacobs and Azmitia, 1992).

Pharmacological studies using electrophysiological techniques demonstrate that serotonin in brain may indeed serve to specifically modulate sensory responsiveness. Thus, the serotonergic input to the noradrenergic LC has been shown to selectively suppress glutamate-evoked responses of LC neurons, while leaving basal activity largely unaffected (Aston-Jones *et al.*, 1991; Chouvet *et al.*, 1988). In addition, SSRIs such as fluoxetine, sertraline and citalopram were subsequently found to significantly suppress LC hyperactivity evoked by excitatory amino acid inputs, which mediate activation responses to various sensory stimuli (Akaoka and Aston-Jones, 1993; Engberg 1992). This mechanism might have clinical significance. Thus, the intense arousal associated with panic attacks in all probability involves profound activation of brain NA neurons in the LC and, moreover, such LC activations are most likely driven by some of its major, excitatory afferent inputs, which utilize excitatory amino acids as neuronal messengers. Accordingly, a continued treatment of panic disorder with SSRIs may help to suppress part of the most intense arousal reactions through the NA–5-HT interaction in the LC, and such an effect may gradually

contribute to extinguish the overall neurobiological hyperreactivity (Svensson 1987, 2000a).

In short, a critical behavioural function of serotonin in the brain may be to dampen the responsiveness of the individual to sensory stimuli of salient nature. Although it is beyond the scope of the present review to cover the full pharmacological significance of central serotonergic systems in psychiatry, the multitude of indications for the SSRIs, for example, demonstrate the profound importance of serotonin in modulating behaviour, including aggression, sexual behaviour and anxiety as well as depression, a modulatory influence that may even include the personality in itself. Thus, brain 5-HT remains one of the most important transmitters in biological psychiatry.

V

The Excitatory Amino Acid System

Daniel T. Monaghan, Patrick A. Howson, David E. Jane and Richard J. Bridges

As one of the last major neurotransmitter systems to be identified, our appreciation of the roles of L-glutamate in synaptic signalling has progressed from the point where it was considered a nonspecific excitant to our present recognition of it as the primary excitatory transmitter in the mammalian central nervous system (CNS). Beyond its participation in standard fast synaptic communication, this excitatory amino acid (EAA) contributes to higher-order processes ranging from synaptic plasticity to neuropathology. The identification and characterization of the receptors through which L-glutamate mediates these processes has led to an understanding of the fundamental signalling machinery of most excitatory synapses in the brain. Instead of being passive transducers of chemical to electrical signals in the dendrite, these receptors display a diversity of physiological and molecular properties that enable them to play dynamic roles in the integration and modulation of synaptic signals. In this chapter, we provide a overview of three components critical to the operation of an EAA synapse: the ionotropic receptors, the metabotropic receptors, and the glutamate transporters.

IONOTROPIC GLUTAMATE RECEPTORS

L-Glutamate excites, or depolarizes, almost all neurons in the vertebrate CNS by activating ligand-gated ion channel receptors. These ionotropic glutamate receptors (Table V.1) span the plasma membrane, and the binding of L-glutamate causes a conformational change that opens a pore formed by the receptor. The opened ion channel allows the flux of Na^+, K^+ and sometimes Ca^{++} ions. It is the influx of these positively charged ions that causes the cell to depolarize. Early studies by Watkins and colleagues identified three classes of L-glutamate ionotropic receptors responsible for the depolarizing actions of L-glutamate. These were named for glutamate analogues that selectively activate each receptor class, *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA), and kainate (for review, see Watkins, 1981). With the development of receptor-selective antagonists, it then became possible to prove that these receptors are responsible for synaptic transmission throughout the brain. These discoveries have established glutamate as the major excitatory neurotransmitter in the vertebrate CNS and, in the process, have revealed several important and unexpected aspects of synaptic transmission.

NMDA Receptors

NMDA receptors have a distinctive role in synaptic transmission due to their unique physiological properties. When NMDA receptor antagonists first became available, initial studies could not identify a specific synaptic response mediated by these receptors, even though NMDA receptors are distributed throughout the brain. Soon, it was discovered that NMDA receptors have novel physiological properties that enable them to play an important role in synaptic transmission, but not in mediating the primary fast synaptic response in a glutamate-using synapse. Under normal physiological conditions, a single stimulation of a synaptic pathway results in a glutamate receptor-mediated synaptic response but with little detectable NMDA-receptor-mediated component (Collingridge *et al.*, 1988). Instead, most of the synaptic current is mediated by AMPA receptors. The apparent absence of an NMDA receptor synaptic component is due to the voltage-dependent properties of the receptor. In contrast to most other ion channel receptors, NMDA receptor currents are both ligand gated and voltage gated (Flatman *et al.*, 1983; MacDonald *et al.*, 1982). To observe more robust NMDA receptor responses, the cell must be moderately depolarized from the resting potential. Thus, partial depolarization results in larger NMDA-evoked currents, even though the voltage-gradient driving force responsible for these currents is reduced. The voltage dependency of NMDA receptors is due to the preferential blockade of NMDA receptor channels by Mg^{++} ions at negative membrane potentials (Mayer *et al.*, 1984; Nowak *et al.*, 1984). Hence, at the normal negative resting membrane potential, physiological concentrations of Mg^{++} ions potently block NMDA receptor channels. However, if the cell has been depolarized previously, such as during high-frequency stimulation, Mg^{++} ions can no longer block activated NMDA receptors, and a larger current results. Thus, NMDA receptor responses are dependent upon the immediately preceding history of the cell, with larger NMDA receptor responses occurring if the cell is currently depolarized from a previous synaptic signal.

Another important property of the NMDA receptor is calcium permeability. Unlike most ligand-gated ion channels, the NMDA receptor has a high calcium permeability in addition to sodium and potassium permeability. In many cases, it is this influx of calcium that is thought to be responsible for the subsequent biological actions induced by NMDA receptor activation. With the combination of these two distinctive physiological properties (voltage dependency and calcium permeability), NMDA receptors are able to use calcium as a trigger for experience-dependent plasticity, most notably the phenomena known as long-term potentiation.

While NMDA receptors are gated by L-glutamate, these receptors also require the presence of another agonist, glycine, to achieve channel activation (Johnson and Ascher, 1987). Thus, L-glutamate or NMDA alone is insufficient to evoke an NMDA-receptor-mediated response. Likewise, glycine alone is insufficient to evoke an NMDA receptor response, but glycine together with L-glutamate results in potent receptor activation. In many preparations, the glycine binding site appears to be saturated, or nearly saturated, in the absence of exogenous glycine. Hence, the presence of endogenous glycine, or a related agonist, makes the receptor responsive to the addition of L-glutamate by itself. Because of the apparent tonic saturation of the glycine site, relatively few studies

have examined the role of cellular mechanisms that modulate glycine levels in the synapse. However, there is some evidence that both glycine and D-serine (also an agonist at the glycine binding site) may have their extracellular levels regulated at subsaturating concentrations, and hence may play a role in modulating the excitability levels of NMDA receptors (Danysz and Parsons, 1998).

Molecular Properties of NMDA Receptors

NMDA receptors are a multimeric complex composed of subunits derived from three related families: NR1, NR2 and NR3 subunits (Nakanishi, 1994; Seeburg *et al.*, 1995; Sucher *et al.*, 1995). Both the NR1 and NR2 subunits are required for receptor function. The NR1 subunit contains the glycine binding site, and the NR2 contains the L-glutamate binding site (Laube *et al.*, 1998). In contrast, the NR3 subunit appears to modulate receptor function in a limited number of situations. Multiple lines of evidence suggest that there are two NR1 subunits and two NR2 subunits in a single NMDA receptor complex. Thus NR1/NR2 complexes may exist as a tetramer (Laube *et al.*, 1998). However, the effect on the stoichiometry of including NR3 subunits is unknown.

In the early 1990s, the laboratories of Nakanishi and Mishina identified cDNA encoding NMDA receptor NR1 subunits from rat and mouse, respectively (Moriyoshi *et al.*, 1991; Yamazaki *et al.*, 1992). The corresponding protein, NR1 (also termed NMDAR1 for rat and $\zeta 1$ for mouse), is over 900 amino acids in length and displays 22–26% identity with AMPA and kainate receptor subunits. The NR1 gene consists of 22 exons; exons 5, 21 and 22 can be alternatively spliced, resulting in eight distinct NR1 isoforms (Hollman *et al.*, 1993; Sugihara *et al.*, 1992). Exon 22 includes a stop codon and hence has a different C-terminal than proteins that do not have exon 22.

Subsequent to the cloning of the NR1 subunit, the NR2 subunits were identified (Ikeda *et al.*, 1992; Ishii *et al.*, 1993; Kutsuwada *et al.*, 1992; Meguro *et al.*, 1992; Monyer *et al.*, 1994; Monyer *et al.*, 1992). The four members of the NR2 subunit family (NR2A–NR2D for rat and $\varepsilon 1$–$\varepsilon 4$ for mouse) are the products of four separate genes. The physiological and pharmacological properties of native and recombinant NMDA receptors vary with the specific NR2 subunit present in the heteromeric complex (Buller *et al.*, 1994; Monyer *et al.*, 1994; Monyer *et al.*, 1992; Williams, 1993). NMDA receptors containing NR2A subunits are potently inhibited by zinc. The NR3 was initially termed χ-1, (Ciabarra *et al.*, 1995; Sucher *et al.*, 1995). Among various glutamate receptor subunits, NR3 has highest identity with NR1 and NR2 subunits (27%). When coexpressed with NR1/NR2B in oocytes, it reduces the magnitude of current responses. Intriguingly, in the NR3 knockout mouse (Das *et al.*, 1998), NMDA-receptor-mediated responses are larger and spine density is increased.

Subunit Topology

When the first glutamate receptor was cloned, there was a high expectation that the receptor would be a member of the so-called ligand-gated ion channel superfamily (e.g. nicotinic, glycine and γ-aminobutyric acid A (GABA-A) receptor channels), which contain four hydrophobic transmembrane domains. Thus, when the initial sequence was identified, it was generally accepted that the four

apparent hydrophobic domains represented transmembrane domains in a pattern analogous to nicotinic and GABA receptors. For these receptors, both the N- and C-terminals are on the extracellular side of the cytoplasmic membrane, consistent with having four intervening transmembrane domains. Subsequent analysis of glutamate receptors revealed, however, that the second hydrophobic domain (M2) did not pass through the membrane but formed a loop within the membrane and had both ends of M2 on the cytoplasmic side of the membrane (Hollmann *et al.*, 1994). This model leaves three transmembrane domains (designated TM1, TM3 and TM4 — from the original nomenclature) with the C-terminal inside the cell (Figures V.1 and V.2).

The three transmembrane topology model of glutamate receptors is supported further by the identification of the glutamate binding site. X-ray crystallographic analysis shows that the glutamate binding site (of the related AMPA receptor) is a bilobed structure (Armstrong *et al.*, 1998). Glutamate binding causes the two lobes to approach each other and, presumably, to open the ion channel in the process (Armstrong and Gouaux, 2000). One lobe arises from the extracellular N-terminal peptide sequence that immediately precedes TM1; the other lobe is formed by the peptide sequence found between TM3 and TM4. These portions of the glutamate receptor display a modest sequence homology and strong three-dimensional structural similarity to bacterial amino acid binding sites. Thus, the three transmembrane topographic structure is important for placing the two lobes of the glutamate binding site on the extracellular surface of the cell.

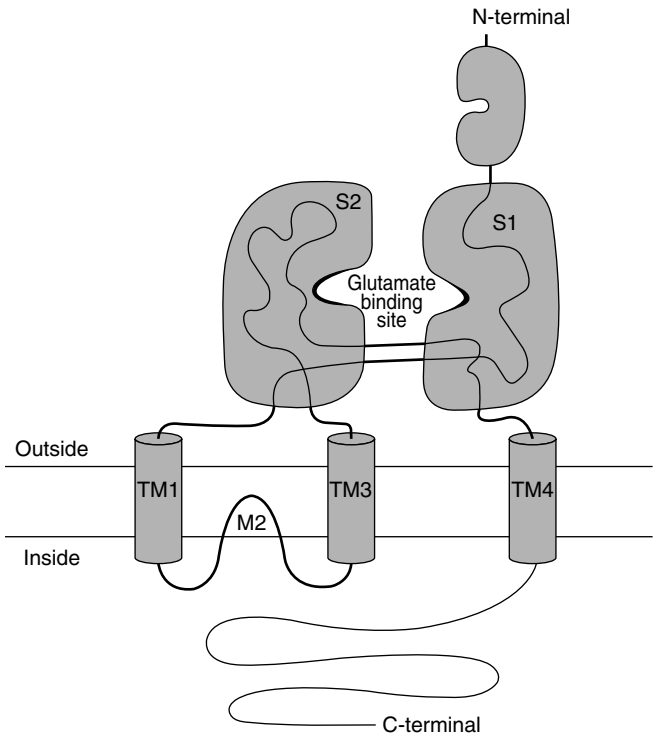

Figure V.1 Ionotropic glutamate receptor structure. Individual ionotropic glutamate receptors subunits have a multidomain structure with an initial N-terminal domain having homology to bacterial amino acid binding proteins (leucine-isoleucine-valine-binding protein, LIVBP). Glutamate (or glycine in the case of NR1 subunits) binds to a cleft between two domains, S1 and S2, which have homology to the bacterial amino acid binding protein lysine-arginine-ornithine-binding protein (LAOBP). There are three transmembrane domains (TM1, TM3, TM4) and one intramembrane loop (M2). In addition, there is an intracellular C-terminal, which can be relatively large and provide an important site for receptor regulation and signal transduction

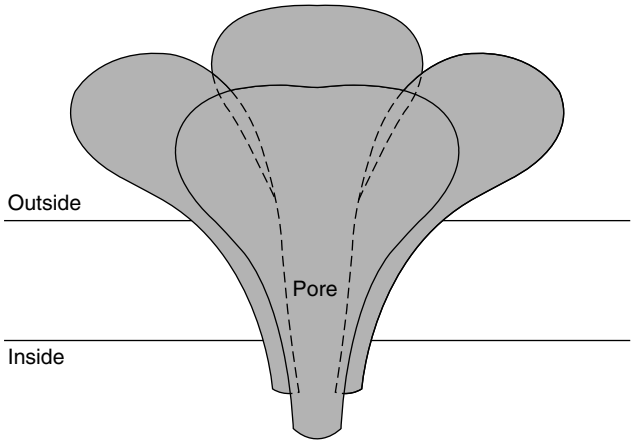

Figure V.2 The glutamate receptor complex is currently thought to be composed of four glutamate receptor subunits, with the ion channel pore formed by the TM1, M2, and TM3 portions of the four subunits

Protein–Protein Associations of the NMDA Receptor

The intracellular C-terminal tail the of NR1 and NR2 subunits appears to be quite important to the function of the receptor. NR2 subunits with truncated C-termini form functional ion channels, but their ability to be localized properly within the cell is impaired. Furthermore, since NR1 and NR2 C-termini bind to various signalling and cytoskeletal proteins, other downstream biochemical signals are probably initiated or modulated by the C-terminal domain. This may account for the fact that mice expressing truncated NR2 subunits act much like mice missing the subunit altogether (Sprenger *et al.*, 1998).

A key protein family that organizes many of these protein–protein interactions are the membrane-associated guanylate kinase (MAGUK) proteins, of which PSD-95 (SAP90) is the prototype. The PDZ domain-containing proteins related to PSD-95 are characterized by having three N-terminal PDZ domains followed by an SH3 (src homology 3) domain and a guanylate kinase (GK) homology domain (Sheng, 1996). Each of these domains mediates specific protein–protein interactions. Specific PDZ domains interact with specific sequences in the C-terminal of proteins, and specific SH3 domains bind to specific, proline-rich sequences in their target proteins. The GK domain is enzymatically inactive and binds to specific sequences in guanylate kinase associated proteins (GKAPs). The PSD-95 family includes PSD-95, SAP97, SAP102 and Chapsyn-110.

The C-terminus of the NR2 subunits end with the sequence S(L/I)ESDV, which preferentially interacts with the second PDZ domain (PDZ2) of PSD-95 (Kornau *et al.*, 1995), SAP102 (Lau *et al.*, 1996; Muller *et al.*, 1996) and other proteins. Further, NR1-3a has been reported to bind to PSD-95 (Kurschner *et al.*, 1998). In addition to the roles of clustering and anchoring, these scaffolding proteins allow for spatially ordered signal transduction systems. Hence, NMDA receptor activation can preferentially activate multiple calcium-activated processes by virtue of the localization of the calcium-responsive systems. For example, n-nitric oxide synthase (n-NOS) (Brenman *et al.*, 1996) and a calcium–calmodulin kinase II-sensitive neuronal ras-GAP (GTPase activating protein) (Chen *et al.*, 1998; Kim *et al.*, 1998) can also associate with PSD-95. Thus, the Ca^{++} current through the NMDA

receptor can selectively modulate nitric oxide (NO) production and ras effector pathways, such as mitogen activated protein (MAP) kinase.

The list of identified proteins that associate with glutamate receptors is growing rapidly. Other recently identified scaffolding proteins include channel-interacting PDZ domain protein (CIPP), which binds NR2s (Kurschner *et al.*, 1998); synaptic scaffolding molecule (S-SCAM), which binds NR2s (Hirao *et al.*, 1998); Cysteine-rich interactor of PD 23 (CRIPT), which binds to PSD-95's PDZ3 domain (Niethammer *et al.*, 1998); yotiao, which binds to NR1 subunits that have the C1 alternatively spliced cassette (Lin *et al.*, 1998); and α-actinin-2, which binds to NR1 and NR2s in a Ca^{++}-sensitive manner (Wyszynski *et al.*, 1997).

AMPA Receptors

With the use of nonselective glutamate receptor antagonists and selective NMDA receptor antagonists, it was discovered that ionotropic glutamate receptors, but not NMDA receptors, were responsible for mediating fast synaptic transmission in the major projection pathways of the CNS (Collingridge *et al.*, 1988; Monaghan *et al.*, 1989). However, it was unclear for many years whether these actions were mediated by AMPA and/or kainate receptors, hence the frequent use of the term 'non-NMDA receptors'. Indeed, at one point many scientists accepted the idea that AMPA and kainate were in fact the same receptor. However, the cloning of distinct AMPA and kainate receptor subunit families, together with the identification of AMPA-receptor-specific and kainate-receptor-specific antagonists, has now established firmly that there are two distinct receptor families corresponding to AMPA and kainate.

Four distinct genes code for the AMPA receptor subunits, GluR-A to GluR-D (also termed GluR1 to GluR4, respectively) (Hollmann *et al.*, 1989). Homomeric or heteromeric expression of the GluR1-4 subunits yields receptors with high affinity for AMPA and low affinity for kainate. The observation that kainate-evoked AMPA receptor responses do not desensitize (whereas AMPA-evoked responses desensitize rapidly) helps to account for why observed kainate-evoked responses are frequently mediated by AMPA instead of kainate receptors. In addition to the four gene products, alternative splicing and RNA editing increases significantly the diversity and complexity of AMPA receptors. Each of the AMPA receptors expresses one of two alternative splice cassettes, termed 'flip' and 'flop'. These two peptide segments result in differing desensitization properties, with the flop form displaying more rapid desensitization.

AMPA receptor channels composed of GluR-A (GluR1), GluR-C (GluR3) or GluR-D (GluR4) subunits are calcium permeable (Hollmann *et al.*, 1991). In contrast, the vast majority of native AMPA receptors do not display calcium permeability. When a GluR-B (GluR2) subunit is included in the receptor complex, the resulting receptor displays little calcium permeability. It is the presence of a single residue change in the M2 domain of GluR-B that inhibits calcium influx (Hume *et al.*, 1991; Verdoorn *et al.*, 1991). Interestingly, this single residue of the GluR-B subunit (arginine, R) is not coded for by the GluR-B gene. Instead, the GluR-B gene, like the other AMPA receptors, codes for a glutamine (Q). Using the process of RNA editing, the RNA sequence of GluR-B is altered to code for arginine.

A significant implication of these studies was the prediction of calcium-permeable native AMPA receptors. These have since been identified (Jonas *et al.*, 1994). A further implication is that cells that do not express the edited GluR-B subunit would be expected to be more vulnerable to calcium overload toxicity and, perhaps, calcium-mediated plasticity.

Pharmacological analysis of a large number of CNS projection pathways has led to the general conclusion that AMPA receptors represent the predominate fast excitatory neurotransmitter receptor in the CNS. In the phenomenon of long-term potentiation (LTP), the enhancement of AMPA receptor currents is responsible for the potentiated synaptic current. Recent studies have shown that a key step to this potentiation of AMPA receptor currents is the rapid delivery of new AMPA receptors to the cell surface (Luscher *et al.*, 1999; Luthi *et al.*, 1999). Currently, studies that characterize the differential regulation of the cellular localization of the various AMPA receptor subunits are emerging rapidly.

Kainate Receptors

Two related subfamilies of proteins comprise the mammalian kainate receptor subunits, GluR 5-7 and KA1 and KA2. The GluR5-7 (Bettler *et al.*, 1990; Bettler *et al.*, 1992; Egebjerg *et al.*, 1991) subfamily display 74–81% sequence similarity to each other and approximately 40% similarity to the AMPA receptor subunits. The KA-1/KA-2 subfamily (Herb *et al.*, 1992; Sakimura *et al.*, 1992; Werner *et al.*, 1991) have 68% sequence identity to each other and approximately 45% identity to the GluR5-7 subfamily. To obtain activity at the KA-1 and KA-2 subunits, the addition of at least one member of the GluR5-7 subfamily is necessary. Thus, native kainate receptors may exist as heteromeric combinations of subunits from the two subfamilies (Herb *et al.*, 1992).

The GluR5 subunit displays multiple forms due to alternative splicing. The sequence designated GluR5-1, in contrast to the GluR5-2 subunit, contains a 15-amino acid insertion on the N-terminal side of the first transmembrane domain (Bettler *et al.*, 1992). In addition, the GluR5-2 has three alternative splice variants (GluR5-2a, b and c) due to differing insertions near the C-terminal side. Both the GluR5 and GluR6 display RNA editing at the site homologous to the AMPA receptor's Q/R site. This modification also alters calcium permeability, but in a more complex manner that is also dependent upon additional RNA editing at sites in the TM1 domain (Seeburg, 1996).

Kainate Receptor Function

Kainate has been known for many years to be a potent convulsant and excitotoxin (for review, see Watkins, 1981). However, it has been possible only recently to establish a role for kainate receptors in synaptic transmission. The hippocampal mossy fibre synapse contains a very high density of kainate receptors (Foster *et al.*, 1981). In this pathway, kainate-receptor-mediated responses have been observed by including AMPA and NMDA receptor blockers and by stimulating the pathway at high frequencies (Castillo *et al.*, 1997; Vignes *et al.*, 1997). Another important synaptic action of kainate receptors may be the presynaptic inhibition of GABAergic neurotransmission (Rodriguez-Moreno *et al.*, 1997). The inhibition of GABAergic neurotransmission may account for the potent convulsant activity of kainic acid and the related seafood toxin domoic acid.

Protein–Protein Associations of Kainate and AMPA Receptors

PSD-95 and SAP102 have been shown to associate with both KA2 and GluR6 kainate receptor subunits, whereas SAP97 can associate with GluR6 but not KA2 (Garcia *et al.*, 1998). In contrast, AMPA receptors have limited interactions with the PSD/SAP proteins; SAP97 complexes with GluR 1, but not GluR2 or GluR3 (Leonard *et al.*, 1998).

AMPA receptors associate with the glutamate receptor interacting protein (GRIP) family of proteins (Dong *et al.*, 1997). GRIP contains seven PDZ domains and interacts with AMPA receptor subunits (GluR2) via its fourth and fifth PDZ domains. A related protein that contains six PDZ domains has been called AMPA

receptor binding protein (ABP) (Srivastava *et al.*, 1998). Interestingly, APB and GRIP can associate with each other, forming heteromultimeric complexes. In addition, other proteins such as the N-methylmalemide-sensitive factor (NSF) and soluble NSF attachment proteins (SNAP) have been shown to associate with, and modulate the function of, select AMPA receptor subunits (Lin *et al.*, 1998; Osten *et al.*, 1998).

METABOTROPIC GLUTAMATE RECEPTORS

Until the mid-1980s, glutamate was considered to exert its actions solely through ligand-gated ion channels. However, in 1987 Sugiyama and co-workers used the term 'metabotropic glutamate (mGlu) receptor' to describe a G-protein-coupled receptor (GPCR) activated by glutamate leading to phosphoinositide hydrolysis. Since then, numerous studies have been carried out examining the structure, anatomy, pharmacology, physiology and function of the mGlu receptors (for reviews, see, Anwyl, 1999; Cartmell and Schoepp, 2000; Conn and Pin, 1997; de Blasi *et al.*, 2001; Holscher *et al.*, 1999; Pin *et al.*, 1999; Pin and Duvoisin, 1995; Schoepp *et al.*, 1999). This work has resulted in the discovery of eight distinct mGlu receptor subtypes.

Classification of Metabotropic Glutamate Receptors

In mammals, eight genes encoding mGlu receptors have been identified so far. These receptors belong to the third family of GPCRs, a family that also includes $GABA_B$ receptors, calcium-sensing receptors and some putative pheromone and taste receptors (Bockaert and Pin, 1999). Within this family, the mGlu receptors can be subclassified into three groups based on their transduction mechanisms, sequence homology and pharmacology (Table V.2; Nakanishi, 1992). Group I receptors are comprised of mGlu1 and mGlu5, which are linked positively to phospholipase C (PLC). Activation of these receptors results in an increase of phosphoinositide (PI) turnover and consequently an increase in intracellular calcium concentration (Conn and Pin, 1997). In contrast, both group II mGlu (comprised of mGlu2 and mGlu3) and group III mGlu (comprised of mGlu4 and mGlu6-8) receptors are coupled negatively to adenylyl cyclase, so that upon activation they inhibit cyclic adenosine monophosphate (cAMP) production (Tanabe *et al.*, 1993). All three groups show some sequence homology (about 40%). However, the degree of homology rises to around 70% when receptors are compared within a group (Nakanishi, 1992). Finally, the three groups can be separated by their different pharmacological profiles.

Structure of Metabotropic Glutamate Receptors

mGlu receptors belong to the third family of GPCRs. As with all GPCRs, mGlu receptors have seven putative transmembrane domains. However, they share no sequence homology with GPCRs outside family three (Bockaert and Pin, 1999). All mGlu receptors have structural similarities, including a large N-terminal extracellular domain and a cytoplasmic carboxy-terminal domain that is variable in length. Splice variants of the mGlu receptors exist, so the carboxy-terminal domain can vary in length within a single subtype (e.g. the mGlu1 receptor has splice variants mGlu1a, b, c, d and e, of which only mGlu1a has a long carboxy-terminal domain). In addition, all mGlu receptors possess 19 cysteine residues that are located in the predicted extracellular domain and extracellular loops. These cysteine residues are thought to be important either in determining the three-dimensional structure of the receptor or for intramolecular signal transduction (Conn and Pin, 1997).

Glutamate Binding Site

Unlike the binding site for small ligands in most GPCRs, which is located in a pocket formed by the seven transmembrane domains, the binding site of mGlu receptors is extracellular and is composed of two globular domains with a hinge region. This site has been proposed to be the equivalent to the binding site of bacterial periplasmic binding proteins (O'Hara *et al.*, 1993). Recently, the crystal structure of the extracellular ligand binding site of the mGlu1 receptor has been elucidated in three states, in a complex with glutamate and two unliganded states (Kunishima *et al.*, 2000). The structure of the binding site is homodimeric, with the two monomers being connected by a disulphide bridge between cysteine residues. Each monomer is made up of two domains named LB1 and LB2; it is the LB1 domain that is predominantly involved in anchoring glutamate (Figure V.3). The bilobed structures are flexible and are able to adopt multiple open or closed conformations. Upon glutamate binding, the lobes are more likely to adopt the closed conformation and hence activate the associated G-protein.

Location of Metabotropic Glutamate Receptors

mGlu receptors are widespread in the mammalian CNS, where they are found notably in the hippocampus, cerebellum, spinal cord and on glial cells. However, mGlu receptors are not restricted to neuronal tissue, and they are also found in tissues as diverse as osteoblasts, ileum and heart tissue (see Skerry and Genever, 2001 for a review of glutamate receptors in non-neuronal tissues).

Table V.2 Classification of metabotropic glutamate receptor subtypes

Group	Subtype	Transduction mechanism	Agonist	Antagonist
I	mGlu1a–e	↑ PI hydrolysis	DHPG	CPCOOEt
	mGlu5a,b	↑ PI hydrolysis	DHPG	MPEP
II	mGlu2	↓ cAMP	(2*R*,4*R*)-APDC	LY341495
	mGlu3	↓ cAMP	(2*R*,4*R*)-APDC	LY341495
III	mGlu4a,b	↓ cAMP	(*S*)-AP4	CPPG
	mGlu6	↓ cAMP	(*S*)-AP4	CPPG
	mGlu7a,b	↓ cAMP	(*S*)-AP4	CPPG
	mGlu8a,b	↓ cAMP	(*S*)-AP4	CPPG

(*S*)-AP4, (*S*)-2-amino-4-phosphonobutanic acid; (2*R*,4*R*)-APDC, (2*R*,4*R*)-4-aminopyrrolidine-2-4-dicarboxylic acid; CPCOOEt, 7-(hydroxyimino)cyclopropa[b]chromen-1a-carboxylate ethyl ester; CPPG, (*RS*)-α-cyclopropyl-4-phosphonophenylglycine; LY341495, (2*S*,1′*S*,2′)-2-(9-xanthylmethyl)-2-(2-carboxycyclopropyl)glycine; MPEP, 2-methyl-6-(phenylethynyl)pyridine.

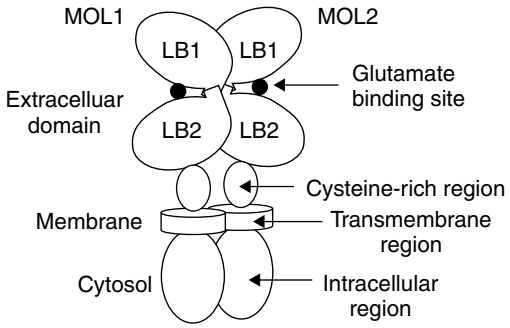

Figure V.3 Schematic diagram of the spatial arrangements of mGluR1 domains. MOL1 and MOL2 represent the two monomers, each of which has two domains (LB1 and LB2), together forming a bilobed structure. Glutamate (shown as a black circle) stabilizes the closed (activated) conformation of the bilobed domain

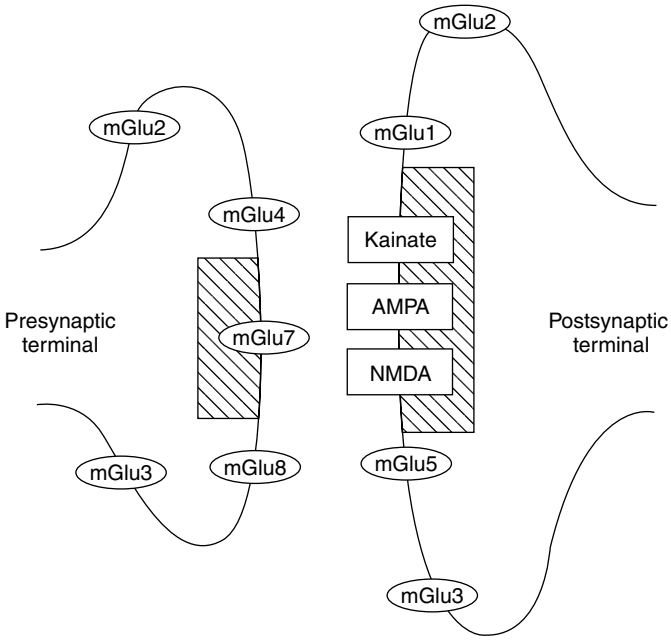

Figure V.4 Diagrammatic representation of the synaptic localization of glutamate receptors at a synapse. Group I mGlu receptors are generally located postsynaptically, away from the active zones (hatched areas). Some studies have indicated, however, that group I mGlu receptors may be localized presynaptically (Cartmell and Schoepp, 2000). Group II mGlu receptors are localized both pre- and postsynaptically, although they are located away from the active zones. Group III mGlu receptors are localized presynaptically, and the mGlu7 receptor is located within the active zone. The mGlu4 and mGlu8 receptors are not found within the active zones

Synaptic Location of Metabotropic Glutamate Receptors

The synaptic localization of the different mGlu receptor subtypes is important as this plays a major role in determining the physiological function of the receptor (Figure V.4). The majority of studies have shown that group I mGlu receptors are generally located postsynaptically and away from the active zones. In addition, immunogold localization studies of mGlu1a, b and c and mGlu5 receptors have shown them to be present at the highest density outside the membrane specializations (Baude *et al.*, 1993; Lujan *et al.*, 1997). In contrast to the group I mGlu receptors, most group III mGlu receptors (mGlu4a, 7a, 7b and 8) are presynaptic and are located in or near the active zones (Shigemoto *et al.*, 1997), the only exception seeming to be mGlu6, which appears to be expressed only in retinal bipolar cells. Group II mGlu receptors have been reported to be both presynaptic, in the presynaptic terminal of the hippocampus, and postsynaptic, on the periphery of longer membrane specializations (Petralia *et al.*, 1996; Shigemoto *et al.*, 1997). In addition, the mGlu3 receptor subtype is highly expressed in glial cells (Mineff and Valtschanoff, 1999).

Pharmacology of Metabotropic Glutamate Receptors

It is beyond the scope of this review to discuss in detail the numerous pharmacological agents acting at mGlu receptors that are now available. Therefore only a table of the major tools commonly used is presented (Table V.3); readers are directed to a comprehensive review for further detail (Schoepp *et al.*, 1999). An important aim is the development of subtype-selective agonists and antagonists for each of the eight mGlu receptors. Such agents are beginning to be developed with highly selective mGlu1 receptor antagonists, mGlu5 receptor agonists and antagonists, and mGlu8 receptor agonists now available (Clark *et al.*, 1997; Doherty *et al.*, 1997; Gasparini *et al.*, 1999; Litschig *et al.*, 1999; Thomas *et al.*, 2001).

Signal Transduction and Second-Messenger Systems

As stated earlier, the mGlu receptor subtypes utilize different signal transduction and second-messenger pathways. However, all the receptors can couple to G-proteins and have certain properties in common. Mutagenesis studies have shown that the second intracellular loop has a critical role in recognition of the G-protein, whereas the other intracellular domains are involved in controlling coupling efficacy. It has also been demonstrated that the extreme carboxy-terminus of the α-subunit of the G-protein is critical for the recognition of the receptor. This has led therefore to the idea that the carboxy-terminus of the G-protein α-subunit is also interacting in a cavity formed by the second and third intracellular loops (Francesconi and Duvoisin, 1998; Gomeza *et al.*, 1996).

Signal Transduction of Group I Metabotropic Glutamate Receptors

Most work examining the signal transduction of group I mGlu receptors has been carried out using cloned receptors expressed in cell lines. Depending on the cell type and mGlu receptor subtype studied, the signal transduction mechanisms can differ. However, in every expression system examined, group I mGlu receptors, including their splice variants, can stimulate PC and PI hydrolysis via coupling to G_{q11} (Figure V.5). Coupling to PI hydrolysis by group I mGlu receptors has also been demonstrated in many native systems, including cultured astrocytes, cultured neurons, synaptoneurosomes and brain slices (for a review, see Conn and Pin, 1997). In addition to inositol trisphosphate (IP_3) being formed upon PI hydrolysis, diacylglycerol (DAG) is also formed. DAG is lipid soluble and stays in the membrane, where it interacts with protein kinase C (PKC). Activated PKC causes phosphorylation of serine and threonine residues on a variety of intracellular proteins, including the group I mGlu receptors, causing them to desensitize (de Blasi *et al.*, 2001). Coupling of group I mGlu receptors to systems other than PI hydrolysis has also been reported in a number of studies. Both the mGlu1a and

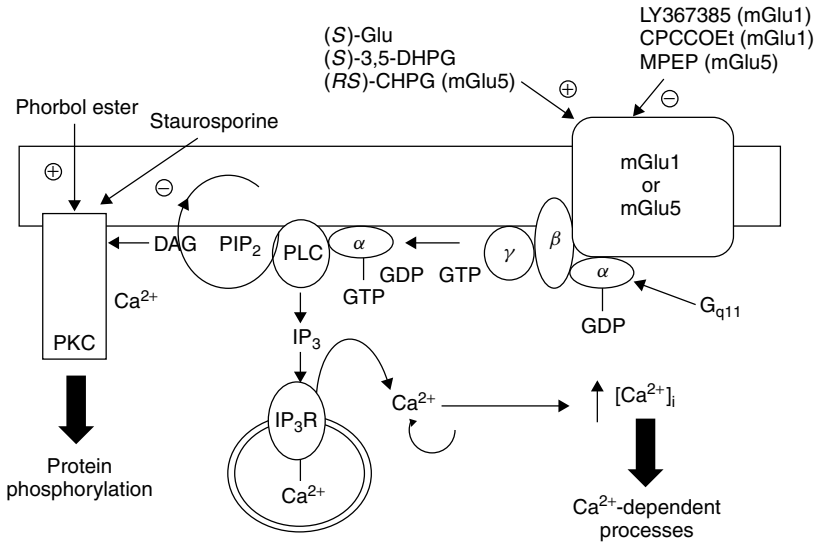

Figure V.5 A composite scheme for the molecular events that are initiated through activation of group I mGlu receptors. Upon receptor activation, the α-subunit of the G-protein activates PLC. This leads to IP_3 and DAG formation, which in turn cause Ca^{2+} release and PKC activation, respectively

mGlu5a receptors have been shown to increase cAMP formation, probably via direct coupling to adenylyl cyclase through G_s proteins (Pin and Duvoisin, 1995). Interestingly, in Chinese hamster ovary (CHO) cells, mGlu1a receptors but not mGlu5a receptors have been shown to increase cAMP formation (Abe *et al.*, 1992; Aramori and Nakanishi, 1992). The mGlu1a receptor has also been shown to couple to G_i protein, though this was using a mutated mGlu1a receptor (Francescori and Duvoisin, 1998). Additionally, when mGlu1a receptors are expressed in superior cervical ganglia neurons, they have been shown to inhibit M-type

potassium channels (Ikeda *et al.*, 1995). The mechanism of this inhibition is unclear, but it may involve direct coupling of the G-protein to the channel or it may be secondary to activation of PI hydrolysis.

Signal Transduction of Group II and Group III Metabotropic Glutamate Receptors

When cloned receptors are expressed in mammalian cells, both group II and group III mGlu receptors can, when activated, inhibit forskolin or G_s-coupled receptor-stimulated cAMP formation. This effect of cloned group II and III mGlu receptors is supported by studies using brain slices and neuronal cultures where inhibition of forskolin-stimulated cAMP formation was observed. In expression systems, both group II and group III mGlu receptors are pertussis toxin sensitive, indicating a role of a G_i- or G_o-type protein in their transduction pathways (Figure V.6). One difference between expression systems of group II and III mGlu receptor coupling is that the inhibition of adenylyl cyclase is often less efficient by group III mGlu receptors than by group II mGlu receptors (Conn and Pin, 1997). This difference may be due to either a lower expression of group III mGlu receptors in the plasma membrane or the inhibition of adenylyl cyclase not being the preferred transduction pathway of group III mGlu receptors. It is also worth noting that most studies of native group II and III mGlu receptors have examined the inhibition of cAMP formation induced by activating adenylyl cyclase using forskolin rather than using agonists of receptors that activate adenylyl cyclase via coupling to G_s-proteins. This method of stimulation means that the question of whether each of the group II and III mGlu receptors is coupled to inhibition of neurotransmitter-induced increases in cAMP accumulation in native systems remains debatable (Conn and Pin, 1997).

PLD-Coupled Metabotropic Glutamate Receptors

In addition to the eight mGlu receptors characterized to date, a body of evidence has been growing to suggest that a novel mGlu receptor exists that is coupled to phospholipase D (PLD). It has been demonstrated that the nonselective mGlu receptor agonist (1*S*, 3*R*)-1-aminocyclopentane-1,3-dicarboxylate ((1*S*,3*R*)-ACPD) is able to stimulate PLD activity in neonatal and adult hippocampal slices. Whereas the PLD stimulation in neonatal hippocampal slices appears to be indirect via PKC activation, the PLD-coupled mGlu receptor in adult hippocampal slices does not. In addition, this PLD-coupled mGlu receptor does not correspond to the known pharmacological profile of any of the known PLC- or adenylyl cyclase-coupled mGlu receptors (Albani-Torregrossa *et al.*, 1999).

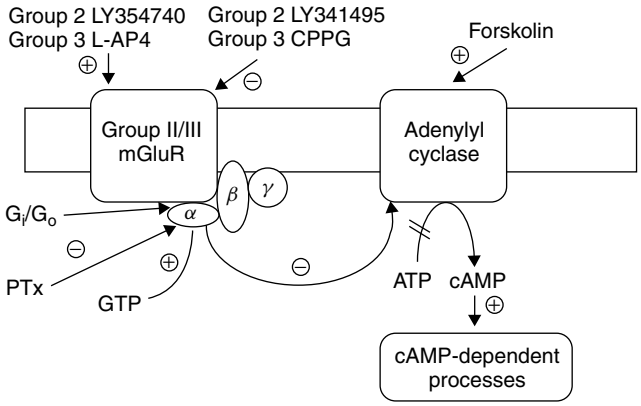

Figure V.6 A composite scheme for the molecular events that are initiated through activation of group II and III mGlu receptors. Upon receptor activation, the α-subunit of the pertussis toxin (PTx)-sensitive G-protein exerts an inhibitory effect on adenylyl cyclase, leading to a decrease in cAMP formation

G-Protein-Independent Signalling

In recent years, evidence has begun to accumulate indicating that mGlu receptors can elicit responses by G-protein-independent mechanisms (for a review, see Heuss and Gerber, 2000). G-protein-independent signalling can occur because the intracellular loops and free carboxy-termini of the mGlu receptors provide potential binding sites for protein interactions. In addition, several of the proteins that are able to bind to these sites exhibit enzymatic activity or are adapter proteins that can, for example, promote kinase binding to the receptor. Binding of these proteins would allow direct cross-talk of the receptor to other transduction pathways without the need for G-protein involvement. G-protein-independent signalling has been demonstrated for the mGlu1 receptor in CA3 pyramidal neurons in the hippocampus, where activation of the receptor produces an increase in a cationic conductance. The mGlu1-receptor-activated current is not blocked by a G-protein inhibitor but is blocked by an SRC tyrosine kinase inhibitor, showing that the response was G-protein-independent (Heuss *et al.*, 1999). It is not known what the link between the receptor and SRC kinase is, but a likely candidate is an arrestin-like protein (Heuss and Gerber, 2000).

Homer Proteins

Homer is a protein, the N-terminal of which interacts with the C-terminus of mGlu1a or mGlu5 receptors. Several types of Homer protein exist (1a,b,c, 2 and 3), and their expression is regulated by an immediate early gene. Homer 1b,c and 3 contain a coiled-coil domain that allows interaction with a group I mGlu receptor and another protein, e.g. the IP_3 receptor. This interaction leads to efficient coupling of the receptor to intracellular calcium release. In contrast to Homer 1b,c and 3, Homer 1a does not contain a coiled-coil domain. Without the coiled-coil domain, Homer 1a cannot couple the mGlu receptor with the IP_3 receptor; however, Homer 1a can still compete with the other Homer proteins for the binding site on the mGlu receptor, disrupting the coupling efficiency. Homer protein expression is dynamically responsive to physiological synaptic activity, with overexcitation leading to a higher expression of Homer 1a and therefore decreasing coupling efficiency. This means that Homer proteins can act as a mechanism controlling calcium release from intracellular stores (Brakeman *et al.*, 1997).

Physiology of Metabotropic Glutamate Receptors

The effects of mGlu receptor activation at the cellular level have been studied extensively using agonists and antagonists in various systems both *in vitro* and *in vivo*. In addition to pharmacological studies, anatomical studies have also been employed using mGlu receptor subtype-specific mRNA probes and antibodies. Finally, targeted disruptions of the mGlu receptor subtype genes have been used to elucidate synaptic and behavioural functions of the mGlu receptors.

Modulation of Cation Currents

Potassium channels are amongst the most common targets for modulation by mGlu receptors. An example of potassium channel modulation occurs in hippocampal pyramidal neurons, where activation

of mGlu receptors results in a reduction of a leak potassium conductance, the calcium-dependent slow after-hyperpolarization current (I_{AHP}), a slow non-inactivating voltage-dependent potassium current (I_M), and a slowly inactivating voltage-dependent potassium current (I_K) (Charpak *et al.*, 1990; Desai and Conn, 1991; Guerineau *et al.*, 1994; Luthi *et al.*, 1996). It has also been shown that mGlu receptor activation can have a direct inhibitory effect on neurons, likely by opening potassium channels. This has been shown in basolateral amygdala neurons, where mGlu receptor activation induces a hyperpolarization. In addition to modulating potassium channels, mGlu receptors can exert excitatory effects on neurons by activating nonselective cation currents, such as a Na^+/Ca^{2+} exchange (Linden *et al.*, 1994), a calcium-activated nonspecific cation current (Crepel *et al.*, 1994), and a calcium-independent nonspecific cation channel (Miller *et al.*, 1995).

Modulation of Voltage-Dependent Calcium Channels

All the three major subgroups of mGlu receptors can modulate calcium channels, mainly by inhibiting them, although in a few instances they have been shown to activate calcium currents. Inhibition of N-type calcium channels has been shown in cortical neurons, and is likely to be mediated by members of group I and group II mGlu receptors (Choi and Lovinger, 1996). Group II mGlu receptors have also been indicated in inhibition of N-type calcium channels in granule cells (Chavis *et al.*, 1995). Group III mGlu receptors have been shown to inhibit calcium currents in the olfactory bulb, retinal ganglia neurons, and a subpopulation of hippocampal neurons (Rothe *et al.*, 1994; Sahara and Westbrook, 1993; Trombley and Westbrook, 1992). Group I mGlu receptor activation has also been reported to increase N-type calcium currents in retinal ganglion neurons and L-type calcium currents in cerebellar granule cells (Chavis *et al.*, 1995; Rothe *et al.*, 1994).

Regulation of Synaptic Transmission by Metabotropic Glutamate Receptors

One of the most prominent physiological effects of mGlu receptor activation, consistent throughout the CNS, is a regulation of transmission at glutamatergic synapses. This effect is typically mediated by presynaptic mGlu receptors acting as autoreceptors (for a review, see Cartmell and Schoepp, 2000), with the most common response being a reduction of glutamate release mediated by group II and group III mGlu receptors. However, over the last decade it has become clear that multiple mGlu receptor subtypes of each of the three major groups can act as autoreceptors. Which receptor subtype acts as the autoreceptor is dependent on the preparation being studied, e.g. in adult hippocampal area CA1, both group I and group III mGlu receptors, but not group II mGlu receptors, act as autoreceptors leading to a reduction in glutamate release (Gereau and Conn, 1995). Immunocytochemical analysis of this area suggests that the subtypes mGlu5 and mGlu7 are responsible for eliciting the reduction in glutamate release. However, in the medial perforant pathway synapse, it is a group II mGlu receptor that is acting as the autoreceptor, again reducing glutamate release (Macek *et al.*, 1996; Ugolini and Bordi, 1995). In the neonatal rat spinal cord, both group II and group III mGlu receptors serve as autoreceptors (Cao *et al.*, 1995; Jane *et al.*, 1994), with recent evidence suggesting that the mGlu8 receptor is responsible at least partly for the group III mGlu receptor-mediated depression of synaptic transmission (Thomas *et al.*, 2001).

The mechanisms underlying the regulation of glutamate release by mGlu receptors acting as autoreceptors are not yet known. However, for receptors responsible for decreasing glutamate release, it seems likely that a reduction of the voltage-dependent calcium currents is one potential mechanism. Other mechanisms to decrease glutamate release that work without the regulation of voltage-dependent calcium currents may exist, such as an activation of presynaptic potassium currents (Sladeczek *et al.*, 1993). Enhancement of glutamate release by (*S*)-3,5-dihydioxy phenylglycine (DHPG) has also been shown under certain conditions (Cartmell and Schoepp, 2000). That the facilitation of glutamate release was still observed in mGlu1 knockout mice is suggestive that this is an mGlu5 receptor-mediated effect.

Metabotropic Glutamate Receptor Activation in Regulation of Release of Other Neurotransmitters

As well as regulating glutamate release, mGlu receptors also regulate the release of other neurotransmitters. As with glutamate, the release of other neurotransmitters can be up- or downregulated depending on the type of mGlu receptor present, the tissue preparation, the agonist used, and the stimulation conditions employed. It is beyond the scope of this chapter to detail the effects of mGlu receptor activation on all these neurotransmitters, and so GABA regulation will be considered as a representative example (for a review of the effects on other neurotransmitters, see Cartmell and Schoepp, 2000).

Presynaptic mGlu receptors have been shown to reduce GABA release and, therefore, to reduce inhibitory synaptic transmission. This occurs in several brain areas and, again, members from each of the three major groups of mGlu receptor can carry out this role. In the CA1 area of the hippocampus in mature rats, a subtype of the group I mGlu receptor regulates GABA release (Gereau and Conn, 1995), whereas group II mGlu receptors have been shown to reduce GABA release in the accessory olfactory bulb (Hayashi *et al.*, 1993), the hippocampal area CA3 in young rats (Poncer *et al.*, 1995), and the thalamus (Salt and Eaton, 1995). Also, in the thalamus activation of group III mGlu receptors has been shown to reduce GABA release (Salt and Eaton, 1995).

Metabotropic Glutamate Receptor-Induced Modulation of Ligand-Gated Ion Channels

A final way in which mGlu receptor activation can regulate synaptic transmission is by modulating currents through glutamate and GABA receptor channels. This modulation of ligand-gated ion channels allows selective modulation of specific components of the synaptic potentials. An example of mGlu receptor activation increasing currents is in the hippocampus, where activation leads to an enhancement of NMDA-receptor-mediated responses without modulating responses of non-NMDA ionotropic glutamate receptors. This effect appears to be mediated by a group I mGlu receptor (Fitzjohn *et al.*, 1996). A similar effect is observed in spinal cord dorsal horn neurons, although in this example mGlu receptor activation potentiates currents through both NMDA and non-NMDA glutamate receptors (Bleakman *et al.*, 1992). Negative modulation of ligand-gated ion channel mediated currents can also occur. In striatal neurons, mGlu receptor activation causes a decrease in the level of depolarization due to NMDA receptor activation (Colwell and Levine, 1994). Therefore, the effect of mGlu receptor activation on ligand-gated ion channels is variable and may play a unique role in regulating inhibitory and excitatory synaptic transmission.

Functions of Metabotropic Glutamate Receptors

As has been outlined above, there is a plethora of ways in which mGlu receptor activation can exert effects. These mechanisms can be separated broadly into excitatory effects, inhibitory effects, presynaptic effects and modulation of neurotransmitter release. As glutamate is the most common transmitter in the mammalian CNS, and as mGlu receptor activation can also modulate the release

of other transmitters, the potential functions of mGlu receptor activation are vast. mGlu receptors have been shown to be important in various motor circuits, including those of the spinal cord, basal ganglia and cerebellum, in pain transmission, and in many forms of synaptic plasticity (Anwyl, 1999; Conn *et al.*, 1994; Salt and Eaton, 1994; Young *et al.*, 1995). In addition, mGlu receptors have been indicated in many pathophysiological roles, such as strokes, epilepsy and neurodegenerative disorders (Bruno *et al.*, 1995; Buisson *et al.*, 1996; Conn *et al.*, 1994). The functional significance of mGlu receptors will be illustrated by an overview of their role in synaptic plasticity (for a more detailed review of the material presented in the following section, see Anwyl, 1999).

Synaptic Plasticity

Synaptic plasticity at glutamatergic synapses is characterized by long-term changes in the synaptic efficacy. LTP and long-term depression (LTD) are the two most common, most well-understood forms of synaptic plasticity. LTP is a long-lasting (hours *in vitro*, days or weeks *in vivo*) enhancement of synaptic transmission, and is a model for the study of the cellular processes that underlie learning and memory. Briefly, LTP in area CA1 of the hippocampus is induced by activation of an AMPA-receptor-associated sodium channel leading to membrane depolarization and removal of the magnesium block of the NMDA-receptor-associated ion channel. On activation of NMDA receptors, calcium enters the neuron and activates a number of kinases and lipases that are part of a cascade that consolidates the LTP. As it is the calcium entry through the NMDA channel that is critical for LTP, it is perhaps not surprising that group I mGlu receptors, which are coupled to PLC, enhance NMDA receptor activity, depolarize neurons and increase intracellular calcium concentration, should facilitate or even induce LTP. This is indeed seen, as group I mGlu receptor agonists such as DHPG or (1*S*,3*S*)-1-aminocyclopentane 1,3-dicarboxylic acid (ACPD) have been shown to enhance LTP and even induce LTP in the CA1 area of the hippocampus and dorsolateral septal nucleus (Zheng and Gallagher, 1992). The exact mechanism involved in LTP induction or potentiation by mGlu receptors is not known, but it is likely to be due to a release of calcium from internal stores and PKC activation. The use of mGlu receptor antagonists to block LTP induction has had mixed results depending on the antagonist used, stimulation conditions, and preparation studied. The variability may be due in part to the presence of an (*S*)-α-methyl-4-carboxyphenylglycine (MCPG)-sensitive receptor with an unknown pharmacological profile that is not one of the known mGlu receptors.

LTD is the counterpart of LTP and is used to describe a long-lasting depression of synaptic transmission. LTD of glutamatergic synapses has been found in many different brain areas. The best-described example of LTD is of the parallel fibre–Purkinje cell synapse that is induced by the coactivation of climbing and parallel fibres. Group I mGlu receptor activation alone is not sufficient to induce LTD at this synapse, although this can be achieved by coactivation of group I mGlu receptors and voltage-sensitive calcium channels.

GLUTAMATE TRANSPORTERS

It is becoming increasingly apparent that the overall functioning of an EAA synapse is governed not only by its constituent receptors but also by those proteins that influence the amount of L-glutamate in the synaptic environment. It is in this regard that attention has focused on two distinct uptake systems: the intracellular transporters that mediate the uptake of L-glutamate into synaptic vesicles, and the cellular excitatory amino acid transporters (EAATs) that effectively sequester glutamate into glia and neurons. In addition to subcellular localization, these systems are readily distinguishable in terms of their protein structure, energetics, and pharmacology (Bridges *et al.*, 1999; Ozkan and Ueda, 1998; Palacin *et al.*, 1998; Seal and Amara, 1999). Each also appears to hold considerable potential to modify EAA synaptic signalling as a target of either pathological mechanisms or therapeutic interventions.

Vesicular Glutamate Transporter

As is characteristic of classic neurotransmission, the release of L-glutamate into the synaptic cleft occurs as a consequence of the calcium-dependent fusion of synaptic vesicles containing the transmitter with the plasma membrane of the presynaptic terminal. The vesicular glutamate transport system (VGLUT; Figure V.7) is responsible for sequestering L-glutamate in these vesicle before release. In this respect, the VGLUT may represent a novel site at which excitatory transmission can be regulated.

Studies of glutamate uptake into isolated synaptic vesicles demonstrate that this transport system is clearly distinct from the cellular EAATs. Rather than ionic gradients of sodium and potassium, the transport of L-glutamate into the synaptic vesicle is driven by a proton gradient generated by a vacuolar type ATPase (V-ATPase) (Maycox *et al.*, 1990). V-ATPases are found on lysosomes, endosomes, and secretory and synaptic vesicles, and can be distinguished from mitochondrial and plasma membrane ATPases by specific inhibitors, such as Bafilomycin. The resulting electrochemical gradient, which is estimated to be capable of concentrating L-glutamate 10–100-fold within the synaptic vesicles, includes an electrical ($\Delta\Psi$, inside positive) as well as a chemical (ΔpH, inside acidic) component (Maycox *et al.*, 1990; Tabb *et al.*, 1992; Wolosker *et al.*, 1996). Comparisons of the relative contributions of $\Delta\Psi$ and ΔpH indicate that, like GABA, the accumulation of L-glutamate in synaptic vesicles appears to depend primarily on $\Delta\Psi$ rather than ΔpH, which predominates in the vesicular transport of monoamines and acetylcholine. Uptake of L-glutamate into synaptic vesicles also exhibits a dependence on chloride ions (Ozkan

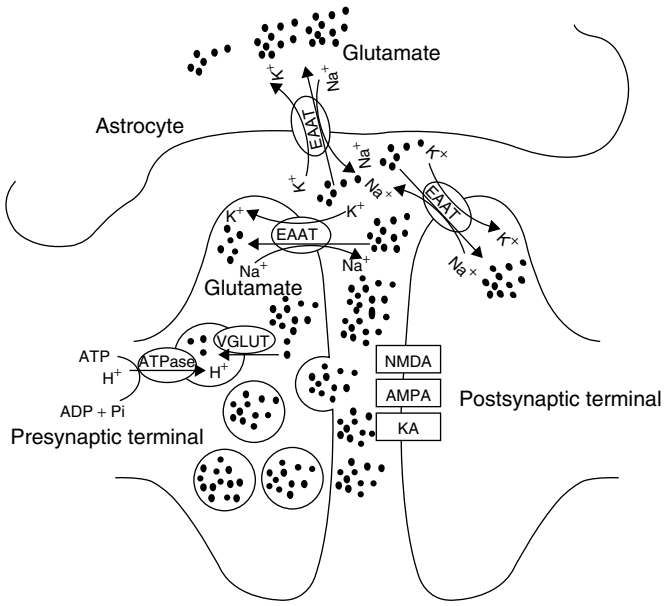

Figure V.7 Diagrammatic representation of the synaptic localization of the vesicular glutamate transporter (VGLUT) and the cellular sodium-dependent excitatory amino acid transporter (EAAT) (KA, kainic acid receptor)

and Ueda, 1998). Transport is stimulated by the concentrations of chloride in the 1–5-mM range and inhibited when levels increase above 20 mM. In addition to its ability to influence ΔpH as a consequence of its presence inside the synaptic vesicle, the inhibitory action of the anion channel blocker 4,4′diisothiocyanatostilbene-2,2′-disulphonic acid (DIDS) suggests the presence of a distinct site at which chloride may regulate VGLUT (Hartinger and Jahn, 1993).

Vesicular Glutamate Transporter Pharmacology

From a kinetic and pharmacological perspective, the VGLUT and EAAT systems share little beyond the basic ability to translocate L-glutamate. Uptake by the vesicular transporter is considered low affinity when compared with the EAATs, as the K_m values for L-glutamate uptake into synaptic vesicles typically fall within the 1–2-mM range (Ozkan and Ueda, 1998). Similarly, specificity differences between the two become readily apparent as soon as the activities of glutamate and aspartate are compared. In contrast to the EAATs, transport of glutamate through VGLUT is both blocked by D-glutamate and insensitive to inhibition by either L- or D-aspartate. Unfortunately, while specificity studies have identified numerous compounds that inhibit the vesicular accumulation of ^{3}H-L-glutamate, the inhibitors represent such a wide spectrum of molecules that a clear structure–activity model has yet to emerge. (This situation may be made worse by the fact that compounds can potentially also inhibit uptake indirectly, by disrupting the vesicular proton gradient.) The list of VGLUT blockers ranges from molecules that are clearly glutamate mimics, such as *erythro*-4-methyl-L-glutamate and 4-*methylene*-L-glutamate (Winter and Ueda, 1993), to those that exhibit little resemblance to the natural substrate, such as the ergot bromocriptine and the azo dyes Chicago Sky Blue and Evans Blue (Carlson *et al.*, 1989; Roseth *et al.*, 1995). This latter group appears to be amongst the most potent inhibitors yet identified, as the azo dyes block uptake with K_i values in the submicromolar range. More recent studies with the dye Rose Bengal suggest that VGLUT inhibitors may be capable of regulating levels of synaptically released glutamate (Ogita *et al.*, 2001). The list of VGLUT inhibitors also includes a number of glutamate analogues best known for their activity at other sites within the EAA system. For example, kynurenate and 7-Cl-kynurenate, which act as antagonists at the EAA ionotropic receptors and the glycine site on the NMDA receptor, respectively, both competitively inhibit VGLUT (Bartlett *et al.*, 1998). Similarly, *trans*-ACPD, which is recognized for its activity at EAA metabotropic receptors, not only inhibits the uptake of L-glutamate into synaptic vesicles but also appears to act as an alternative substrate (Winter and Ueda, 1993). Lastly, a family of inhibitory protein factors (IPF_α, IPF_β, IPF_γ) has also been identified that potently block L-glutamate uptake into isolated synaptic vesicles (Tamura *et al.*, 2001).

Molecular Biology of Vesicular Glutamate Transporters

The circumstances surrounding the molecular characterization of the VGLUT system are particularly fascinating, as the transporter was actually cloned several years before it was recognized as a vesicular transporter of L-glutamate (Bellocchio *et al.*, 2000; Otis, 2001; Takamori *et al.*, 2000). Originally identified as a consequence of upregulated mRNA expression in cerebellar granule cells treated with NMDA, this protein exhibited considerable sequence homology with known sodium-dependent inorganic phosphate transporters. As Northern analysis revealed its presence to be restricted to the brain, and heterologous expression in *Xenopus* oocytes produced an increase in sodium-dependent inorganic phosphate (P_i) uptake, the protein was referred to as BNPI (brain, Na-dependent P_i transporter). Its potential role in vesicular uptake was suggested by later immunocytochemical studies demonstrating a localization to presynaptic vesicles and genetic studies in *Caenorhabditis elegans* demonstrating that mutations in a BNPI-like protein compromised glutamate-mediated signalling. Confirmation that BNPI was indeed capable of mediating the uptake of L-glutamate followed shortly. Consistent with L-glutamate transport into isolated synaptic vesicles, uptake by BNPI demonstrated a dependence on both ATP and chloride, yielded K_m values in the low-millimolar range, and exhibited the appropriate pharmacological profile (Bellocchio *et al.*, 2000). Intriguingly, it was also reported that when BNPI was transfected into GABAergic neurons maintained in culture, the neurons exhibited a new glutamate-mediated postsynaptic signal when stimulated (Takamori *et al.*, 2000). The combination of these pharmacological data and the localization to synaptic vesicles prompted the renaming of BNPI to VGLUT1. Following the identification of VGLUT1, a second sodium-dependent transporter, DNPI, was also shown to mediate vesicular glutamate transport and consequently was renamed VGLUT2 (Fremeau *et al.*, 2001). The two vesicular transporters exhibit complementary distributions: VGLUT1 is preferentially expressed in glutamate terminals in the cortex, hippocampus and cerebellum, while VGLUT2 is present in thalamus, hypothalamus and brainstem. The identification of distinct VGLUT isoforms raises the interesting possibility that transporter expression may be a factor in determining the release properties of a particular synapse.

Cellular Excitatory Amino Acid Transporters

Although a number of uptake systems have been identified that can mediate the translocation of L-glutamate across the plasma membrane, those systems that are thought to play the most significant role in excitatory transmission are grouped together on the basis of a high affinity for L-glutamate (K_m values in the 5–50-μM range) and a dependence upon sodium ions (Gegelashvili and Schousboe, 1997b; Robinson, 1998; Seal and Amara, 1999; Takahashi *et al.*, 1997). These transmembrane proteins use sodium and potassium ionic gradients to drive the uptake of L-glutamate into neurons and glia, where it can be concentrated several thousand-fold above extracellular levels (Zerangue and Kavanaugh, 1996). Current stoichiometric models couple the intracellular translocation of one molecule of glutamate with the uptake of three Na^+ ions and one H^+ ion and the outward movement of one K^+ ion. As a consequence of the ability to effectively clear L-glutamate from the extracellular synaptic environment, the transporters have been postulated to play a number of critical roles in excitatory transmission, including signal termination, transmitter recycling, and the maintenance of L-glutamate levels below those that would result in excitotoxic damage. Of equal interest are studies suggesting that under pathological conditions, these transporters also have the capacity to participate in excitotoxic mechanisms as a primary site of efflux for the large intracellular pools of L-glutamate normally present in neurons and glia (Takahashi *et al.*, 1997).

A major advance in the characterization of these cellular transporters was the almost simultaneous cloning of three distinct proteins that, when expressed, exhibited kinetic and pharmacological properties consistent with high-affinity, sodium-dependent uptake: glutamate/aspartate transporter (GLAST) and glutamate transporter 1 (GLT-1) from rat brain, and excitatory amino acid carrier 1 (EAAC-1) from rabbit intestine (Kanai and Hediger, 1992; Pines *et al.*, 1992; Storck *et al.*, 1992). Shortly thereafter, the homologous counterparts for these three transporters were isolated from human tissue: EAAT1, EAAT2 and EAAT3, respectively (Arriza *et al.*, 1994). The subsequent identification of EAAT4 and EAAT5 brings the total number of glutamate transporters to at least five (Arriza *et al.*, 1997; Fairman *et al.*, 1995). The existence of these distinct EAAT subtypes is also consistent with more traditional uptake studies with CNS preparations (e.g. synaptosomes,

Table V.4 Sodium-dependent excitatory amino acid transporters

Transporter	CNS distribution	Alternative substrates	Non-substrate inhibitor
EAAT1 (GLAST, rat)	Cerebellar glia	L-Glutamate L-Aspartate D-Aspartate (2*S*,4*R*)-4-methylglutamate L-Serine-O-sulfate L-*trans*-2,4-Pyrrolidine dicarboxylate	*β-threo*-Benzyloxy-aspartate
EAAT2 (GLT1, rat)	Forebrain glia	L-Glutamate L-Aspartate D-Aspartate L-*trans*-2,4-Pyrrolidine dicarboxylate	Dihydrokainate *β-threo*-Benzyloxy-aspartate
EAAT3 (EAAC1, rabbit)	Cortical neurons	L-Glutamate L-Aspartate D-Aspartate L-*trans*-2,4-Pyrrolidine dicarboxylate	
EAAT4	Cerebellar Purkinje neurons	L-Glutamate L-Aspartate D-Aspartate L-*trans*-2,4-Pyrrolidine dicarboxylate L-α-Aminoadipate	
EAAT5	Retina	L-Glutamate L-Aspartate D-Aspartate	*β-threo*-Hydroxy-aspartate L-*trans*-2,4-Pyrrolidine dicarboxylate

tissue slices, primary cultures) where pharmacological, kinetic and anatomical differences pointed to heterogeneity within the uptake process. The EAATs appear to be part of a novel gene family that also includes the neutral amino acid transporters alanine serine cysteine transporters 1 and 2 (ASCT1 and ASCT2) (Palacin *et al.*, 1998). Sequence analysis reveals about 50% sequence homology among the EAATs, as well as the presence of a conserved heptapeptide sequence [AA(I/Q)FIAQ] in the C-terminal region of the transporter that may be a defining structural motif for the family. Further structural studies reveal a lack of a cleavable signal sequence, greater level of conservancy in the C-terminal half, and at least two sites for N-glycosylation. While there is general agreement on the presence of six highly conserved putative transmembrane domains in the NH_2-terminal portion of the protein, predictions as to the exact number of such domains in the C-terminal have been somewhat controversial. Consequently, structural models have been put forward containing 10–12 membrane-spanning domains. The topological structure is, however, distinct from the 12 transmembrane domains that typify the superfamily of the sodium- and chloride-dependent neurotransmitter transporters.

Anatomical and Cellular Distributions of the Excitatory Amino Acid Transporters

Cloning of the EAATs was soon followed by the development of specific antibodies and molecular probes with which to investigate the distribution of the transporters. Distribution studies in a number of species reveal that in addition to a presence in brain, EAAT1–4 can be variously detected in peripheral tissues (e.g. heart, muscle, placenta, lung, liver, kidney, intestine) (Gegelashvili and Schousboe, 1997a; Palacin *et al.*, 1998). Within the CNS, each of the transporters exhibits a distinctive combination of cellular and anatomical expression. EAAT1 and EAAT2 are considered principally to be glial transporters, with enriched levels of expression localized to cerebellar and forebrain regions, respectively. An exception to this patterns is found on the Bergmann glia of the cerebellar molecular layer, where high levels of EAAT2 are present. In contrast to EAAT1 and EAAT2, the expression of EAAT3 and EAAT4 is limited to neurons. EAAT3 is distributed generally throughout the brain, although higher levels of expression are typically found in cortical areas. The distribution of EAAT4, on the other hand, appears to be restricted to the Purkinje cells of the cerebellum. Lastly, EAAT5 stands apart from the other EAATs in that its expression appears to be localized to the retina. Table V.4 gives an overview of the sodium-dependent EAATs.

Pharmacology of the Excitatory Amino Acid Transporters

The existence of EAAT subtypes raises obvious questions as to pharmacological differences among the subtypes and the potential to identify subtype-selective inhibitors. Like many transporters, however, the pharmacological specificity of glutamate transport was initially delineated by quantifying the ability of a wide range of EAA analogues to inhibit the uptake of radiolabelled substrates (e.g. ^{3}H-L-glutamate, ^{3}H-D-aspartate) into a variety of CNS preparations, such as synaptosomes, tissue slices, and primary cultures of neurons or glia. While in retrospect these uptake assays were (and continue to be) confounded somewhat by transporter heterogeneity, the studies were instrumental in establishing glutamate uptake as sodium-dependent, high-affinity (i.e. K_m values in the micromolar range), and stereoselective (i.e. D-glutamate is inactive as an inhibitor) (Balcar and Johnston, 1972; Hertz *et al.*, 1978; Logan and Snyder, 1972; Roberts and Watkins, 1975). Early structure–activity studies demonstrated that competitive inhibitors of L-glutamate uptake are typically α-amino acids that possess a second acidic group two to four carbon units away from the α-carboxyl group. With the cloning of the various EAATs, selective expression systems could be used to evaluate the potential subtype-selective action of the inhibitors, many of which were identified in these early specificity studies. The *Xenopus* oocyte preparation has proven particularly useful in this regard. The combination of its suitability for electrophysiological studies and the electrogenic nature of EAAT-mediated uptake permits transport to be quantified by recording substrate-induced currents (Zerangue and Kavanaugh, 1996). This not only eliminates a reliance on radiolabelled substrates but also overcomes a serious limitation of classic competition assays, allowing substrates and non-substrate inhibitors (i.e. analogues that bind

to the substrate site on the transporter but are not translocated intracellularly) to be readily differentiated (Koch *et al.*, 1999). Indeed, many studies now report substrate activity in terms of the currents generated relative to the maximum current produced by L-glutamate (I_{max}), rather than the more traditional values used to quantify uptake (e.g. pmol min^{-1} mg protein).

Specificity studies have demonstrated that in addition to L-glutamate, each of the EAAT subtypes can also utilize L- and D-aspartate as substrates. Pharmacological differences among the EAATs begin to emerge when the activities of structurally modified or conformationally constrained analogues of L-glutamate were compared (Bridges *et al.*, 1999). Compounds that have been particularly useful in this regard include the pyrrolidine dicarboxylates (PDCs, e.g. L-*trans*-2,4-PDC, L-*trans*-2,3-PDC, L-*anti-endo*-3,4-methano-3,4-PDC), *β-threo* substituted aspartates (e.g. *β-threo*-benzyloxy-aspartate), methyl-substituted glutamates (e.g. (2*S*,4*R*)-4-methylglutamate), and the 2-(carboxycyclopropyl)glycines (CCGs, e.g. (2*S*,3*S*,4*R*)-2-CCG, (2*S*,3*R*,4*S*)-2-CCG) (Chamberlin and Bridges, 1993; Nakamura *et al.*, 1993; Shimamoto *et al.*, 1998; Vandenberg *et al.*, 1997). While the point has not yet been reached where selective inhibitors or substrates are readily available for each of the individual EAATs, a number of interesting pharmacological differences have been observed among the transporter subtypes (Bridges *et al.*, 1999). For example, EAAT2 is easily distinguished from the other transporters based on its sensitivity to the non-substrate inhibitors dihydrokainate and L-*trans*-2,3-PDC. Although not quite as straightforward as EAAT2, EAAT1 stands apart from the other transporters because of its ability to effectively utilize (2*S*,4*R*)-4-methylglutamate and L-serine-O-sulphate as substrates. Studies on EAAT3 and EAAT4 suggest that these systems may be differentiated from the other transporters based on an increased sensitivity to inhibition by L-aspartate-*β*-hydroxymate and L-*α*-aminoadipate, respectively. Lastly, EAAT5 is distinguished by the action of *β-threo*-hydroxy-aspartate and L-*trans*-2,4-PDC, which act as non-substrate inhibitors of this system but as alternative substrates all the other EAATs.

Physiological Roles of the Excitatory Amino Acid Transporters

Investigations into the roles of transport in excitatory transmission have focused primarily on two central issues: its contribution to shaping the postsynaptic signal, and its significance in protecting neurons from glutamate-mediated excitotoxic injury. By influencing the amount and/or time course of L-glutamate in extracellular environment accessible to EAA receptors, it is easy to envision how transport might contribute to either process. Estimations of binding rates obtained from EAAT1 expressed in oocytes suggest the values are comparable to those reported for binding to postsynaptic receptors (Wadiche and Kavanaugh, 1998). Consequently, if transporters are present in sufficient densities near the site of glutamate release, then they may compete with the receptors for transmitter. Experimental evidence with transport inhibitors suggests, however, that the contribution of uptake in shaping postsynaptic signals appears to vary among glutamatergic synapses (Barbour *et al.*, 1994; Diamond and Jahr, 1997; Isaacson and Nicoll, 1993; Sarantis *et al.*, 1993; Tong and Jahr, 1994). Thus, while studies with hippocampal neurons in cultures and Purkinje neurons in cerebellar slices both indicate that inhibition of transport does influence the excitatory postsynaptic signal, studies carried out with other model systems suggest that this is not always the case. In a related capacity, transporter density and activity may also be factors in determining the extent to which synaptically released glutamate can 'spill over' and activate receptors at sites distant to the location of release (Bergles *et al.*, 1999; Diamond and Jahr, 2000; Scanziani *et al.*, 1997).

The importance of regulating extracellular levels of L-glutamate takes on even greater significance when the potential excitotoxic properties of this neurotransmitter are considered. Accumulating evidence suggests that excessive activation of EAA receptors is a fundamental mechanism of neuropathology in acute CNS injury (e.g. stroke, spinal cord injury, head trauma) as well as chronic neurodegenerative disorders (e.g. amyotrophic lateral sclerosis, epilepsy, Huntington's disease, Alzheimer's disease) (Choi, 1994; Meldrum, 2000). In this respect, the transporters appear ideally suited to play a vital role in excitotoxic protection. That this is indeed the case is supported by *in vitro* and *in vivo* experiments in which the excitotoxic properties of L-glutamate are exacerbated when EAAs are administered to the CNS in combination with uptake blockers (McBean and Roberts, 1985; Robinson *et al.*, 1993). In a number of studies, transport inhibitors by themselves have also been observed to produce neuronal injury (Lievens *et al.*, 1997). For example, the direct administration of either *β-threo*-hydroxy-aspartate or L-*trans*-2,4-pyrrolidine to rat striatum produced significant neuropathology. In other studies, these same inhibitors produced a slow degeneration of motor neurons when added chronically to organotypic spinal cord cultures (Rothstein *et al.*, 1993). The loss of motor neurons in this model system is particularly intriguing in view of the reduction in transporter capacity observed in amyotrophic lateral sclerosis (see below). Also consistent with an inverse relationship between transporter function and vulnerability to glutamate-mediated damage are molecular studies demonstrating that chronic administration of antisense oligonucleotides for GLAST, GLT-1 or EAAC1 (homologues of EAAT1-3, respectively) in both *in vitro* and *in vivo* models induce neuronal injury consistent with excitotoxicity (Rothstein *et al.*, 1996). Equally compelling, mice carrying a homozygous deficiency for GLT-1 (EAAT2 homologue) exhibit lethal spontaneous seizures and increased susceptibility to cortical damage (Tanaka *et al.*, 1997).

Glutamate Transport in Neurological Disorders

In view of the evidence indicating that these transporters serve in a neuroprotective capacity, it is ironic that data are also coming forth that suggest these uptake systems may, under certain pathological conditions, actually participate in the processes of excitotoxicity as sites of cellular L-glutamate efflux (Takahashi *et al.*, 1997). Thus, CNS insults that severely compromise energy levels may lead to the collapse of the ion gradients that enable the cells to accumulate and maintain high intracellular concentrations of L-glutamate. This may, in turn, lead to a concentration-dependent efflux of L-glutamate into the extracellular space through the reverse action of the transporters. The end result would be increased levels of extracellular L-glutamate, decreased transport capacity, and a corresponding increase in the likelihood of excitotoxic pathology. Such a possibility is supported by experiments demonstrating that the efflux of EAAs observed following metabolic insults can be influenced by alternative substrates and non-substrate inhibitors of the EAATs (Koch *et al.*, 1999; Longuemare and Swanson, 1995). It is much more difficult, however, to determine whether the process of transporter reversal occurs *in vivo* and to what extent it contributes to neuronal injury.

To a large degree, a similar problem arises in trying to assess the significance of changes observed to occur in glutamate transport systems in a variety of neurological disorders. For example, both increases and decreases in transport capacity have been reported to occur in schizophrenia (Aparicio-Legarza *et al.*, 1997; Simpson *et al.*, 1998; Smith *et al.*, 2001). In the case of neurodegenerative diseases, glutamate uptake appears to be compromised in both Alzheimer's disease and amyotrophic lateral sclerosis (ALS). It is probably within ALS that the strongest connection has been made between transport and a disease process (Rothstein, 1996). Studies at the functional level have demonstrated that activity is

attenuated, while those at the molecular level indicate that the loss of activity may be linked to aberrant mRNA processing (Lin *et al.*, 1998). A complexity, however, that remains with all such studies is the difficulty in assessing not only the specific pathological contribution of compromised transport but also whether observed losses in transport are a primary or secondary result of the disease. The latter is particularly likely, as several studies have demonstrated that the EAATs are especially sensitive to inactivation by the reactive oxygen species (Trotti *et al.*, 1998). Given the wide range of CNS disorders to which increased oxidative stress is believed to contribute (e.g. stroke, spinal cord injury, chronic neurodegenerative diseases, and even ageing), it should not be surprising to find excitotoxicity linked to losses in glutamate transport as a common feature of CNS pathology.

VI

Peptidergic Transmitter Systems

Miklós Palkovits

INTRODUCTION

The past decades of research on peptides have provided convincing evidences that neuronal peptides play an important role in the nervous system as neurotransmitters, neuromodulators and neurohormones. The identification and localization of neuropeptides in the brain have been greatly facilitated by the development of biochemical, immunohistochemical and *in situ* hybridization histochemical techniques. A variety of neuropeptides and peptide receptors has been isolated, characterized and localized in the central nervous system (CNS). This chapter gives a brief summary of the topography of peptidergic neurons in major brain areas, as well as their participation in central regulatory mechanisms. Instead of the overwhelming list of the original references for each neuropeptides listed below, we refer to review articles for information and references (Hökfelt *et al.*, 1986; Hökfelt *et al.*, 1987; Palkovits, 1987a; Palkovits, 1987b; Palkovits, 1996; Palkovits, 1999).

BRAIN-BORN NEUROPEPTIDES

The classification of neuropeptides in different groups is rather arbitrary. The *hypothalamic neuropeptides* are synthesized mainly in the hypothalamus and act partly as neurohormones at the pituitary level (releasing and release-inhibiting hormones) or in the periphery (posterior pituitary hormones: vasopressin and oxytocin). Since many of them have been identified in neurons of other brain areas, the terminology does not relate exclusively to their hypothalamic topography. The *pituitary peptides* are characteristically of pituitary origin, but they are also synthesized in neuronal cells, especially in the hypothalamus. Their concentrations in the brain, however, are in orders of magnitude less than in the pituitary. The third group includes the *opioid peptides*, which are distributed widely in the CNS, some of them in high concentrations in the hypothalamus. The fourth group is the *brain-born gastrointestinal or brain–gut peptides*. These were discovered in the gastrointestinal tract, but they are also expressed by neurons in the central and peripheral nervous systems. The *other neuropeptides* are classified in the artificially constructed fifth group; many of the neuropeptides in this group participate in the central control of blood pressure and food intake.

Hypothalamic Neuropeptides

These neuropeptides are involved intimately in regulating anterior pituitary functions or acting as neurohormones on the periphery. All of them are highly concentrated in the median eminence (Table VI.1).

Luteinizing Hormone-Releasing Hormone or Gonadotropin-Releasing Hormone

The decapeptide luteinizing hormone-releasing hormone (LH-RH) has been identified in hypothalamic extracts. This is a signalling molecule that regulates reproduction in all vertebrates. Recently, genes encoding two other LH-RH forms have been discovered that are identical in all species (Fernand and White, 1999).

LH-RH is synthesized mainly in preoptic and anterior hypothalamic neurons in the rat and cat, and in the arcuate nucleus of birds, dogs, monkey and human brains. In the rat, the majority of LH-RH fibres travel along the fibres of the medial forebrain bundle in the lateral hypothalamic area and enter the medial basal hypothalamus through the lateral retrochiasmatic area. This small area, at the caudal edge of the optic chiasm, serves as a gate for a number of peptidergic and aminergic fibres to reach the median eminence (Palkovits, 1984). In the external layer of the median eminence, LH-RH is secreted into portal vessels transported to the anterior pituitary, where it stimulates secretion of luteinizing hormone and follicle-stimulating hormone from pituitary gonadotrophs.

LH-RH fibres from the medial preoptic neurons innervate the organum vasculosum laminae terminalis (OVLT), one of the circumventricular organs where no blood–brain barrier exists. LH-RH neurons and fibres in the accessory olfactory bulb, medial olfactory tract and the septum represent the migration path of LH-RH neurons during the prenatal life.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) stimulates anterior pituitary cells to produce and release thyrotrophin hormone and acts as a neurotransmitter/neuromodulator in the brain. TRH secretion is also regulated by neurotransmitters, such as noradrenaline, somatostatin and opioids, as well as by stressful stimuli, including acute cold exposure. This tripeptide is distributed widely in the CNS. Neuronal perikarya were demonstrated mainly in the hypothalamus and the medulla oblongata. In the hypothalamus, TRH is synthesized in the parvicellular portion of the paraventricular nucleus (PVN), the preoptic suprachiasmatic nucleus, the dorsomedial nucleus and the perifornical nucleus, the lateral hypothalamus, and the premamillary region. In the medulla oblongata, TRH immunoreactivity occurs in neurons of the raphe nuclei in coexistence with substance P and serotonin. These neurons project to the spinal cord and participate in pain inhibition. The densest concentration of TRH fibres and terminals is in the median eminence (mainly of PVN origin) and in the OVLT. TRH-immunoreactive axons and terminals form relatively dense networks in the amygdala, the lateral septal nucleus, and the dorsomedial medulla oblongata, mainly in the nucleus of the solitary tract (NTS).

CGRP		Average	NA	
CART		Average	NA	

MPO, medical preoptic nucleus; NA, arcuate nucleus; NPE, hypothalamic periventricular nucleus; PVN, paraventricular nucleus; SON, supraoptic nucleus.

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) represents the major stress hormone in the brain. It stimulates the release of adrenocorticotropic hormone (ACTH) from the corticotroph cells of the anterior pituitary and acts as a neurotransmitter in the CNS. This neuropeptide shows a wide distribution in the hypothalamus and extrahypothalamic brain. The PVN contains a high number of CRH-immunopositive cells, mainly in the medial and anterior parvicellular subdivisions of the nucleus (exclusive sources of the CRH fibbers in the median eminence). CRH cells merge into the posterolateral parvicellular subdivision as far caudal as the posterior edge of the nucleus (neurons from here project to spinal and medullary autonomic centres). CRH fibres leave the PVN in a lateral direction. One set of fibres turns around the fornix and approaches the median eminence, while others travel through the lateral hypothalamus and the ventrolateral corner of the lower brain stem to parasympathetic (vagal nuclei) and sympathetic (thoracic spinal cord) preganglionic neurons.

The presence of various numbers of CRH cells has been reported in other hypothalamic regions, mainly in the medial preoptic, anterior hypothalamic, dorsomedial, and perifornical nuclei (Table VI.2). A number of CRH-immunoreactive cells were demonstrated in the central nucleus of the amygdala, the bed nucleus of the stria terminalis (NIST; only its lateral subdivision), the lateral parabrachial nucleus, and the NTS. Considerable amounts of CRH are synthesized in inferior olivary neurons and transported through the olivocerebellar tract to the cerebellum (CRH coexists with aspartate in the climbing fibres).

The densest accumulation of CRH-immunoreactive terminals is seen in the external layer of the median eminence. The concentration of CRH in the median eminence measured by radioimmunoassay is almost two orders of magnitude higher than that of other brain nuclei (Table VI.1). Moderate to dense networks of CRH fibres and terminals are present in several brain areas and nuclei.

Recently, a potent mammalian CRH-related neuropeptide, urocortin II, was discovered and shown to be bound with high affinity to type 2 CRH receptors. This 38-amino acid peptide is expressed in the paraventricular and arcuate nuclei of the hypothalamus and in the locus coeruleus. Initial functional studies are consistent with urocortin II involvement in central autonomic and appetitive controls (Reyes *et al.*, 2001).

Growth Hormone-Releasing Hormone

Two forms of growth hormone-releasing hormone (GRH), GRH-40 and GRH-44, have been isolated from a tumour of human pancreatic islet cells causing acromegaly. Both forms stimulate growth hormone release from the anterior pituitary. It is known that full biological activity of these peptides resides in the first 29 amino acids.

GRH-synthesizing cells are found almost exclusively in the medial basal hypothalamus (in the arcuate and ventromedial nuclei) with a major projection to the median eminence–pituitary stalk. Scattered GRH-immunopositive fibres can be traced to several hypothalamic regions, mainly to the periventricular nucleus (they form synaptic contact with somatostatin neurons here) and the lateral hypothalamic area.

Somatostatin

Somatostatin was first identified in the hypothalamus, where it is highly concentrated in neuronal cells. This peptide is also produced in a wide variety of neurons throughout the CNS and in various cell types in peripheral organs. Besides its inhibitory effect on growth hormone release and thyroid-stimulating hormone secretion in the anterior pituitary, somatostatin acts as a neurotransmitter in the brain and appears to regulate the activity of pancreatic islet, gastrointestinal and immune cell functions in the periphery. These

Higher number of peptide-expressing neurons is indicated by encircled crosses.

actions are mediated by five different subtypes of G-protein-coupled somatostatin receptors (Patel, 1999).

The majority of somatostin-synthesizing neurons are present in the preoptic and hypothalamic periventricular nuclei along the third ventricle. These cells project to the external layer of the median eminence. Axon collaterals of these cells reach GRH-containing neurons in the medial basal hypothalamus and establish synaptic contacts with these cells (Horváth *et al.*, 1989).

Somatostatin-immunostained perikarya are found scattered in the cerebral cortex, hippocampus, olfactory bulb and tubercle, striatum, nucleus accumbens, lateral septal nucleus and amygdaloid nuclei. In the lower brainstem, somatostatin cells were demonstrated in the periaqueductal central grey and the reticular formation. A number of cells in the dorsal horn (lamina II) and the intermediolateral cell column of the thoracic spinal cord also synthesize somatostatin.

Somatostatin fibres and terminals are present throughout the entire CNS in varying density, but by far the highest concentration is in the median eminence (Table VI.1). The major somatostatin-containing neuronal systems include the hypothalamic pathway connecting the preoptic and hypothalamic periventricular neurons with the limbic system, cortical interneurons, and amygdala-limbic connections through the stria terminalis.

Somatostatin is regarded as a phylogenetically ancient multigene family of peptides with two bioactive products: somatostatin-1–14 and somatostatin-1–28. These forms are synthesized from a large pre-prosomatostatin precursor molecule. Recently, a novel somatostatin-like gene, *cortistatin*, has been discovered that gives rise to two cleavage products, cortistatin-14 and cortistatin-29 (Patel, 1999; Spier and de Lecea, 2000). In contrast to the wide distribution of somatostatin in the brain, cortistatin is restricted to the cerebral cortex and the hippocampus (Spier and de Lecea, 2000).

Prolactin-Releasing and -Inhibiting Factors

Much physiological evidence supports the existence of the peptides Prolactin-releasing factor (PRF) and Prolactin-inhibiting factor (PIF) in the hypothalamus, but neither PRF nor PIF has been identified yet. Many neuropeptides (TRH, oxytocin, β-endorphin, vasoactive intestinal peptide (VIP)) have been shown to elevate prolactin release. In contrast, hypothalamic dopamine and γ-aminobutyric acid (GABA) may act as PIFs.

Vasopressin

Vasopressin was one of the first neuropeptides (along with oxytocin) to be isolated in the hypothalamus. Cells are located mainly in magnocellular neurosecretory nuclei: two-thirds of the supraoptic neurons and about half of the paraventricular magnocellular neurons synthesize vasopressin. Evidence has been furnished on the synthesis of vasopressin in parvicellular PVN cells coexpressing with CRH, especially in response to stressful stimuli. A distinct group of vasopressin-synthesizing cells is present in the suprachiasmatic nucleus.

Vasopressin fibres from the supraoptic and paraventricular nuclei, in addition to oxytocin fibres, constitute the hypothalamo-hypophyseal neurosecretory tract. This passes through the lateral retrochiasmatic area and the internal layer of the median eminence–pituitary stalk on the way into the posterior pituitary, where vasopressin is stored until its release into the general circulation.

Solitary vasopressin-immunoreactive fibres from the hypothalamic nuclei can be traced in different forebrain and limbic areas. Long, descending vasopressin fibres to the lower brainstem and spinal cord have been demonstrated by immunohistochemical techniques. These axons appear to arise in the PVN.

Oxytocin

This peptide is synthesized only by neurons in the magnocellular hypothalamic nuclei, in almost equal numbers in the supraoptic, paraventricular and accessory magnocellular nuclei. In neurons of these nuclei, oxytocin is coexpressed with cholecystokinin (CCK) and enkephalins. Oxytocin fibres constitute a substantial component of the hypothalamo-hypophyseal neurosecretory tract, which terminates in the posterior pituitary. Descending oxytocin fibres to the medullary and spinal autonomic centres are exclusively of paraventricular origin. They form a relatively strong terminal network in the NTS, the caudal ventrolateral medulla and the

spinal cord (substantia gelatinosa in the dorsal horn and the intermediolateral cell column).

Brain-Born Pituitary Neuropeptides

The presence of anterior pituitary hormones, such as luteinizing hormone (LH), thyrotropin, growth hormone (GH) and prolactin, has been reported in rat forebrain structures as revealed by radioimmunoassay and immunohistochemistry. Their origin in the brain is supported by their invariable presence after hypophysectomy.

Three brain-born pituitary peptides arise from a common 31-kDa precursor molecule, ***pro-opiomelanocortin (POMC)***: ACTH, β-endorphin and α-melanocyte-stimulating hormone (α-MSH). (Although, β-endorphin is one of the opioid peptides, because of its origin from the POMC molecule and colocalization with ACTH and α-MSH, it is classified into this group of neuropeptides.) The ACTH molecule is cleaved to α-MSH and Corticotropin-like intermediate lobe peptide (CLIP) (ACTH-18–39). The vast majority of ACTH immunoreactivity in arcuate neurons is actually CLIP.

The POMC peptides colocalize in the same neurons of the medial basal hypothalamus, almost exclusively in the arcuate and ventral premamillary nuclei. Some additional ACTH and β-endorphin neurons have also been found in the NTS.

ACTH- and β-endorphin-containing fibres and terminals are found in several hypothalamic (mainly in the PVN) and extrahypothalamic nuclei. Pronounced β-endorphin fibre labelling is present in the amygdala, thalamic PVN, midbrain central grey, raphe nuclei, lateral parabrachial nucleus, and in high concentration in the NTS.

Melanocyte-Stimulating Hormones

The presence of α-, β- and γ-MSH has been shown in the CNS of rats by biochemical and immunohistochemical techniques. Two sets of *α-MSH*-containing cell groups are present in the hypothalamus: the first in the arcuate nucleus (in POMC neurons with ACTH and β-endorphin), and the second (immunostained only for α-MSH) in the dorsal part of the lateral hypothalamic area, the perifornical nucleus and the ventral portion of the zona incerta. (The distribution area of these neurons overlaps the area where orexin and melanin-concentrating hormone neurons are localized; see p. 90) This group of cells appears to project exclusively to the cerebral cortex, hippocampus, olfactory bulb and striatum.

α-MSH exerts an anorexigenic action in the brain. It has been demonstrated recently that leptin has a stimulatory effect on the production of α-MSH.

γ-MSH-containing cells were identified in the arcuate nucleus, the dorsolateral tegmentum of the pons, and the NTS.

Brain-Born Opioid Peptides

Five groups of opioid peptides have been identified in the CNS: (1) enkephalins (Met- and Leu-enkephalin, Met-enkephalin-Arg-Phe, Met-enkephalin-Arg-Gly-Leu), (2) β-endorphin, (3) the dynorphins (dynorphin A, dynorphin 1–8, dynorphin B, α-neo-endorphin, β-neo-endorphin), (4) endomorphins and (5) nociceptin (orphanin FQ). They distribute in the brain in individual topographical patterns. The opioid neuropeptides frequently coexist with other neuropeptides or neurotransmitters. Besides their potent antinociceptive actions, they appear to participate in regulation of secretion of pituitary hormones, and are involved in autonomic regulations.

Enkephalins

Met- and Leu-enkephalins are distributed widely in the CNS. Enkephalin-containing perikarya were demonstrated in all major brain regions, including the cerebral cortex (high density in the cingulate and piriform cortex), hippocampus, striatum, hypothalamus (ventromedial, arcuate and paraventricular nuclei), amygdala, and NIST. In the lower brainstem, enkephalin-containing cells occur in the periaqueductal central grey, raphe nuclei, parabrachial nucleus, spinal trigeminal nucleus and NTS. In the dorsal horn of the spinal cord (lamina III), enkephalin is synthesized in inhibitory interneurons.

The most abundant enkephalinergic networks are seen in the hypothalamic ventromedial nucleus and several extrahypothalamic regions (globus pallidus, nucleus accumbens, central grey, NTS, spinal trigeminal nucleus, dorsal horn). In the hypothalamus, enkephalin-expressing neurons are coexpressed with CRH (in the PVN) and oxytocin (in the supraoptic nucleus). Enkephalins are coexpressed with almost all of the classical neurotransmitters in particular brain areas: with acetylcholine in the spinal cord, with dopamine in the arcuate nucleus, with noradrenaline in the locus coeruleus, with serotonin in medullary raphe nuclei, and with GABA in the caudate nucleus.

Met-enkephalin-Arg-Phe was originally isolated from the adrenal gland, but it is also distributed widely in the brain. Its topographical distribution pattern in the brain is similar but not identical with that of met- and leu-enkephalins.

β-Endorphin

As a member of the POMC-derived peptides, endorphin was discussed earlier.

Dynorphins

The five dynorphin-related peptides are derived from a common precursor molecule, pro-neo-endorphin/dynorphin. The distribution patterns of dynorphin A and α-neo-endorphin are identical, while those of the other three dynorphins are individual. They establish high analgesic activities at both hypothalamic (action on β-endorphin neurons) and spinal cord levels.

The hypothalamus contains one of the highest concentrations of dynorphins in the CNS. The most prominent cell types containing dynorphins are the magnocellular hypothalamic neurons (coexisting with vasopressin) and neurons in the arcuate nucleus, where they are likely to coexist with dopamine. In addition, dynorphin-containing perikarya are expressed in the striatum, dentate gyrus, central amygdaloid nucleus and lower brainstem (substantia nigra, central grey matter, parabrachial, spinal trigeminal and solitary tract nuclei). Dynorphins are expressed in lamina I and II neurons of the dorsal horn.

Among the several brain regions where dynorphins are present in nerve terminals, five regions are prominently rich in these opioid peptides: nucleus accumbens, globus pallidus, hippocampus CA3 area, hypothalamic paraventricular nucleus, and pars reticulata of the substantia nigra.

Endomorphins

Endomorphins (endomorphin 1 (EM1) and endomorphin 2 (EM2)) are endogenous tetrapeptides with high affinity and selectivity for the μ-opiate receptor and potent analgesic activities. Both are synthesized by neurons in the hypothalamus (dorsomedial and posterior nuclei), but only EM1 perikarya are present in the nucleus of the solitary tract (Martin-Schild *et al.*, 1999). EM1-like immunoreactivity is distributed widely and densely in the brain, while EM2 is more restricted to the superficial laminae of the dorsal horn and the spinal trigeminal nucleus. Dense networks of EM1-like immunoreactive fibres and terminals were detected in the lateral parabrachial and solitary tract nuclei.

Moderate EM1 immunostaining was present in the frontal cortex, nucleus accumbens, NIST, several hypothalamic and amygdaloid nuclei, medial septal-diagonal band complex, periaqueductal central grey, locus coeruleus, and lamina I of the dorsal horn. The neuroanatomical distributions of these two peptides suggest that endomorphins participate in modulating nociceptive and autonomic nervous system processes (Martin-Schild *et al.*, 1999).

Nociceptin

Nociceptin/orphanin FQ (N/OFQ) is a heptadecapeptide opioid-like endogenous agonist of the opioid receptor homologue, N/OFQ receptor. This peptide and its precursor, pre-proN/OFQ, exhibit structural features suggestive of the opioid peptides. N/OFQ, its precursor protein and its receptor are distributed widely throughout the CNS. There are several regions where N/OFQ cells colocalize with other opioid peptides. N/OFQ cells are present in numerous neuronal circuits and systems, supporting its possible involvement in many behavioural, autonomic and physiological functions, including nociception (Neal *et al.*, 1999; Houtani *et al.*, 2000).

Brain-Born Gastrointestinal or Brain–Gut Neuropeptides

Substance P

The undecapeptide substance P is the main member of the tachykinin peptide family. The pre-protachykinin A precursor molecule contains sequences encoding substance P and neurokinin A, while pre-protachykinin B encodes neurokinin B. All of these are present in the central and peripheral nervous systems and in gut endocrine cells.

The major substance P pathways and systems in the brain are extrahypothalamic. This neuropeptide is strongly involved in pain conduction. Neurons are present in dorsal root ganglion cells (coexpressed with glutamate and calcitonin gene-related peptide (CGRP)) and also in the secondary nociceptive neurons in the dorsal horn and the spinal trigeminal nucleus.

Several other brain areas contain substance P-synthesizing neurons. Substance P represents one of the major transmitters in the striato-nigral connections. Small- to medium-sized cells in the caudate-putamen project to the globus pallidus and the substantia nigra, where substance P facilitates dopaminergic neurons. Substance P neurons are present in other telencephalic regions (amygdala, nucleus of the diagonal band, lateral septal nucleus, NIST), but cerebral cortical areas are devoid of substance P cells. One of the limbic pathways, the habenulo-interpeduncular tract, contains substance P fibres in colocalization with acetylcholine.

Almost all of the hypothalamic nuclei contain substance P neurons. The moderate amount of substance P in the median eminence is of arcuate nucleus origin.

Substance P is frequently coexpressed with other neuropeptides and serotonin (substance P–CCK in central grey neurons, substance P–TRH–serotonin in the ventromedial medulla oblongata). Axons of the medullary substance P–TRH–serotonin neurons constitute the major antinociceptive pathway in the CNS, from the brainstem to the spinal dorsal horn.

Neuropeptide Y

Neuropeptide Y (NPY) is a 36-amino acid peptide. It shares important sequence homology with another peptide isolated from porcine intestine, peptide YY. These two peptides share important similarities with the pancreatic polypeptides. NPY is a potent stimulator of feeding behaviour, influences the activity of the gastrointestinal and cardiovascular systems, and participates in body temperature regulation.

NPY is one of the most abundant neuropeptides in the rat brain. Several NPY-containing perikarya have been demonstrated in the cerebral cortex (especially in the entorhinal cortex), hippocampus, striatum and amygdala. In the hypothalamus, the arcuate nucleus contains a fairly large set of NPY neurons. These neurons appear to play a key role in the central regulation of food intake. A group of arcuate NPY cells project to the PVN and lateral hypothalamic neurons, while other NPY cells innervate sympathetic preganglionic neurons in the thoracic spinal cord. These spinal cord-projecting NPY cells coexpress cocaine- and amphetamine-regulated transcript (CART) peptide (Elias *et al.*, 1998).

NPY is coexpressed in lower-brainstem noradrenergic neurons, mainly in the A1 and A2 noradrenergic cell groups of the medulla oblongata (Everitt *et al.*, 1984). Some of the fibres in the ascending ventral noradrenergic bundle also contain NPY. These fibres may innervate hypothalamic and limbic (septal and amygdaloid) nuclei. A high degree of coexpression has also been demonstrated between NPY and somatostatin, particularly in neurons of the cerebral cortex, hippocampus and striatum.

Vasoactive Intestinal Polypeptide

VIP has been designated as a member of the glucagon–secretin peptide family. It is related structurally to PHI-27 (peptide histidine isoleucine of 27 amino acids). VIP has a wide range of effects on the cardiovascular, respiratory and gastrointestinal systems.

Numerous VIP-immunoreactive neurons have been demonstrated in the brain, especially in the cerebral cortex (bipolar neurons in layers II–IV). They are frequently coexpressed with acetylcholine. Evidence from surgical isolation of cortical areas suggests that VIP cells in the cortex are local interneurons. VIP perikarya have also been found in the hippocampus, olfactory bulb, claustrum and amygdala. In the hypothalamus, the suprachiasmatic nucleus is the major source of VIP neurons. Axons leave the nucleus in a dorsal direction and terminate in the periventricular and anterior hypothalamic nuclei. A number of VIP cells have been found in the periaqueductal central grey, dorsal raphe nucleus and NTS.

Numerous VIP axons and terminals have been demonstrated throughout the entire CNS, mainly in forebrain areas.

PHI-27

This peptide has an NH_2-terminal histidine and a COOH-terminal isoleucine amine and 27 amino acid residues. It has considerable structural similarities to VIP, and they have a common precursor molecule. PHI-27 is highly concentrated in the suprachiasmatic nucleus, and is coexpressed with CRH and enkephalin in same parvicellular PVN neurons. Axons from these neurons run into the median eminence and form a dense network around the capillaries in the external layer. It has been suggested that these neurons are involved in the control of prolactin, ACTH and growth hormone secretion in the anterior pituitary (Hökfelt *et al.*, 1983).

Pituitary Adenylate Cyclase Activating Peptide

The neuropeptide Pituitary adenylate cyclase activating peptide (PACAP) belongs to the VIP–secretin–glucagon family. It is a 38-amino acid residue peptide with 68% homology with VIP. As indicated by its name, PACAP is a potent stimulator of pituitary adenylate cyclase. PACAP-containing neurons occur in all major brain regions (cerebral cortex, thalamus, amygdala, nucleus accumbens), but the highest density of PACAP-immunoreactive cells and fibres is found in hypothalamic nuclei (Arimura and Shioda, 1995). The supraoptic and paraventricular nuclei are the major sources of PACAP-immunostained fibres in

the median eminence. PACAP-synthesizing cells have been demonstrated in the medulla oblongata, vagal nuclei and lateral reticular nucleus.

Cholecystokinin

CCK is a 33-amino acid residue peptide. Among different forms of CCK, CCK-8 appears to be the main representative in the brain. It has a strong analgesic effect, acting in the brainstem, thalamus and cerebral cortex by stimulating opioid receptors in these regions. CCK also facilitates sleep and reduces food intake.

CCK is distributed widely in the brain. Several bi- and multipolar but not pyramidal CCK-immunopositive cells are seen in the cerebral cortex, mainly in laminae II and III, having a similar but not identical pattern to VIP. CCK cells are distributed widely in the hippocampus; mainly interneurons (basket cells) but few pyramidal cells express CCK. CCK is coexpressed with GABA in cortical and hippocampal neurons.

CCK perikarya were recognized in the NIST and the medial and cortical amygdaloid nuclei. In the hypothalamus, CCK neurons occur in the magnocellular neurons (coexpressed with oxytocin) and in the periventricular and dorsomedial nuclei. Two groups of CCK-containing cells are seen in the midbrain: one in the substantia nigra-ventral tegmental area (coexpressing with dopamine) and another in the central grey matter. CCK-immunopositive cells are also located in the central grey (lamina X) of the spinal cord.

Several CCK-containing neuronal pathways have been demonstrated in the brain: (1) descending corticostriatal projections in the external capsule from the piriform and prefrontal cortex to the caudate-putamen; (2) hippocampal-septal projections through the fornix and the fimbria; (3) parabrachial CCK neurons project to the hypothalamic ventromedial nucleus (Záborszky *et al.*, 1984); (4) CCK–dopamine fibres from the substantia nigra and the ventral tegmental area ascend in the medial forebrain bundle to the nucleus accumbens, olfactory tubercle, NIST and central amygdaloid nucleus; and (5) evidence for periaqueductal central grey-spinal cord CCK projections has also been reported.

Gastrin-Releasing Peptide/Bombesin

Gastrin-releasing peptide (GRP) is homologous at its carboxy terminus to the tetradecapeptide bombesin, which can be isolated from amphibian skin. They share many physiological activities, therefore GRP has been proposed as a mammalian counterpart of amphibian bombesin. This neuropeptide is the most potent modulator of thermoregulation, acting on the preoptic thermoregulator centre. It also increases blood pressure, inhibits feeding and acts as an antidiuretic.

GRP/bombesin is highly concentrated in the hypothalamus, especially in the arcuate nucleus. These cells project to the parvicellular PVN and may participate in the central control of food intake. High densities of GRP/bombesin-immunoreactive terminals are found in nociceptive brain areas: this peptide and substance P codistribute in the marginal layers of the dorsal horn and the spinal trigeminal nucleus.

Galanin

This peptide was originally isolated from the upper small intestine. It is a 29-amino acid residue peptide that derives from the precursor molecule, pre-progalanin. Galanin stimulates plasma growth hormone and prolactin levels, inhibits insulin secretion, and is involved in the central regulation of food intake.

Galanin shows a wide distribution in the brain, with a high density in the hypothalamus, including the median eminence (Table VI.1). The expression of galanin in primary sensory neurons in dorsal root and Gasserian ganglia has been demonstrated by immunostaining and *in situ* hybridization. Galanin coexists with oxytocin in the PVN and with acetylcholine in the septo-hippocampal system.

The presence of other gastrointestinal peptides, such as secretin, motilin and glucagon, in brain nuclei has been shown by immunostainings (see the reviews listed in the introduction to this chapter).

Other Neuropeptides

A number of neuropeptides in this group (neurotensin, bradykinin, atrial natriuretic polypeptide, angiotensin II) have a common feature: they all participate in central baroreceptor mechanisms.

Neurotensin

Neurotensin was first isolated and sequenced from the hypothalamus on the basis of its strong cardiovascular effect. This 13-amino acid residue peptide is synthesized from the large neurotensin/neuromedin precursor molecule. A large amount of neurotensin is present in endocrine cells of the gastrointestinal mucosa, and its activity there is ten times higher than in the brain. (This is one of the reasons why neurotensin is frequently classified into the brain–gut neuropeptides family.) Neurotensin reduces body temperature, locomotor activity and food intake.

The presence of neurotensin-immunostained perikarya can be demonstrated in several brain areas. Neurotensin is highly concentrated in the caudate nucleus, nucleus accumbens, globus pallidus and mamillary body. In the hypothalamus, neurotensin-synthesizing perikarya have been shown in the arcuate, periventricular and medial preoptic nuclei, in the periventricular subdivision of the PVN, and in the lateral hypothalamic area. Neurotensin fibres are concentrated densely in the external layer of the median eminence, where neurotensin is released into the hypophysial portal circulation and stimulates secretion of prolactin at the level of the anterior pituitary (Rostene and Alexander, 1997). In the pituitary, neurotensin occurs in subsets of gonadotrophs and thyrotrophs.

Many lower-brainstem regions contain dense neurotensin networks of fibres and terminals, such as the ventral tegmental area, parabrachial nucleus, marginal layer of the spinal trigeminal nucleus, and NTS. In the spinal cord, neurotensin fibres are concentrated in the lamina II of the dorsal horn. Neurotensin is coexpressed with dopamine in the substantia nigra and the arcuate nucleus, and with noradrenaline in the NTS.

Angiotensins

All components of the renin–angiotensin system (renin, angiotensinogen, angiotensin-converting enzyme (ACE), angiotensin I, II, III, IV, angiotensin 1–7, and angiotensin receptors) have been demonstrated in the brain. The two major effective peptides (angiotensin II and III) increase blood pressure, drinking behaviour, salt appetite, and the release of anterior and posterior pituitary hormones.

Angiotensin II-immunoreactive perikarya are visualized in the hypothalamus (mainly in the preoptic, paraventricular, supraoptic, suprachiasmatic, perifornical and premamillary nuclei). Substantial numbers of angiotensin II-expressing cells are also present in the subfornical organ, lateral septal, thalamic paraventricular and central amygdaloid nuclei. Two major angiotensin II pathways have been described: (1) interconnections between the subfornical organ and the median preoptic, paraventricular and supraoptic nuclei, and (2) a pathway connecting the hypothalamus to the medulla oblongata (Lenkei *et al.*, 1997).

The effects of angiotensin II and III are mediated through interactions with specific angiotensin receptors (AT1A, AT1B, AT2). The

highest densities of AT1A and AT2 receptors have been demonstrated in the hypothalamus (median preoptic and paraventricular nuclei, retrochiasmatic area), the medulla oblongata, and the circumventricular organs, including the organum vasculosum laminae terminalis, subfornical organ and area postrema (Lenkei *et al.*, 1997). These circumventricular organs may serve as open gates for the circulating angiotensin to enter the brain and influence the activity of hypothalamic vasopressin and atrial natriuretic polypeptide (ANP) neurons.

Apelin

The peptide apelin originates from a larger precursor pre-proapelin molecule. It has recently been isolated and identified as the endogenous ligand of the human orphan G-protein-coupled receptor, APJ (putative receptor protein related to the angiotensin receptor AT1). Apelin-containing perikarya are visualized in the preoptic region, supraoptic and paraventricular nuclei, and (in the highest density) arcuate nucleus. Apelin cells are also seen in the pons and the medulla oblongata. Apelin-immunoreactive nerve fibres and terminals appear in many hypothalamic nuclei and the internal layer of the median eminence. They are present in circumventricular organs, paraventricular thalamic nucleus, periaqueductal central grey matter, dorsal raphe nucleus, parabrachial and Barrington nuclei in the pons, and in the NTS, lateral reticular, prepositus hypoglossal and spinal trigeminal nuclei in the medulla oblongata (Reaux *et al.*, 2002). The topographical distribution of apelinergic neurons in the brain suggests a multiple role for apelin, especially in the central control of feeding behaviours, pituitary hormone release and circadian rhythms.

Atrial Natriuretic Polypeptides

The atrial natriuretic peptides (ANP, cANP, brain natriuretic peptide [BNP]) are found in high concentrations in the brain (hypothalamus, limbic system, brainstem), where they regulate fluid balance, thirst and drinking behaviour, and cardiovascular functions, and inhibit the release of vasopressin. They are dominantly synthesized by neurons of the preoptic and hypothalamic periventricular nuclei. These cells are connected synaptically with subfornical angiotensin II, as well as with supraoptic and paraventricular vasopressinergic neurons. Reportedly, periventricular ANP neurons project downwards to innervate medullary baroreceptor neurons in the NTS.

Bradykinin

The presence of the nonapeptide bradykinin in neurons of the CNS was demonstrated by immunohistochemistry. This neuropeptide regulates blood pressure and acts as one of the most potent pain-transmitting substances in the brain. Bradykinin-containing perikarya are mainly present in the periaqueductal central grey and the posterior and lateral hypothalamus. Fibres are seen in the lateral hypothalamus, preoptic area and periaqueductal central grey.

Calcitonin Gene-Related Peptide

CGRP originates from a gene common with calcitonin. This 37-amino acid peptide acts on central and peripheral brain tissues via distinct receptor mechanisms. CGRP inhibits growth hormone release, feeding and gastric acid secretion, and participates in conduction of pain signals. CGRP is coexpressed with glutamate and substance P in sensory ganglion cells (in dorsal root and Gasserian ganglia). Very dense CGRP-immunoreactive terminal networks are seen in the marginal layers of the spinal dorsal horn and spinal trigeminal nucleus. Besides nociceptive areas, CGRP is distributed widely in the entire CNS. In the hypothalamus, CGRP is synthesized by neurons in the dorsomedial, perifornical and ventral premamillary nuclei and the retrochiasmatic and lateral hypothalamic areas.

Cocaine- and Amphetamine-Regulated Transcript (CART) Peptide

In situ hybridization studies have revealed that CART mRNA is localized in neuronal groups involved in a large variety of neural, endocrine and autonomic functions, including the regulation of feeding behaviour (Broberger, 1999). CART-expressing neurons are found in the paraventricular, arcuate and dorsomedial hypothalamic nuclei, and in the lateral hypothalamic area, olfactory bulb, lateral septal nucleus and medial posterodorsal amygdaloid nucleus (Koylu *et al.*, 1997). CART is coexpressed in a percentage of NPY neurons in the arcuate nucleus. Axons of these cells descend to the spinal cord and innervate preganglionic sympathetic neurons (Elias *et al.*, 1998). CART peptide is coexpressed with TRH in the PVN, and with melanin-concentrating hormone (MCH) in lateral hypothalamic neurons (Broberger, 1999).

Orexin

Two orexin (hypocretin) peptides (orexin-33 (hypocretin-1) and orexin-28 (hypocretin-2)) have been isolated. Orexin is synthesized exclusively in the lateral hypothalamus and adjacent areas (Broberger *et al.*, 1998). These peptides have a prominent role in sleep–wake regulation by actions on basal forebrain structures (medial preoptic area, medial septal nucleus, substantia innominata).

Melanin-Concentrating Hormone

MCH-expressing cells occupy the dorsal part of the caudal hypothalamus, including a portion of the dorsomedial nucleus, the perifornical nucleus and the lateral hypothalamic area (Broberger *et al.*, 1998). A smaller population of MCH neurons exist in the olfactory tubercle and pontine tegmentum. MCH neurons in the lateral hypothalamic area receive inputs from arcuate NPY and agouti-related protein (AgRP) neurons (Broberger *et al.*, 1998). These neurons participate in the hypothalamic neuronal circuit that controls food intake.

Agouti-Related Protein

AgRP, a melanocortin receptor antagonist, is a potent orexigenic peptide. It is coexpressed with NPY in the arcuate nucleus, but not all NPY neurons express AgRP. Axons of these neurons project to the lateral hypothalamus and establish synaptic contacts with orexin- and MCH-expressing cells, whereby AgRP is considered to be an important component of the central neuronal circuit that controls food intake (Broberger *et al.*, 1998). The expression of AgRP in arcuate neurons is suppressed by leptin.

Tuberoinfundibular Peptide of 39 Residues

Tuberoinfundibular peptide of 39 residues (TIP39) peptide was recently purified from bovine hypothalamus based on selective parathyroid hormone-2 receptor activation (Usdin *et al.*, 2000). TIP39 is expressed in the caudal hypothalamus (subparafascicular area) and in the pons (caudal paralemniscal nucleus). Among other functional activities, this peptide may participate in pain perception.

NEUROPEPTIDE-RICH AREAS IN THE CENTRAL NERVOUS SYSTEM

Neuropeptides in general are present in almost all major brain areas, but there are high variations regarding their concentrations and cell/terminal densities. In this section, we introduce brain regions and nuclei where the expression or concentration of neuropeptides is higher then the average in the brain (Table VI.2). The region that is most rich in neuropeptides in the brain is the median eminence. Almost, all of the known brain-born neuropeptides are present in the median eminence (Table VI.1).

Cerebral Cortex

The 'classical' neurotransmitters (GABA, glutamate, acetylcholine) dominate in both local and projecting cortical neurons. Neuropeptides in cerebral cortical neurons are represented by somatostatin, NPY, VIP and CCK. These neuropeptides are expressed by neurons located mainly in layers II–IV. Their cell density here is not particularly high, but they occur in each neocortical and most of the limbic cortical areas such that their total number in the cortex is much higher then that in the extracortical brain.

Limbic System

Hippocampus

Several neuropeptides are present in the hippocampus, almost all of them in interneurons. VIP, PHI-27 and CRH are coexpressed in the same neurons in the molecular and granule cell layers throughout the hippocampal formation, including the dentate gyrus, subicular complex and entorhinal area. Within the pyramidal layer, the basket cells contain these neuropeptides. In addition, CCK, somatostatin, NPY, substance P, enkephalins and dynorphins have been localized in the hippocampus.

Septum

The lateral septal nucleus is rich in neuropeptides (Table VI.2). They are present in both perikarya and nerve terminals.

Amygdala

In general, the amygdala is rich in neuropeptidergic neurons. Somatostatin, VIP and CCK neurons are present in the lateral and basal amygdaloid nuclei. In addition, substance P, enkephalin and neurotensin have been demonstrated in the cortical and medial nuclei. Neuronal perikarya of the central amygdaloid nucleus contain one of the richest assortments of neuropeptides in the brain (Table VI.2). These cells express CRH, somatostatin, neurotensin, substance P, CCK, enkephalin and dynorphins. At least ten other neuropeptides have been immunostained in networks of neuronal fibres and terminals innervating central amygdaloid cells.

The NIST serves as a relay nucleus for amygdaloid efferent (and partly afferent) fibres. This nucleus is rich in neuropeptides in both perikarya and nerve terminals. It contains all the neuropeptides in the neurons found in the central and medial amygdaloid nuclei (Table VI.2).

Thalamus

The paraventricular thalamic nucleus is the only thalamic nucleus that contains neuropeptides in both high numbers and high concentration (Table VI.2).

Hypothalamus

The hypothalamic-pituitary interactions, and control of the production and release of pituitary hormone, represent the most significant function of the hypothalamic neuropeptides. They also play a significant role in other mechanisms controlling the autonomic nervous system, temperature regulation, biological rhythms and behavioural responses.

Peptidergic Neuronal Perikarya

Preoptic Area

Several neuropeptides are synthesized by preoptic neurons (Table VI.2). In the rat, LH-RH is mainly present in the medial preoptic nucleus. This nucleus is one of the major centres of temperature regulation. Neuropeptides here, such as CRH, NPY, neurotensin and CCK, may participate in this regulatory mechanism. The periventricular preoptic nucleus is one of the major pools of brain-born ANP. Neurons here receive inputs from subfornical angiotensin neurons and project to vasopressinergic neurons in the supraoptic and paraventricular nuclei.

Anterior Hypothalamus

The PVN serves as an integrator of endocrine, autonomic and behavioural functions, having neuronal interconnections with most of the limbic and autonomic brain areas. Several neuropeptides (Table VI.2) are synthesized in the magno- or parvicellular neurons of this nucleus. Many of the neuropeptides, including CRH, enkephalin, VIP/PHI-27, neurotensin, vasopressin, oxytocin and galanin, are coexpressed in the same PVN neurons or are colocalized in the subdivisions of the nucleus (Hökfelt *et al.*, 1983; Sawchenko *et al.*, 1984; Ceccatelli *et al.*, 1989).

Besides vasopressin and oxytocin, the magnocellular neurons in the supraoptic nucleus synthesize other neuropeptides (CCK, dynorphins, angiotensin II, apelin, galanin).

The suprachiasmatic nucleus serves as a biological clock, regulating sleep–wake and other body rhythms. Several kinds of neuropeptide-synthesizing neurons are distributed in this nucleus. VIP, vasopressin and somatostin are colocalized here, occupying different portions of the nucleus.

The hypothalamic periventricular nucleus is the major source of the neurohormonal somatostatin in the hypothalamus. These cells project directly to the median eminence, while through their axon collaterals they may influence the activity of hypothalamic GRH neurons. This nucleus, like the preoptic periventricular nucleus, is also rich in ANP and CCK (Table VI.2).

Middle Hypothalamus

The arcuate nucleus contains the major POMC neuronal pool in the CNS. Besides POMC, arcuate neurons synthesize several other neuropeptides (Table VI.2). The major projection area for arcuate neurons is the external layer of the median eminence. Along several intrahypothalamic targets, arcuate neurons innervate vagal and spinal autonomic preganglionic neurons. A significant portion of the descending arcuate fibres contain POMC and CART peptide (Palkovits *et al.*, 1987c; Elias *et al.*, 1998).

Several peptidergic neurons have been visualized in the dorsomedial and perifornical nuclei (Table VI.2). Many of these peptidergic neurons (cells those express angiotensin II, α-MSH, MCH, orexin/hypocretin, CART) are strongly involved in the central regulation of food and water intake. They do not respect the anatomical borders of the above two nuclei, but are scattered through the dorsal part of the middle hypothalamus from the third ventricle into the lateral hypothalamic area. These neurons receive strong NPY and AgRP innervation from the arcuate nucleus.

Posterior Hypothalamus
A wide variety of neuropeptides are synthesized by premamillary, supramammillary and posterior hypothalamic neurons (Lantos *et al.*, 1995).

Peptidergic Pathways

Neuropeptides in the Median Eminence–Pituitary Stalk
Almost all of the neuropeptides discovered in the brain are present in nerve fibres and terminals in the median eminence (Table VI.1). The majority are synthesized in hypothalamic neurons.

Internal Layer
Fibres arising mainly in the supraoptic, paraventricular and accessory magnocellular nuclei run through the internal layer–pituitary stalk to the posterior pituitary. Scattered fibres from other nuclei join this tract (Palkovits, 1986). Most of these fibres contain vasopressin and oxytocin, but other neuropeptides, such as CRH, enkephalins, dynorphins, CCK, neurotensin, galanin, substance P, angiotensin II and apelin, have also been demonstrated among the fibres in the hypothalamo-hypophyseal tract and the posterior pituitary. These neuropeptides may colocalize with either vasopressin or oxytocin. POMC-containing fibres from the arcuate nucleus do not project to the posterior lobe but terminate around the subependymal plexus in the internal layer.

External Layer
A number of peptidergic fibres terminate in the pericapillary space of the external layer. According to their origin and pathway to the external layer, they can be classified into two major groups: (1) tuberoinfundibular fibres arise in the arcuate nuclei and, in small numbers, the periventricular, ventromedial and ventral premamillary nuclei. These neurons may synthesize GRH, POMC, galanin, substance P, neurotensin and apelin; (2) fibres from the parvicellular PVN (TRH, CRH vasopressin, enkephalin, dynorphin, CCK, apelin and ANP), the medial preoptic nuclei (LH-RH) and the periventricular nuclei (somatostatin, ANP) travel through the lateral retrochiasmatic area and reach the median eminence from an anterolateral direction. Neuropeptides in the external layer may have two different physiological roles. First, after their release into the pericapillary space, they reach the portal blood and are transported to the anterior pituitary, where they exert their neurohormonal effects on pituitary cells. Second, some of the neuropeptides act locally in the external layer as neuromodulators by stimulating or inhibiting the release of neurohormonal peptides into the portal circulation.

Descending Peptidergic Fibres from the Hypothalamus
The majority of the descending hypothalamic fibres are peptidergic (Sawchenko and Swanson, 1982; Cechetto and Saper, 1988; Moga *et al.*, 1990). Vasopressin and oxytocin are the most prominent peptidergic neurotransmitters to the lower brainstem and the spinal cord, but several other neuropeptides (enkephalin, dynorphins, neurotensin, POMC, CRH, angiotensin II, galanin) also participate in this system. Besides the PVN (Sawchenko and Swanson, 1982), descending fibres arise in the arcuate, perifornical, dorsomedial and medial preoptic nuclei, and in the dorsal part of the lateral hypothalamus.

Peptidergic Afferents to the Hypothalamus
Several peptidergic afferents to the hypothalamus arise in the lower brainstem: NPY inputs from A1 and A2 catecholaminergic cell groups, where NPY is coexpressed with noradrenaline project to the PVN (Everitt *et al.*, 1984; Sawchenko *et al.*, 1985). Carrying viscero-sensory signals, peptidergic (neurotensin, somatostatin, enkephalin, dynorphin, NPY) neurons in the NTS project to the hypothalamus, mainly to the PVN (Riche *et al.*, 1990; Sawchenko *et al.*, 1990).

Lower Brainstem

Parabrachial Nuclei

The lateral parabrachial nucleus is considered as a secondary viscero-sensory centre in the brainstem with strong afferent inputs from the NTS and projections to the hypothalamus and the limbic system, especially to the NIST and the central nucleus of the amygdala. In contrast to the medial parabrachial and Kölliker–Fuse nuclei (the other two components of the parabrachial cell group), the lateral parabrachial is rich in peptide-synthesizing neurons (Table VI.2), and CRH-, enkephalin-, dynorphin-, CGRP- and CART-containing nerve fibres form a dense network in this nucleus.

Nucleus of the Solitary Tract

A great variety of neuropeptide-synthesizing neurons are present in the nucleus of the solitary tract, which serves as the primary autonomic (viscero-sensory) centre in the lower brainstem (Table VI.2). Neurons in this nucleus receive viscero-sensory inputs mainly through the glossopharyngeal and vagal nerves (CCK, somatostatin, enkephalins) and somatosensory input through descending trigeminal fibres (CGRP), and fibres from hypothalamic and limbic (mainly amygdaloid) nuclei terminate here.

Spinal Cord

Substance P and CGRP are the major neuropeptides in primary sensory neurons in the spinal cord. Both of them are coexpressed with glutamate in dorsal root ganglionic neurons. In addition, somatostatin, VIP, dynorphin, bombesin, galanin and endomorphin are synthesized in the dorsal root ganglion. Strong networks of substance P and CGRP nerve terminals are seen in the marginal layers of the dorsal horn. Enkephalin is one of the major neuropeptides in the inhibitory interneurons in the lamina III of the dorsal horn. Enkephalin acts on μ-receptors, inhibiting the release of substance P and other transmitters from the primary afferents. The activity of these inhibitory enkephalin neurons is controlled by descending inputs from substance P-, TRH- and serotonin-containing neurons in the ventromedial medulla and noradrenergic neurons in the ventrolateral medulla (A5 catecholaminergic cell group).

PEPTIDERGIC TRANSMISSION

To be considered as a neurotransmitter, a neuropeptide should meet eight criteria: (1) it should be present in the presynaptic neurons; (2) the peptide precursor and the synthetic enzyme should be present in the neuron; (3) the peptide should be released from the neuron by afferent stimulation; (4) effects of direct application of the neuropeptide to the synapse should be identical to those produced by stimulating nerve afferents; (5) specific neuropeptide receptors should be present on the presynaptic neurons; (6) interactions of neuropeptides with their receptors should induce changes in postsynaptic membrane permeability; (7) specific inactivating mechanisms should exist that stop interactions between neuropeptides and their receptors; and (8) agonists should mimic the action of the neuropeptide and antagonists should block its effects (McGeer *et al.*, 1987). Neuropeptides listed in this chapter meet many of these criteria.

Coexpression and Colocalization of Neuropeptides

During the past two decades, it has become evident that we cannot find any homogeneous cell groups in the CNS that contain only a single neuropeptide. Furthermore, it is hard to find any neuronal cell in the brain that may express only one neuropeptide. In certain brain areas, such as the hypothalamic and amygdaloid nuclei, lateral septal nucleus, NIST, parabrachial nuclei, and nucleus of the solitary tract, a high number of different neuropeptides can be visualized in neuronal perikarya (Table VI.2). They may be synthesized by different cell types of the nucleus (colocalization), but frequently several neuropeptides are synthesized by the same neuronal cell (coexpression). (Unfortunately, these two terms are, incorrectly, used interchangeably. When using the word 'colocalization', it should be made clear whether neuropeptides are colocalized in separate neurons in a brain nucleus or colocalized in the same neuronal cell. In the latter case, 'coexpression' is the correct term.)

The degree of convergence of neuropeptidergic fibres in brain regions is very high. None of the cell groups in the brain receives single peptidergic input: various peptidergic fibres of different origins enter a brain nucleus or an area and form terminal networks there. A similar degree of neuronal divergence has been revealed by immunohistochemistry: a single peptidergic neuron can innervate hundreds, and in certain cases thousands, of other neurons.

Neurohormones/Neuromodulators/Neurotransmitters

Depending on the site of action, neuropeptides can act as neurotransmitters, neurohormones or both. Brain neuropeptides may be transported by axons to the nerve terminals and released into the blood circulation, thus exerting their effects as hormones on the pituitary or in the periphery. Since they are synthesized in neuronal cells, neuropeptides in this case may be called 'neurohormones'. Brain neuropeptides may also be transported by axons into the synapses and bind to receptors on the postsynaptic neuronal cells, influencing their activity as neurotransmitters. In certain cases, a neuropeptide may act as both neurohormone and neurotransmitter, e.g. the axon of a hypothalamic neuronal cell terminates in the median eminence and releases its peptide into the portal blood (neurohormonal action), while its axon collaterals terminate on other hypothalamic neurons (neurotransmitter action); this is the case for the GRH–somatostatin interaction at hypothalamic level (Horváth *et al.*, 1989).

Neuropeptides may act at presynaptic levels, stimulating or inhibiting the release of other neuropeptides or neurotransmitters. When neuropeptides bind nonsynaptic receptors and act at presynaptic neurons, they are considered to have neuromodulator activity. As neuromodulators, neuropeptides can alter the release of neurotransmitters from the nerve terminals of presynaptic neurons, and regulate receptor sensitivity, G-protein coupling and the activation of second-messenger systems in postsynaptic neurons, altering the responses of these cells to synaptic stimulation. Neuropeptides may act as both neurotransmitters and neuromodulators (possible action of cotransmitters at pre- and postsynaptic receptors).

Neuropeptide Receptors

After the neuropeptide is released into the synapse, it binds to its receptor(s) on the surface membrane of the postsynaptic neurons. In general, neuropeptides bind to G-protein-coupled membrane receptors to regulate the levels of cyclic adenosine monophosphate (cAMP) and other second messengers (cyclic guanosine monophosphate (cGMP), inositol-phospholipid, calcium-calmodulin) in pre- and postsynaptic target cells. In the cAMP system, neuropeptide receptors may be bound to stimulatory or inhibitory transducer proteins, and may stimulate (like TRH and VIP) or inhibit (like somatostatin and opioid peptides) cAMP synthesis.

Each neuropeptide may have more than one type of receptor or receptor subtypes. Most of the peptide receptors have a wide distribution throughout the brain. Overall, the correspondence between neuropeptides and their related peptide receptors in the brain is quite good. In several cases, however, there is an apparent mismatch between their distribution that needs further studies to elucidate it. The detailed description of the topographical distribution of peptide receptors in the brain is beyond the scope of this chapter. Instead, we refer to related chapters in two excellent handbooks (Björklund *et al.*, 1990; Björklund *et al.*, 1992).

GENERAL REMARKS

There are more then 60 neuropeptides in the mammalian nervous system that have been identified, characterized and cloned. These peptides bind receptors that belong to the G-protein-coupled receptor supergene family. All of these peptides may act as neurohormones or neurotransmitters, or exert a modulatory effect on neurotransmission. The increasing arsenal of powerful new techniques, such as subtractive hybridization approach, orphan receptor strategy, combinatorial chemistry and molecular modelling, helps researchers to identify new neurotransmitters. Studies on known and newly discovered neuropeptides will increase our knowledge about functional brain mechanisms, help us to understand molecular psychiatry and psychology, and, as a final goal, help us to understand neurological disorders.

VII

Neuroendocrinology

David A. Gutman and Charles B. Nemeroff

INTRODUCTION

The occurrence of psychiatric symptoms such as thought disturbances and depressed mood in patients with primary endocrine disorders is common. In addition, a significant percentage of patients with psychiatric disorders demonstrate a consistent pattern of endocrine dysfunction. Our understanding of the neurobiology of depression and other psychiatric disorders has been aided tremendously by a systematic analysis of the neuroendocrine axes and the actions of neurohormones in the pituitary gland and throughout the central nervous system (CNS). The occurrence of prominent psychiatric symptoms in patients with primary endocrine disorders, including Cushing's disease and primary hypothyroidism, provided a rationale for exploring the connection between hormones and both affective and cognitive function. In fact, disorders of neuroendocrine dysregulation in subpopulations of psychiatric patients are among the most consistent neurobiological findings in all of biological psychiatry.

Bleuler was among the first investigators to investigate systematically the association between hormones, mood and behaviour. He first demonstrated that patients with primary endocrine disorders have higher-than-expected psychiatric morbidity, which often resolved after correcting the primary hormonal abnormality. Work over the past 25 years has demonstrated clearly that the CNS tightly regulates endocrine gland secretion and, further, that neurons are influenced directly by hormones.

The concept that neurons are capable of synthesizing and releasing hormones initially sparked a controversy in endocrinology and neuroscience when first introduced in the 1950s; namely, is it possible that certain neurons subserve endocrine functions? Two major findings fuelled this debate. First, neurohistologists working with mammalian as well as lower-vertebrate and invertebrate species made several key observations. Led by a husband-and-wife team, the Scharrers, early researchers documented by both light and electron microscopy the presence of neurons that had all the characteristics of previously studied endocrine cells. These neurons stained positive with the Gomori stain, which was believed to be specific to endocrine tissues; further, they contained granules or vesicles containing known endocrine substances. The second key area of research centred around the brain's control of the secretion of pituitary trophic hormones. These trophic hormones were long known to control the secretion of peripheral target endocrine hormones, e.g. thyroid hormone, gonadal steroids and adrenal steroids. These interactions were particularly compelling because of the earlier identification of an extremely important neuroendocrine system, namely the magnocellular cells of the paraventricular nucleus (PVN) of the hypothalamus, which synthesize vasopressin and oxytocin. These two nonapeptides were shown to be transported from PVN cell bodies down the axon to nerve terminals located in the posterior pituitary (neurohypophysis), and released in response to appropriate physiologic stimuli. Vasopressin, also known as antidiuretic hormone (ADH), is a critical regulator of fluid balance, and oxytocin regulates the milk-letdown reflex during breastfeeding.

The ability of neurons to function as true endocrine tissues has now been clearly established. Neural tissue can both synthesize and release substances known as (neuro)hormones directly into the circulatory system; these (neuro)hormones have effects at sites far removed from the brain. One important example noted above is the action of vasopressin on the kidney. Although early in the development of the emerging discipline of neuroendocrinology it seemed important to document the ability of neurons to function as neuroendocrine cells, particularly those in the CNS, classification of specific chemical messengers as endocrine or neuronal or neuroendocrine soon lost its heuristic value. It is now recognized that the same substance can act as a neurotransmitter and a hormone depending on its location within the CNS and periphery. A good example of this is adrenaline, which functions as a classical hormone in the adrenal medulla but as a conventional neurotransmitter in the mammalian CNS. Similarly, it has been demonstrated that corticotropin-releasing factor (CRF) functions as a true peptide hormone in its role as a hypothalamic-hypophysiotropic factor in promoting the release of adrenocorticotropin (ACTH) from the anterior pituitary, yet it also functions as a 'conventional' neurotransmitter in cortical and limbic areas. Thus, the field now seeks to elucidate the role of particular chemical messengers in particular brain regions or endocrine axes.

The traditional endocrine and hormonal functions for several peptides discussed above have been well established, but many of these substances may also possess paracrine roles as well, i.e. secretion of these substances from one cell acts upon proximal cells. These paracrine interactions remain largely unexplored. The importance of these paracrine effects has been demonstrated in the gastrointestinal tract, where several peptides that act as hormones or neurotransmitter substances at other sites, including the CNS, have influences on local cellular function. Examples include vasoactive intestinal peptide (VIP), cholecystokinin (CCK) and somatostatin.

OVERVIEW OF COMPONENTS AND CONTROL MECHANISMS

The hypothalamic-pituitary-end-organ axes are generally organized in an hierarchical fashion (Figure VII.1). A large percentage of the neuroendocrine abnormalities in patients with psychiatric disorders are related to disturbances of target hormone feedback. A generic description is outlined here. More comprehensive reviews on this topic are available (e.g. Levine, 2000). In general, the hypothalamus contains neurons that synthesize and release factors that either promote or inhibit the release of anterior pituitary hormones, so-called release or release-inhibiting factors. These peptide hormones,

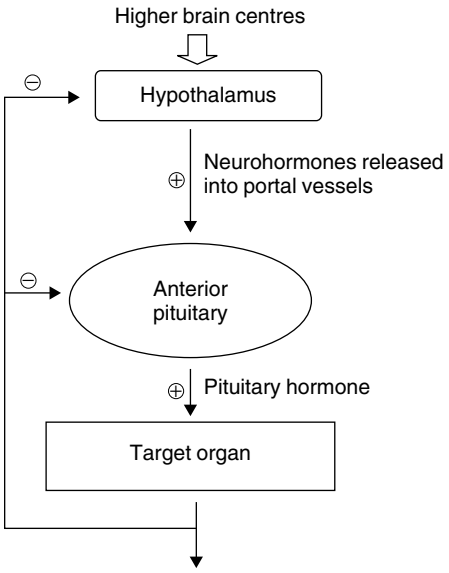

Figure VII.1 Overview of the common organizational motif of the neuroendocrine axes. The neurosecretion of hypothalamic factors into hypophyseal portal vessels is regulated by a set point of activity from higher brain centres. Neurohormones released from the hypothalamus into hypophyseal portal vessels in turn stimulate cells in the pituitary. These adenohypophyseal hormones then regulate the hormone output from the end organ. The end organ then exerts negative feedback effects at the pituitary and hypothalamus to prevent further neurohormone and pituitary hormone release via long-loop negative feedback. Short-loop negative feedback may also occur where pituitary hormones feed back directly on hypothalamic neurons to prevent further neurohormone release

Table VII.1 Major releasing factors and their hormonal targets

Neurohormone/releasing factor	Hormone stimulated

as summarized in Table VII.1, are synthesized by transcription of the DNA sequence for the peptide prohormone. After translation in the endoplasmic reticulum, these prohormones are processed during axonal transport and packaged into vesicles destined for the nerve terminals. These now biologically active peptides are then released following appropriate physiological stimuli from the median eminence, the most ventral portion of the hypothalamus, and secreted into the primary plexus of the hypothalamo-hypophyseal portal vessels (Figure VII.2). These peptides are transported in high concentrations to the sinusoids of the anterior pituitary (adenohypophysis), where they bind to specific membrane receptors on their targets, the pituitary trophic-hormone-producing cells. Activation of these receptors promotes or inhibits the release of pituitary trophic hormones into the systemic circulation. The increase or decrease in the plasma concentrations of these pituitary trophic hormones produces a corresponding increase or decrease in their respective end-organ hormone secretion. The hormones of the end-organ axes, such as gonadal and adrenal steroids, feed back on both pituitary and hypothalamic cells to prevent further release, often referred to as long-loop negative feedback. Short-loop negative feedback circuits have also been identified in which pituitary hormones feedback directly on hypothalamic neurons to prevent further release of hypothalamic-releasing factors.

Disturbances in the feedback regulation of the hypothalamic-pituitary-end-organ axes are of considerable interest in psychiatry. The common occurrence of psychiatric symptoms in many primary endocrine disorders, such as hypothyroidism and Cushing's syndrome, served as an impetus for investigation into the regulation of neuroendocrine systems in psychiatric disease states, such as depression, schizophrenia and bipolar disorder. Thus, a large part of psychoneuroendocrinology has focused on identifying changes in basal levels of pituitary and end-organ hormones in patients with psychiatric disorders. For many of the axes discussed below, tests have been developed to assess the functional status of these feedback systems. In these so-called stimulation tests, hypothalamic and/or pituitary-derived factors or their synthetic analogues are administered exogenously, and the hormonal response to this challenge is assessed. For example, in the standard CRF stimulation test, a 1-$\mu g\,kg^{-1}$ dose of CRF is administered intravenously, and the ACTH and cortisol response is measured over a period of 2 or 3 h. This test is a very sensitive measure of hypothalamic-pituitary-adrenal (HPA) axis activity, and changes in the magnitude and/or duration of the response relative to normal control values are characteristic of one or another type of dysregulation of the HPA axis.

Limitations of Stimulation Tests

Such studies as outlined above provide valuable information, but a brief discussion of some inherent limitations is warranted before a detailed review of the literature is presented. Normal

circadian rhythms and the pulsatile release of many of the hypothalamic-pituitary-end-organ axes components are often not taken into account when these stimulation tests are designed. Further, differences in assay sensitivity, gender, inclusion criteria for patients used in studies, and severity of symptoms in the target patient population studied can potentially generate confounding or at least quite variable results. Nevertheless, a great deal about the neurobiology of psychiatric disorders has been discovered through such experiments.

Although used less commonly today, a strategy that was often utilized in the 1970s and 1980s was based on the perception that the neuroendocrine axes served as a window into CNS function. Peripheral neuroendocrine markers were often used to assess indirectly CNS function because the brain was relatively inaccessible for study, with the exception of cerebrospinal fluid (CSF) and post-mortem studies. With the emergence of the monoamine theories of mood disorders and schizophrenia, many investigators attempted to draw conclusions about the activity of noradrenergic, serotonergic and dopaminergic circuits in patients with various psychiatric disorders by measuring the basal and stimulated secretion of pituitary and end-organ hormones in plasma. Although these approaches have severe limitations, they have been useful in elucidating the pathophysiology of mood and anxiety disorders and, to a lesser extent, schizophrenia.

In summary, neuroendocrinology broadly encompasses the following:

- The neural regulation of the secretion of peripheral, target-organ hormones, pituitary trophic hormones, and hypothalamic-hypophysiotropic hormones.
- The effects of each of the hormones that comprise the various endocrine axes on the CNS, e.g. the effects of synthetic glucocorticoids on memory processes.
- Study of alterations in the activity of the various endocrine axes in major psychiatric disorders and, conversely, the behavioural consequences of endocrinopathies.

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Dysregulation of the HPA axis has frequently been reported in patients with psychiatric disorders, and is among the most robustly demonstrated neurobiological changes among psychiatric patients. The primary regulator of this axis is CRF, also known as corticotropin-releasing hormone (CRH), a 41-amino-acid-containing peptide synthesized in parvocellular neurons located primarily in the PVN of the hypothalamus. CRF-containing cells in the PVN receive input from a variety of brain nuclei, including the amygdala, bed nucleus of the stria terminalis, and other brainstem nuclei (Hauger and Dautzenberg, 2000). These CRF-containing neurons in turn project to nerve terminals in the median eminence (Swanson *et al.*, 1983); when CRF is released into the hypophyseal portal system it activates CRF receptors on corticotrophs in the anterior pituitary to promote the synthesis of pro-opiomelanocortin (POMC) and the release of its post-translational products, ACTH, β-endorphin and others (Figure VII.3). Arginine-vasopressin (AVP) also promotes the release of ACTH from the anterior pituitary, though CRF is necessary for AVP to exert this effect. Chronic stress can also upregulate AVP expression in the PVN, where under these conditions it may be coexpressed in CRF-containing neurons (Hauger and Dautzenberg, 2000). ACTH released from the anterior pituitary in turn stimulates the production and release of cortisol, the primary glucocorticoid in humans, from the adrenal cortex.

The concentration of circulating glucocorticoids is modulated via long-loop negative feedback. An increase in circulating glucocorticoids inhibits hypothalamic CRF gene expression and ACTH secretion from the pituitary. This in turn prevents further glucocorticoid release. The HPA axis also undergoes a circadian rhythmicity in humans, where serum cortisol levels peak immediately before awakening and reach a nadir in the evening.

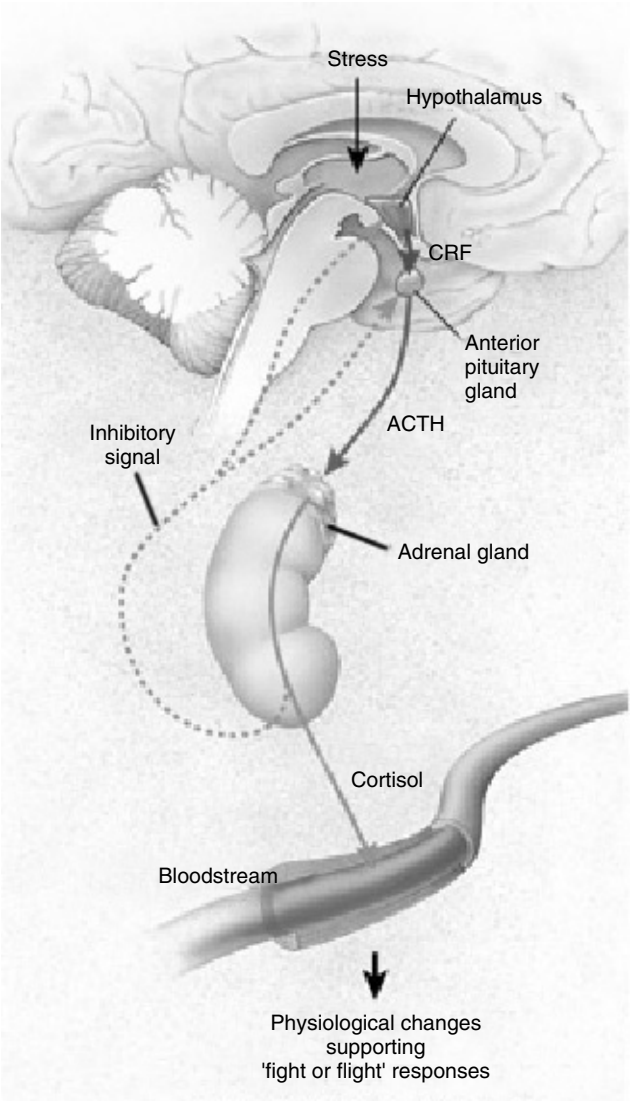

Figure VII.3 Overview of the feedback mechanisms of the HPA axis. Following relevant stimuli, including stress, CRF is released from the hypothalamus into hypophyseal portal vessels, where it is transported in high concentrations to the pituitary gland. CRF then promotes the release of ACTH, which in turn promotes the release of cortisol from the adrenal glands. Cortisol acts as an inhibitory signal at both the hypothalamus and pituitary, preventing further CRF and ACTH release, respectively. Mounting evidence suggests that chronic overactivity of the axis, and particularly overproduction of CRF, may contribute to the pathophysiology of depression. Reproduced with permission of Tomo Narashima from Nemeroff, C.B., 1998. *Scientific American*, June, 47

The biological effects of glucocorticoids are regulated by two cytosolic receptors: the glucocorticoid receptor and the mineralocorticoid receptor, both of which belong to a large superfamily of steroid hormone receptors. Because the mineralocorticoid receptor has a much higher affinity for glucocorticoids than does the glucocorticoid receptor, mineralocorticoid receptor binding sites may be saturated with glucocorticoids under physiological conditions.

In contrast, the occupancy of glucocorticoids receptor binding sites changes in response to changes in circulating glucocorticoid levels. The main genomic affects of glucocorticoids are mediated by glucocorticoids receptor binding to glucocorticoid response elements (GREs) in the promoter regions of specific genes. Glucocorticoid receptors may also inhibit or enhance the actions of other transcription factors, such as AP-1, NF-κB and CREB, by direct protein–protein interactions (Nestler *et al.*, 2001).

The Biology of Corticotropin-Releasing Factor

Although Saffran and Schally identified a crude extract that promoted the release of ACTH from the pituitary in 1955 (Saffran *et al.*, 1955), it was not until 1981 that CRF was isolated and chemically characterized. Working with extracts derived from 500 000 sheep hypothalami, Vale and colleagues at the Salk institute isolated, synthesized and elucidated the structure of CRF (Vale *et al.*, 1981). This discovery led to the availability of synthetic CRF, which allowed a comprehensive assessment of the HPA axis to proceed. It is now clear that CRF coordinates the endocrine, immune, autonomic and behavioural responses of mammals to stress. The regulation of CRF transcription is under control of a number of promoter elements. A cyclic adenosine monophosphate (cAMP) response element (CRE) is located in the 5′-flanking region of the human CRF gene, consistent with evidence that protein kinase A (PKA) activity regulates CFR gene expression. A glucocorticoid response element (GRE) is also located in the 5′-flanking region of the CRF gene, which is apparently the substrate where glucocorticoids act to inhibit CRF gene transcription (Hauger and Dautzenberg, 2000).

Two CRF-receptor subtypes, CRF_1 and CRF_2, with distinct anatomical localization and receptor pharmacology have been identified (Chalmers *et al.*, 1996; Lovenberg *et al.*, 1995; Grigoriadis *et al.*, 1996; Chang *et al.*, 1993; Chen *et al.*, 1993) in rats and humans. Both receptors are G-protein-coupled receptors and are coupled positively to adenylyl cyclase via G_s. In addition, a putative CRF_3 receptor has been identified recently in catfish (Arai *et al.*, 2001). The CRF_1 receptor is predominantly expressed in the pituitary, cerebellum and neocortex in the rat (Primus *et al.*, 1997). A growing body of evidence from animal studies has shown that the CRF_1 receptors may specifically mediate some of the anxiogenic-like behaviours observed after administration of CRF (Heinrichs *et al.*, 1997). The CRF_2 receptor family is composed of two primary splice variants, CRF_{2A} and CRF_{2B}. The CRF_{2A} receptor is more prevalent in subcortical regions, such as the ventromedial hypothalamus, lateral septum and dorsal raphe nucleus, whereas CRF_{2B} is expressed more abundantly in the periphery. A structurally related member of the CRF peptide family, urocortin, has also been identified in the mammalian brain. The endogenous neuropeptide urocortin has equally high affinity for both the CRF_1 and CRF_2 receptor subtypes (Vaughan *et al.*, 1995), whereas CRF displays a higher affinity at CRF_1 receptors than it does at CRF_2 receptors. The newly discovered urocortin II shows high selectivity for CRF_{2A} receptors, although its anatomic localization does not correlate precisely with the distribution of the CRF_{2A} receptor (Reyes *et al.*, 2001). With the discovery of a new ligand and a putative third receptor in the CRF family, much of the pharmacology and functional interactions between these ligands and receptors remains to be discovered.

The Effects of Changes in Glucocorticoid Availability

A deficiency of endogenous glucocorticoids produces overt clinical symptoms, including weakness, fatigue, hypoglycaemia, hyponatraemia, hyperkalaemia, fever, diarrhoea, nausea and shock. This condition, also known as Addison's disease, is caused most often by autoimmune destruction of the adrenal cortex. However, it is important to note that abrupt withdrawal from exogenous corticosteroids or ACTH can also induce an Addisonian crisis, because the exogenous administration of these compounds suppresses endogenous HPA axis activity. This is why tapering of the dose of adrenal steroids is essential before discontinuation. Glucocorticoid deficiency may also produce mild to severe depression or, less commonly, psychosis.

Excessive glucocorticoid secretion leads to a number of characteristic symptoms, including moon face, plethoric appearance, truncal obesity, purple abdominal striae, hypertension, protein depletion and signs of glucose intolerance or overt diabetes mellitus. Psychiatric symptoms, specifically depression and anxiety, are also associated with glucocorticoid excess. Cognitive impairment, especially decrements in memory function and attention, are also common and may be due to the direct effects of corticosteroids on the hippocampal formation (Sadock and Sadock, 2000).

The most common form of non-iatrogenic hypercortisolism is due to an ACTH-secreting pituitary adenoma, also known as Cushing's disease. Harvey Cushing, for whom the disease is named, first documented the occurrences of psychiatric symptoms, particularly depression, in 1913 in his first description of the illness. Other causes of hypercortisolism are often referred to as Cushing's syndrome. Since Dr Cushing's initial description, the occurrence of depression in Cushing's syndrome has been well documented (Spillane, 1951; Zeiger *et al.*, 1993).

Hypothalamic-Pituitary-Adrenal Axis Abnormalities in Depression

The occurrence of depression and other psychiatric symptoms in both Cushing's disease and Addison's disease served as an impetus for researchers to scrutinize HPA axis abnormalities in depression and other psychiatric disorders. Most investigators would agree that one of the most venerable findings in all of psychiatry is the hyperactivity of the HPA axis observed in a significant subset of patients with major depression (Table VII.2). Based on the work of research groups led by Board, Bunney and Hamburg, as well as by Carroll, Sachar, Stokes and Besser, literally thousands of studies have been conducted in this area.

The earliest studies in this field demonstrated elevated plasma cortisol concentrations in depressed patients (Carpenter and Bunney, 1971; Gibbons and McHugh, 1962). Other markers of hypercortisolism that have been demonstrated reliably in depressed patients include elevated 24-hour urinary-free cortisol concentrations and increased levels of cortisol metabolites in urine (Sachar *et al.*, 1970). One commonly used test to measure HPA axis function is the dexamethasone suppression test (DST). In this test, 1 mg of dexamethasone is given at 11 p.m.; blood is then drawn at 8 a.m. the following morning and cortisol levels are measured.

Table VII.2 HPA axis changes demonstrated in depression

↑ CRF in cerebrospinal fluid[a]
↓ ACTH to CRF stimulation
↓ Density of CRF receptors in frontal cortex of suicide victims
Enlarged pituitary gland in depressed patients[a]
Adrenal gland enlargement in suicide victims and depressed patients
↑ Plasma cortisol during depression[a]
↑ Urinary free cortisol concentrations[a]
Non-suppression of plasma cortisol and ACTH after dexamethasone administration[a]

[a]State-dependent.

Dexamethasone is a synthetic steroid similar to cortisol that suppresses ACTH secretion and subsequently cortisol release in healthy volunteers. Non-suppression of plasma glucocorticoid levels following the administration of dexamethasone is common in depression. The rate of cortisol non-suppression after dexamethasone administration generally correlates with the severity of depression (Evans and Nemeroff, 1987). In fact, nearly all patients with major depression with psychotic features exhibit DST non-suppression (Arana *et al.*, 1985; Evans and Nemeroff, 1983). Since Carroll's initial reports (Carroll *et al.*, 1968a; Carroll *et al.*, 1968b) and subsequent claims for diagnostic utility (Carroll, 1982), the DST has generated considerable controversy as to its diagnostic utility (Arana and Mossman, 1988). Diagnostic issues notwithstanding, the overwhelming conclusion from a myriad of studies demonstrates that a sizeable percentage of depressed patients exhibit HPA axis hyperactivity.

Another method used to assess HPA axis activity is the CRF stimulation test, which became available shortly after the synthesis of CRF. In this paradigm, CRF is administered intravenously (usually a $1\,\mu g\,kg^{-1}$ dose), and the ensuing ACTH and cortisol response is measured at 30-minute intervals over a 2–3-hour period (Hermus *et al.*, 1984). Numerous studies have now demonstrated a blunted ACTH and β-endorphin response to exogenously administered ovine CRF (oCRF) or human CRF (hCRF) in depressed patients when compared with non-depressed subjects, although the cortisol response in depressed patients and non-depressed control subjects did not differ consistently (Amsterdam *et al.*, 1988; Gold *et al.*, 1984; Holsboer *et al.*, 1984a; Kathol *et al.*, 1989; Young *et al.*, 1990). The attenuated ACTH response to CRF is presumably due to either chronic hypersecretion of CRF from nerve terminals in the median eminence, which results in downregulation of CRF receptors in the anterior pituitary, and/or to the chronic hypercortisolaemia. This receptor downregulation results in a reduced responsivity of the anterior pituitary to CRF, as has been demonstrated in laboratory animals (Aguilera *et al.*, 1986; Holmes *et al.*, 1987; Wynn *et al.*, 1983; Wynn *et al.*, 1984; Wynn *et al.*, 1988). Following recovery from depression, the documented disturbances in the HPA axis generally remit.

A combined dexamethasone/CRF test has also been developed. In this test, 1.5 mg of dexamethasone is administered orally at night (11 p.m.), and subjects receive an intravenous bolus of $100\,\mu g$ of hCRF at 3 p.m. the following day. Patients with HPA axis dysfunction, which is frequently encountered in depression, display a paradoxically increased release of ACTH and cortisol relative to controls. These abnormalities disappear following remission of depression, and normalization of HPA axis function seems to precede full clinical remission (Holsboer, 2000; Heuser *et al.*, 1994). The combined dexamethasone/CRF test appears to have much higher sensitivity for detecting subtle alterations in HPA axis function, and approximately 80% of patients with major depression exhibit an abnormal response to the dexamethasone/CRF test. In contrast, only approximately 44% of patients with major depression demonstrate an abnormal response when the DST is administered alone (Holsboer, 2000; Heuser *et al.*, 1994). Furthermore, otherwise healthy individuals with first-degree relatives with an affective illness, which greatly increases their own risk for psychiatric disorders, demonstrated cortisol and ACTH responses to the dexamethasone/CRF test that were higher than those of a control group but less than those of patients currently suffering from major depression. This suggests that a genetically transmittable defect in corticosteroid receptor function may render these individuals more susceptible to developing affective disorders (Holsboer *et al.*, 1995).

Structural changes in the components of the HPA axis have also been documented in depressed patients. Perhaps in part due to the trophic effects of CRF, pituitary gland enlargement has been documented in depressed patients as measured by magnetic resonance imaging (MRI) (Krishnan *et al.*, 1991). Enlargement of the adrenal glands, presumably due to ACTH hypersecretion, has been demonstrated repeatedly in both depressed patients *post mortem* (Nemeroff *et al.*, 1992; Amsterdam *et al.*, 1987) and suicide victims (Dorovini-Zis and Zis, 1987). It is reasonable to hypothesize that the normal plasma cortisol response to CRF seen in depressed patients is due to adrenocortical hypertrophy, in light of the blunted ACTH and β-endorphin responses to CRF seen in these same patients (Gold *et al.*, 1984; Kathol *et al.*, 1989; Amsterdam *et al.*, 1987; Gold *et al.*, 1986; Holsboer *et al.*, 1984b). Presumably, although the ACTH response to CRF is decreased in depressed patients, the enlarged adrenal cortex may secrete relatively greater quantities of cortisol when compared with control subjects in response to a given amount of ACTH. There are reports of increased cortisol responses to pharmacological doses of ACTH that support this hypothesis (Amsterdam *et al.*, 1983; Jaeckle *et al.*, 1987; Kalin *et al.*, 1982; Krishnan *et al.*, 1990; Linkowski *et al.*, 1985), although discordant findings have also been reported (Heim *et al.*, 2001).

The studies discussed thus far have focused primarily on dysregulations of the HPA axis, but, CRF controls not only the neuroendocrine but also the autonomic, immune and behavioural responses to stress in mammals. Moreover, results from clinical studies, and a rich body of literature conducted primarily in rodents and lower primates, have indicated the importance of CRF at extrahypothalamic sites. In rodents, primates and humans, CRF and its receptors have been localized heterogeneously in a variety of regions, including the amygdala, thalamus, hippocampus and prefrontal cortex (Suda *et al.*, 1984; Sanchez *et al.*, 1999; Van Pett *et al.*, 2000; Charlton *et al.*, 1987). These brain regions are important in regulating many aspects of the mammalian stress response and in regulating affect. The presence of CRF receptors in both the dorsal raphe and locus coeruleus, the major serotonergic- and noradrenergic-containing regions in the brain, respectively, also deserves comment. Because most available antidepressants, including the tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI), are believed to work via modulation of noradrenergic and/or serotonergic systems, the neuroanatomical proximity of CRF and monoaminergic systems suggests a possible site of interaction between CRF systems and antidepressants.

Involvement of extrahypothalamic CRF systems in the pathophysiology of depression is suggested by numerous studies showing elevated CRF concentration in the CSF of patients suffering from depression (Banki *et al.*, 1987; Arato *et al.*, 1989; France *et al.*, 1988; Nemeroff, 1988; Risch *et al.*, 1992), although discrepant results have been reported (Roy *et al.*, 1987). Elevated CSF CRF levels have also been detected in depressed people who committed suicide (Arato *et al.*, 1989). A reduction in concentration of CRF in CSF has been reported in healthy volunteers treated with the tricyclic antidepressant desipramine (Veith *et al.*, 1993), providing further evidence of a possible interconnection between antidepressants, noradrenergic neurons and CRF systems. Similar effects have been reported with electroconvulsive therapy (ECT) in depressed patients (Nemeroff *et al.*, 1991).

Depressed patients who are non-suppressors on the DST also have significantly higher levels of CSF CRF than depressed patients with normal DST results. Presumably, the elevated CSF concentrations of CRF are due to CNS CRF hypersecretion (Post *et al.*, 1982), which may be acting at sites throughout the brain and contributing to many of the behaviours characteristic of depression. A reduction in the density of CRF receptors in the frontal cortex has also been reported in the frontal cortex of suicide victims (Nemeroff *et al.*, 1988). Presumably, hypersecretion of CRF results in a downregulation of CRF receptors in the frontal cortex.

While the exact mechanism contributing to CRF hyperactivity remains obscure, studies from our group and others have documented long-term persistent increases in HPA axis activity and

extrahypothalamic CRF neuronal activity after exposure to early untoward life events, e.g. neglect and child abuse, respectively, in laboratory animals (rat and non-human primates) and patients (Holsboer *et al.*, 1995; Nemeroff, 1999; Holsboer *et al.*, 1987; Coplan *et al.*, 1996). Early-life stress apparently sensitizes permanently the HPA axis and leads to a greater risk of developing depression later in life. In one schema, early sensitization of CRF systems results in heightened responses to stress later in life. To measure HPA responsivity to stress, the Trier Social Stress Test (TSST) was developed. This laboratory paradigm involves a simulated 10-minute public speech and a mental arithmetic task. The TSST has been validated as a potent activator of the HPA axis in humans (Kirschbaum *et al.*, 1993). Recently, our group has reported increased plasma ACTH and cortisol concentrations, presumably due to hypersecretion of CRF, after exposure to the TSST in women (both depressed and non-depressed) who were exposed to severe physical and emotional trauma as children (Heim *et al.*, 2000). These data provide evidence for functional hyperactivity of CRF systems that may be influenced by early adverse life events.

Space constraints do not permit an extensive review of the preclinical literature, but several additional points are worth noting. Numerous studies have documented that when CRF is injected directly into the CNS of laboratory animals, it produces effects reminiscent of the cardinal symptoms of depression, including decreased libido, reduced appetite and weight loss, sleep disturbances and neophobia. Indeed, newly developed CRF_1 receptor antagonists represent a novel putative class of antidepressants. Such compounds show activity in nearly every preclinical screen for antidepressants and anxiolytics currently employed. Recently, a small open-label study examining the effectiveness of R121919, a CRF_1 receptor antagonist, in major depression was completed (Zobel *et al.*, 2000). Severity measures of both anxiety and depression were reduced in the depressed patients. Although this drug is no longer in clinical development, it is clear that CRF_1 antagonists may represent a new class of psychotherapeutic agents to treat anxiety and affective disorders.

Hypothalamic-Pituitary-Adrenal Axis Alterations in Other Psychiatric Disorders

Patients with other psychiatric disorders also exhibit HPA axis dysregulation, although the vast majority of the available data is concerned with HPA axis alterations in depression. When depression is comorbid with a variety of other disorders, such as multiple sclerosis, Alzheimer's disease, multi-infarct dementia, Huntington's disease and others, both CRF hypersecretion and HPA axis hyperactivity are common. In contrast, HPA axis dysfunction has rarely been reported in schizophrenia. Consistent with the role of CRF in both depression-like and anxiety-like behaviours in preclinical animal studies, increased CSF CRF concentrations have been reported in post-traumatic stress disorder (PTSD) (Bremner *et al.*, 1997). A recent, elegant study using indwelling cannula in the lumbar space, allowing repeated sampling of CSF several hours after the initial, and presumably stressful, lumbar puncture, demonstrated elevated CSF CRF levels in PTSD combat veterans (Baker, *et al.*, 1999). In contrast, low serum cortisol and urinary free cortisol levels have been detected repeatedly, yet unexpectedly, in PTSD. One possible mechanism that has been proposed by Yehuda and colleagues suggests heightened negative feedback within the HPA axis in chronic PTSD patients (Yehuda *et al.*, 1996). Finally, CRF neuronal degeneration is now well known to occur in the cerebral cortex of patients with Alzheimer's disease with a compensatory upregulation of CRF receptor number, and this effect precedes the better-studied cholinergic neuronal involvement (Bissette, 1998).

OVERVIEW OF HYPOTHALAMIC-PITUITARY-THYROID AXIS COMPONENTS AND FUNCTION

The thyroid gland, composed of two central lobes connected by an isthmus, synthesizes the hormones thyroxine (T_4) and triiodothyronine (T_3). These iodine-containing compounds serve as global regulators of the body's metabolic rate, and are also critical for brain development. The release and synthesis of these hormones is controlled ultimately by signals from the CNS.

The hypothalamic-pituitary-thyroid (HPT) axis is composed of three main parts, as its name suggests. The tripeptide thyrotropin-releasing hormone (TRH) (pGlu-His-Pro-NH_2) is synthesized predominantly in the paraventricular nucleus in the hypothalamus and stored in nerve terminals in the median eminence, where it is released into the vessels of the hypothalamo-hypophyseal portal system (Figure VII.4). TRH is then transported to the sinusoids in the anterior pituitary, where it binds to thyrotrophs and releases the peptide thyroid stimulating hormone (TSH) into the systemic circulation. TRH is distributed heterogeneously in the brain, which strongly suggests a role for this peptide as a neurotransmitter as well as a releasing hormone. Thus, TRH itself can produce direct effects on the CNS independent of its actions on pituitary thyrotrophs. The HPT axis exhibits an ultradian rhythm, where TSH secretion, and consequently T_3 and T_4 levels, rise in the afternoon and evening, peak some time after midnight, and decline throughout the day (Veldhuis, 2000).

TSH is a 28-kDA glycoprotein composed of two non-covalently linked protein chains, TSH-α and TSH-β. The α subunit is identical to the α subunit contained in other pituitary hormones, including follicle-stimulating hormone (FSH), luteinizing hormone (LH) and human chorionic gonadotropin. Upon release from the pituitary, TSH circulates through the blood and exerts its effects via binding to the TSH receptor in the thyroid, a G-protein-coupled receptor that stimulates the activation of adenylate cyclase.

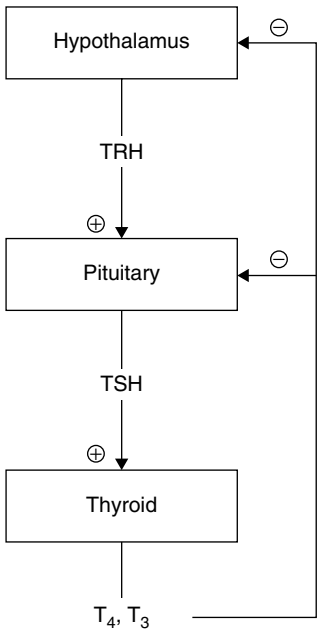

Figure VII.4 Overview of the feedback system of the HPT axis. TRH from the hypothalamus stimulates TSH from the pituitary, which stimulates thyroid hormone release. As circulating thyroid hormone levels increase, they inhibit further release of TSH and TRH. Other hypothalamic-pituitary-end-organ axes exhibit similar feedback control mechanisms

Upon stimulation by TSH, the thyroid gland releases the iodinated amino acids T_3 and T_4. Of the two hormones, T_3 is much more physiologically active. Although debate still exists in the literature, T_4 is often considered a prohormone that becomes active after monodeiodination in peripheral tissues. Thyroid hormones influence gene expression via two major thyroid hormone receptors, TRα-1 and TRβ-1, which in turn bind to specific DNA elements known as thyroid response elements (TREs) located in the promoter regions of a diverse number of genes. These receptors can function as homodimers or bind with other nuclear factors, such as thyroid hormone receptor auxiliary proteins, as heterodimers to modulate the transcription of target genes (Nestler, 2001). T_3 directly regulates the HPT axis by inhibiting TSH release and gene expression in the pituitary and TRH gene expression in the hypothalamus (DeVito, 2000). This is characteristic of the end-product negative feedback seen in the hypothalamic-pituitary-end-organ axes. In the circulation, these hormones are primarily bound to a carrier protein, thyroglobulin, although it is the unbound forms of these hormones that are metabolically active. Thyroid hormones have numerous effects on metabolism, and increase heat production, oxygen consumption, lipid metabolism, intestinal absorption of carbohydrates, cardiac function and the activity of the Na^+/K^+-ATPase. All of these functions are consistent with increasing metabolic rate.

Disorders of the Hypothalamic-Pituitary-Thyroid Axis

Disorders of the HPT axis lead to numerous psychiatric manifestations, ranging from mild depression to overt psychosis. Numerous conditions can lead to hypothyroid states, also known as myxoedema, including CNS causes of decreased TSH or TRH secretion, severe iodine deficiency, thyroid surgery, drugs and autoimmune disorders. The most common cause of hypothyroidism is Hashimoto's thyroiditis, which is due to autoimmune destruction of thyroid tissue. Regardless of the aetiology, hypothyroidism leads to a number of clinical manifestations, including slowed mentation, forgetfulness, decreased hearing, cold intolerance and ataxia. Decreased energy, weight gain, depression, cognitive impairment or overt psychosis ('myxoedema madness') may also result. Due to the overlapping symptoms with clinical depression, thyroid hormone deficiency must be ruled out when evaluating patients with depression.

Hypothyroidism is frequently subclassified into the following groups:

- *Grade 1* hypothyroidism is classic primary hypothyroidism (increased TSH), decreased peripheral thyroid hormone (T_3 and T_4) concentrations, and an increased TSH response to TRH.
- *Grade 2* hypothyroidism is characterized by normal, basal thyroid hormone concentrations, but an increase in basal TSH concentrations and an exaggerated TSH response to TRH.
- *Grade 3* hypothyroidism can be detected only by a TRH-stimulation test. Basal thyroid hormone and TSH concentrations are normal, but the TSH response to TRH is exaggerated.
- *Grade 4* hypothyroidism is defined as normal findings on the three thyroid axis function tests noted above, but the patients have the abnormal presence of anti-thyroid antibodies.

Without treatment, most patients will progress from grade 4 to grade 1 hypothyroidism.

The first treatments for hypothyroidism became available in the 1890s; prior to this, many patients with this condition spent their final days in psychiatric hospitals. One of the earliest descriptions of the effects of treatment with thyroid extracts was reported by Shaw and Stansfield in 1892. These physicians studied the effects of thyroid extracts in a patient suffering from severe thyroid deficiency secondary to trauma to her thyroid gland. Within 10 weeks following treatment with a sheep thyroid extract, the mental signs associated with myxoedema disappeared in this patient and she was discharged (Shaw, 1892). Stansfield followed this patient's progress for several months, and five months after the last injection of thyroid extract symptoms of hypothyroidism began to recur. Following ingestion of additional thyroid extracts, the symptoms were ameliorated again. These results demonstrated clearly the profound psychiatric effects of thyroid deficiency, and provided an early demonstration that treatment of primary endocrine abnormalities can resolve the psychiatric manifestations of the disease (DeVito, 2000).

The first prospective study that scrutinized psychiatric comorbidity in patients with hypothyroidism was carried out by Whybrow and colleagues (1969). In this seminal study, five of the seven patients manifested symptoms of depression at the time of the evaluation, while six of the seven displayed cognitive impairment. Interestingly, of the four patients with depression who were followed, thyroid replacement alone ameliorated the symptoms of depression in all. In a later study, Jain (1972) studied 30 hypothyroid patients; in this study, 13 (43%) of the patients had a clinical depression, ten (33%) had symptoms of anxiety, and eight (27%) were confused. Furthermore, these symptoms were improved or resolved following treatment of the thyroid condition alone. These early studies demonstrated clearly that hypothyroid states have pronounced psychiatric manifestations, predominantly depression and dementia, that can be reversed following thyroid hormone replacement. Later studies have demonstrated varying degrees of cognitive disturbance in up to 48% of psychiatrically ill hypothyroid cases (Boswell, 2001), and approximately 50% of unselected hypothyroid patients have symptoms characteristic of depression (Boswell, 2001). Anxiety symptoms are also common, occurring in up to 30% of unselected patients. Mania and hypomanic states have been reported rarely in hypothyroid patients. Finally, although psychosis is the most commonly reported symptom in the literature on hypothyroidism (52.9%), it accounts for only approximately 5% of the psychiatric morbidity in an unselected sample (Boswell, 2001), presumably due to reporting bias.

Hypothalamic-Pituitary-Thyroid Axis Dysfunction in Patients with Primary Psychiatric Disorders

Excluding patients with primary endocrine disorders, considerable amounts of data have revealed an elevated rate of HPT axis dysfunction, predominantly hypothyroidism, in patients with major depression (Table VII.3). In 1972, research groups led by Prange and Kastin demonstrated that approximately 25% of patients with major depression exhibit a blunted TSH response to TRH (Prange *et al.*, 1972; Kastin *et al.*, 1972). Presumably, this is due to hypersecretion of TRH from the median eminence, which leads to TRH receptor downregulation in the anterior pituitary, resulting in reduced sensitivity of the pituitary to exogenous TRH. This hypothesis seems plausible in light of evidence showing elevated TRH concentrations in the CSF of drug-free depressed patients (Banki *et al.*, 1988). Depressed patients have also been shown to have an increased occurrence of symptomless autoimmune thyroiditis (SAT), defined by the abnormal presence of anti-thyroglobulin and/or antimicrosomal thyroid antibodies consistent with grade 4 hypothyroidism (Nemeroff *et al.*, 1985).

Recently, Duval *et al.* (1996) performed a standard TSH stimulation test at both 8 a.m. and 11 p.m. in depressed patients and normal controls. The difference between the ΔTSH from 11 p.m. and the ΔTSH at the 8 a.m. time point was defined as $\Delta\Delta$TSH. These researchers demonstrated that depressed patients had a much lower $\Delta\Delta$TSH than did controls. Normal HPT axis function returned following remission from depression, but patients who did not respond to antidepressant medication continued to show blunted $\Delta\Delta$TSH. This suggests that treatment with antidepressants *per se* is not responsible for the improvement in HPT axis function.

Table VII.3 HPT axis alterations in depression

↑ CSF TRH in depressed patients
↓ Nocturnal plasma TSH
Blunted TSH in response to TRH stimulation (state-dependent)
Exaggerated TSH response to TRH stimulation
↓ ΔΔTSH (difference between 11 p.m. ΔTSH and 8 a.m. ΔTSH after TRH administration)
Presence of anti-thyroglobulin and/or antimicrosomal thyroid antibodies

Further, patients with the lowest pretreatment evening thyrotropin secretion also had the lowest rate of antidepressant response. This new methodology may serve as a more sensitive method to detect changes in HPT axis function.

Interestingly, Post's group recently measured both cerebral blood flow and cerebral glucose metabolism using positron emission tomography (PET) in both clinically depressed and bipolar patients. Both measures of cerebral activity were correlated inversely with serum TSH levels, and the authors suggested that HPT axis function contributes to primary and secondary mood disorders (Marangell *et al.*, 1997b). Also, the current literature has clearly demonstrated elevated TRH release in some depressed patients, but it is unknown if this is a causative factor in depression. The same group proposed that elevated TRH levels might instead be a compensatory response to depression. In fact, they reported that a lumbar intrathecal infusion of 500 μg of TRH into medication-free inpatients with depression produced a clinically robust, but short-lived, improvement in mood and suicidality (Marangell *et al.*, 1997a). Although this work is preliminary, it does suggest that the development of a systemically administered TRH receptor agonist may represent a novel class of antidepressant agents.

Bipolar Disorder and Hypothalamic-Pituitary-Thyroid Axis Abnormalities

HPT axis abnormalities have also been reported in bipolar disorders. Both elevated basal plasma concentrations of TSH and an exaggerated TSH response to TRH have been demonstrated (Haggerty *et al.*, 1987; Loosen and Prange, 1982). There is also evidence that bipolar patients with the rapid cycling subtype have a higher prevalence rate of hypothyroidism (grades I, II and III) than bipolar patients who do not (Bauer *et al.*, 1990; Cowdry *et al.*, 1983). A blunted or absent evening surge of plasma TSH, a blunted TSH response to TRH (Sack *et al.*, 1988; Souetre *et al.*, 1988), and the presence of anti-thyroid microsomal and/or anti-thyroglobulin antibodies (Lazarus *et al.*, 1986; Myers *et al.*, 1985) have also been demonstrated in bipolar patients.

Treatment of Hypothyroid States

As noted above, thyroid hormone extracts from sheep or cattle were the first treatments used that demonstrated efficacy in ameliorating the signs and symptoms of hypothyroidism. Several synthetic derivatives were introduced in the 1960s that quickly replaced desiccated thyroid tissue for the treatment of patients with thyroid disease. Among these are levothyroxine, synthetic forms of thyroxine (T_4) and liothyronine, and the synthetic levo-rotary isomer of triiodothyronine (T_3). Moreover, due in part to the seminal work carried out by Prange and collaborators in the USA in the 1960s, the use of thyroid hormones in augmenting antidepressant response in depression was established.

Hyperthyroid States

Although a number of conditions, including pituitary adenomas, can lead to hyperthyroid states, the most common non-iatrogenic cause of thyroid hormone excess is Graves' disease. In Graves' disease, the body generates an autoantibody to the TSH receptor, which directly stimulates thyroid follicular cells to secrete excessive amounts of T_3 and T_4. In this state, the normal negative feedback that T_3 and T_4 usually exert on TRH and TSH release is disrupted. The clinical manifestations of thyroid hormone excess are exaggerations of the normal physiological effects of T_3 and T_4, including diaphoresis, heat intolerance, fatigue, dyspnoea, palpitations, weakness (especially in proximal muscles), weight loss despite an increased appetite, hyperdefecation, increased psychomotor activity, and visual complaints. Psychiatric manifestations are also common, including anxiety (13% of unselected cases), depression (28% of patients), and cognitive changes (approximately 7% of patients). Psychotic manifestations and mania are less common, occurring in only 2% of unselected cases. Overall psychiatric morbidity is much less common in hyperthyroid states relative to hypothyroid states (Boswell *et al.*, 2001).

Hypothalamic-Pituitary-Thyroid Axis: Conclusions

Overall, there is clear evidence linking psychiatric symptomatology and thyroid disorders that extends back over 100 years. The observations that hypothyroid patients exhibit symptoms reminiscent of major depression led to a search for thyroid axis abnormalities in patients with affective illness. The efficacy of thyroid augmentation in the treatment of depression (Dording, 2000) and other affective disorders provides further evidence linking HPT axis function and psychiatric illness (Prange, 1996). Although work over the past 40 years has demonstrated a number of HPT axis abnormalities in depressed and bipolar patients, the aetiological connection between these findings remains elusive.

THE HYPOTHALAMIC-PITUITARY-GONAD AXIS

The overall organization of the hypothalamic-pituitary-gonad (HPG) axis is similar to the other major neuroendocrine axes. A 'pulse' generator in the arcuate nucleus of the hypothalamus controls gonadotropin-releasing hormone (GnRH) secretion, which occurs in a pulsatile fashion (Knobil, 1990) at intervals of 60–100 minutes (Nestler *et al.*, 2001). GnRH, previously known as luteinizing hormone-releasing hormone (LHRH), is released into the portal circulation connecting the hypothalamus and anterior pituitary, where it binds to gonadotrophs and promotes the release of LH and FSH into the systemic circulation (Midgley and Jaffe, 1971). These hormones then bind to Leydig cells in the testes to promote testosterone synthesis and secretion from Leydig cells or in the ovaries to promote oestrogen secretion. In females, FSH also promotes the development of ovarian follicles and the synthesis and secretion of androgen-binding proteins and inhibin. Inhibin acts directly on the anterior pituitary to inhibit FSH secretion without affecting LH release. In both sexes, testosterone/oestradiol generated by the testes/ovaries feeds back on the pituitary and hypothalamus to inhibit further FSH, LH and GnRH release. Gonadal steroids, in a similar fashion as glucocorticoids, modulates gene transcription. Gonadal steroids can bind to androgen or oestrogen response elements located in the regulatory regions of specific genes and directly modulate the expression of those genes. Gonadal steroids may also interact with transcription factors such as AP-1 or CREB, in turn influencing the expression of the genes controlled by those transcription factors (Nestler *et al.*, 2001).

Despite the significantly higher rates of depression in women, data on HPG abnormalities in psychiatric disorders remain remarkably limited. Early studies showed no differences in plasma concentrations of LH and FSH in depressed postmenopausal women compared with non-depressed matched control subjects (Nathan *et al.*, 1995). However, a later studied showed decreased plasma LH concentrations in depressed postmenopausal women compared with matched controls (Brambilla *et al.*, 1990). In a more recent study, significantly lower oestradiol levels were detected in women with depression, but the blood levels of other reproductive hormones fell within the normal range (Young *et al.*, 2000). Because oestradiol affects a number of neurotransmitter systems, including noradrenaline and serotonin, these results merit further study.

The response to exogenous administration of GnRH in depressed patients has also been investigated. Normal LH and FSH responses to a high dose of GnRH (250 μg) have been reported in male depressed and female depressed (pre- and postmenopausal) patients (Winokur *et al.*, 1982), whereas a decreased LH response to a lower dose of GnRH (150 μg) has been reported in pre- and postmenopausal depressed patients (Brambilla *et al.*, 1990). Unden and colleagues (1988) observed no change in basal or TRH/LHRH-stimulated LH concentrations in a depressed cohort including both sexes, although depressed males with an abnormal DST response showed a significantly higher increase in FSH compared with the controls.

The prevalence of mood disorders in women, including premenstrual syndrome and post-partum depression, also deserves mention. Premenstrual dysphoric disorder (PMDD) is a cyclic recurrence of symptoms that are both somatic (oedema, fatigue, breast tenderness, headaches) and psychological (depression, irritability, affective liability). The symptoms start following ovulation and disappear within the first day or two of menses, followed by a symptom-free interval between menses and the next ovulation. Although some of these symptoms may occur in all women, in some cases (5–10%), symptoms may be severe enough to interfere with normal functioning, leading to the diagnosis of PMDD (Altshuler *et al.*, 1995). GnRH agonists that produce a 'clinical ovariectomy' by downregulation of GnRH receptors in the pituitary and reduced gonadotropin secretions have been shown to be an effective treatment for premenstrual syndrome (PMS), suggesting that the HPG axis is involved in the manifestation of symptoms (Freeman *et al.*, 1997). However, significant variations in HPG axis function have yet to be identified in women especially susceptible to PMS.

Post-partum mood disorders are also common, occurring in approximately 10% of women after childbirth. Both post-partum depression and the less frequent post-partum psychosis occur with highest prevalence in the first three months after childbirth (Wisner and Stowe, 1997). The timing of these syndromes would suggest that neuroendocrine dysregulation may contribute to the expression of such disorders, but no major abnormalities in HPG axis function were detected in a prospective investigation of post-partum disorders (O'Hara *et al.*, 1990). Additional research on the HPG axis in depression and other mood states is needed.

THE HYPOTHALAMIC-PROLACTIN AXIS

Unlike other anterior pituitary hormones, prolactin release is regulated via tonic inhibition by prolactin-inhibitory factor (PIF), which was later determined to be dopamine. Dopamine neurons in the tuberoinfundibular system of the hypothalamus directly inhibit prolactin release. Prolactin can also inhibit its own release by a short-loop negative feedback to the hypothalamus. Prolactin primarily regulates the behavioural aspects of reproduction and infant care. Serum prolactin levels are normally low through life in males. Basal prolactin levels increase in females following parturition, and suckling stimulates prolactin release. Prolactin itself stimulates breast growth and milk synthesis. TRH, oxytocin, serotonin, oestrogen and other neuroregulators have prolactin-releasing factor (PRF) activity (Fink, 2000).

Excess circulating prolactin can lead to a number of clinical symptoms. The most common causes of hyperprolactinaemia are tumours, usually microadenomas of pituitary lactotrophs, or following treatment with conventional antipsychotic medications because of their potent blockade of dopamine receptors. Hyperprolactinaemia often leads to reduced testosterone secretion in men and a decreased libido in both men and women. Patients may also complain of depression, stress intolerance, anxiety and increased irritability, which usually resolve following treatments that reduce serum prolactin levels. Despite these effects, alterations in the hypothalamic-prolactin axis have not been demonstrated clearly in psychiatric disorders (Nicholas *et al.*, 1998). Because prolactin release is inhibited by dopamine, the prolactin response to infusions of dopaminergic agonists has also been used to estimate CNS dopaminergic tone, although it likely only reflects hypothalamic dopamine neuronal function.

Although abnormalities in prolactin secretion have not been demonstrated clearly in depression *per se*, a large number of reports have used provocative tests of prolactin secretion in patients with psychiatric disorders (for a review, see Van de Kar, 1989). Briefly, these tests use agents that increase serotonergic transmission, e.g. L-tryptophan, 5-hydroxytryptophan (5-HTP) and fenfluramine, among others. In general, the prolactin response to agents that increase serotonergic activity is blunted in depression (Mann *et al.*, 1995; Golden *et al.*, 1992), as well as in patients with cluster-B personality disorders (Coccaro *et al.*, 1997). These data suggest that the blunted prolactin response is mediated by alteration in 5-HT_{1A} receptor responsiveness and that serotonergic transmission in these patients is dysfunctional.

OXYTOCIN AND VASOPRESSIN

Oxytocin and arginine-vasopressin (AVP), also known as antidiuretic hormone (ADH), are nonapeptides synthesized in the magnocellular neurons of the paraventricular nucleus of the hypothalamus and released directly into the bloodstream from axon terminals in the posterior pituitary. This is in contrast to the hypothalamic-releasing factors we have discussed thus far, which are released in the portal system from the median eminence, and distinct from the anterior pituitary hormones that are released following the activation of pituicytes by the releasing factors synthesized in the hypothalamus.

AVP has prominent roles in controlling fluid balance via its effects on the kidney, in regulating blood pressure by its vasoconstrictive effects on blood vessels, and can directly promote the sensation of thirst. AVP also promotes the release of ACTH from the anterior pituitary in the presence of CRF and is released following stressful stimuli (Insel, 1997). In humans, oxytocin is involved predominantly in controlling smooth muscle contraction during parturition (myometrium) and during breastfeeding by mediating milk letdown in lactating mothers. In rodents, oxytocin promotes a number of reproductive (grooming, arousal, lordosis, orgasm, nesting, birthing) and maternal behaviours.

Although there are marked species differences in the effects of oxytocin, central infusion of this peptide in females of a monogamous prairie vole species promotes lifelong pair bonding in the absence of mating. Furthermore, pair bonding in this species, which normally accompanies mating, can be blocked by oxytocin antagonists, thus implicating oxytocin's key role in the expression this lifelong behaviour in some species. Rodent studies have also demonstrated that AVP has a pair-bonding function in males, analogous to the pair-bond-promoting behaviours induced by oxytocin administration in females. AVP promotes monogamy and paternal behaviour in some male prairie vole species. These studies

have led some researchers to speculate that oxytocin and AVP may play a role in psychiatric disorders characterized by disrupted affiliative behaviours, such as Asperger's disease and autism (Insel, 1997). Clearly, more work is needed in order to better understand the function of these two hormones in the human brain.

THE PITUITARY GROWTH HORMONE AXIS

Growth hormone (GH) is synthesized and secreted from somatotrophs located in the anterior pituitary. Its release is unique in that it is controlled by two peptide hypothalamic-hypophysiotropic hormones, growth-hormone-releasing factor (GHRF), also known as growth-hormone-releasing hormone (GHRH) and somatostatin, also known as growth hormone-release-inhibiting hormone (GHIH) or somatotropin release-inhibitory factor (SRIF). Somatotropin was first isolated from ovine hypothalamus in 1974. It is a tetradecapeptide, containing a disulphide bridge linking the two cysteine residues. Somatostatin is released predominantly from the periventricular and paraventricular nucleus of the hypothalamus; it inhibits GH release. Somatostatin has a wide extrahypothalamic distribution in brain regions, including the cerebral cortex, hippocampus and amygdala.

GHRF was characterized and sequenced in 1981 after considerable difficulty. The long-postulated GHRF was discovered several years after the elucidation of the structure of somatostatin, from extracts of an ectopic tumour associated with acromegaly. GHRF is a 44-amino-acid peptide, and has the most limited CNS distribution of all the hypothalamic-releasing hormones that have been identified. GHRF-containing neurons are concentrated in the infundibular and arcuate nuclei of the hypothalamus and stimulate the synthesis and release of GH. Dopamine, noradrenaline and serotonin innervate GHRF-containing neurons to modulate GH release. Both GHRF and SRIF are released from the median eminence into the hypothalamo-hypophyseal portal system, where they act on somatotrophs in the anterior pituitary to regulate GH release. Negative feedback is provided by GH, which stimulates somatostatin release, preventing further GH release. The GH axis is unique in that it does not have a single target endocrine gland; instead, GH acts directly on targets, including bone, muscle and liver. GH also stimulates the release of somatomedin from the liver and insulin-like growth factors.

GH is released in a pulsatile fashion, with highest release occurring around the time of sleep onset and extending into the first non-REM (rapid eye movement) period of sleep (Finkelstein *et al.*, 1972). A variety of stressors, including starvation, exertion and emotional stress, also promote GH release (Nestler *et al.*, 2001). GH is necessary for the longitudinal bone growth that occurs during late childhood; accordingly, GH levels are high in children, reach their peak during adolescence, and decline throughout adulthood. In addition to its effects on the long bones, GH has predominantly anabolic effects and leads to increased muscle mass and decreased body fat.

GH release to a variety of stimuli, including L-dopa, a dopamine precursor (Boyd *et al.*, 1970), apomorphine, a centrally active dopamine agonist (Fink, 2000), and the serotonin precursors L-tryptophan (Muller *et al.*, 1974) and 5-HTP (Imura *et al.*, 1973), has been demonstrated. Several findings indicate dysregulation of GH secretion in depression (Table VII.4). Studies have demonstrated a blunted nocturnal GH surge in depression (Schilkrut *et al.*, 1975), whereas daylight GH secretion seems to be exaggerated in both unipolar and bipolar depressed patients (Mendlewicz *et al.*, 1985). A number of studies have also demonstrated a blunted GH response to the α-adrenergic agonist clonidine in depressed patients (Siever *et al.*, 1982a; Charney *et al.*, 1982). Siever *et al.* (1982b) demonstrated that the blunted GH response to clonidine was not related to age or sex, and this study provided evidence that the diminished GH response to clonidine may be secondary to decreased α_2-adrenergic receptor sensitivity in depression. Using a GHRF stimulation test, our group later demonstrated a slight exaggeration of GH response to GHRF in depressed patients compared with controls, although this group difference was mainly attributable to three of the 19 depressed patients who exhibited markedly high GH responses to GHRF (Krishnan *et al.*, 1988a). Others, however, have reported a blunted GH response to GHRH in depressed patients. Thus, it is unclear whether the blunted GH response to clonidine seen in depression is due to a pituitary defect in GH secretion, further implicating a subsensitivity of α-adrenergic receptors in depression, or to a GHRH deficit. Recently, a diminished GH response to clonidine was demonstrated in children and adolescents at high risk for major depressive disorder. When considered with evidence demonstrating GH dysregulation in childhood depression (Ryan *et al.*, 1994), this suggests that the blunted GH response seen in high-risk adolescents may represent a trait marker for depression in children and adolescents (Birmaher *et al.*, 2000). Arguably, the blunted GH response to clonidine seen in depression may be the most reproducible and specific finding in the biology of affective disorders.

A GHRH stimulation test has also been developed and studied in depressed patients. Two groups have shown a blunted GH response to GHRH in depressed patients (Lesch *et al.*, 1987a; Lesch *et al.*, 1987b; Risch, 1991). However, Krishnan and colleagues (Krishnan *et al.*, 1988a; Krishnan *et al.*, 1988b) found minimal differences in serum GH response to GHRH between depressed and control patients. A comprehensive review of GHRH stimulation tests in depression, anorexia nervosa, bulimia, panic disorder, schizophrenia and Alzheimer's disease was conducted; the authors concluded that the results of this test are not always consistent and in some cases are contradictory (Skare *et al.*, 1994). Factors including the variability of GHRH-stimulated GH among controls, lack of standard outcome measures, and age- and gender-related effects may account for some of this variability. Further studies using GHRH will help develop a standard stimulation test to clarify further the response to GHRH in depression and other psychiatric disorders.

Several studies have demonstrated decreased SRIF levels in the CSF of patients suffering depression (Agren and Lundqvist, 1984; Gerner and Yamada, 1982), dementia, schizophrenia (Bissette *et al.*, 1986) and Alzheimer's disease (Molchan *et al.*, 1993; Bissette *et al.*, 1998). Somatostatin concentrations are also markedly elevated in the basal ganglia of patients with Huntington's disease (Nemeroff *et al.*, 1983), although the implications of this finding are unknown. Somatostatin also inhibits the release of both CRF and ACTH (Brown *et al.*, 1984; Heisler *et al.*, 1982; Richardson and Schonbrunn, 1981) indicating a direct interaction between the GH and HPA axes. No published studies measuring GHRH concentration and GHRH-mRNA expression have been conducted in post-mortem tissue of depressed patients and matched controls, which, in light of the evidence presented here, is of interest. Similarly, CSF studies of GHRH are also lacking.

Table VII.4 GH axis changes in depression

↑ Circulating daily GH levels (uni- and bipolar depression)
↓ Noctural GH in depression
↓ Response of GH to clonidine

SUMMARY AND CONCLUSION

Basic clinical observations of psychiatric disorders associated with primary endocrine disorders such as Cushing's syndrome and

hypothyroidism have led to our broader understanding of the role of neuroendocrine disturbances in a variety of psychiatric disorders, including depression and bipolar disorders. These studies have led to major advances in biological psychiatry by helping to understand the brain circuits involved in the pathophysiology of mood and anxiety disorders. Foremost among these is the CRF theory of depression, which is supported by studies from a variety of disciplines, and which has led to the development of a novel therapeutic approach, namely CRF receptor antagonists. Further, this work has provided a mechanism to explain the increase in depression seen in patients exposed to trauma early in life (first postulated by Freud in the early part of the twentieth century). If CRF truly is the 'black bile' of depression, then CRF antagonists may represent a novel class of antidepressants with a unique mechanism of action from other commonly used antidepressants. Indeed, a number of CRF-receptor antagonists are now in clinical development as novel anxiolytics and antidepressants.

In addition to the HPA axis and CRF alterations observed in depression, HPT axis abnormalities are also very common; the majority of depressed patients, in fact, exhibit alterations in one of these two axes. Furthermore, there is widely replicated blunting of GH response to clonidine and the blunted prolactin response to serotonergic stimuli in depressed patients. Although these studies have not added much understanding to the prevailing monoamine theory of depression, the mechanistic studies that have followed have been remarkably fruitful. It is obvious that the vast majority of studies have been focused on patients with mood disorders, particularly unipolar depression. Clearly, other disorders, including eating disorders, anxiety disorders, schizophrenia and axis II diagnoses, should also be evaluated with similar scrutiny.

The availability of selective ligands that can be utilized with PET will mark the next major leap in our understanding of the neuroendocrine axes in psychiatric disorders. The ability to determine peptide-receptor alterations in the brains and pituitaries of patients with psychiatric disorders will contribute immensely to our understanding of the neurobiological underpinnings of such disorders.

Finally, a growing number of studies have demonstrated that depression is a systemic disease that increases vulnerability to other disorders. Depressed patients demonstrate increased incidence of coronary artery disease and stroke, osteoporosis and, perhaps, cancer. These observations may be attributed, at least partly, to the endocrine alterations observed in depression.

ACKNOWLEDGEMENTS

We would like to thank Tomo Narashima and Julia Knox for their artistic assistance, and we acknowledge support from MH-42088 and the Conte Centre for the Neuroscience of Mental Disorders (MH-58922).

Psychoneuroimmunology: Basic Principles

Ziad Kronfol and Madhavan M.P.N. Nair

Until recently, a chapter on psychoneuroimmunology, particularly in the basic principles part of a book entitled *Biological Psychiatry*, would have appeared as an anomaly. The brain, for a long period of time, has been considered an immunologically privileged organ, with immune responses different in quantity and quality from the rest of the organism. A series of discoveries over the last decade or two has provided us with startling information regarding the immune functions of the brain. The brain, we now know, plays an important role as a regulator of immune responses. We also know that this relationship is bidirectional, with the immune system also serving as a sensory organ, relaying to the brain important information about the internal milieu, particularly the presence or prevalence of invading micro-organisms and changes in antigenic properties. Furthermore, the brain influences immune responses not only directly but also through the endocrine system and the autonomic nervous system. In fact, interactions between cells and the products of nervous, immune or endocrine origins, and their clinical implications in health and disease, constitute a major focus of the field of psychoneuroimmunology today.

The goal of this chapter is to provide the reader with an overview of major advances in psychoneuroimmunology that may be of relevance to the general psychiatrist/clinical neuroscientist. Because most psychiatrists are not very familiar with the field of immunology, we provide a very brief introduction to basic immunological principles, including a distinction between innate and adaptive immune responses, as well as a summary of major principles in immune physiology. This section will also include a brief description of common laboratory tests, particularly those that are used frequently to assess immune functions in clinical psychoneuroimmunology. The following section deals with neural-immune interactions, stressing the bidirectional nature of these interactions. First, we summarize the neural effects on immune regulation, focusing on autonomic innervation of immune tissues and neurochemical, neuroendocrine and behavioural effects on different immune functions. Then we review the effects of changes in immune activity on central nervous system (CNS) function, again emphasizing neurochemical, neuroendocrine and behavioural effects. Both animal studies and human investigations are covered. We then turn our attention to the mediators of these neural-immune interactions, particularly neurotransmitters, neurohormones and cytokines. The chapter ends with a review of important clinical implications, particularly the role of stress in immune-related disorders on the one hand and the possible role of immune factors in the aetiology of psychiatric disorders on the other.

As with most other chapters in the first part of this book, this chapter presents an overview of basic principles, in this case the basic principles of psychoneuroimmunology. For some readers, the information may be rudimentary; for others, it may appear too advanced. Because of space limitation, we have refrained from detailed discussion of specific topics, suggesting to the reader specific references instead. Our hope is that the chapter will provide enough background information to allow the reader better appreciate the clinical syndromes that are discussed in detail in the second part of the book.

Neuroimmunological processes may play a role in the aetiology of various psychiatric disorders. They may also play a role in the pathophysiology of specific psychiatric symptoms. An understanding of basic principles in psychoneuroimmunology and an appreciation of the constant dialogue between the brain and the immune system are therefore warranted.

OVERVIEW OF IMMUNE PRINCIPLES

The word 'immunity' is derived from Latin, meaning protection from foreign substances, mainly against infectious and non-infectious agents and cancer. The organized system that consists of cells and molecules specialized in mounting defence against infection or insult is called the immune system, and the collective and coordinated response induced by the immune system against any infection or insult is called the immune response. The immune system operates in two fundamentally different ways: the natural or innate immune response, and the acquired or adaptive immune response. The extent of natural or innate immune response occurs essentially at the same degree or level every time an infection or insult to the body occurs, whereas the acquired or adaptive immune response increases in magnitude with repeated episodes of infection or insult.

The Innate Immune Response

The innate immune responses provide the first line of defence against infection or insult in the host. The main components of this system include both molecular and cellular elements. The cellular components include epithelial cells, basophils, mast cells, eosinophils and phagocytic cells such as neutrophils, monocytes, macrophages and natural killer lymphocytes. A key member of the cellular innate immunity is represented by the interdigitating dendritic cells, such as Langerhans' cells, which are located in the epithelia of the skin and the gastrointestinal and respiratory systems, and are heavily involved in the endocytosis of microbes (Bell *et al.*, 1999). Dendritic cells are functionally immature; however, as they migrate to the lymph nodes, they mature and become extremely efficient at presenting antigen to the T-cells to initiate an adaptive immune response.

Another prominent member of the cellular innate immune system is the natural killer (NK) cell (Biron *et al.*, 1999). The term 'natural killer' originates from the fact that these cells can kill certain target cells naturally or spontaneously without any previous activation. These cells derive from bone marrow precursors, and

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

appear as large lymphocytes with numerous killer granules in their cytoplasm. NK cells can essentially be activated by three types of targets, namely antibody-coated target cells, cells infected with virus or intracellular bacteria, and cells lacking class 1 major histocompatibility complex (MHC) molecules. One of the most unusual specificities of NK cells is their inability to kill normal cells by virtue of the fact that most normal cells express class 1 MHC molecules. It is not known what activating receptors are involved in NK-mediated cytotoxicity. However, it is believed that NK cell activation is controlled by signals that are being generated between killer inhibitory and killer activating receptors that are characteristic of NK cells (Lanier, 1998).

The molecular basis of the innate immune response involves the complement system, acute-phase proteins and cytokines. The complement system consists of several blood proteins that help to develop inflammation and link effector cells to the site of microbial invasion. The complement usually operates through one of three different pathways: the classical pathway is activated by antigen–antibody complex, the alternative pathway is triggered by microbial antigen, and the lectin pathway is triggered by the interaction between mannose-binding lectin in the plasma and microbial carbohydrates. Irrespective of the pathway of complement activation, the final result is the formation of lysis complex on the membrane of the target, which leads to the death of the target cell.

The acute-phase proteins are plasma proteins. Their levels change rapidly in response to trauma, injury or inflammation. These proteins help to magnify the resistance to infection and promote the repair of tissue damage. Acute-phase proteins include complement components, haptoglobin, C-reactive proteins, serum amyloid A protein, protease inhibitors and coagulation proteins. These plasma proteins can recognize certain unique receptor structures present on invading microbes and thus afford protection to the host from these invading microbes. Further, mediator molecules of the innate immune response also stimulate and regulate the adaptive immune response. The acute-phase proteins appear in early stages of infection, and the hepatic synthesis of these molecules is upregulated by inflammatory cytokines, especially interleukin 1 (IL-1), interleukin 6 (IL-6) and tumour necrosis factor-α (TNFα).

Cytokines represent another group of soluble immune mediators produced by both innate and adaptive immune cells in response to microbes and other antigen (Mire-Sluis and Thorpe, 1998). They act as an integrated network within and between humoral and cellular immune systems. They function at two main phases of the immune response, namely at the activation phase to stimulate the growth and differentiation of lymphocytes, and at the effector phase to eliminate infectious agents and foreign antigens. Because most of the cytokines are produced by leukocytes and act mainly on leukocytes, they are also called interleukins (incorrectly, because cytokines are also produced by non-leukocytes and act on cells other than leukocytes, as will be discussed later in this chapter). There are at least 21 different types of cytokines that have been cloned and characterized. They include interleukins 1–18 (IL-1–IL-18) in addition to other cytokines, such as TNFα tumour necrosis factor β (TNFβ), transforming growth factor β (TGFβ), granulocyte-macrophage colony-stimulating factor (GCSF), and interferons α, β and γ (IFN α, β and γ). In addition, another family of structurally homologous cytokines, called chemotactic cytokines, which stimulate or regulate leukocyte movements from blood to tissue, also participate in the innate immune response. The roles of cytokines in innate immunity and inflammation vary depending on the nature of microbes, such as extracellular or intracellular bacteria or lipopolysaccharide (LPS)-producing bacteria or viruses. Table VIII.1 describes the major cytokines and their sources, along with major biological functions in innate and adaptive immune responses.

Table VIII.1 Major cytokines with cellular sources and major biological activities

Cytokine	Cellular sources	Major biological functions
Innate immunity		
IL-1	Macrophages, endothelial cells	Inflammatory responses
IL-6	Th_2 helper cells, endothelial cells	Induces acute-phase proteins, B-cell differentiation
IL-8	Leukocytes, endothelial cells, epithelial cells, fibroblasts	Promotes leukocyte recruitment and inflammation
IL-10	Th_2 helper cells, macrophages	Inhibits IL-12 production Induces class 11 MHC molecules Stimulates B-cells
IL-11	Bone marrow stromal cells	Induces acute-phase proteins
IL-12	Macrophages, B-cells, dendritic cells	Induces IFNγ/cytotoxic reactions Th_1 differentiation
IL-15	Macrophages and other cells	Stimulates NK cells and T-cells
IL-18	Macrophages	Stimulates IFNγ production
TNFα	T-cells, B-cells, NK cells, macrophages, mast cells	Induces inflammation, apoptosis
IFNα	Macrophages	Viral resistance, MHC-1 molecules
IFNβ	Fibroblasts	Viral resistance, activates NK cells
Adaptive immunity		
IL-2	Th_1 helper cells	Induces T-/B-cell proliferation/clonal expansion Activates NK/macrophages Induces apoptosis
IL-4	Th_2 cells, mast cells, basophils, eosinophils	Th_2 cells differentiation, IgE class switching Activates monocytes
IL-5	Th_2 cells, mast cells, eosinophils	Eosinophil differentiation, B-cell proliferation Produces IgA
IL-13	Th_2 cells, epithelial cells	Suppresses macrophage activation
IFNγ	Th_1 cells, CD8 and NK cells	Inhibits Th_2 helper Activates macrophages, epithelial and endothelial cells Stimulates MHC-11 molecules Increases antigen presentation
TGFβ	T-/B-cells, macrophages, mast cells	Promotes immunosuppression/macrophage inhibition

The Adaptive Immune Response

The acquired or adaptive immune response traditionally has been divided into humoral immunity and cell-mediated immunity. The humoral immune response is mediated primarily by antibodies that can be transferred from an immunized donor to a naive host in the absence of cells. The effector phase of the humoral immune response involves the neutralization of extracellular microbes or toxins that are accessible to antibodies. The cell-mediated immune response (CMI) can be transferred by viable T-lymphocytes. The effector phase of the CMI involves the recognition of the antigen present on the surface of the cells or invading organism in the presence of self MHC molecules. CMI also eliminates foreign cells such as tumour or neoplastic cells or foreign MHC antigen such as allograft. T-cells also stimulate macrophages to become cytotoxic cells through cytokine production; these activated macrophages thus eliminate microbes that reside within the phagosomes.

The main cellular components of the adaptive immune system are B-lymphocytes and T-lymphocytes. B-cells recognize extracellular and cellular surface antigens and differentiate into antibody-secreting plasma cells. B-lymphocytes are the only cells capable of producing antibodies. The T-lymphocytes are divided further into the functionally distinct classes of helper T-cells and cytotoxic T-cells (Figure VIII.1). Helper T-cells secrete cytokines, whose function is to stimulate T-cells and other cells to eliminate microbes and other foreign antigens. Based on the profile of cytokines secreted, helper T-cells have also been divided into Th_1 and Th_2 cells. Th_1 cells secrete cytokines such as IL-2, IL-12 and IFN, which promote mostly cellular immune responses. Th_2 cells secrete cytokines such as IL-4, IL-6 and IL-10, which promote mostly humoral immune responses. The clinical value of such a distinction, however, has been questioned by some investigators. Another class of T-cells has been identified as suppressor T-cells, whose main function is to inhibit immune responses.

The adaptive phases of the immune response may be divided into different events, such as recognition of antigen, activation of lymphocytes, and finally elimination of the antigen. In the recognition stage, each foreign antigen is being recognized by specific lymphocytes, which proliferate and differentiate into memory cells that show enhanced immune response on subsequent exposure to antigen. In the effector phase, the antibodies and T-lymphocytes participate to eliminate the microbes or antigens. In addition to T-cells and antibodies, mediators of the innate immune system such as non-lymphoid cells, complement, phagocytes and other soluble mediators take part in the effector phase of the adaptive immune response.

The cardinal features of both the cell-mediated and humoral immune responses are specificity, diversity, memory and tolerance.

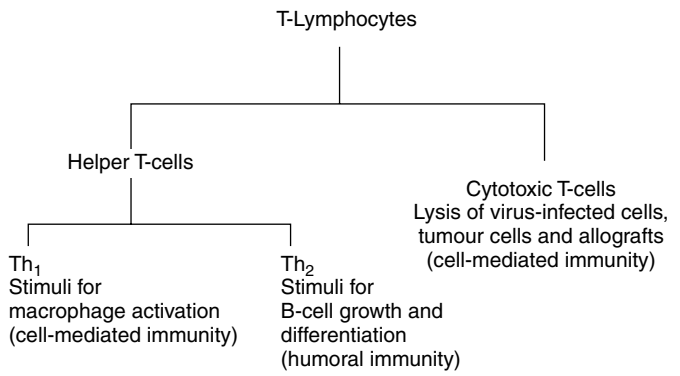

Figure VIII.1 T-lymphocyte subsets

The specificity refers to the distinct immune response for each antigen or each structural component of a complex protein, or any subtle differences in antigenic profile of a given macromolecule. The diversity enables the immune system to react to an array of microbes or invading stimuli simultaneously. Immunologic memory refers to the ability of the host's immune system to 'recall' a prior exposure to a particular antigen or microbe, and to react to it in an enhanced fashion. Both T- and B-cells play a significant role in this process. Tolerance refers to the remarkable feature of the normal immune system to recognize invading microbes or antigens and mount an efficient immune response against them, while at the same time not reacting harmfully to the self-antigenic system. Disorders of tolerance often lead to autoimmune diseases.

Methods Commonly Used in the Laboratory to Measure Immune Functions

Since the immune system can be divided mainly into humoral and cellular components, several assays are currently employed to measure these two immune functions (Lowell, 1990; Abbas *et al.*, 2000). Assays to measure the B-cell functions or humoral immune functions are separate from T-cell and other cellular immune functions. However, since both immune components and their soluble mediators, such as cytokines, chemokines and other immunoregulatory factors, are closely interlinked, the quantitative assessment of different immune functions is often quite interdependent. The widespread use of monoclonal antibodies has improved dramatically the method of antigen detection that forms the basis of antigen–antibody binding reactions. All modern antigen and antibody reactions are quantitated by an indicator molecule that is labelled with either a radioisotope (radioimmunoassay [RIA]) or an enzyme (enzyme-linked immunosorbent assay [ELISA]). Antibodies can also be used to purify proteins; the commonly used methods are immunoprecipitation and affinity chromatography. Western blot is commonly used to determine the size and the presence of proteins in biological fluids. The common methods to identify antigens expressed on given populations of cells, or to sort out a population of cells bearing a particular antigen (such as a specific cluster of differentiation (CD) antigen), utilize enzyme-linked or fluorescent-labelled antibodies by flow cytometry, fluorescence-activated cell sorting and immunofluorescence or immunohistochemistry techniques. Flow cytometry is one of the most commonly used assays in the clinical immunology laboratory; it allows for the sorting out and enumeration of T-cells (CD_3+), T-helper cells (CD_4+), T-suppressor cells (CD_8+), NK cells ($CD_{56}+$), and others.

The most commonly used clinical laboratory methods to detect cellular immunity are leukocyte phenotyping, delayed hypersensitivity skin testing, lymphocyte activation assays, cytokine production assays, and neutrophil function assays. Leukocyte phenotyping allows the quantification of cells carrying a specific antigen, as described above. This is usually done today using flow-cytometry technology. The delayed-type hypersensitivity skin testing is an *in vivo* test used primarily to assess immune competence and to test the memory T-cells that recognize a prior exposure of an antigen or infection. Lymphocyte activation assays are designed to determine the changes on the cell-surface markers and the ability of lymphocytes to undergo stimulation or proliferation in response to activation by a specific antigen, a mitogen such as phytohaemagglutinin (PHA) or concanavalin-A (Con A), or an endotoxin such as LPS.

Activation of lymphocytes also leads to the synthesis of cytokines and generation of cytotoxic cells. The production of cytokines in cells can be measured by ELISA or enzyme-linked immunospot (ELISPOT). Cytotoxicity can be measured by cytotoxic assays, such as cytotoxic T-cell (CTL), NK and antibody-dependent cellular cytotoxicity (ADCC) assays. Quantification of monocytes and macrophages, which are the essential components

of the innate immune system, can be made by the flow-cytometry method and histochemical staining for nonspecific esterase. Polymorphonuclear neutrophils (PMNs), which are the primary effector cells of the innate immune system, can be measured by neutrophil adhesion, chemotaxis, phagocytosis, and determination of respiratory burst and degranulation assays.

In recent years, advances in biomedical technology have permitted the characterization, expression, synthesis and modulation of various genes of interest in cells using molecular techniques. Southern blot hybridization is used to study the DNA profile, while Northern blot has been used to analyse the mRNA of the genes. The latest method of copying and amplifying specific DNA sequences is called polymerase chain reaction (PCR); this is used widely in molecular immunology. The most widely used *in vivo* methods for studying the functional effects of specific genes in immunology involve transgenic and gene-knockout animal models. In the case of transgenic models, a particular gene of interest can be overexpressed in a defined tissue, whereas in knockout models the function of a particular gene is knocked out by targeted mutation or disruption of the gene. The resultant changes in biological and/or clinical properties associated with the gene can then be assessed.

NEURAL-IMMUNE INTERACTIONS

Neural Effects on Immune Regulation

Autonomic Innervation of Immune Tissues/Organs

The immune system, while complex and intricately regulated, is not completely autonomous. Recent studies show that immunological processes can be influenced by signals from the central and/or peripheral nervous system. This is evidenced by the autonomic innervation of lymphoid tissue and organs, including thymus, bone marrow, spleen and lymph nodes. Work regarding the innervation of lymphoid tissue has been reviewed extensively by Bellinger *et al.* (2001). For most of these organs, there is evidence of autonomic innervation, with sympathetic, parasympathetic and/or peptidergic supply, as well as sensory innervation. The thymus, for instance, gets its sympathetic innervation from postganglionic cell bodies in the upper paravertebral ganglia of the sympathetic chain, mostly the upper superior cervical and stellate ganglia (Tollefson and Bulloch, 1990). Other innervation includes fibres from the vagus nerve, the phrenic nerve, and the recurrent laryngeal nerve (Bulloch and Pomerantz, 1984). The sympathetic innervation of the thymus is predominantly noradrenergic. Noradrenergic fibres enter the thymus mostly along blood vessels. They can form a dense plexus around the vessels or branch into the parenchyma, and can be found adjacent to thymocytes. Experimental studies suggest that noradrenaline affects the maturation of thymocytes. Through its action in β-adrenoreceptors, this catecholamine can inhibit proliferation and enhance differentiation (Singh, 1985a; Singh, 1985b). Cholinergic supply presumably provided through the vagus nerve appears weak and of doubtful clinical significance.

Nerve supply to the bone marrow is provided through the appropriate branch of the spinal nerve supplying the same region (Tokunaga, 1967). Most, if not all, of the nerve supply to the bone marrow appears to be noradrenergic (DePace and Webber, 1975). Sympathetic nerve fibres in bone marrow are usually associated with blood vessels. They are thought to be mostly vasomotor, controlling blood flow to the bone marrow.

The innervation of the spleen has been studied more extensively than other lymphoid organs. For a long time, the splenic nerve has been known to be rich in sympathetic nerve fibres (Elfvin, 1961). There is extensive noradrenergic innervation of the spleen, particularly in association with spleen vasculature and the smooth muscle of the capsule and trabeculae (Reilly, 1985). The functional aspects of this dense noradrenergic supply are not understood completely. In addition to the vasomotor component, there are probably complex neural-immune interactions that need to be defined more clearly; data remain rather slim regarding cholinergic innervation of the spleen.

There is also scattered evidence of innervation to lymph nodes and other lymphoid tissue (Felten *et al.*, 1984). As with other immune organs, the innervation could be noradrenergic, cholinergic or peptidergic in origin. There is also evidence of possible sensory innervation of different immune organs (Baron and Janig, 1988). More recently, efforts have been under way to describe lymphoid innervation not so much in anatomical terms, but more with regard to neurochemical pathways and their functional significance. More research is needed for a complete mapping of these networks.

Neuroendocrine Effects on Immune Function

The immune system and the endocrine system are tightly interconnected. There are several lines of evidence for these close interactions: (1) Immune cells express receptors for several hormones, such as cortisol, corticotrophin-releasing hormone (CRH), enkephalins, endorphins and neuropeptide Y (Schafer *et al.*, 1997; Malmstrom, 2001). (2) Both hormones and neurotransmitters, such as adrenaline, noradrenaline, dopamine and acetylcholine, affect immune function both *in vitro* and *in vivo* (McEwen *et al.*, 1997; Madden, 2001). (3) Surgical manipulations involving endocrine organs, such as hypophysectomy, thyroidectomy, adrenal removal or gonadal ablation, produce specific and predictable changes in the immune response (Goujon *et al.*, 1996). (4) Several immune parameters have intrinsic biological rhythms, usually circadian, that seem to be connected with the circadian rhythm of cortisol, albeit with a time lag of varying magnitude (Kronfol *et al.*, 1997). (5) Many immune cells are capable, under specific conditions, of secreting neurohormones that can influence directly or indirectly immune function through special feedback loops (Goetzl *et al.*, 1991). (6) Products of immune activation, such as cytokines, have well-documented neuroendocrine properties, such as hypothalamic-pituitary-adrenal axis (HPA) activation, which ultimately downregulates the immune response and prevents an excessive or exaggerated response from spiralling out of control (Sapolsky *et al.*, 1987; McEwen *et al.*, 1997). (7) Glucocortisoids have often been used successfully to treat immune-related disorders, such as rheumatoid arthritis, multiple sclerosis, and systemic lupus erythematosus (LSE) (Kirwan, 1995). A detailed discussion of the immunological effects of various hormones is beyond the scope of this chapter; however, Table VIII.2 presents a summary of the *in vivo* and *in vitro* effects of glucocorticoids.

Effects of Brain Lesions on Immune Function

The production of specific lesions using stereotaxis procedures was among the earliest strategies to study central sites underlying

Table VIII.2 Effects of glucocorticoids on immune function

Affect leukocyte trafficking
Inhibit leukocyte migration and activation
Produce lymphopoenia
Inhibit lymphocyte proliferative responses
Inhibit NK and ADCC cytotoxic activities
Inhibit proinflammatory cytokine production
Produce a shift in Th_1/Th_2 balance
Inhibit polyclonal B-cell activation and immunoglobulin synthesis
Inhibit delayed hypersensitivity
Activate oncogenes

brain–immune system communications. Although somewhat primitive, this strategy provided a first insight into the potential brain circuitry underlying CNS–immune system communications. For instance, lesions in the anterior hypothalamus have been associated with a decrease in nucleated spleen cells and thymocytes (Brooks *et al.*, 1982), a decrease in proliferative T-cell responses to mitogen stimulation (Brooks *et al.*, 1982), a decrease in NK cell activity (Cross *et al.*, 1984), a decrease in antibody production (Tyrey and Nalbandov, 1972), and an inhibition of a lethal anaphylactic response (Stein *et al.*, 1981). These studies suggest that the anterior hypothalamus is implicated, either directly or indirectly, in the stimulation of both humoral and cell-mediated immune responses. Lesions of the medial or posterior hypothalamus have provided mixed results. Lesions in the limbic forebrain structures (e.g. dorsal hippocampus or amygdala) resulted in transient increases in splenocytes and thymocytes, as well as T-cell proliferative response to mitogen (Cross *et al.*, 1982). Some of these results could be reversed by hypophysectomy, suggesting that neuroendocrine pathways play an important role. Furthermore, work by Renoux and colleagues suggests that lesions in the cerebral cortex can affect immune regulation, and that there seems to be a lateralization effect, since lesions in the left cerebral hemisphere of mice were associated with decreased T-cell responses, whereas lesions in the right cerebral hemisphere produced increased T-cell responses (Renoux *et al.*, 1983; Renoux *et al.*, 1987). The notion that brain lesions can affect immune responses leads to the next question: can psychological stress have a similar effect? The behavioural effects on immune function are discussed next.

Behavioural Effects on Immune Regulation

It has been known for many years that stressed animals are more susceptible than non-stressed animals to developing infections following exposure to an infectious organism. The reasons for this increased susceptibility have never been very clear. With the influx of data showing extensive interactions between the brain and the immune system, the effects of stress on immune regulation became an important and fertile area for research investigation. Keller *et al.* (1981) showed that both lymphocyte numbers and function (response to mitogenic stimulation) were decreased in animal models of stress (foot shock). Further, they showed that intensity of the stressor, timing, duration, and control over the stressor were all important variables that could influence the overall effect of stress on immune function (Keller *et al.*, 1984). Another source of variation in these studies was the origin of the cells being investigated, since studies have also shown that the stress effects on lymphoid tissues derived from different compartments often differ substantially. Other experiments using restraint/immobilization stress, forced swim, maternal deprivation, and other stressors yielded mixed results. An intriguing and still somewhat unresolved issue is the notion that stress can also enhance certain immunological parameters (Lysle *et al.*, 1990; Shurin *et al.*, 1994). Dhabbar and McEwen (1997) proposed an interesting paradigm whereby acute stress stimulates certain components of the immune system, while chronic stress suppresses those same parameters. They argued that from an evolutionary perspective, an acute or fresh attack by a predator requires a strong immunological response to prevent the spread of infection, but if the stress becomes chronic, then a weakened immune response may be an advantage to the organism since it shifts limited resources away from the immune system and into more important organs, such as the muscles and the heart (Dhabbar and McEwen, 2001).

Human studies exploring the effects of stress on immune function have also been conducted (for a comprehensive review, see Biondi, 2001). The types of stressors used in these studies are either real-life stressors (e.g. bereavement, natural disaster such as earthquake or hurricane, academic examination, divorce, unemployment) or experimental stressors (e.g. mental challenge, sleep deprivation, acute overexertion). Many of the immune parameters were essentially the same as with the animal studies, notably enumeration of leukocyte and lymphocyte subsets, *in vitro* lymphocyte responses to mitogen stimulation, NK cell activity and cytokine production; again, results vary. Kiecolt-Glaser and colleagues, in a series of experiments, found that medical students had lower immune function indices the morning of a medical school examination compared with other less stressful mornings (Kiecolt-Glaser *et al.*, 1986). They also found that stress can modulate the immune response to vaccine (Glaser *et al.*, 1998). The same investigators have also found that wound healing was delayed (Kiecolt-Glaser *et al.*, 1995), and cytokine production within the wound decreased (Glaser *et al.*, 1999), in chronic caregivers to patients with Alzheimer's disease compared with non-stressed controls. Other investigators, however, have found the same immune parameters to be either increased or unchanged in association with similar or other stressors (Biondi, 2001). Therefore, it has been suggested that other factors besides the nature of the stressor, such as personality characteristics of the individual, amount of social support, and coping skills, all play a role in the immunological response to a specific stressor. As in the case of animal studies, more research is needed to elucidate the mechanisms of stress-induced immunomodulation. Another unresolved issue is the clinical significance of such changes. Any association between stress-induced immune changes and the risk of developing an immune-related disorder, such as infection or cancer, remains very tentative at best.

Immunological Influences on Central Nervous System Activities

Neural-immune interactions are bidirectional in nature. Not only does the CNS affect immune regulation, but recent evidence also indicates that the immune system influences different CNS functions. In the following sections we will briefly review the neurochemical, neuroendocrine and behavioural effects of immunological stimulation.

Neurochemical Effects

It is well known that viral infections produce specific changes in animal brain chemistry. The mechanisms of such changes, however, have been elucidated only recently. Controlled administration of Newcastle disease virus to mice was shown to alter the levels of several neurotransmitters and their metabolites in specific brain regions. More specifically, 3-methoxy-4-hydroxyphenylglycol (MHPG) and MHPG : noradrenaline ratios, an index of activation of noradrenergic neurons, dihydroxyphenylacetic acid (DOPAC) and DOPAC : dopamine ratios, an index of activation of dopaminergic neurons, and 5-hydroxyindoleacetic acid (5-HIAA) and 5-HIAA : 5-hydroxytryptamine (5-HT) ratios, an index of activation of 5-HT neurons, were all increased in a number of brain regions (Dunn *et al.*, 1987; Dunn and Vickers, 1994). Dunn and colleagues also showed a great similarity between the neurochemical responses to infections and other stressors, such as foot shock and physical restraint (Dunn *et al.*, 1999). Similar results were also obtained with the endotoxin LPS, particularly in relation to noradrenaline. *In vivo* microdialysis studies indicated increased extracellular concentrations of dopamine, DOPAC, noradrenaline, 3,4-dihydroxyphenylethyleneglycos (DHPG), MHPG and 5-HIAA in the medial prefrontal cortex and hypothalamus following LPS administration in rats (Lavicky and Dunn, 1995). Linthorst and colleagues, using similar techniques, found an increase in 5-HT in the hippocampus (Linthorst *et al.*, 1996) and increases in noradrenaline, MHPG, 5-HT and 5-HIAA in the preoptic area (Linthorst *et al.*, 1995). The effects of peripherally administered cytokines on

the turnover of specific brain neurotransmitters have been reviewed (Dunn *et al.*, 1999). IL-1, for instance, seems to be associated with an increased turnover of noradrenaline and 5-HT, IL-2 increases the turnover of noradrenaline and dopamine, IL-6 increases the turnover of 5-HT but not noradrenaline or dopamine, and IFN seems to produce no significant changes in any of these neurotransmitters.

Neuroendocrine Effects

The notion that infection is accompanied by an increase in glucocorticoid secretion is not new (Wexler *et al.*, 1957). However, this has recently been reinforced by experiments such as those described above with the Newcastle virus and showing stimulation of the HAP axis along with specific neurochemical changes (Dunn and Vickers, 1994). Here, again, the mechanism of these interactions has been elucidated only recently. The involvement of immune cells was first illustrated by the early experiments of Besedovsky *et al.* (1975), showing that the injection of sheep red blood cells into rats produced an increase in the level of glucocorticoid. The authors subsequently reported that supernatants from ConA-stimulated rat spleen cells administered into rats also produced an increase in the plasma levels of corticosterone (Besedovsky *et al.*, 1981). This was a clear demonstration that the activation of the neuroendocrine system was due to an immunogenic rather than a pathogenic mechanism. The bioactive product responsible for stimulating the HPA axis was identified later as the cytokine IL-1 (Berkenbosch *et al.*, 1987; Bernton *et al.*, 1987; Sapolsky *et al.*, 1987). It is now believed that IL-1 acts directly in the CNS to stimulate the HPA system. In addition to stimulating the release of CRH, there is also evidence that IL-1 acts directly on corticotrophs to induce the secretion of adrenocorticotropic hormone (ACTH) (Woloski *et al.*, 1985) and indirectly to produce excess glucocorticoids. The action of excess glucocorticoids on immune cells can result in downregulation of the immune response, thus providing a negative feedback to sometimes exaggerated and possibly damaging immune reactions (Table VIII.2) However, it is important to keep in mind that the effects of glucocorticoids on immune function are not always inhibitory, and that immune stimulation can occur under certain conditions (Dhabbar and McEwen, 2001). Immune responses can also affect other neuroendocrine pathways, such as the hypothalamic-pituitary-thyroid (HPT) axis (Rivier, 1993) and the hypothalamic-pituitary-gonadal (HPG) axis (Rivest and Rivier, 1993). There are also reports of interactions between growth hormone and the immune system, leaving some investigators to wonder whether growth hormone and insulin-like growth factor can be considered as cytokines (Venters *et al.*, 2001).

Behavioural Effects

As any patient knows, sickness is often accompanied by a number of behavioural attributes, such as apathy, fatigue, lack of motivation, and lack of concentration. Other attributes may include disturbed sleep, decreased appetite, or decreased sex drive. These symptoms have traditionally been considered a 'psychological reaction' to being ill. Research, however, indicates that many of these symptoms can be reproduced through the action of proinflammatory cytokines. Animal studies indicate that central or peripheral administration of IL-Iα, IL-1β or TNFα to healthy laboratory animals produces fever, activation of the HPA axis, and behavioural symptoms, such as a decrease in social exploration (Kent *et al.*, 1992), a decrease in night-time feeding (Plata-Salaman *et al.*, 1996), and an increase in delta-sleep (Krueger and Majde, 1994). For many of these cytokines, the association with the particular behaviour is dose-dependent, and tends to be abolished if the cytokine is heat-inactivated or given with its receptor antagonist, suggesting an important role for the specific cytokine in the pathophysiology of the specific behaviour.

Human studies addressing the behavioural effects of cytokines have been somewhat limited in scope because of ethical and safety considerations. However, because cytokine therapy, particularly IL-2 and IFN, has been used for a variety of medical conditions, investigators have been able to assess the behavioural effects of cytokines in these patients. Because of their antiviral as well as antiproliferative and immunomodulatory properties, interferons are now being used effectively in the treatment of several medical conditions, including malignant melanoma, hepatitis C and multiple sclerosis. The most common side effects include flu-like symptoms, such as fever, malaise and arthralgia. These side effects occur early in treatment and tend to decrease in intensity as treatment continues. Other side effects affecting roughly one-third of the patients on interferon are neuropsychiatric or behavioural in nature, and include mood changes (depression, anxiety, manic-like symptoms, irritability, and even suicidal behaviour), cognitive changes (decreased concentration, memory disturbance, delirium) and, rarely, psychosis. IL-2 and lymphokine-activated killer (LAK) cells have been used in the treatment of metastatic malignancies. In one longitudinal study, up to 50% of patients experienced severe cognitive and/or behavioural adverse effects (Denicoff *et al.*, 1987) that were dose-related but usually reversible. While the exact mechanism for these neuropsychiatric manifestations is not well understood, it is believed that cytokines interact with neurotransmitters and neurohormones to produce these adverse effects. Furthermore, in human experiments aimed at assessing directly the behavioural effects of cytokines, healthy volunteers were given LPS injections under controlled conditions. The associated rise in IL-1β and TNFα was accompanied by a significant increase in depressed mood and a significant decline in cognitive performance. There were also significant correlations between the change in the levels of these cytokines and the change in the associated behavioural measures (Reichenberg *et al.*, 2001).

MEDIATORS OF NEURAL-IMMUNE INTERACTIONS

Now that bidirectional communication between the brain and the immune system has been well established, the next important question relates to the mediators of these interactions. This section will summarize the role that neurotransmitters/neurohormones and cytokines play in this communication network.

Neurotransmitters and Neurohormones

As mentioned earlier, immune tissues and organs are innervated by the autonomic nervous system. Neurotransmitters such as adrenaline/noradrenaline, dopamine, serotonin (5-HT) and acetylcholine play a role in immunomodulation. Neurotransmitter receptors are found in most lymphoid cells. The functional evidence is based on both *in vivo* and *in vitro* findings using pharmacological agonists and antagonists selective for specific neurotransmitter subtypes. In addition, data have been presented to confirm the presence of the receptor at the cellular level using radioligand binding analysis and at the molecular level using reverse-transcription PCR and Northern analysis (for a comprehensive review, see Sanders *et al.*, 2001). Adrenergic receptors, for instance, can be found on thymic cells, bone marrow cells, T-cells, B-cells, NK cells and macrophages. Although results vary, β-adrenergic stimulation seems to increase bone marrow cell proliferation *in vivo* (Lipski, 1980), decrease *in vitro* thymic cell proliferation (Cook-Mills *et al.*, 1995), decrease T-cell proliferation by mitogen (Johnson *et al.*, 1981), and decrease IL-2 production (Selliah *et al.*, 1995). LPS-induced TNF production by macrophages is also decreased (Szabo *et al.*, 1997), as is lytic activity by NK cells (Takamoto *et al.*, 1991).

The results are mixed with T-cell-dependent antibody production (Besedovsky *et al.*, 1979; Shreurs *et al.*, 1982). Results with the α-adrenergic receptors differ. Studies have also shown that thymocytes and mature circulating T-lymphocytes express the muscarinic receptor, and that stimulation of this receptor increases cell viability and the proliferative capacity of these cells *in vivo* (Rinner *et al.*, 1995; Fujino *et al.*, 1997). As for serotonergic receptors, studies suggest that predominantly the 5-HT_1A receptor is expressed on T-cells, B-cells and macrophages, and that stimulation of this receptor can either suppress (Ferriere *et al.*, 1996) or enhance (Iken *et al.*, 1995) different immune functions. Results concerning the effects of dopaminergic stimulation on immune function have been mixed, so no definite conclusion can be reached at the present time (Panajotova, 1997).

In addition to the biogenic amine neurotransmitters, mediators of CNS-immune communication include specific neuropeptides such as calcitonin gene-related peptide (CGRP) and substance P. These neuropeptides, which are synthesized in the cell body of the neuron and transported to the nerve ending where they are released when the neuron is depolarized, can diffuse out of the tissue and into the local microenvironment. Their functions range from control over local vasculature (Brain, 1997) to various immunological effects. For instance, substance P can regulate cytokine production by immune cells, immunoglobulin production by B-lymphocytes, and the migration of cells into sites of infection (Rameshwar *et al.*, 1994). CGRP on the other hand seems to exert inhibitory effects on mitogen-induced cell proliferation and cytokine production (Boudard and Bastide, 1991). It is now widely believed that these and other neuropeptides are involved in the regulation of immune and inflammatory responses in the local microenvironment. More research is needed to delineate their varied and adaptive roles further.

Cytokines

We have already addressed the immunological effects of cytokines. In addition to their immune and inflammatory effects, cytokines have been shown to be secreted by, and to affect the functions of, several organs, including the brain. The brain's effects of cytokines have been the subject of numerous reviews (Kronfol and Remick, 2000). However, before these effects are discussed, it is important to keep in mind that cytokine-to-brain signalling can occur in several ways: (1) passive transport of cytokines into the brain at circumventricular sites lacking a blood–brain barrier, such as the organum vasculosum of lamina terminalis; (2) binding of cytokines to cerebral vascular endothelium, thereby inducing the generation of secondary messengers, such as prostaglandins and nitric oxide; (3) carrier-mediated transport of cytokines across the blood–brain barrier and into the brain; and (4) activation by cytokines of peripheral afferent nerve terminals at the sites where cytokines are released. These mechanisms are not mutually exclusive. Furthermore, regardless of the mechanism(s) of brain signalling, it is now evident that cytokine genes and their receptors are expressed in the CNS and participate in the response to specific stimuli, such as infection or injury. The precise mapping of various cytokine pathways and their receptors in the brain, however, remains incomplete (Licinio and Wong, 1997).

A detailed discussion of the various cytokine actions in the brain is beyond the scope of this chapter. We will, however, offer examples of the various immunological/inflammatory, neurochemical, neuroendocrine and behavioural effects as an illustration (Figure VIII.2). The immunological/inflammatory effects of brain cytokines include gliosis, neovascularization and induction of other cytokines (Giulian *et al.*, 1988). The neurochemical effects were discussed earlier; they include changes in the brain turnover of the neurotransmitters noradrenaline, dopamine, serotonin and acetylcholine. The neuroendocrine effects include actions on the HPA (Sapolsky *et al.*, 1987), HPT (Rivier, 1993) and HPG (Rivest and Rivier, 1993) axes. The behavioural effects include changes in sleep regulation (Krueger and Majde, 1994), appetite regulation (Plata-Salaman *et al.*, 1996), sexual behaviour (Avitsur *et al.*, 1999) and cognition (Reichenberg *et al.*, 2001). There is also growing evidence that the behavioural effects of cytokines, including lethargy, increased sleep and decreased appetite, which are often referred to as 'sickness behaviour', are part of a well-organized central motivational state that, along with metabolic and physiological changes, represents the systemic response to local infection. From an evolutionary perspective, it has been suggested that these adaptive measures are meant to mobilize all the necessary resources to combat the infection/insult and return the organism to its previous state of homeostasis and health (Dantzer *et al.*, 2001).

CLINICAL IMPLICATIONS

Medical Illness

In spite of the dramatic advances in the field of psychoneuroimmunology at the basic science level, the advances at the clinical level have been somewhat timid in comparison. The immune system plays a major role in various medical illnesses, particularly infectious diseases, autoimmune/inflammatory disorders, and cancer. The notion that the CNS and the immune system are in constant dialogue raises the possibility that emotional factors and/or stressful life events may play a role in the aetiology and/or progression of these disorders through interference with immune regulation. Although to date there have been numerous studies addressing the issue of the connection between stress-induced immunomodulation and specific immune-related disorders, the results in general have been mixed and inconclusive. We will, however, provide some examples as an illustration.

Infection

The outcome of an infectious process depends on the interplay of complex phenomena related to both the infectious agent (e.g. specific strain, virulence, dose) and the host (e.g. genetic make-up, prior exposure, nutritional status). The importance of lifestyle factors in this equation has been recognized only recently. This may be obvious in cases such as the association between smoking and upper respiratory tract infection, and the association between sexual promiscuity and sexually transmitted diseases. The relation of infection to issues such as stressful life events, depression or exercise, however, has been addressed only recently. In one such study, Cohen *et al.* (1991) experimentally exposed a number of healthy volunteer subjects to five different respiratory viruses following a thorough psychological assessment that included life events, perceived stress and negative affect. The subjects were followed up for 7 days for signs of the common cold (illness) and for 28 days for rise in viral-specific antibody titre (infection). Results indicate that higher levels of stress were associated with significantly higher incidences of both infection and illness (common cold). The same pattern was seen for all five viruses. In a subsequent study, the same authors examined the effects of stress characteristics and social support on susceptibility to the common cold (Cohen *et al.*, 1998). They found a significant positive association between the duration of life stressors and the risk of having a cold. They also found that social support network diversity tended to decrease the frequency of the cold. There is also recent evidence that stress-induced increases in IL-6 concentrations may play a role as

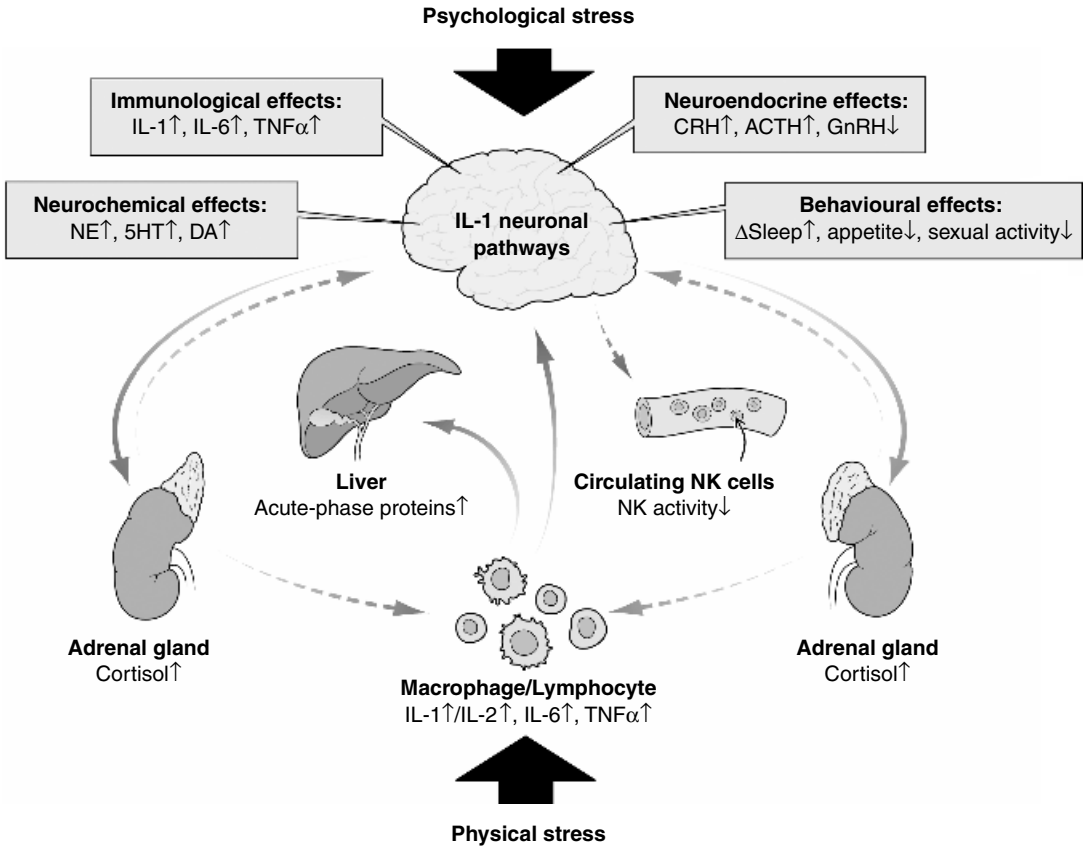

Figure VIII.2 Stress and IL-1 secretion. Both psychological stress (e.g. academic stress, depression) and physical stress (e.g. infection, trauma) can activate IL-1. IL-1 activation is associated with various phenomena, both peripherally (e.g. cascade activation of other cytokines, induction of acute-phase proteins) and centrally (e.g. various immunological, neurochemical, neuroendocrine and behavioural effects). Feedback mechanisms occur at several levels; they include negative feedback exerted by cortisol. Only selected effects are shown as an example. *Reproduced by permission from The American Journal of Psychiatry*, 157, 683–694, 2000. Copyright 2000, The American Psychiatric Association. GnRH, gonadotropin-releasing hormone; NE, noradrenaline

mediators between stress and upper respiratory infection (Cohen *et al.*, 1999).

Cancer

The relation between psychosocial stress and cancer is complex and multifaceted. Several questions have been addressed in the literature: Does psychosocial stress and/or depression increase the risk for the development of cancer? Does psychosocial stress and/or depression play any role in cancer progression? Can psychosocial intervention improve the outcome? Are there specific neuroimmunological pathways that explain these interactions? Whereas animal studies have established an association between stress-induced immunosuppression and both tumour development (Ben Eliyahu *et al.*, 1999) and tumour metastasis (Ben Eliyahu *et al.*, 1991), the association in humans between psychosocial factors and cancer development and/or progression has not been well documented. In a meta-analysis of studies addressing the relation between depression and the development of cancer, there was a small but statistically significant association between depressive symptoms and the occurrence of cancer (McGee *et al.*, 1994). The effects of stress and depression on cancer progression have also been controversial, with some studies reporting an association between stressful life events and cancer recurrence (Ramirez *et al.*, 1989), and others showing no evidence for such an association (Cassileth *et al.*, 1985). One reason for the variation in findings may be related to coping styles, with studies showing that a 'fighting spirit' is associated with a more positive prognosis (Greer and Watson, 1985), and other studies showing a fatalistic attitude or helplessness to be associated with a negative outcome (Temoshok *et al.*, 1985). Regarding the effects of psychosocial intervention, the evidence remains inconclusive. Spiegel and co-workers, in a 10-year follow-up study of women with metastatic breast cancer, found that women who participated in a group psychotherapy intervention lived for up to 18 months longer than those in the non-intervention group (Spiegel *et al.*, 1989). Similar effects were also reported by Fawzy *et al.* (1990b) in malignant melanoma patients. Unfortunately, not all studies agree (Gellert *et al.*, 1993; Van der Pompe *et al.*, 1997). Furthermore, in the few studies where immunological measures were obtained (e.g. relative percentage of CD_4+ and/or NK cells), results regarding these measures in the intervention and non-intervention groups were also mixed (Van der Pompe *et al.*, 1997; Fawzy *et al.*, 1990b).

Acquired Immune Deficiency Syndrome

The course of infection with the human immunodeficiency virus (HIV) is highly variable, with some patients remaining asymptomatic for many years but others progressing quickly to full-blown acquired immune deficiency syndrome (AIDS). While many factors relating to both the virus (such as the specific strain) and the host (such as concurrent infection) have been recognized to explain this discrepancy, psychosocial influences have also been suggested. A

summary of the studies addressing these factors has been provided by Cole and Kemeny (2001). Again, the psychosocial factors have included stressful life events, such as awareness of a serious health problem (a positive HIV test), bereavement (particularly death of a loved one), and financial difficulties, and also depression, coping skills and social support. As in the case of other infectious diseases and cancer, the results have varied. In a follow-up study of 330 gay men, Burack *et al.* (1993) found a significant negative association between CD_4+ cell levels and depressive symptoms. This association, however, did not affect disease progression or mortality. In a larger study of 1809 gay men, Lyketsos *et al.* (1996) were unable to find any relationship between CD_4+ cells, morbidity or mortality. In a different line of work, Cole *et al.* (1996) showed that gay men who concealed their homosexual identity had lower CD_4+ levels and faster HIV progression than those who did not conceal their homosexual identity. These and other findings illustrate the extent and the complexity of the relationship between psychosocial factors, immune parameters, and HIV progression.

Psychiatric Illness

Because major psychiatric disorders such as schizophrenia and bipolar affective disorder are thought to be brain disorders associated with abnormal brain chemistry and/or disrupted neuronal circuitry, and because these same neurochemicals and/or neuronal pathways have been shown to affect immune regulation, it has been postulated that major psychiatric disorders will also be accompanied by dysregulation of immune function. In fact, a good deal of research over the last few years has addressed the characterization and clinical significance of immune system abnormalities in patients with schizophrenia, major depression, Alzheimer's disease and other diseases. These issues are addressed in the clinical chapters later in this book. In addition to examining the immunological characteristics of the disorder (Kronfol and House, 1989), researchers have also investigated the relation of any demonstrated immunopathology to the clinical manifestation of the disorder (Ganguli *et al.*, 1995), as well as the possible association between neurochemical/neuroendocrine characteristics of the disorder and the demonstrated immunological anomalies (Maes *et al.*, 1993). Furthermore, in view of the frequent comorbidity between medical and psychiatric illness, and the poor prognosis associated with such events, researchers have studied a possible role for specific immune measures in such interactions (Burack *et al.*, 1993).

CONCLUSION

As this chapter demonstrates, the CNS and the immune system are in constant dialogue. In addition to its traditional role in defending the organism against invading micro-organisms and other insults, the immune system can also act as a sensory organ. In that capacity, components of the immune system collect information about the local microenvironment and transmit it to the brain (afferent loop), which in turn analyses the information and accordingly initiates a series of steps to either enhance or suppress the immune response (efferent loop). The purpose of this dialogue, therefore, is to coordinate between the local microenvironment and the rest of the organism for the purpose of mobilizing the necessary resources to best deal with a stressful event such as infection, inflammation or trauma.

As some of the reasons for this dialogue between the CNS and the immune system are getting clearer, the language used is also unfolding. Neurotransmitters, neuropeptides, hormones and cytokines are all involved. It is this constant dialogue that keeps the organism healthy by facilitating activities such as controlling and eliminating an infection and healing a wound. However, if for whatever reason the dialogue is compromised or interrupted, then the risk for medical and/or psychiatric symptoms increases significantly. Relations between the immune system and specific psychiatric disorders are presented later in this book.

ACKNOWLEDGEMENTS

This work was supported in part by a grant from the National Alliance for Research on Schizophrenia and Depression.

Psychophysiology

Gary G. Berntson, John T. Cacioppo and Martin Sarter

Psychophysiology is an interdisciplinary science that seeks to elucidate the relations between the mind and the body. Historically, psychophysiologists have been interested in the impact of psychological states and processes on physiological (especially autonomic) functions, and hence have often focused on psychosomatic or psychophysiological disorders. Psychophysiology is considerably broader than this, however, and psychophysiological perspectives have expanded and matured considerably over the past decades. Currently, many psychophysiologists are equally interested in the impact of neural and physiological factors on psychological processes. In fact, it is difficult to draw clear distinctions between psychophysiology and disciplines such as psychobiology, behavioural neuroscience, cognitive neuroscience and neuropsychology. There are a few general perspectives, however, that characterize the contemporary field of psychophysiology. These include an emphasis on reciprocal relations between psychological and physiological domains, a focus on interactions among systems (e.g. behavioural, endocrine, autonomic, immune) and levels of neurobehavioural organization (e.g. reflexive, affective, cognitive), and an interest in explicating higher-level psychological processes.

HISTORICAL TRENDS IN PSYCHOPHYSIOLOGY

Although the roots of psychophysiology may be traced back thousands of years, its establishment as an independent, formal discipline is generally pinpointed to the 1960s with the formation of the Society for Psychophysiological Research in 1960 and the publication of its official journal *Psychophysiology* in 1964 (Cacioppo *et al.*, 2000b; Sternbach, 1966). Systematic research with a predominant psychophysiological perspective, however, has been pursued since the late nineteenth century. This includes investigations of electrodermal responses and their sensitivity to psychological processes (Fere, 1888; Tarchanoff, 1890), studies of emotion and autonomic control (Cannon, 1928), and work on the conditioning of autonomic and visceral responses (Pavlov, 1927). From these early beginnings, the field of psychophysiology has developed and matured considerably. Of note are several general conceptual trends in this historical development that are relevant to applications of psychophysiology to contemporary psychology and psychiatry. This is an especially important consideration, as the prevailing conceptual landscape serves to frame empirical findings and theoretical perspectives, and thus can powerfully shape clinical concepts, research and applications.

These closely related historical trends include (1) a general shift in perspective from a peripheral to a central psychophysiology; (2) a progressive trend from an emphasis on lower reflex mechanisms to the influence of higher and more complex rostral neural systems, together with a related shift from simplistic regulatory models to more complex, multidetermined conceptions of psychophysiological regulation; (3) a corresponding shift from a predominant focus on efferent processes to the recognition of reciprocal afferent–efferent interactions; and (4) a parallel transition from constructs of global influences on mind and body to more specific patterns of determinants.

From Peripheral to Central Psychophysiology

Much of the early history of psychophysiology revolved around the autonomic nervous system (ANS) and measures of visceral function. Nineteenth-century concepts of the involuntary or vegetative nervous system generally focused on peripheral components; Langley (1921) originally proposed the phrase 'autonomic nervous system' to refer to the visceral nerves of the thoracic, cranial and sacral outflows. By the beginning of the twentieth century, the impact of this peripheral system on visceral function was recognized, and opposing effects of the vagal and sympathetic branches on heart rate had been articulated. Both Langley (1921) and Cannon (1928) recognized central nervous system (CNS) components of the ANS, including the sympathetic motor neurons of the thoracic and lumbar divisions of the cord, and Cannon specifically elucidated the impact of psychological factors such as fear and rage on autonomic function. Even behavioural influences, however, were considered as manifestations of relatively simple, reflex-like reactions that mediate peripheral adjustments to adaptive challenge and support the requisite energy mobilization for emergency reactions of fight or flight (Cannon, 1939, p. 227).

The baroreceptor–heart rate reflex is a prototypic brainstem reflex that exerts powerful control over the autonomic outflows in the service of blood pressure regulation. As depicted in Figure IX.1, baroreceptor reflexes are controlled by afferents from pressor receptors in the heart and great arteries. An increase in blood pressure results in enhanced baroreceptor afferent activity to the nucleus of the tractus solitarius (NTS), which in turn issues a relatively direct excitatory projection to the parasympathetic source nuclei in the nucleus ambiguous and dorsal motor nucleus of the vagus. The resulting increase in parasympathetic outflow slows the beat of the heart and reduces cardiac output, thereby opposing the pressor increase. This is accompanied by a reciprocal inhibition of sympathetic motor neurons in the intermediolateral cell column of the cord. The resulting decrease in sympathetic cardiac outflow tends to further diminish the heart rate and to reduce ventricular contractility, which, together with reductions in adrenergic vasoconstrictor tone, synergistically serve to compensate for the disturbance and to restore blood pressure. The opposite pattern of autonomic control (i.e. sympathetic activation and reciprocal parasympathetic withdrawal) is triggered by the unloading of arterial baroreceptors (e.g. during assumption of an upright posture), which, provides important cardiovascular support to maintain adequate blood pressure and circulation in the face of this

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

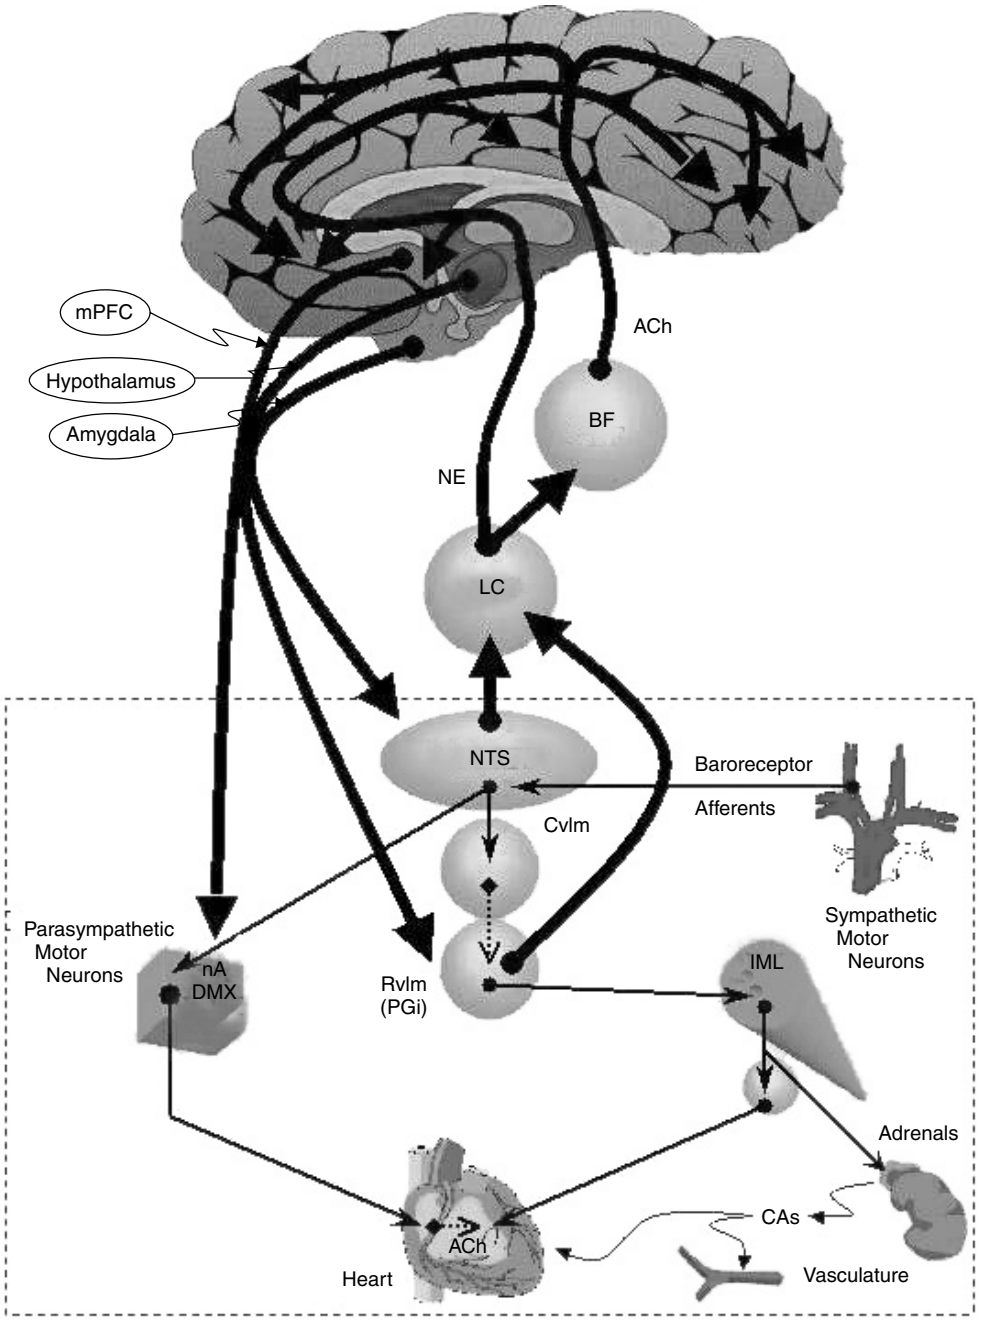

Figure IX.1 Baroreflex circuits. Dashed box: classical brainstem systems underlying baroreceptor cardiac reflex. Baroreceptor afferents project to nucleus tractus solitarius (NTS), which in turn leads to activation of parasympathetic motor neurons in the nucleus ambiguous (nA) and dorsal motor nucleus of the vagus (DMX). The NTS also activates the caudal ventrolateral medulla (Cvlm), which in turn inhibits the rostral ventrolateral medulla (Rvlm), leading to a withdrawal of excitatory drive on the sympathetic motor neurons in the intermediolateral cell column of the cord (IML). Upper section: expansion of the baroreflex circuit to illustrate the ascending and descending pathways to and from rostral neural areas, such as the medial prefrontal cortex (mPFC), hypothalamus and amygdala. Ascending systems include routes from the rostral ventrolateral medulla (Rvlm) and the nucleus of the tractus solitarius (NTS) to the locus coeruleus (LC) noradrenergic system, and indirectly to the basal forebrain (BF) cortical cholinergic system. Adapted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 466, with permission from Cambridge University Press. orthostatic challenge. Although mediated by the CNS, baroreceptor reflexes are rather rigid in organization and expression, being regulated by specific baroreceptor afferent activity, and characterized by a reciprocal excitatory/inhibitory control of the two autonomic branches.

The early focus on peripheral components and lower reflexes was natural given the existing state of knowledge, the relative accessibility of the peripheral autonomic nerves and visceral organs, and the limited methods for central physiological measurement and analysis. Consequently, the empirical database was most conducive

to the development of a peripherally focused psychophysiology, and this focus impacted both research and theory.

An example of this focus comes from the early work of Eppinger and Hess (1915) on individual differences in autonomic reactivity, which were considered to reflect distinct constitutional dispositions. Some individuals were reported to show relatively greater parasympathetic reactivity to pharmacological or physiological challenges (*vagotonia*), whereas others displayed greater sympathetic reactivity to the same challenges (*sympaticotonia*). Based on these and other findings, Eppinger and Hess formulated an early individual differences model of psychosomatic disorders, in which these basic constitutional factors were seen to differentially dispose the individual toward particular types of pathology (e.g. asthma in vagotonics, Reynaud's disease in sympathicotonics). This work spearheaded an extensive literature on individual differences and the situational and constitutional determinants of autonomic responses. The subsequent work of Wenger (1941) confirmed individual differences in autonomic dispositions, but suggested that autonomic balance was distributed normally rather than categorically across individuals (i.e. vagotonics and sympathicotonics). Additional research suggested a further differentiation of complex but stable patterns of reactivity across multiple measures that cannot be characterized along a single sympathetic–parasympathetic dimension (Lacey and Lacey, 1958). Other early work suggested that the pattern of autonomic response was influenced by the specific evocative stimulus or psychological state (e.g. fear *v*. anger, Ax, 1953; anxiety *v*. resentment, Wolf and Wolff, 1947).

Research on these issues continues, and it is now clear that patterns of autonomic response are determined by multiple factors, including individual differences in response disposition (*individual response stereotypy*) as well as stimulus or situational variables (*stimulus-response specificity*). Of particular importance is the contribution of psychological states, and interactions with response dispositions and situational factors, in the determination of psychophysiological relations. This is an important area, because experimental interest often concerns the central psychological state whereas classical measures have been primarily peripheral. Because the complexity of psychophysiological mappings is likely to increase with the number of intervening mediational steps or processes (Cacioppo *et al.*, 2000a), there has been increasing recognition of the need for more proximal (central) as well as distal (peripheral) measures.

The importance of this is apparent, even at the most peripheral levels. Heart rate is a common psychophysiological measure with documented relations to psychological states and processes, and heart rate measures have been reported to predict atherosclerosis (Manuck *et al.*, 1997), survival after myocardial infarction (La Rovere, 2001), and immune responses (Cacioppo *et al.*, 1995; Cohen, 2000). The heart, however, is innervated dually by both branches of the ANS, and an increase in heart rate, for example, could arise from sympathetic activation, vagal withdrawal, or both. This is significant, because the central processes underlying these patterns of autonomic response may be fundamentally different and may have distinct psychophysiological implications. Thus, it appears to be the sympathetic component of heart rate response, and not the heart rate response *per se*, that is most predictive of the neuroendocrinological and immunological response to stress (Cacioppo *et al.*, 1995). Moreover, it is the relative sympathetic and parasympathetic control of the heart that is most predictive of recovery after myocardial infarction (Altschuld and Billman, 2000). These and other findings reveal that the understanding of peripheral psychophysiology can be informed by knowledge of the more central origins of these relations. This has led to the development and deployment of more specific measures of activities of the autonomic branches, including selective pharmacological blockades and non-invasive measures, such as pre-ejection period (PEP), which provides an index of sympathetic control, and respiratory sinus arrhythmia (RSA), which reflects parasympathetic control (see Berntson *et al.*, 1994a; Cacioppo *et al.*, 1994). Further elucidation of psychophysiological relations is emerging from more direct measures of higher neural activity, including electrophysiological recording and brain imaging methods, as well as from the consequences of natural (neuropsychological) or experimental manipulations (e.g. direct or magnetic stimulation, pharmacological manipulations, selective inactivations, etc.). We consider next the historical shift from a focus on lower to higher neural systems.

From Lower to Higher Levels, and from Simple to Complex Neural Regulation

In his treatise on Evolution and dissolution of the nervous system, John Hughlings Jackson in 1878 recognized that functions are represented at multiple levels of the neuraxis, as they become represented and elaborated by higher-level systems in the progress of neural evolution. Reactions to aversive stimuli, for example, can be seen in pain-withdrawal reflexes organized at the level of the spinal cord. Elaborated systems of the brainstem, however, can generate more complex and organized patterns of escape and aggressive reactions as evidenced by decerebrate organisms (Berntson *et al.*, 1993a). Higher limbic structures, such as the amygdala, have been shown to be important in affective processes and conditioned fear reactions, whereas cortical systems appear to be particularly important for contextually based fear and anxiety and for cognitively and strategically based reactions (Berntson *et al.*, 1998; LeDoux, 2000; Lang *et al.*, 2000). The multiple levels of organization and processing in neurobehavioural systems have substantive implications for psychophysiology. A comprehensive conceptualization of psychobiological and psychophysiological relations will require attention to the multiple levels of processing, as distinct levels may be differentially sensitive to specific aspects of the stimulus and associative context, and may vary in their response repertoires and access to output mechanisms. Of special relevance are interactions among levels of processing, and the conditions that foster expression of one of more processing levels. In view of these considerations, an understanding of a given functional level of processing may require an appreciation of the broader range of neuraxial levels of function, as well as a multilevel analysis of events in the psychological, neural, cellular and molecular domains.

The historical shift in focus across levels of neural organization represents an extension of the trend from a peripheral to a central emphasis in psychophysiology. At progressively higher levels of organization, one sees an expansion in the range and relational complexity of stimulus processing, and an increase in the variability and flexibility of responses. This is highly relevant for the present consideration because it implies that psychophysiological mappings for higher psychological processes, although lawful, may be highly complex. Moreover, as noted above, the complexity of this mapping may increase with the number of intervening processing levels or steps. Consequently, an understanding of the autonomic psychophysiology of anxiety, for example, may benefit from experimental methods that allow for more direct measurement or manipulation of the higher central systems that underlie these relationships.

Although simple fear conditioning may be mediated at the level of the amygdala, cortical systems appear to be especially important for contextual fear conditioning and the cognitive aspects of anxiety (Berntson *et al.*, 1998; LeDoux, 2000; Phillips and LeDoux, 1992). In addition to supporting the highest-level cognitive and behavioural strategies for adaptive response, these rostral processing substrates are capable of a top-down activation of lower-level systems involved in more basic behavioural reactions as well as autonomic and neuroendocrine responses. This top-down activation can manifest even in the absence of a relevant environmental fear stimulus. Mental imagery of aversive or anxiogenic contexts is

associated with cortical activation, especially in limbic, paralimbic and associated cortical areas, as evidenced by positron emission tomography (PET) studies (Kosslyn *et al.*, 1996; Rauch *et al.*, 1995; Rauch *et al.*, 1996; Rauch *et al.*, 1997; Shin *et al.*, 1999). Such imagery can evoke autonomic responses characteristic of anxiety (Witvliet and Vrana 1995), can potentiate startle responses in a fashion similar to a conditioned fear conditioned stimulus (Vrana 1995), and can trigger anxiety symptoms in patients with phobias or post-traumatic stress disorder (McNeil *et al.*, 1993; Rauch *et al.*, 1995; Rauch *et al.*, 1996).

On the other hand, particular contexts may not require, or may even preclude, higher-level processing, and the relative contributions of processing levels may vary across conditions. Conditioned fear stimuli have been shown to increase activity in both the amygdala and cerebral cortex, as revealed by PET and functional magnetic resonance imaging (fMRI) studies (Hugdahl *et al.*, 1995; LeBar *et al.*, 1998; Morris *et al.*, 1999). Backward visual masking of a fear stimulus, however, may preclude conscious awareness and higher-level processing of the stimulus, without eliminating lower-level processing and associated autonomic responses (Ohman and Soares, 1994; Ohman and Soares, 1998). In this regard, a recent fMRI study revealed that masked-fear stimuli, relative to non-masked stimuli, preferentially enhance activity in thalamic-amygdala circuits and decrease amygdala-cortical activity (Morris *et al.*, 1999). These findings are consistent with the view that processing of fear- and anxiety-related stimuli and associations can occur at multiple interrelated levels of the neuraxis, and illustrate the utility of recently developed psychophysiological methods that provide relatively direct measures of patterns of higher neural activity. These findings may help clarify the functional bases for some complexities in the autonomic features of anxiety states.

Levels of Organization and the Complexity of Psychophysiological Mappings

The levels of neurobiological function within the CNS are often considered to be organized in a hierarchical fashion, with higher levels receiving inputs from, and implementing actions via, immediately lower levels (Figure IX.2). Because of the afferent convergence and efferent divergence of higher levels, a hierarchical organization would allow for broadened and more elaborated stimulus processing and an increased range of outputs at progressively more rostral levels. Furthermore, this organization would ensure integration and coordination among levels because of the hierarchical processing of ascending and descending information.

The hierarchical model is compatible with the views of Walter Cannon, who significantly shaped early conceptions of autonomic control and autonomic psychophysiology (Cannon, 1928; Cannon, 1929). Cannon proposed that a primary role of the ANS was in maintaining the constancy of the internal mileau, a regulatory process he termed 'homeostasis' (Cannon, 1929; Cannon, 1939). Cannon viewed the sympathetic branch as the primary homeostatic regulator, with the parasympathetic branch serving to fine-tune reactions across organs. Historically, the two autonomic branches have been considered to be reciprocally regulated by central systems (Fulton, 1945), a view that continues to be espoused in the contemporary literature (Malliani *et al.*, 1997). There is ample evidence for such a reciprocal mode of autonomic control in simple reflex responses such as the baroreceptor–heart rate reflex, and this mode of control would have considerable regulatory advantage as reciprocal changes would synergistically amplify actions at the end organ and expand the dynamic range of control of the heart (see Berntson *et al.*, 1993b).

The homeostatic model of autonomic function dominated early conceptions of psychophysiology, and behavioural-autonomic relations were often viewed as hierarchical extensions of homeostatic processes. In a hierarchical system, rostral levels could access a wider range of response mechanisms, but the actions of these systems would be constrained by the more primitive organizations at lower levels. Hence, the basic reciprocal mode of control apparent in brainstem reflexes might be expected to manifest in behavioural contexts as well. However, it is now clear that while there are hierarchical aspects to neural organization, there also exist long ascending and descending projections that cross multiple levels of organization and allow far more flexibility of control by rostral neural systems, a pattern of organization that has been termed 'heterarchical' (Berntson and Cacioppo, 2000). Figure IX.2(b) illustrates long descending projections that extend from rostral brain regions such as the hypothalamus, amygdala and medial prefrontal cortex to lower reflex substrates of the brainstem and even directly to autonomic source nuclei. Thus, higher systems may be able to bypass or override lower substrates, yielding non-homeostatic and/or non-reciprocal modes of autonomic control. It has now been shown that autonomic responses in behavioural contexts can exceed metabolic demands (Obrist, 1981; Turner, 1994), that conditioned autonomic responses may be seen prior to homeostatic perturbations and their associated afferent feedback (Dworkin, 1993), and

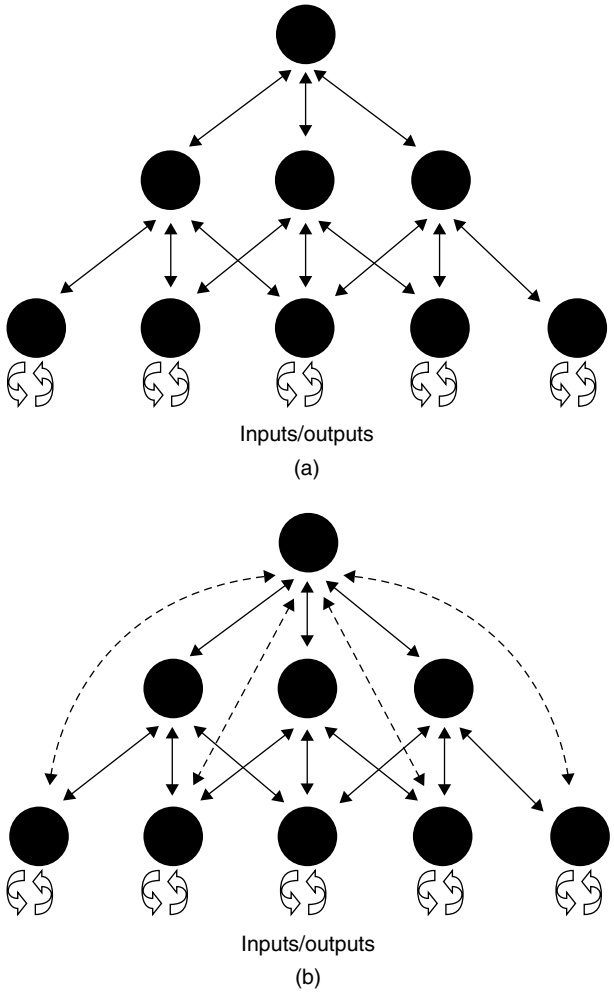

Figure IX.2 Organizational structure. (a) Classical hierarchical organization, with sensory inputs and motor outputs associated with lowest levels, and maximal convergence/divergence at the highest level. (b) Heterarchical organization, with long ascending and descending pathways (dashed arrows). Not illustrated are additional complexities associated with the presence of lateral interactions

that autonomic responses in behavioural contexts may entail non-reciprocal changes in activities of the autonomic branches (Berntson *et al.*, 1993b; Berntson *et al.*, 1994b). Moreover, under some conditions, psychological stressors may actively inhibit homeostatic baroreceptor reflexes (Steptoe *et al.*, 1996; Nosaka, 1996), permitting the concurrent increase in heart rate and blood pressure often observed under stress. These responses may well be adaptive, but they are certainly not homeostatic.

Whereas lower-level autonomic substrates may be characterized by relatively fixed patterns of response, higher-level systems can generate a broader and more flexible range of reactions. This increases the complexity of psychophysiological relations. Although baroreflex responses may entail tightly regulated reciprocal patterns of autonomic control, the autonomic branches may change reciprocally, independently or coactively in behavioural contexts (Berntson *et al.*, 1993b; Berntson *et al.*, 1994b). This has necessitated an expansion in the simple reciprocal bipolar model of autonomic control (Figure IX.3), in which autonomic states are considered to lie along a single continuum with maximal sympathetic (and minimal parasympathetic) activity at one end and maximal parasympathetic (and minimal sympathetic) activity at the other. Although this model may apply to simple brainstem reflexes, the greater output flexibility of higher neural systems in behavioural contexts necessitates a bivariate model of autonomic space with sympathetic activity along one axis and parasympathetic activity along the other. As illustrated in Figure IX.3, this has important implications for psychophysiological mapping. For the bipolar model, there would be a rather simple mapping between heart period and the underlying autonomic state, and hence measures of heart rate would offer an index of that underlying state. In contrast, for a bivariate mode of control, heart period is ambiguous with regard to its autonomic origins, as evidenced by the isofunctional contour lines on the autonomic plane. These lines illustrate different locations on the autonomic plane that translate into equivalent chronotropic states of the heart. Although knowledge of autonomic states could allow inferences concerning heart period, heart period measures do not permit ambiguous inferences concerning autonomic states.

In addition, there may be far greater individual differences in autonomic responses arising from the operations of rostral neural systems in psychological contexts. At a group level, the heart rate response of human subjects to orthostatic stress and to standard psychological stressors (mental arithmetic, speech stress, reaction time task) were found to be similar (Berntson *et al.*, 1994a; Cacioppo *et al.*, 1994). Analysis of the separate contributions of the two autonomic branches by the use of single and dual pharmacological blockades revealed that the orthostatic stress (transition from sitting to standing) yielded a rather consistent response across subjects, characterized by a highly correlated sympathetic activation and parasympathetic withdrawal. In contrast, psychological stressors yield a more varied pattern of response across subjects, with no overall correlation between the responses of the autonomic branches. Some subjects showed a predominant sympathetic activation, others a predominant parasympathetic withdrawal, and others varying combinations of these responses (Figure IX.4). Although there were considerable individual differences in the responses, individual response patterns were stable across the three psychological stressors (Berntson *et al.*, 1994a; see also Malarkey *et al.*, 1995). These

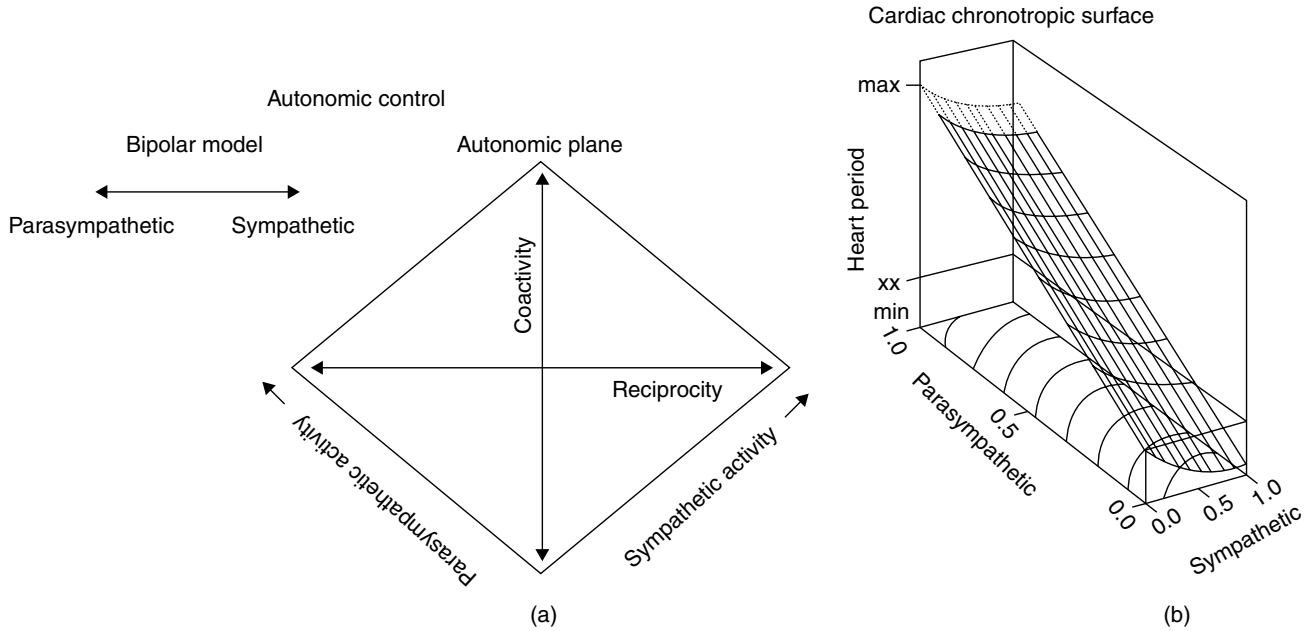

Figure IX.3 Autonomic space. (a) Bipolar versus bivariant representations of sympathetic and parasympathetic control. (b) Bivariate autonomic plane and associated chronotropic effector surface. The plane bounded by the parasympathetic and sympathetic axes represents all possible combinations of sympathetic and parasympathetic activities (on a relative scale from 0 to 1). The effector surface overlying the autonomic plane represents the chronotropic state of the target organ, expressed in heart period, for all loci within autonomic space (see Berntson *et al.*, 1993b for details of derivation). Parasympathetic activation exerts relatively linear effects on the heart period, whereas sympathetic activation yields somewhat nonlinear effects. The dotted surface at maximal levels of parasympathetic activation represents the ambiguity in effects at this extreme. For illustrative purposes, the lengths of the axes are scaled in proportion to relative dynamic ranges of control of the autonomic branches; Beta represents the 'intrinsic' heart period in the absence of autonomic input. The curved lines on the autonomic plane represent isoeffector contours projected from the effector surface on to the autonomic plane. These contour lines illustrate loci on the autonomic plane that yield equivalent chronotropic effects. Adapted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 467, with permission from Cambridge University Press

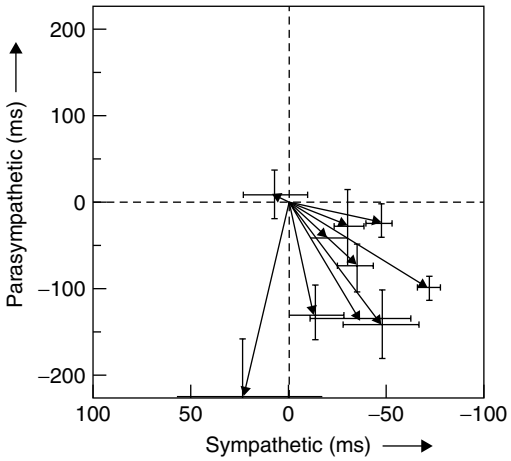

Figure IX.4 Individual patterns of response to psychological stress depicted on the autonomic plane. The intersection of the dotted lines in the centre of the graph represents the basal resting state, and the arrows depict the individual response vectors along the sympathetic and parasympathetic axes, with the peak response at the arrowheads. Vectors were derived from independent estimates of the contributions of the autonomic branches under selective pharmacological blockades. Note that some subjects responded primarily with parasympathetic withdrawal, some primarily with sympathetic activation, and some with reciprocal sympathetic activation and parasympathetic withdrawal. These individual response vectors were stable. Three stressors were used (mental arithmetic, reaction time task, speech stressor), and the error bars at the tip of each response vector illustrate the standard errors of the response across the three tasks. Units on the axes are in milliseconds of heart period. Adapted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 470, with permission from Cambridge University Press

considerations are important because they bear on the probable complexity of psychophysiological relations in behavioural contexts.

Fear, Anxiety and Autonomic Control

The importance of multilevel analysis in psychophysiology is illustrated by recent work on anxiety and autonomic control. Anxiogenic or fear-eliciting contexts are often associated with robust autonomic responses, and the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) recognizes abnormal visceral reactivity as a common feature of anxiety disorders (American Psychiatric Association, 1994). The empirical research on the specific autonomic correlates of anxiety is complex, however, and the behavioural significance of the autonomic correlates of fear and anxiety remain uncertain (Berntson *et al.*, 1998; Cacioppo *et al.*, 1992). This is a consequential issue, because anxiety disorders represent a clear risk factor for cardiovascular disease and sudden cardiac death (Hayward, 1995; Kawachi *et al.*, 1994; Kubzansky *et al.*, 1998), and autonomic states may underlie these relations in part.

As considered above, fear- and anxiety-related stimuli may be processed at multiple levels of the neuraxis, which may contribute to the complexity of psychophysiological relations in anxiety states. Studies on the pharmacology of anxiety support this view. The classical antianxiety agents, the benzodiazepine receptor (BZR) agonists such as chlordiazepoxide (CPZ, Librium®), are positive γ-aminobutyric acid (GABA) modulators (increase GABA-gated chloride flux) and selectively reduce anxiety reactions with minimal effects on pain sensitivity. Conversely, BZR inverse agonists or partial inverse agonists, such as the beta carbolines, exert opposite actions at the GABA/BZR receptor complex (negative GABA modulators that decrease GABA-gated chloride flux) and have been shown to have potent anxiogenic-like actions in a number of paradigms (see Berntson *et al.*, 1998). In uncontrolled human studies, for example, BZR partial inverse agonists have been reported to induce severe anxiety, fear, restlessness, and striking autonomic reactivity (Dorow *et al.*, 1983; Gentil *et al.*, 1989).

In a series of studies, we found that the BZR partial inverse agonist FG 7142 selectively enhances the behavioural and autonomic (cardioacceleratory) defensive-like responses to contextually conditioned stimuli but not to a simple conditioned fear stimulus (Berntson *et al.*, 1998; Stowell *et al.*, 2000). Because the effects of FG 7142 interact with the behavioural context, they cannot be considered to reflect a direct drug-induced state. Rather, this compound appears to selectively facilitate a specific class of processing. This selectivity may be due to differences in requisite levels of processing underlying contextually and explicitly conditioned stimuli. Simple fear conditioning entails a close temporal association between an explicit fear conditioned stimulus and an aversive unconditioned stimulus, and can be mediated at the level of the amygdala. In contrast, contextual conditioning entails an aversive reaction to more generalized and pervasive cues, more reminiscent of clinical anxiety, and has been shown to depend on cortical processing.

In this regard, FG 7142 has been shown to enhance cortical processing, and its anxiogenic effects appear to arise in part from this action. The effects of BZR agonists and (partial) inverse agonists on anxiety are mediated in part by modulations of the basal forebrain cortical cholinergic system, which constitutes the primary source of cholinergic innervation of the cortex (see Berntson *et al.*, 1998; Hart *et al.*, 1999; Stowell *et al.*, 2000). This system constitutes an important regulator of cortical activation and cortical/cognitive processing, and atrophy of this system underlies in large part the cognitive decline and dementia of Alzheimer's disease (Sarter, 1994). Because the processing of contextually conditioned stimuli is cortically dependent, it would be expected to be enhanced by FG 7142. In contrast, simple conditioned fear stimuli can be processed subcortically at the level of the amygdala, and consequently may be less subject to modulation by FG 7142. Thus, FG 7142 appears to selectively promote the cortical/cognitive processing of, and autonomic reactivity to, more anxiogenic stimuli (see Berntson *et al.*, 1998). This is consistent with emerging cognitive theories of anxiety (e.g. Eysenk, 1991; Gray and McNaughton, 2000).

Activity of the basal forebrain cholinergic system is normally regulated in part by inhibitory GABAergic inputs, which serve to dampen ongoing activity. Moreover, this GABAergic inhibition is enhanced by BZR agonists and reduced by BZR inverse agonists or partial inverse agonists. Indeed, it is likely that the dampening effects of BZR agonists on cortical cholinergic activity underlie the clinical anxiolytic actions of these agents, and account for the well-known impairments in cognitive function attendant on use of these compounds. This is supported by the finding that the bidirectional modulation of anxiety-associated behaviours and autonomic reactivity is abolished by selective immunotoxic lesions of the basal forebrain cholinergic neurons (Stowell *et al.*, 2000).

A model of selected components of central systems underlying fear, anxiety and autonomic control is illustrated in Figure IX.5(a). An important feature of this model is that autonomic responses are determined by multiple processes and at multiple levels of the neuraxis. Consequently, it is not surprising that psychophysiological relations are complex, especially when indexed by peripheral visceral responses that represent the final common pathway for autonomic reactions arising from varied levels of processing. A meaningful understanding of these relations will require attention to the multiple levels of neural processing and the physiological, behavioural and social factors that impact these processes.

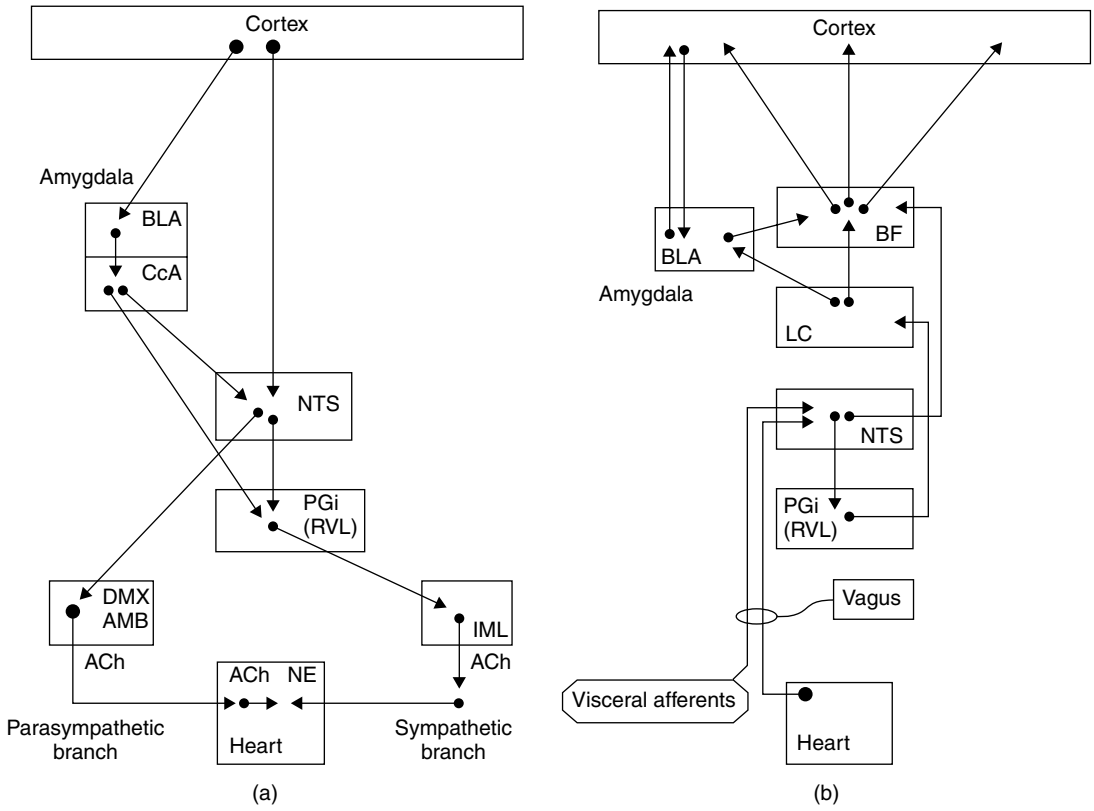

Figure IX.5 Anxiety and autonomic control. (a) Descending branch of an anatomical model of neuronal substrates by which cortical/cognitive processes may contribute to the development and expression of anxiety and its autonomic features. (b) Ascending branch of an anatomical model of neuronal substrates by which cortical/cognitive processes may contribute to the development and expression of anxiety and its autonomic features. Ascending pathways illustrate the potential routes by which sympathetic activity and visceral afference may modulate rostral systems. The model is not intended to present an anatomically complete description of relevant circuits and transmitters; rather, it is conceptually driven and focuses on hypotheses derived in part from experimental evidence (see Berntson *et al.*, 1998). From Efferent Processes to Reciprocal Interactions

Much early work in psychophysiology focused on the efferent side, with a primary emphasis on peripheral effector systems and patterns of physiological reaction to psychological states and processes. Although limited in perspective, this prevailing focus on outputs fostered important theory and research on the determinants of autonomic response patterns. Early theoretical models ranged from generalized autonomic and neuroendocrine reactions to stress and arousal (Cannon, 1936; Selye, 1956) to a bipartite focus on stimulus or situational determinants on the one hand and individual response dispositions on the other (stimulus-response specificity versus individual response stereotypy; e.g. Lacey and Lacey, 1958).

However important they are, efferent processes represent only one aspect of psychophysiological relations, and there were early exceptions to the predominant efferent focus in psychophysiology. A notable example was the James and Lange conception of the role of visceral feedback in emotion. In contrast to Cannon's (1927) thalamic theory, in which separate thalamic output pathways were considered to underlie emotional behaviour (via descending projections) and emotional feeling (via cortical projections), James (1884) considered strong emotion to reflect the perceptual consequence of afferent feedback from somatic and visceral responses. Based in part on the effects of adrenaline priming on emotional reactions, Schachter and Singer (1962) later proposed an alternative view that specific emotions arise from cognitive appraisals initiated by the perception of a rather undifferentiated physiological arousal. Although these theories have been challenged on both empirical and conceptual grounds (e.g. Cacioppo *et al.*, 1992; Reisenzein, 1983), it does appear that somatovisceral afference can prime or bias affective reactions (for review, see Cacioppo *et al.*, 1992). Somatic flexion and extension responses have been shown to bias evaluative judgments (Cacioppo *et al.*, 1993), and adrenaline or other visceral priming has been shown to enhance emotional memories in humans and rats (Ferry *et al.*, 1999; McGaugh *et al.*, 1993).

There are ample routes by which visceral afference can modulate higher neural systems. The vagus nerve and its terminal site in the NTS has been shown to be a critical pathway for the visceral priming of emotional memories, as this priming is blocked by either vagotomy or NTS lesions (Ferry *et al.*, 1999; McGaugh *et al.*, 1993; Williams and McGaugh, 1993). Figure IX.5(b) illustrates a proposed ascending model of central systems involved in anxiety and autonomic control (Berntson *et al.*, 1998). A important component of this model is the paragigantocellular nucleus (PGi). Activity of the PGi is closely related to the state of sympathetic activity, as it receives direct afferent projections from the NTS and is partially coextensive with the rostral medullary pressor area that

contributes direct projections to the sympathetic motor neurons in the intermediolateral column of the cord (Aston-Jones *et al.*, 1996). The PGi also projects extensively to the noradrenergic neurons in the locus coeruleus (LC), which is known to be highly activated in emotional states (Aston-Jones *et al.*, 1996). The LC, in turn, issues ascending noradrenergic projections to the amygdala and cerebral cortex, the former being particularly important for visceral memory priming (Clayton and Williams, 2000). As illustrated in Figure IX.5, the LC also has an additional route of access to cortical systems via an excitatory projection to the basal forebrain cholinergic system (Berntson *et al.*, 1998). This may be an important route by which visceral feedback can activate cortical processing systems, including those of the medial prefrontal cortex that have been implicated previously in anxiety and autonomic control (see Berntson *et al.*, 1998; Hart *et al.*, 1999). Indeed, we have speculated that this may be a conduit by which visceral activity is able to trigger panic attacks via a bottom-up activation of rostral systems.

It is now clear that, in addition to traditional afferent sensory systems, there are important neural and chemical signals emanating from the periphery that can exert powerful control over the operations of central networks. Even the 'sickness response' (lethargy and behavioural depression, anorexia, fever, etc.) to the presence of foreign antigens now appears to be triggered in part by a lymphocyte-derived peripheral cytokine (interleukin 2), which triggers a critical, vagally mediated signal to the brain (Maier and Watkins, 1998). Contemporary psychophysiology is increasingly cognizant of the reciprocal interactions between central and peripheral processes.

From Global to Specific Influences on Mind and Body

An additional trend that characterizes the historical development of contemporary psychophysiology is the shift from conceptual guidance by nonspecific, unitary or global influences on mind and body to more realistic and useful models that include complex and often interacting sets of more specific determinants. An example derives from the discussion above of the homeostatic model of autonomic function and regulation. Although the ANS may play an important role in maintaining the internal environment within limits compatible with life, the feedback-regulated, homeostatic model of autonomic control is far too restrictive. Rather, as discussed above, autonomic adjustments are far more flexible, and may entail conditioned adjustments that anticipate and thereby precede perturbations (Dworkin, 1993), may exceed metabolic demands (Obrist, 1981; Turner, 1994), and may reflect an active suppression of homeostatic reactions such as stress-related inhibition of baroreflexes (Steptoe *et al.*, 1996; Nosaka, 1996), allowing the conjoint increase in both blood pressure and heart rate often observed during stress. In each of these cases, the autonomic adjustment may be highly adaptive, but they are not homeostatic. Rather than a generalized homeostatic pattern of response, the ANS is capable of a much wider range of context-specific adjustments. This is important because models of physiological regulation shape concepts of health and disease.

In keeping with early global models, Selye (1956) proposed a generalized pattern of autonomic and neuroendocrine response to stress, the *general adaptation syndrome* (GAS), which was considered to reflect a uniform pattern of reaction to stress. Although autonomic and adrenocortical responses were seen to have distinct temporal dynamics, even these differences were thought to be consistent across individuals and stress conditions. The global features of the GAS, in turn, fostered a relatively simplistic peripheral model of psychosomatic disease (diathesis stress model), in which distinct disorders to a common stress-reaction were considered to reflect specific end-organ vulnerabilities. Thus, although Selye acknowledged individual differences in stress-related disorders, these differences were considered to arise largely from peripheral end-organ dispositions.

Other early researchers considered individual differences not only in psychosomatic symptomatology but also in the individual pattern of autonomic response to a given stressor. Eppinger and Hess (1915) observed that some individuals tend to show larger and more pervasive sympathetic reactions (sympathicotonics) whereas others display more parasympathetic-like responses (vagotonics) to the same set of challenges. For Eppinger and Hess, it was the difference in autonomic response disposition, rather than end-organ vulnerabilities, that disposed toward distinct patterns of psychophysiological disorder. Accordingly, vagotonics were more likely to display asthma whereas Reynaud's disease was more frequent in sympathicotonics. Moreover, different evocative stimuli or psychological states were also found to yield differentiated patterns of autonomic response (Ax, 1953; Wolf and Wolff, 1947). These early studies spearheaded an extensive literature documenting multiple determinants of autonomic response, including complex patterns of individual response dispositions that do not fall along a simple sympathetic–parasympathetic dimension (individual response stereotypy), as well as stimulus or situational determinants (stimulus-response specificity) associated with orienting, defensive and other contextually-specific reactions (Graham and Clifton, 1966; Lacey and Lacey, 1958).

An additional example comes from the literature on activation and arousal. In the first half of the twentieth century, Cannon emphasized the activational role of generalized sympathetic discharge in mobilization for emergency reactions. Elizabeth Duffy (1951) focused attention on the role of activation as a determinant of motivation, emotion and performance, and suggested that this construct could be indexed by autonomic and electroencephalographic measures. This work spearheaded the widespread application of concepts of arousal and activation in psychology, and generalized arousal became a central organizing theme in psychophysiology. Although it was recognized that the relationship between activation and performance may not be simple or monotonic (e.g. the inverted U function; Hebb, 1955), it was thought that the unitary dimension of activation exerted a pervasive impact on cognition and behavior (Lindsley, 1957). Contributing to the notion of a generalized dimension of activation were rapidly emerging developments on the role of the brainstem reticular formation and the ascending reticular activating system (ARAS) in cortical and behavioural arousal (Lindsley, 1957; Magoun, 1960). The powerful influence that the construct of general arousal had on psychology and psychophysiology was due in part to the promise that the ARAS concept held as a fundamental link between physiology and behaviour. Partly because of this appeal, the concept of general arousal survived despite the fact that such a unitary dimension was belied by early recognition of distinct attentional processes and distinctions between phasic and tonic arousal (Pribram and McGuinness, 1975), as well as by lesion-induced dissociations of cortical and behavioural arousal (Feldman and Waller, 1962).

Neither psychophysiological nor behavioural measures of arousal correlate very highly across contexts, and it is now clear that arousal and attention are multidimensional phenomena (Cacioppo *et al.*, 1996; Neiss, 1988). This does not undermine the early hope of relating behavioural processes to specific neural systems. Indeed, the concept of a general ARAS is also no longer tenable from a neurobiological standpoint, as recent work has documented multiple and differentiated ascending systems (adrenergic, cholinergic, dopaminergic, serotonergic) underlying sleep, arousal and attention (Robbins *et al.*, 1998; Sarter and Bruno, 2000; Hobson *et al.*, 2000). Moreover, increasingly it has been possible to relate specific ascending neural systems to particular aspects of attention and performance (Robbins *et al.*, 1998; Sarter and Bruno, 2000). Of these multiple systems, perhaps the two related most closely to the original ARAS concept are the activational influences of the ascending noradrenergic systems and the 'amplifying' effects of the basal forebrain

cortical cholinergic system on cortical processing (Robbins *et al.*, 1998; Sarter and Bruno, 2000).

CONTEMPORARY PSYCHOPHYSIOLOGY

As a discipline, psychophysiology has advanced and matured considerably over the past several decades. Of particular importance in this development were the historical trends outlined above, which served to position psychophysiology as a critical hub discipline between psychology, psychiatry and the neurosciences. Also influential has been the expanding recognition of the complex interactions between psychological processes and a range of systems, such as the immune system, in addition to traditionally recognized links with the autonomic and hypothalamic-pituitary-adrenal (HPA) systems. Of further impact have been the dramatic development of sophisticated methods and measures, especially those related to the brain, that allow meaningful studies of these interactions. Especially consequential have been the growing interdisciplinary collaborations between psychophysiology and behavioural and cognitive neuroscience, neuropsychology, endocrinology, neurochemistry, immunology, molecular biology and behavioural genetics.

At present, it is difficult to distinguish clearly the work of many contemporary psychophysiologists from other neuroscientists. Psychophysiology is no longer limited to behavioural independent variables and peripheral physiological dependent measures. Psychophysiologists are as likely to measure central events and processes as peripheral physiological changes, and they increasingly employ psychological states and processes as dependent as well as independent variables. Moreover, with the increasing understanding of the integration among multiple behavioural and physiological systems, there has been a considerable expansion of the scope of psychophysiology into areas such as psychoneuroimmunology, neuropsychology and psychiatry. What continues to characterize psychophysiology is its abiding interest in psychological processes, and how the understanding of these processes can be informed through multilevel analysis of the interactions between psychological and physiological systems. This includes the manner in which psychological processes are implemented in, and in turn impact on, physiology.

In summary, what characterizes contemporary psychophysiology is its emphasis on reciprocal relations between psychological and physiological domains, a focus on interactions among systems (e.g. behavioural, endocrine, autonomic, immune) and levels of neurobehavioural organization (e.g. reflexive, affective, cognitive), and an interest in explicating higher-level psychological processes. As a critical bridge discipline, psychophysiology is particularly relevant for psychiatry.

SOME APPLICATIONS OF PSYCHOPHYSIOLOGY IN PSYCHIATRY

Clinical issues were often central in the early history of psychophysiology, and a clinical focus within the discipline continues in the contemporary literature. In this section, we consider three examples of psychophysiological approaches in clinical psychiatry, and see how these approaches have contributed to theory and research. The following discussions are not intended to be comprehensive or exhaustive, but rather to illustrate the utility of psychophysiological perspectives and multilevel analysis.

Anxiety

As discussed above, fear- and anxiety-related stimuli can be processed at multiple levels of the neuraxis, each with distinct access to autonomic source nuclei and regulatory systems of the brainstem and cord. An additional complexity is that simple fear may be primarily an emotional response, whereas anxiety is characterized by salient cognitive components. These considerations, together with the wide range of anxiety conditions, individual response stereotypy, and stimulus-response specificity in autonomic reactions, preclude a simple psychophysiological mapping of autonomic states and reactions in clinical anxiety. In anxiety conditions where there is a focal evocative stimulus or event, such as specific phobias or post-traumatic stress disorder (PTSD), a relatively selective enhancement of autonomic reactivity to the target stimulus is often observed (Davidson *et al.*, 2000; McNeil *et al.*, 1993; Pitman *et al.*, 1999). In some cases, this may reflect processing in subcortical systems. Backwardly masked visual fear stimuli can trigger exaggerated autonomic responses in phobic subjects, and can support conditioned fear responses, despite being unrecognized (Ohman and Soares, 1994; Ohman and Soares, 1998). In accord with animal research, PET studies have suggested that these reactions are mediated by a subcortical pathway entailing the superior colliculus, pulvinar and right amygdala (Morris *et al.*, 1999). In contrast, more cognitively mediated anxiety-like reactions appear to be dependent on cortical systems (Berntson *et al.*, 1998; Lang *et al.*, 2000; McNaughton and Gray, 2000; Morris *et al.*, 1999). As might be expected, psychophysiological mappings, like behavioural relations, become more complex with the involvement of higher-level processing systems. Anxiety patients may show either increases or decreases in basal and reactive autonomic states, or they may show more complex patterns of response among autonomic measures (see Berntson *et al.*, 1998). A decrease in high-frequency heart rate variability (respiratory sinus arrhythmia), an index of vagal tone and vagal reactivity, has been reported to be diminished in a number of anxiety conditions, including general anxiety disorder, panic disorder, and blood phobia (Thayer and Lane, 2000). This and other findings have led to the suggestion that anxiety may be associated with a diminished physiological variability and flexibility (Thayer and Lane, 2000; Hoehn-Saric and McLeod, 2000).

From a psychiatric perspective, however, a more relevant issue might be the functional consequences of autonomic and neuroendocrine reactions for psychological states. At the extreme, it has been suggested that frank neural degeneration resulting from excess glucocorticoids may underlie PTSD (Bremner, 2001; Pitman, 2001), although questions remain concerning this hypothesis. Prolonged stress has been shown to result in glucocorticoid-dependent hippocampal degeneration in animals, and several imaging studies have reported a reduced hippocampal volume, as well as memory impairments that might be expected from such damage, in PTSD (Bremner, 2001; Sapolsky, 2001). However, it remains unclear whether the smaller hippocampal volumes in PTSD are due to enhanced cortisol levels or even whether they are related causally to PTSD or its symptoms (McEwen, 2001; Pitman, 2001; Yehuda, 2001). This is an important area for further study, and the implications of the neurotoxicity hypothesis, if confirmed, would be substantial for our understanding of psychiatric conditions.

Regardless of the resolution of this issue, evidence for other feedback effects of autonomic or neuroendocrine responses is growing. The effects of glucocorticoids on multiple brain systems is well established, and reciprocal relations between the brain and adrenal cortical hormones has been studied extensively. Glucocorticoids, for example, have complex and dose-dependent effects on fear and anxiety via multiple actions at central glucocorticoid and mineralocorticoid receptors (Korte, 2001). In addition, brain corticotropic releasing hormone (CRH) systems appear to play a central role in the orchestration of behavioural, autonomic and neuroendocrine responses to stress, and glucorticoids modulate these systems by regulating a CRH-binding protein (Behan *et al.*, 1996; Heim and Nemeroff, 1999). Recent developments suggest an important role for central CRH systems in anxiety. CRH acts on two receptor

populations, Crhr1 and Crhr2, with the Crhr1 receptor type primarily responsible for the stress-like and anxiogenic actions of CRH (Heim and Nemeroff, 1999; Owens and Nemeroff, 1999). In view of these considerations, and evidence of CRH neuronal hyperactivity in affective disorders and anxiety, Crhr1 antagonists are currently undergoing clinical trials to determine their clinical efficacy in patients with affective and anxiety disorders (Owens and Nemeroff, 1999).

As illustrated in Figure IX.5, there are also ample ascending routes by which the peripheral autonomic states can influence higher neural systems. Although it is no longer tenable to maintain that emotional feeling is merely the perceptual consequence of somatovisceral feedback, there are a variety of ways in which visceral afference may impact emotional reactions. Even a rather generalized pattern of autonomic reaction may contribute to specific emotional states by priming or biasing neural processing, or by a 'visceral illusion' process akin to the distinct percepts that are possible with visual ambiguous figures (Cacioppo *et al.*, 1992). Empirically, it has been shown that post-training visceral activation by systemic adrenaline can enhance emotional memories in rats (Williams and McGaugh, 1993; Croiset *et al.*, 2000) and increase pain sensitivity in humans (Janssen *et al.*, 1998). Moreover, adrenaline administration has been reported to trigger panic attacks in human subjects (van Zijderveld *et al.*, 1999). As this effect was not related to anxiety sensitivity or the fear of autonomic reactions, it did not simply reflect a perceptual consequence of visceral activity (Veltman *et al.*, 1998). As illustrated in Figure IX.5, a final common pathway by which visceral afference may enhance anxiety is the basal forebrain cortical cholinergic system (see Berntson *et al.*, 1998). The importance of this system in anxiety is supported further by the report that anxiolytic actions of the BZR agonist, chlordiazepoxide, are mediated at least in part via an inhibition of this system (Stowell *et al.*, 2000). Moreover, Crhr1 receptors that underlie the anxiogenic actions of CRH have been identified on basal forebrain cholinergic neurons. Together, these findings support the view that basal forebrain cholinergic systems may enhance anxiety by promoting the cortical processing of threat- and anxiety-related stimuli.

In summary, psychophysiological approaches to the study of anxiety can contribute to our understanding of the nature of anxiety. Moreover, conceptual models derived from multilevel analysis and psychophysiological studies can help to elucidate the neurobiological bases of anxiety, and contribute to the development of more effective pharmacological and behavioural treatment strategies.

Schizophrenia Spectrum Disorders

There has been a substantial history of psychophysiological studies of schizophrenia. Although much remains to be learned about this spectrum of disorders, a broad albeit sketchy conceptualization of this disorder is emerging from the integration of multidisciplinary data and perspectives. It is now recognized that among the central cognitive disturbances in schizophrenia are disorders of attention (for reviews, see Braff, 1993; Gray, 1998; Keller *et al.*, 2000; Sarter, 1994; Sarter *et al.*, 2001). Deficits in sensory or attentional 'gating' have been reported regularly in pre-pulse inhibition paradigms with measures that include acoustic-event-related potentials (e.g. P50) and electromyographic startle responses (Dawson *et al.*, 2000; Keller *et al.*, 2000; Light and Braff, 1999), and neuroleptic medication may normalize gating deficits (Weike *et al.*, 2000). Additional studies document high basal levels of autonomic variables, low reactivity, and slow habituation of autonomic responses (Zahn, 1988; Zahn *et al.*, 1997).

Slowed habituation is consistent with a gating or filtering deficit, although the low level of autonomic reactivity is more consistent with additional findings suggesting deficient attentional processing in schizophrenia, as indicated by smaller evoked potentials, or by behavioural measures (Keller *et al.*, 2000; Knight, 1993). Other studies suggest a deficiency in working memory in schizophrenia (Keller *et al.*, 2000; Selemon and Goldman-Rakic, 1999; Perlstein *et al.*, 2001). The latter is in accord with indications of 'hypofrontality' or dysfunction in schizophrenia, as indicated by structural, functional brain imaging, and behavioural measures (Callicott *et al.*, 2000; Hazlett *et al.*, 2000; Perlstein *et al.*, 2001; Selemon and Goldman-Rakic, 1999; Staal *et al.*, 2001).

These and other psychophysiological approaches have been highly significant in defining the cognitive and behavioural features of schizophrenia. In view of the above findings, additional work will be needed to characterize more precisely the nature of the cognitive processing in schizophrenia spectrum disorders. Differences in the literature on deficits in gating, attentional failures and working memory may be more apparent than real. Inability to selectively filter or disattend may tax the processing capacity of working memory (as would a primary working memory deficit) and lead to attentional failures due to capacity limits, and any of these features may manifest in schizophrenia depending on the context (Sarter, 1994; Sarter *et al.*, 2001).

Psychophysiological studies have also been influential in highlighting potential neural systems underlying the cognitive and behavioural features of schizophrenia, and contribute importantly to the multilevel analyses that are essential in understanding the basic neurobiology and neuropsychology of schizophrenia. Indeed, multilevel interdisciplinary approaches are now beginning to clarify the links between underlying neuropathology and the cognitive features of schizophrenia. Because of the therapeutic efficacy of dopamine receptor (D2) antagonists, schizophrenia has often been considered to reflect a disturbance in dopamine systems. Dopamine releasers such as amphetamine or cocaine can trigger or exacerbate schizophrenic symptoms, and specialized single positron emission computerized tomography (SPECT) and PET brain imaging techniques have revealed sensitized mesolimbic dopaminergic systems and enhanced amphetamine-induced dopamine release in schizophrenics (Laruelle, 2000; Kugaya *et al.*, 2000). Phencyclidine (PCP) and other antagonists of *N*-methyl-D-aspartate (NMDA) glutaminergic receptors, however, may provide an even better model of schizophrenia than amphetamine, especially for both positive and negative symptoms (Jentsch and Roth, 1999). These and other findings lead to hypoglutaminergic models of schizophrenia. Additional results have suggested a hypercholinergic state in schizophrenia. Amphetamine and dopamine agonists can both enhance cortical acetylcholine release, schizophrenic patients have been reported to show abnormal acetylcholine receptor density in the prefrontal cortex, and potentiation of the basal forebrain cortical cholinergic system may provide the closest model of many of the cognitive features of schizophrenia (Crook *et al.*, 2000; Sarter, 1994; Sarter *et al.*, 2001). These seemingly disparate findings are beginning to be organized by more integrative, multilevel theories and models.

Although there is considerable evidence implicating altered dopamine function in schizophrenia, this may not be the primary disturbance. Based on extensive studies and integrative reviews of the literature, a primary cortical disturbance has been proposed in schizophrenia, one consequence of which is a disturbance in the (glutaminergic) cortical regulation of subcortical dopamine systems (Grace, 2000; Moore *et al.*, 1999). Reduced tonic glutaminergic driving of dopamine systems is hypothesized to result in dopamine upregulation and enhanced phasic dopamine driving, which in turn can enhance cholinergic activity by disinhibiting the basal forebrain cortical cholinergic system (Sarter, 1994; Sarter *et al.*, 2001). While much work remains to be done in this area, the emerging schema organizes a wide range of otherwise disparate findings extending from the anatomy (e.g. hypofrontality), to the neuropharmacology (dopaminergic, glutaminergic, cholinergic), to the psychological

features (attentional and working memory impairments and frontal lobe symptoms) of schizophrenia.

What has been important to the progress in this area is the integration of information derived from multiple levels of analysis, which provides the empirical and conceptual depth to allow meaningful hypotheses and constructive theorizing. Thus, although atypical antipsychotic compounds may not have the dopamine-blocking effects of the conventional antipsychotics, they do share a common effect of attenuating cholinergic activity, which may account for their therapeutic benefit on cognitive and attentional processing in schizophrenia (Sarter, 1994; Sarter *et al.*, 2001). We can look forward to additional genetic and molecular biological contributions to our understanding of schizophrenia, but molecular biology alone can never yield a comprehensive account of schizophrenia or any other psychiatric condition. For this, multilevel analyses are required, and psychophysiological approaches can play an important role in these analyses.

Summary

The examples above illustrate some applications of psychophysiology in psychiatry, and how such approaches may inform psychiatric issues. Psychophysiological methods can provide a unique perspective, although as with any approach there are limits to the inferences that can be derived. Consequently, psychophysiological approaches are most useful in multilevel analyses, where they can provide information that complements and converges with that derived from other methods and levels of analysis. Below, we consider some of the features of psychophysiological methods and designs, and the logic of psychophysiological inference.

PSYCHOPHYSIOLOGICAL INFERENCE

Psychophysiology seeks to elucidate the reciprocal relations between mind and body, including the highest-level processes of language, symbolic representation and problem solving. In psychophysiology, 'the emphasis is on integrating data from multiple levels of analysis to illuminate psychological functions and mechanisms rather that physiological structures *per se*' (Cacioppo *et al.*, 2000b). Methodologically, this may entail measures of behavioural, physiological or neural activity in psychological contexts. Important advances continue to be made in measurement systems, and current devices for neural and physiological recording are often highly sophisticated and precise. Regardless of measurement precision, the question arises as to how signals are to be interpreted and inferences drawn. Generally, physiological measures are of interest primarily to the extent to which they allow one to index a psychological process.

One common approach in the literature is the subtractive method, in which experimental and control or contrast conditions differ by one element, stage or process (Cacioppo *et al.*, 2000b). Outcome differences between the experimental and control conditions are then considered to reflect the impact of that single component. In this fashion, physiological indices of particular psychological processes can be identified, and within a hypothetico-deductive framework, concepts and theories can be developed and tested. This approach, for example, allowed Helmholtz to determine the propagation velocity in nerves by the difference in reaction times to a somatic stimulus delivered at a proximal and a more distal site on the arm. The assumption was that all aspects of the task and neural processing were identical, except for the extra component associated with the longer distance the neural signal must travel when the stimulus was presented distally. Knowing the difference in reaction times and the distance between the stimulus sites, we can derive the propagation velocity (dx/dt).

A contemporary example comes from brain imaging studies, in which the difference in the neural maps under experimental and control conditions are interpreted to reflect the activity uniquely associated with the experimental condition. If, under a sufficient set of conditions, a consistent difference is apparent that comports with a model or hypothesis (e.g. amygdala activation mediates aversive reactions to pain), then the results provide some support for the hypothesis. This approach does not allow a strong inference, however. The confidence in such an interpretation would be enhanced if the particular pattern (amygdaloid activation) was shown to arise consistently under a wide range of pain conditions and could not be attributable to some other aspect of the contexts (i.e. well-designed control conditions). Even then, amygdaloid activation could not be used to infer the presence of pain or aversion, as other emotional states may yield the same result. Moreover, even if amygdala activation was shown to be highly specific to pain conditions, its causal role in that psychological state would need to be confirmed by converging evidence (e.g. amygdaloid stimulation or inactivation, anatomical connections, etc.). In fact, converging evidence is always important because the subtractive method assumes that components or processes can be inserted or deleted without altering other components or processes, and that may not always be true. We will return to this example below.

More generally, the question arises as to how we are to understand psychophysiological relations. Below, we present a framework for thinking about such relationships (for further development, see Cacioppo and Tassinary 1990; Cacioppo *et al.*, 2000b). We further outline the rules of evidence for, and limitations to, psychophysiological inference.

Psychophysiological Relations

Psychophysiological relationships are relations between two general domains: the psychological domain, which can be represented as comprised of a set of elements ψ, and the physiological domain, which we can represent as the set ϕ. Figure IX.6 illustrates the logical relations between elements in these two domains. All psychological elements in the set ψ are assumed to have some physiological referent or physical substrate.

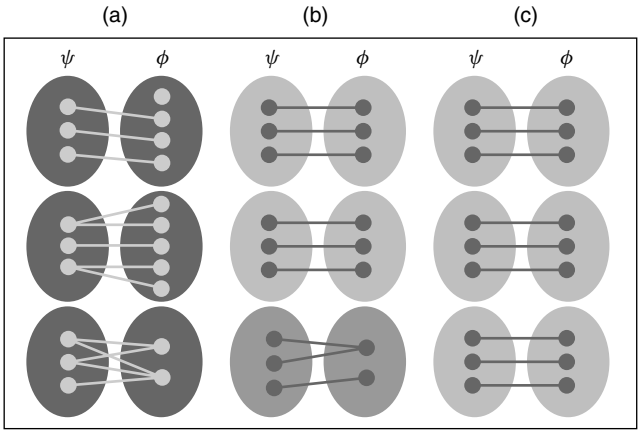

Figure IX.6 Logical relations among elements in the psychological (ψ) and physiological (ϕ) domains. (a) Relations between ψ elements and individual physiological responses. (b) Relations between ψ and physiological response patterns. (c) Relations between ψ elements and profiles of physiological response across time. Reprinted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 13, with permission from Cambridge University Press

Figure IX.6 illustrates several types of relationships. First, there are elements within the physical domain that have no psychological referent (Figure IX.6a, top row). This represents psychologically irrelevant sources of variance in physiological measures (e.g. temperature effects on electrodermal activity or postural effects on heart rate). These are important because they constitute a source of variance or artefact in physiological measures that needs to be controlled or accounted for. This is accomplished by careful recording methods, good research designs, and rigorous experimental controls. In the ideal case, this effectively eliminates the impact of these elements on the results (Figure IX.6b, top row).

As illustrated in Figure IX.7, there are five general relations that could characterize the mapping between elements in the sets ψ and ϕ:

- *One-to-one*, in which an element in ψ is associated with one, and only one, element in ϕ.
- *One-to-many*, in which elements in ψ are related to more than one element in ϕ.
- *Many-to-one*, in which two or more ψ elements are associated with a single element in ϕ.
- *Many-to-many*, where two or more ψ elements are associated with overlapping ϕ elements
- *Null*, in which there is no association between elements in ψ and ϕ.

Of these relations, only the first and third allow logical inferences concerning psychological states or processes (ψ) from physiological measures (ϕ). This is important, because psychophysiological research often entails manipulation or blocking of elements in the psychological domain and measurement of elements within the physiological domain. Consequently, the basis for theoretical interpretations in psychophysiology can be enhanced if relationships between ψ and ϕ could be specified in terms of one-to-one or even many-to-one.

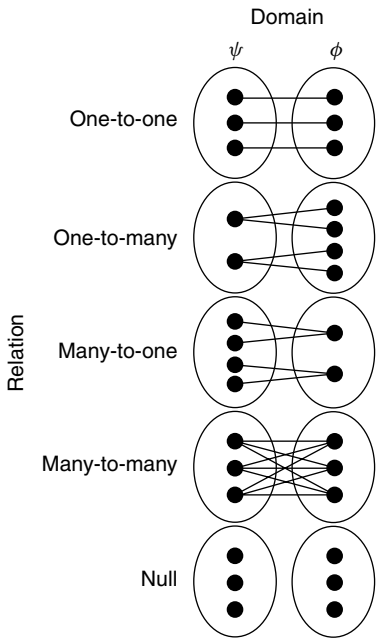

Figure IX.7 Possible relationships between elements in the psychological (ψ) and physiological (ϕ) domains. Reprinted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 13, with permission from Cambridge University Press

Unfortunately, one-to-one relationships that allow strong inference are not common in psychophysiology. One approach to this problem is to recast the ϕ elements of a one-to-many relationship into a higher-order syndrome (ϕ') that is comprised of a combination or pattern of ϕ elements (Figure IX.6b). In this fashion, a one-to-one relationship may be identified between a psychological element and a pattern of physiological responses.

Similarly, the many-to-many relations may be simplified by reconceptualizing the physiological elements into a syndrome or profile of physiological responses (Figure IX.6b). This serves to simplify a many-to-many relation to a many-to-one (or even a one-to-one) relation. Adding additional dimensions (ϕ'') to the definitions of the physiological elements or profile (e.g. amplitudes, temporal dynamics, etc.) may allow further simplification to a one-to-one relationship (Figure IX.6c). Complex psychophysiological relationships, however, may not always be reducible to a one-to-one or even a many-to-one relation.

Psychophysiological Inference

When a psychological factor serves as the independent or blocking variable and a physiological factor the dependent variable, the experimental design can be conceptualized as examining the $P(\phi/\psi)$, or the probability of ϕ given ψ. In contrast, when a physiological factor serves as the independent or blocking variable and a psychological factor the dependent variable, the experimental can be conceptualized as investigating the $P(\psi/\phi)$, or the probability of ψ given ϕ.

For illustration, we return to our brain imaging study of pain and the amygdala. If differences in amygdala activation ϕ (assuming that the imaging method is actually measuring activation) are found during aversive reactions (ψ) to pain compared with control conditions, the data are often interpreted prematurely to indicate that ϕ (the amygdala activation) is associated with ψ (aversive reactions). These types of results are also sometimes treated as if ϕ were manipulated directly (amygdala activation as the independent variable) and ψ was measured (aversive reaction as the dependent variable). This form of interpretation, however, assumes an isomorphism between ψ and ϕ that may not be true (Sarter *et al.*, 1996). Causal hypotheses regarding the involvement of a brain structure (ϕ) in a psychological process (ψ) are of the form $\psi = f(\phi)$. This implies that the occurrence of ϕ (e.g. amygdala activation) is a sufficient condition for ψ (aversive reaction), but it does not imply that ψ is necessarily preceded by ϕ. Moreover, brain activity is often of interest as an index of a psychological state or process, and the desired inference is of the form $\psi = f(\phi)$ rather than not-$\psi = f$(not-ϕ). Consequently, the goal of psychophysiology may be characterized by the conditional probability of ψ given ϕ:

$$P(\psi|\phi) = 1$$

But imaging studies are generally of the form:

$$P(\phi|\psi) = ?$$

Psychophysiological measures provide information on ϕ as a function of ψ, but the conditional probabilities are equivalent $[P(\psi|\phi) = P(\phi|\psi)]$ only if there is a one-to-one relationship between the physiological element ϕ (e.g. amygdala activation) and the psychological element ψ (e.g. aversive reaction) (Cacioppo and Tassinary, 1990). This cannot be assumed but must be tested. In the present example of aversive reactions and the amygdala, the isomorphism does not exist, as aversive reactions do not depend on amygdala activation (although data discussed earlier suggest that conditioned aversive reactions may, and that redefining the element ψ

may be in order). In interpreting psychophysiological data, isomorphism between a psychological variable and a physiological variable (one-to-one relationship) must be tested, and deviations from isomorphism must be considered. In this regard, interdisciplinary, multilevel approaches are particularly useful as they can also provide complementary and converging evidence from direct manipulations of the physiological variables (ϕ as independent variable).

Categories of Psychophysiological Relationships

In addition to the mappings illustrated in Figure IX.7, psychophysiological relations can vary in terms of their generality, yielding four general classes of relations: outcomes, markers, concomitants and invariants.

A psychophysiological *outcome* is a many-to-one, situation-specific relation. If a physiological element (ϕ) is shown to vary as a function of a psychological element (ψ), then there is at least an outcome relationship among the variables. This is often the first level of findings in psychophysiology. If that relation can also be shown to be isomorphic (one-to-one), then it becomes at least a marker, whereas if it is shown to be independent of context, it is at least a concomitant. If it proves to be both isomorphic and context independent, then it is an invariant relationship.

The inferential power of an invariant is far greater than an outcome, but even an outcome relation can provide the basis for strong inference. For example, if two psychological theories predict different psychophysiological outcomes, then the outcome alone can serve as a test of those theories, based on hypothetico-deductive logic. An outcome relationship, however, does not allow one to draw inferences concerning the psychological state from the physiological measure. As an example, an increase in heart rate may have an outcome relation to the state of arousal, but an increase in heart rate alone cannot be interpreted as a reflection of an increase in arousal. As the probability of ψ given $\phi[P(\psi, \phi)]$ approaches 1, and the $P(\text{not-}\psi, \phi)$ approaches 0, then the element in the physiological domain becomes an ideal marker of the element in the psychological domain.

A psychophysiological *marker* is a context-specific, isomorphic relation between ψ and ϕ. Consequently, markers provide a valid indication of one element (often ψ) on the occasion of the other (often ϕ) within an assessment context. Markers may merely signal the occasion of an event in the other domain, or they may inform as to the amplitude or temporal features of the other event. To be established as a marker, an element in one domain must be shown to predict reliably an element in the other domain, and the boundary conditions for this relation must be identified. A heart rate decrease might be considered a concomitant of the orienting response within an experimental context that sufficiently controls other physical (e.g. temperature) and behavioural (e.g. activity, arousal) variables that can also alter heart rate.

A psychophysiological *concomitant* is a context-independent, many-to-one relationship between ψ and ϕ. It entails a cross-situational covariation between events in the two domains. It is less restrictive than an invariant, as it does not require a one-to-one relationship. Consequently, although a psychological event (e.g. aversive reaction to pain) may predict reliably the occurrence of a physiological event (amygdala activation), the presence of the amygdala activation event cannot be interpreted as a reflection of a pain reaction, as other psychological events may also produce activation of the amygdala.

Finally, a psychophysioloigcal *invariant* is a context-independent, isomorphic (one-to-one) relation between ψ and ϕ. This requires that the element ψ is present if, and only if, the element ϕ is present, and vice versa, across contexts. It is the only relation in which $P(\psi|\phi) = P(\phi|\psi)$ and $P(\text{not-}\psi, \phi) = P(\text{not-}\phi, \psi) = 0$. Invariant relations allow for strong inferences in psychophysiology. Unfortunately, however, invariant relations are sometimes assumed, rather than established, which can lead to specious interpretations and obfuscations. Although invariant relations afford the most powerful basis of inference, as considered above, some psychophysiological inferences can be derived with other categories of relation. It is crucial, however, to be cognizant of the differences.

CONCLUSION

Psychophysiology is the study of the relations between the mind and the body, or between psychology and physiology, hence it is extremely relevant to psychiatry. Its emphasis on multilevel analysis and the explication of psychological processes offers an important approach to the understanding and treatment of psychiatric disorders. The multilevel, interdisciplinary nature of psychophysiology is particularly viable in view of increasing documentation of extensive links and reciprocal interactions between psychological processes and autonomic, neuroendocrine and immune systems. The utility of psychophysiological approaches, however, is dependent on the recognition and application of the logic and principles underlying psychophysiological inference.

X

Neuropsychology

Marie T. Banich

INTRODUCTION

Neuropsychology is the study of how the neurological organization of the brain influences the way people think, feel and act. Knowledge about the relationship between the brain and the mind is obtained from a broad array of techniques and from a range of different populations. Traditionally, neuropsychology weds a fine-grained behavioural assessment of individuals who have suffered brain damage with data that localize the anatomical location of such damage. With the advent of new brain-mapping methods, neuropsychological inquiry has expanded to include investigations that provide information on the location and/or time course of brain activity in either brain-damaged individuals, psychiatric patients or neurologically intact people. In the first part of this chapter, we provide an overview of these methods and how they can be fruitfully applied to a deeper understanding of psychiatric disorders. In the second part of the chapter, we give an overview of the organization of the brain for different mental functions, with an eye towards delineating those regions that are most likely to be affected in psychiatric disorders.

METHODS

Examining Patients with Delineated Brain Damage: The Lesion Method

The most venerable method of linking activity of the brain with mental functioning is that of the lesion method. The seeds for this method date back some 2000 years. During Roman times, Galen, a physician who ministered to the wounds of gladiators, noticed that contestants sustaining injury to the arm, leg or torso retained their powers of thought, whereas those who sustained injury to the head or the brain did not. From these observations, he inferred that the brain was linked to the mind, becoming one of the first scientists to use individuals with brain damage to understand brain–behaviour relationships.

The logic of the lesion method is to assume that if damage to a particular region of the brain results in an inability to perform a specific function, then the lost function must be supported by that brain region. Because damage to different regions of the human brain has distinct functional consequences, we now assume some degree of localization of function, i.e. that a particular brain region supports a specific mental function. This was not always accepted fact, as it had been proposed that the brain worked via mass action, meaning that all pieces of brain contributed to all functions. According to this theory, the nature of cognitive deficits observed after brain damage hinged not on which brain regions were destroyed but on the extent of the damage.

Even though specific functions may appear to be localized, it is important to remember that the brain is comprised of about 50 billion interconnected neurons. Thus, almost all functions rely on the smooth and integrated functioning of many of these areas. In addition, there is some redundancy, so that lesions in different brain regions can sometimes have similar effects. Therefore, we must remember that the brain relies on both localization of function and diffuse processing to carry out mental function in a seamless fashion.

The major strength of the lesion method is that it allows a direct linkage between a specific region of brain tissue and a particular aspect of mental processing. When using the lesion method, a researcher can take one of two conceptual approaches. One approach emphasizes knowledge about neural substrates; the other emphasizes knowledge about mental function. For the purposes of expanding our understanding of the neuropsychological organization of the brain, researchers often ask, what functions are supported by a particular piece of brain tissue? Under such conditions, a researcher assembles a group of individuals in whom the site, cause and extent of damage are as comparable as possible. An example of the power of this approach is the work of Brenda Milner and colleagues at the Montreal Neurological Institute. By examining patients who underwent removal of portions of the temporal lobe (because it was the source of epileptiform activity), they were able to demonstrate that removal of the hippocampus and nearby structures are critical for the production of new long-term memories about factual information (e.g. Milner, 1978).

The other conceptual approach to the lesion method emphasizes mental functioning. When taking this approach, researchers select a group of individuals that have the same diagnosis or exhibit the same behavioural symptoms and then determine the neural concomitants of those behavioural characteristics. One example of this approach is to differentiate schizophrenics who predominately exhibit negative symptoms (e.g. anhedonia, alogia, avolitional behaviour, etc.) from those that exhibit positive symptoms (e.g. hallucinations, delusions) and examine the integrity of frontal regions in each. A greater degree of frontal atrophy is associated with negative symptoms compared with positive symptoms (Baaré *et al.*, 1999). Such findings suggest that degeneration of neural tissue, especially in prefrontal regions, may in fact be predictive of the poor outcome associated with negative symptoms (Sanfilipo *et al.*, 2000). Another variation of this approach is to make an even more fine-grained selection with regard to a specific behavioural symptom (e.g. alogia), rather than grouping individuals according to a diagnostic category that encompasses a variety of behavioural manifestations (e.g. negative symptoms). Such an approach assumes that a particular syndrome may result from dysfunction with regard to a variety of brain regions, and that associations may best be revealed by examining the relationship between a specific symptom and a specific brain region (e.g. Stolar *et al.*, 1994).

The patterns of mental dysfunction among groups of individuals with lesions in different locations can provide important insights into the architecture of the mind. First, comparisons across groups

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

can help to distinguish whether a brain region is *involved* in a function, or whether it is *critical* to that function. Taking our example above, Milner was able to demonstrate that the hippocampus was critical in this long-term memory function because individuals with damage to these other regions, such as the frontal lobes, did not exhibit problems in forming new long-term memories.

Second, comparisons across groups, via a double dissociation, can provide information as to whether two mental functions are independent (e.g. Shallice, 1988; Teuber, 1955). A double dissociation occurs when lesions have converse effects on two distinct cognitive functions: one brain lesion causes a disruption in cognitive function A but not cognitive function B, whereas a different lesion causes a disruption in cognitive function B but not cognitive function A. We infer that the functions are independent because the viability of one cognitive function does not depend on the viability of the other. For example, one might assume, a priori, that all auditory language processing is localized to the same region of the brain. If that were the case, then losing the ability to understand auditory language would be accompanied by a loss of speech output as well. However, the dissociation between Broca's and Wernicke's aphasia illustrates that the ability to produce and the ability to comprehend spoken language are distinct mental faculties. In Broca's aphasia, comprehension of auditory language is, for the most part, intact, but speech production is halting, slow and effortful. In contrast, in Wernicke's aphasia, individuals cannot understand what is said to them but nonetheless fluently produce grammatically correct sentences (even though these sentences are usually nonsensical). Hence, disruptions in speech output are independent of whether a disruption in speech comprehension occurs, and vice versa.

The importance of the lesion method in expanding our knowledge in neuropsychology cannot be underestimated. It has led to classic conceptualizations about the neural underpinnings of language, memory and perception, to mention just a few areas (see Damasio and Damasio, 1989 for further discussion). Nonetheless, the lesion method has two major limitations. First, variability in characteristics of the participant population and inconsistency in the location and the extent of the lesion can make straightforward inferences difficult. Prior to brain damage or a psychiatric illness, individuals have often had diverse life experiences, typically varying widely in socioeconomic status, educational background, and age. Afterwards, their life experiences also vary, depending on the type of treatment they receive, their compliance with treatment regimens, their social support network, and time since onset or insult, to name only a few factors. Differences in these characteristics between populations can produce seemingly contradictory results across studies, and the variable(s) responsible for such dissimilarities may remain obscure or difficult to tease out.

The second major limitation of the lesion method is that it does not allow direct observation of the function performed by the damaged portion of the brain. Rather, all we can do is observe how the rest of the brain performs without that particular area, and from these observations infer the previous role of the damaged region. Although such inferences are usually sound, they may have certain limitations and liabilities. One is that the lesion method can identify only the regions of the brain that are absolutely necessary to perform a given mental function; it cannot identify the entire set of brain regions that may participate in that function. Another limitation is that a brain region's contribution to a particular cognitive function can go undetected if a task can be performed via multiple strategies. If an individual utilizes an effective alternative strategy, performance may appear intact when indeed some functions have been lost. Finally, behavioural impairment may result after damage to a region not because that region is critical to the task, but because that region connects two or more brain regions that must interact for correct performance of the function, a situation known as a disconnection syndrome.

In some cases, generalizations from the results obtained with the lesion method have been applied fruitfully to psychiatric disorders; in other cases, they have clear limitations. One case in which generalizations have been relatively straightforward is that of major depression. Lesions to left frontal lesions result in major depression in half of all individuals who sustain them, and an extensive body of research indicates that underactivity of left frontal regions is associated with major depression (We discuss this issue in more detail later.) However, other psychiatric disorders, such as schizophrenia, are much less likely to result from dysfunction of a specific region. Although much research indicates dysfunction of the frontal region in schizophrenia (e.g. Goldstein *et al.*, 1999), there are numerous other brain regions, including the basal ganglia (e.g. Menon *et al.*, 2001), hippocampus, temporal regions (e.g. Sigmundsson *et al.*, 2001), and thalamus (e.g. Blennow *et al.*, 2000), that also appear to be dysfunctional. Furthermore, recent research has suggested that disconnections between different brain regions, either between prefrontal and temporal regions (Halliday, 2001; Fuster, 1999) or within temporal regions themselves, such as between the hippocampus and entorhinal regions (e.g. Young *et al.*, 1998), may characterize schizophrenia. Clearly, such findings indicate that brain dysfunction in this disorder involves a diffuse and broad network, rather than being well characterized as resulting from a circumscribed lesion.

Techniques for Determining Brain Anatomy

As should be obvious from the discussion above, the lesion method relies critically on determining where in the brain damage was sustained. Our ability to make such linkages has been undergoing a revolution since the mid-1970s due to the advent of different brain-imaging techniques that provide information on the location of damage in living individuals. The first of the modern brain-imaging techniques, computerized axial tomography (CAT), uses X-rays to provide information on the density of brain structures. Although CAT scanning was a breakthrough, in many ways it has been superseded by magnetic resonance imaging (MRI). This technique relies on the use of magnetic fields to distort the behaviour of atoms; the information gained on how long the atoms take to recover from this distortion can then be used to create an image of the anatomy of the brain (for a more advanced, but readable, discussion of this method and some of its applications, see Andreasen, 1989).

MRI has two main advantages over CAT. First, MRI does not require X-rays and hence does not involve transmitting high-energy radiation through the body. Second, the spatial resolution of the image is far superior with MRI than with CAT. However, MRI cannot be performed on individuals with pacemakers or people with metal in the body that is not connected to hard tissue (e.g. a clip on an artery or a metal shaving in the eye from welding). A new, MRI-derived method, diffusion tensor imaging, has the potential to provide much information about the anatomical connectivity of different brain regions. This method looks at the axes along which water diffuses, and hence provides information on the main directional orientation of white matter tracts as well as their structural integrity (Conturo *et al.*, 1999). Since white matter tracts connect distant brain regions, this method can be utilized to detect disorders that arise from a partial or complete disconnection between brain regions, or to detect demyelinating disorders.

Techniques for Determining Physiological Activity

Following quickly on the heels of the revolution of brain-imaging techniques that provide a structural description of the brain's anatomy has been a revolution in the ability to measure the

physiological functioning of the brain. These methods divide into two major classes: those that mainly provide information about *where* activity is occurring, and those that mainly provide information about *when* activity is occurring. These two classes of methods can be viewed as complementary rather than rivals, since each provides a different type of information (i.e. where *v*. when). As such, researchers are attempting to gain a more complete picture of brain systems supporting mental thought by performing identical experiments with each type of method and cross-comparing the results (e.g. Martinez *et al.*, 1999). Although these functional brain-imaging techniques are often used with individuals with brain insult or psychiatric disorders, these techniques can be used with neurologically intact individuals to great advantage. They allow the direct observation of the activity of a brain region during performance of a specific task, and they can identify the entire network of brain structures that participate in performing a particular mental function, neither of which is provided by the lesion method.

Methods that Provide Information about the Location of Brain Activity

The two main techniques for localizing where activity is occurring are positron emission tomography (PET), which uses a radioactive agent to determine the brain's metabolic activity, and functional magnetic resonance imaging (fMRI), which uses a variant of the MRI techniques discussed above. In PET, the radioactive tags utilized to measure brain activity typically are either 2-deoxy-D-glucose, a physiologically inert sugar similar to the one that supplies the brain with energy, which is altered by the introduction of a radioactive fluorine atom (^{18}F) into 2-deoxy-2-fluoro-D-glucose, or ^{15}O delivered in water. To reach a more stable state, the radioactive isotope emits a positively charged electron (positron). After emission, the positron collides with an electron, causing annihilation of their mass and a release of energy in the form of two photons of light that travel from the site of annihilation exactly 180 degrees opposite each other. A ring of photocells surrounding the patient's head detects the coincident arrival of two photons of light from opposite directions. Extrapolating backwards, region(s) of the brain from which the photons came can be determined, providing information on brain activity. The time required to obtain a picture of brain activity is dictated by how quickly a given isotope goes from a radioactive state to a non-radioactive state (known as its half-life), because a critical number of photons must be detected before an image is interpretable. A related technique, single photon emission tomography (SPECT), is a much scaled-down version of PET using a small set of sensors and isotopes that have a longer half-life. Hence, the spatial resolution of the image and the temporal precision of SPECT images are reduced relative to PET.

PET has a distinct advantage over other functional brain-imaging methods in that it allows investigation of the metabolic activity with regard to a large number of molecules. As long as a (positron-emitting) version of the molecule can be created, metabolic action of that molecule can be observed. This advantage makes PET a particularly important method for understanding psychiatric disorders because it allows for the investigation of neurotransmitter function (e.g. Wong *et al.*, 1986). There are many linkages between psychiatric illnesses and dysregulation of neurotransmitter systems, including (1) the dopaminergic system with regard to schizophrenia (e.g. Lidlow *et al.*, 1998), certain forms of substance abuse (e.g. Spanagel and Weiss, 1999), and attention deficit disorder (e.g. La Hoste *et al.*, 1996); (2) the serotonergic system with regard to depression (e.g. Blier and de Montigny, 1999) and obsessive–compulsive disorder (Baumgarten and Grozdanovic, 1998; Delgado and Moreno, 1998); and (3) GABAergic transmission in alcoholism (Hoffman and Tabakoff, 1996) and the anxiety disorders (Leonard, 1999). As an example of the utility of PET in exploring such issues, this method has demonstrated that the binding of dopamine D1 receptors in prefrontal regions of the brains of schizophrenics predicts the severity of negative symptoms as well as dysfunction on a cognitive tasks relying on frontal regions (Okubo *et al.*, 1997).

Despite this major advantage, PET has some drawbacks. First, it involves radiation, which limits an individual to about three to four scans a year. This precludes certain studies, such as those designed to monitor changes in brain activity during the course of a treatment regimen. Second, the time periods over which brain activity is recorded are exceedingly long (on the order of minutes or hours), making precision with regard to specific mental processes difficult.

With fMRI, changes in neuronal activity are accompanied by local changes in cerebral blood flow and blood oxygenation (e.g. Fox *et al.*, 1988), which in turn can be used to infer the activity levels of different brain regions. Since the mid-1990s, there has been an explosion of research using the blood oxygenation level-dependent (BOLD) method, which measures the relative proportion of oxygenated blood to deoxygenated blood. Active brain regions exhibit an increase in oxygen-rich blood, which is infused to these regions faster than it can be extracted by brain tissue. This increase can be picked up as an amplification of the magnetic resonance signal because the binding of iron to haemoglobin varies between oxygenated and deoxygenated blood (e.g. Kwong *et al.*, 1992).

For a number of reasons, fMRI has characteristics that make it advantageous compared with PET. First, scans can be obtained with standard clinical MRI machines routinely located in hospitals (rather than relying on a facility for creating a radioactive isotope, as is the case with PET). Second, it does not involve ionizing radiation. Third, multiple scans can be run on a single subject, which allows examination of changes in brain function over time, such as might occur during treatment or time from insult.

The main drawback of this method, however, is that it is measuring the haemodynamic response of the brain, rather than a derivative of neuronal activity. This haemodynamic response has a characteristic waveform, peaking about 4–6 seconds after stimulation and coming back to baseline after around 12–16 seconds. Although certain experimental designs make the temporal precision much greater than 16 seconds (Aguirre and D'Esposito, 1999), the time course of the haemodynamic response does impose limitations.

Methods that Provide Information on the Time Course of Brain Activity

There are other electromagnetic methods that provide precise information about the time course of brain activity, although they do not provide as much precision with regard to the location of such activity. The main methods for examining the time course of brain activity are event-related potentials (ERPs) and magnetoencephalography (MEG). ERPs are recordings of the brain's electrical activity that are linked to the occurrence of an event (e.g. the presentation of a stimulus) rather than a continuous measure of ongoing activity, as is the case with electroencephalography (EEG). For ERPs, metal electrodes positioned on the scalp record the electrical signals produced by the brain, which are then amplified. The electrical waveform recorded on the scalp is the summed or superimposed signal of electrical activity of fields of postsynaptic potentials of neuronal dendrites. The electrical potential recorded in response to a stimulus can be divided into components, which are characteristic portions of the waveform that have been linked to certain psychological processes, such as sensory processing, attention and memory. ERP components are labelled with a letter and a subscript number (e.g. P_{300}). The letter, *P* or *N*, denotes whether the deflection of the electrical signal is positive or negative, while the number represents, on average, how many milliseconds after stimulus presentation the

component appears. Whereas the early components (up to first 150 ms) tend to be driven by physical features of the presented stimulus (e.g. loudness, physical similarity to the last item), the later components tend to be linked to internal cognitive states, such as the degree to which memory must be updated in the current context (P_{300}) (Donchin and Coles, 1998) or the degree to which a stimulus is semantically anomalous given the context (N_{400}) (Kutas and Hillyard, 1984). A related method, MEG, examines the magnetic fields at the brain's surface derived around dipoles located in the brain. This method has the advantage of providing some information about the depth within the brain from which activity is emanating (as derived from the characteristics of the magnetic field recorded at the surface). Development of methods for interpreting MEG data as well as high-density ERP recordings (e.g. 128 electrodes) are allowing more precise localization of the source of electrical activity (see Davidson *et al.*, 2000 for a discussion of some of these issues). One common approach is to utilize information derived from PET or fMRI that serve to constrain modelling the source of electrical activity (see Mangun *et al.*, 1998 for a longer discussion of this issue).

A number of different components, ranging from those that reflect perceptual process to those that reflect more central processes, have been linked to specific psychiatric disorders. We will cite a couple of examples here. Schizophrenic individuals show an abnormal P_{50}, which has been suggested to index the early gating of sensory information. Furthermore, the degree of abnormality of this component has been found to predict negative (but not positive) symptoms (e.g. Erwin *et al.*, 1998) and appears to result from nicotinic receptor desensitization (for a longer discussion of this association, see Adler *et al.*, 1998). An asymmetry between the hemispheres in the N_{100} recorded via MEG has been found in paranoid schizophrenics (for a review of the utility of MEG in psychiatry research, see Reite *et al.*, 1999). The latency of the P_{300}, which is though to reflect the attentional resources that can be brought to bear to a task, has been found to be elongated in depressed individuals and to predict performance on executive tasks (e.g. Kindermann *et al.*, 2000). Furthermore, the latency of the P_{300} in depression is linked to serotonergic activity, implicating this neurotransmitter system in the generation of this component (Hansenne and Ansseau, 1999).

A newly developed method, event-related optical signal (EROS), has the exciting potential to provide simultaneously information about the location and time course of brain activity. This method utilizes the beaming of near-infrared light through the skull into the cortex. The deformation of the path of the light back out of the head provides two types of information. The first, known as the slow signal (which tracks changes on the order of seconds) appears to detect changes in the brain's haemodynamic response similar to that measured by fMRI. The second, known as the fast signal (which tracks changes on the order of milliseconds), appears to detect changes in the shape of neurons associated with neuronal firing. Because the position of input of the light source, and the site of the detector, can be controlled, it is possible to localize the source of the signal. In addition, the data can be recorded in a millisecond-by-millisecond manner, providing temporal information (see Gratton and Fabiani, 1998 for a longer description of the technique, validation of the method, and applications).

This new method has large potential. It is less costly than MRI systems, can provide both temporal and spatial information, and is non-invasive. Its limitations are that it cannot reveal activation of deep structures in the brain (because light will not penetrate that deeply) and that it is relatively untested at present.

Methods that Modulate Brain Activity

Recently, methods have emerged that temporarily modulate the activation of the brain in humans. These methods have been used both with regard to understanding brain–behaviour relationships and in a therapeutic manner. The most notable of these is transcranial magnetic stimulation (TMS). In this method, a magnetic coil is placed over a particular portion of the brain and a pulse of magnetic stimulation is applied. This magnetic field disrupts the electrical activity of the neurons in the vicinity. Although this method has been referred to as causing a 'reversible' lesion, which would suggest that it blocks neuronal activity, it is better understood as influencing activity by causing neurons to fire in a random pattern rather than in a coherent manner. The result is that at low frequencies TMS disrupts mental functioning, whereas at higher frequencies it can enhance activity (see Fitzpatrick and Rothman, 2000 and Walsh and Cowey, 2000 for a description of these techniques).

This method has numerous theoretical advantages. First, it can be used to confirm findings from the lesion method that implicate a brain region as playing a critical role in a specific mental function. If a brain area is critical for a particular mental function, then applying TMS to the region should disrupt that function. Second, it has been useful in demonstrating that some clinical syndromes result from an imbalance of activity between two brain regions, rather than dysfunction of a specific region. For example, hemi-neglect (a syndrome we will discuss in more detail later on) causes an individual to ignore information on one side of the world (e.g. information on the left). There are various theories as to the mechanism underlying this disorder, which typically occurs after unilateral damage to parietal regions of the right hemisphere. Recently, it has been demonstrated that TMS to the intact left hemisphere can eradicate hemi-neglect (Oliveri *et al.*, 1999), restoring normal function. Such a finding indicates that it is an imbalance between the left and right hemispheres, rather than damage to the right hemisphere, that causes hemi-neglect. Third, TMS can be used clinically to restore imbalances in activation between brain regions. Much work suggests that underactivation of left as compared with right frontal regions is associated with depression (Heller and Nitscke, 1998). Repetitive trains of TMS (rTMS) over left prefrontal areas have been used successfully to treat depression (e.g. Eschweiler *et al.*, 2000). Finally, TMS can be utilized along with another brain-mapping method, such as PET, to determine the functional connectivity between brain regions. In a series of clever experiments, Paus (1999) applied TMS in a focal manner while simultaneously obtaining PET data on activation across the entire brain. He reasoned that remote areas of the brain influenced by the region disrupted by TMS should exhibit decreased activity. In this way, a map of the functional connectivity of the brain could be obtained.

Assessment of Behaviour

Careful and thoughtful behavioural testing is one of the most powerful tools we have for analysing how the brain constrains and influences the way we think. Just as we need precise tools to measure brain anatomy and brain physiology, we also need precise tools to examine behaviour. Although a variety of quick screening devices, such as the mini-mental status exam (MMSE), are available and used widely in the medical profession, they provide a very poor metric of mental abilities. They are lacking as measures on which to base treatment decisions or mental competency (Guilmette and Krupp, 1999). Rather, a standard neuropsychological assessment is a far superior method for evaluating the degree to which damage to the central nervous system may have compromised a person's cognitive, behavioural and emotional functioning. The goals and uses of this assessment are numerous: to provide a profile of mental capacity exhibited by an individual including both strengths and weaknesses, as a tool for providing prognosis, and as a means to evaluate the person's progress during rehabilitation or treatment.

Table X.1 Components of the Halstead–Reitan neuropsychological test battery

Test	Measures	How the ability is measured
MMPI	Psychiatric symptomatology, e.g. depression and schizophrenia	Individual answers a large number of yes/no questions to provide a profile relative to individuals who have been diagnosed with specific psychiatric disorders.
Categories test	Abstract reasoning	Individual views four items on the screen and pushes one of four buttons, with different sets of items requiring different responses (e.g. push the button corresponding to the atypical item, push the button corresponding to the Roman numeral on the screen). The only feedback provided is a bell for correct answers and a buzzer for incorrect answers.
Rhythm test	Auditory perception and timing	Individual decides whether two patterns of sounds are similar.
Speech sounds perception test	Verbal abilities Attentional abilities	On each trial, the individual chooses a previously heard sound from among a number of choices. The sounds are nonsense syllables that begin and end with different consonants.
Finger tapping test	Motor function	Tapping rate of each index finger is determined.
Grip strength test	Motor function	Strength with which a dynamometer can be squeezed by each hand is assessed.
Trail making test	Visual search Attention	*Part A*: examines whether the individual can draw a line connecting consecutively numbered circles. *Part B*: examines whether the individual can connect, in an alternating manner, numbered and lettered circles (e.g. A1B2C3).
Aphasia screening test	Language	Examines the ability to use and perceive language, to pantomime simple actions, and to reproduce simple geometric forms.
Tactile perception test	Tactile ability	Determines whether the individual can identify objects by touch (each hand separately), identify letters traced on the fingertips (when the eyes are closed), and perceive being touched on different fingers of both hands.
Tactual performance test	Tactual memory Spatial localization	Without any visual input (blindfolded or eyes closed), a set of felt shapes must be placed into a single board from which they are cut out. Afterwards, with eyes open and the board obscured from view, each shape must be drawn at its correct location in the board.
Sensory-perceptual exam	Sensory loss Hemi-neglect	Assesses the perception of simple information in the visual, tactile and auditory modality. To determine whether neglect is present, stimuli are presented to just one side of the body or to both simultaneously.
WAIS-III	General intellectual abilities	11 separate subtests that assess a variety of intellectual functions.

MMPI, Minnesota multiphasic personality inventory-2; WAIS-III, Wechsler Adult Intelligence Scale–Third edition.

There is a tension in neuropsychological assessment between the desire to provide a tool that will detect the presence of brain damage regardless of its source and the desire to provide a fine-grained componential analysis of behaviour that delineates precisely the specific cognitive or emotional functions that have been disrupted. To cast a wide net to detect brain dysfunction of either neurological or psychiatric origin, neuropsychologists often utilize a test-battery approach. These batteries typically assess a variety of mental functions and have at least one test designed to measure overall intelligence. Probably the most widely used neuropsychological test battery is the Halstead–Reitan battery, which consists of a number of tests that generally require about 6–8 hours to administer. The abilities examined in this battery range from simple tests of sensory function to complex tests of reasoning, from tests of verbal function to tests of spatial function, and from tests of immediate recognition to tests of memory. In addition, the battery is used to assess functioning in different sensory modalities. A complete Halstead–Reitan battery for adults (Boll, 1981) includes the tests described briefly in Table X.1.

Other test batteries, such as the Luria–Nebraska test, take a similar approach. The tasks on the Luria–Nebraska test are divided into 12 content scales: motor functions, rhythm and pitch, tactile and kinaesthetic functions, visual functions, receptive language, expressive language, reading, arithmetic, writing, memory, intermediate memory, and intelligence. These batteries were designed to determine whether an individual suffered brain damage, and they are effective at discriminating patients with brain damage from neurologically intact individuals (e.g. Golden *et al.*, 1978; Vega and Parsons, 1967). However, these batteries may not be as effective at discriminating between individuals with brain damage and those with psychiatric disorders (e.g. Adams, 1980).

Another popular battery is the Cambridge Neuropsychological Test Automated Battery (CANTAB), a computerized battery. This has been designed to emphasize assessment of abilities that rely on frontal regions and associated subcortical areas, but also assesses parietal and temporal lobe function. All tests in this battery are non-verbal (Sahakian and Owen, 1992). One set of tasks act as control tasks designed to assess psychomotor speed, the ability to follow instructions, and gross spatial perceptual skills. Another set is designed to be sensitive to frontal lobe damage; this set consists of tasks that test the ability to utilize a search strategy to find a target, the ability to switch sets (e.g. from one dimension of a stimulus to another), the ability to plan towards a goal, and the ability to remember the spatial location of a visual stimulus. The tests sensitive to functioning of the temporal and parietal lobe assess the ability to recognize complex visual displays after different time delays, the ability to recognize abstract patterns, the ability to associate visual patterns with specific locations, and the ability to remember the order in which visual stimuli are presented. This battery has been utilized with a variety of populations, ranging from people with dementia and Parkinson's disease (e.g. Sahakian, 1990) to those with bipolar and unipolar mood disorders (e.g. Sweeney *et al.*, 2000). Unfortunately, the test–retest reliability of certain portions of the battery is not as high as would be ideal (e.g. Lowe and Rabbitt, 1998).

An alternative strategy to the test-battery approach is customized neuropsychological assessment. In such an assessment, a small set of standard tests is used, such as the Wechsler Adult Intelligence Scale–III (Wechsler, 1997) to survey general intellectual

abilities, and the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 1983) to ascertain language functioning. The examiner uses information from the initial set of tests to generate hypotheses about the set of particular abilities that were compromised by the brain damage. Each hypothesis is evaluated with a specific neuropsychological test, and, depending on the individual's performance, the hypothesis is either pursued further with another test or abandoned (e.g. Lezak, 1995). Myriad tests can be used for assessing specific functions, such as those measuring memory, attention, spatial ability and abstract reasoning. Compared with a standardized battery, the individualized approach requires a more skillful examiner. In this case, the neuropsychologist's expertise may be critical to elucidating the nature of the disorder, especially in atypical or unusual cases. The interested reader is referred to Lezak (1995), which is the definitive reference with regard to clinical assessment of neuropsychological dysfunction.

Probably the set of tests used most widely to assess intellectual abilities is the Wechsler family of intelligence tests: the Wechsler Pre-school and Primary Scale of Intelligence–revised (WPPSI-R; Wechsler, 1989), for children aged 3 years and 7 months to 7 years and 3 months; the Wechsler Intelligence Scale for Children–third edition (WISC-III; Wechsler, 1991), for children aged 6 years to 16 years and 11 months; the Wechsler Adult Intelligence Scale III (WAIS-III; Wechsler, 1997); and the Wechsler Adult Intelligence Scale–revised as a neuropsychological instrument (Kaplan *et al.*, 1991). These tests generally take about 3 hours to administer. They all provide an overall or full-scale estimate of IQ (FSIQ). In addition, they provide scores on two major subscale scores, a verbal IQ (VIQ) and a performance IQ (PIQ), which, generally speaking, break down into verbal tests and non-verbal tests, respectively. The WAIS family of tests are useful because (1) they provide a profile of abilities rather than a single score; (2) they are well-normed, based on a large sample of individuals who were chosen to match the demographics of the US population with regard to gender, region of the country in which they reside, and type of environment (i.e. rural or urban); and (3) they provide different norms for different age ranges. The WAIS-NI is tailored to neuropsychological assessment because it allows for an evaluation of an individual's abilities, even if he or she has difficulty in motor output, and it provides the examiner with information on the strategies that a patient uses in solving problems.

Even though test batteries and tests of general intellectual abilities provide information on how well a person is functioning, it is often important to have some estimate of premorbid functioning before an injury or onset of psychiatric illness. Sometimes, a person's educational and occupational history can serve as such a standard, but in other cases this may be inadequate. The vocabulary subtest of the WAIS-III has been used to estimate premorbid IQ, because the abilities it measures seem relatively resistant to brain damage, even damage that affects many different arenas of intellectual functioning, such as Alzheimer's disease. Another test used to estimate premorbid functioning is the National Adult Reading Test (Nelson, 1982), which is an oral reading test consisting of 50 words, most of which are short and do not follow normal rules of pronunciation (e.g. 'ache'). Because the words cannot be sounded out, an ability to read them indicates some previous familiarity and hence provides an estimate of premorbid abilities (Crawford, 1992). When estimates of premorbid intelligence are much higher than present test scores, the results suggest that psychiatric illness or brain damage has affected adversely the individual's intellectual abilities.

Although many researchers who are trying to understand fundamental aspects of brain–behaviour relationships often adopt tests utilized in neuropsychological assessment (e.g. the Wisconsin card sorting test) in brain-mapping studies, such an approach may not be optimal. These tests serve as good assessment tools because they are sensitive to dysfunction due to a variety of aetiologies involving a number of brain regions (e.g. Anderson *et al.*, 1991). However, that makes them inherently poor at pinpointing a specific cognitive operation. For example, numerous brain-imaging studies have utilized the Stroop task, which is known as the gold standard of attentional functioning (MacLeod, 1992). In this task, individuals attend to and identify the colour in which a word is printed while ignoring the word. Attentional demands are increased in the incongruent condition, in which it is hard to ignore the word because it names a colour distinct from the word's ink colour (e.g. the word 'red' printed in blue ink), than in the neutral condition, in which the word contains no colour information (e.g. the word 'lot' printed in blue ink). Although many researchers have identified a series of neural structures that aid in attentional selection of this task (Pardo *et al.*, 1990; Bench *et al.*, 1993; Carter *et al.*, 1995; Carter *et al.*, 1997; Bush *et al.*, 1998; Brown *et al.*, 1999; Petersen *et al.*, 1999), the specific components of attentional control have not been well specified.

An alternative approach is to understand more precisely the different component processes and the neural regions that support those processes by performing specific comparisons, while considering neurocognitive theories of how these processes might dissociate. We took such an approach with the Stroop task. Our guiding heuristic was a neurocognitive theory of attentional control that conceives it as being divided into an anterior system that provides top-down control of attention and a posterior system that selects information on the basis of sensory characteristics (e.g. Posner and Dehaene, 1994). We reasoned that any top-down system that serves as a general mechanism for selecting task-relevant information should be engaged, regardless of the specific attribute to which an individual must attend. In contrast, we hypothesized that posterior brain regions should be sensitive to the type of information that is being selected, and that the pattern of activity in posterior regions should differ between these two regions. To test these predictions, we compared brain activation for the standard colour-word Stroop task described above to that of a spatial-word Stroop task. In this latter task, an individual identifies the position of a word relative to a box (an incongruent trial would be one in which the word 'below' is positioned above the box). Notice in this comparison that we have held the task-irrelevant information constant — in both cases the information to be ignored is a word. Hence, similarities between patterns of activation between the two tasks must indicate a common mechanism for attentional selection, regardless of the task-relevant attributes, whereas differences in patterns would indicate sensitivity to the nature (e.g. colour, spatial) of task-relevant information. We found the expected dissociation between anterior and posterior regions. Both tasks activated similar regions of the middle frontal gyrus, whereas a differentiation in the pattern of brain regions activated was observed for posterior regions (Banich *et al.*, 2000).

PRINCIPLES OF HUMAN BRAIN ORGANIZATION FOR MENTAL FUNCTION

Having reviewed the ways of obtaining information about the brain and behaviour, we will now spend the rest of the chapter providing an overview of how the brain is organized for different cognitive and emotional functions. On a gross level, the brain has a functional organization front/back and left/right. Frontal regions are involved in motor programming and planning, whereas posterior regions are responsible for sensory processing. The two hemispheres of the brain also play distinct roles in mental operations. We will discuss the organization for the receipt of sensory information and the control of motor output. This is followed by a discussion of the differences between the cerebral hemispheres, and the role of

the four major lobes of the brain in higher-order mental functions: frontal, parietal, occipital and temporal.

Primary Sensory and Motor Cortices

In general, the frontal regions are involved in motor processing, while sensory processing occurs in the posterior regions. The organization of primary sensory and motor areas share some general characteristics of organization. First, all these brain areas are organized so that specific aspects of the physical world are 'mapped' on to brain tissue (e.g. a particular region of visual space is perceived by a specific region of primary visual cortex). Second, these maps are distorted relative to the physical world, so that more brain tissue is devoted to those regions for which we have a higher density of receptors (e.g. more of the primary visual cortex is devoted to processing visual information from the fovea). Third, for vision, touch and motor control, the mapping of the world on to brain tissue occurs in an upside-down, backward manner (e.g. information from the upper right-hand portion of the visual world is processed by the ventral region of the primary visual cortex of the left hemisphere).

The primary motor cortex resides directly in front of the central fissure in a long, narrow band that begins deep within the longitudinal fissure and continues down until the Sylvian fissure. The amount of brain tissue devoted to a body part is proportional to the degree of fine motor control exhibited by that body part. Neurons in the motor cortex control the amount of force to be applied by muscles, so that damage to primary motor cortex leads to muscle weakness on the opposite side of the body, especially those abilities required for fine motor control, such as are needed to grasp something between the thumb and forefinger.

The primary somatosensory cortex is located directly posterior to the central fissure and receives information about tactile stimulation, proprioception, and pressure and pain sensations from internal organs and muscles. The distortion is similar but not identical to that observed for the motor strip, because the parts of our body for which we have fine motor control, such as our hands, are the same areas for which we need a fine sense of touch. Damage to the somatosensory strip compromises fine discriminations of touch (e.g. differentiating velvet from burlap, or knowing how many times one is touched in succession) on the side of the body contralateral to the damaged primary somatosensory cortex.

The primary visual cortex is located within the calcarine fissure in the occipital cortex. Neurons in this region code the contrast between light and dark, and destruction of the visual cortex leaves an individual functionally blind, as no visual information can be perceived. The mapping of the visual world on to the brain occurs such that information to the right of fixation (i.e. the right visual field) projects to the left hemisphere, whereas information to the left of fixation (i.e. the left visual field) projects to the right hemisphere. Almost the entire occipital cortex is devoted to processing visual information. After being processed by the primary sensory cortex, information is relayed to the secondary sensory cortex, which, like primary sensory regions, processes information from only one sensory modality. Although there are secondary sensory regions for all modalities, those for visual processing are vast, comprising more than 30 distinct regions of secondary visual cortex, each of which varies in its sensitivity to important visual attributes, such as colour, orientation and motion.

The primary auditory cortex is located in Heschl's gyrus, tucked inside the Sylvian fissure. Unlike other sensory systems in which information from one side of the body projects solely to the contralateral hemisphere, the organization of the auditory system is such that there are both ipsilateral and contralateral projections from the ear to the brain; hence, auditory information received at the right ear projects to the left and right hemispheres. The organization of the primary auditory cortex is tonotopic, meaning that it is organized with regard to the frequency of a tone. The mapping of the auditory cortex is such that the lowest tones are processed caudally and laterally, and tones of increasing frequency are processed as one moves rostrally and medially through the cortex. Unilateral damage to the primary auditory cortex does not impair the ability to perceive all sound because of the redundancy provided by both crossed and uncrossed connections in the auditory system. Rather, the softest intensity that can be perceived, i.e. the sound threshold, becomes higher contralateral to the damaged hemisphere, and the ability to perceive the location of a sound becomes poorer for the contralateral side of space.

Lateralization of Function

The idea that the hemispheres had different functions first caught the attention of the scientific community in the 1860s when Paul Broca, a French neurologist and anthropologist, provided evidence from numerous case studies that the left hemisphere, but not the right, was critical in language processing. Broca's discovery was sparked by an encounter with one of his patients, who exhibited an unusual syndrome. The man could utter only the syllable 'tan', yet he could understand language as evidenced by his ability to follow simple verbal commands. Furthermore, his problem was specific to speech output, in that he did not exhibit paralysis of the vocal musculature or the vocal tract. At autopsy, Broca noticed that a specific region of the left hemisphere was damaged. He then proceeded to accumulate a small series of brains from individuals who had the same type of language problem, and noticed that in each case the damage was restricted to the same brain region; more importantly, he noticed that the damage was always localized to the left hemisphere. Furthermore, Broca found that individuals with damage to the analogous area of the right hemisphere displayed no difficulties in language. The importance of the left hemisphere for language processing was confirmed by other neurologists, such as Karl Wernicke. He found that individuals with lesions to the temporal-parietal region of the left hemisphere exhibited the converse syndrome of that discovered by Broca — difficulties in language comprehension along with intact production. By the end of the 1800s, the scientific community had accepted the idea of cerebral dominance, the notion that one hemisphere dominates or leads for a given mental function. At that time, it was believed that the left hemisphere dominated almost all mental thought because language was considered synonymous with thought.

Research in the late 1950s and early 1960s dramatically changed scientists' conceptions of the functioning of the hemispheres, revealing each to have its own specialization. Effects of the surgical removal of regions of the right hemisphere, or disruption in right hemisphere performance after brain lesions, were noted by researchers across the globe, including those in Canada (e.g. Milner, 1968), France (e.g. Hecaen, 1962) and the USA (e.g. Benton, 1969). Probably the most dramatic demonstration of differences in function between the hemispheres, however, came from the research of Roger Sperry and associates (e.g. Sperry, 1974) at the California Institute of Technology, who tested a unique set of patients known as split-brain patients. As treatment for severe intractable epilepsy, the corpus callosum, the major fibre tract connecting the cerebral hemispheres, was cut in these individuals. This split-brain surgery provided a fascinating and unique opportunity — the ability to test the individual competency of each hemisphere separate from that of its partner.

Because the observations of Broca and subsequent neurologists suggested that the left hemisphere was dominant for speech output, Sperry and colleagues wished to determine which hemisphere controlled speech output in these split-brain patients. To do so, these researchers asked the patients to feel objects hidden from view

with just one hand (limiting information to the tactile modality). Because of the contralateral organization of the somatosensory system, objects felt by a given hand are perceived exclusively by the contralateral hemisphere. The patients were able to name the objects placed in the right hand but not those placed in the left hand. To determine whether the right hemisphere was indeed without much mental competency, or whether it just could not express itself, the researchers changed the task so that the patient had to demonstrate the correct use of familiar objects, such as pencils, cigarettes and drinking glasses. Under these conditions, the objects placed in the left hand could be identified correctly, indicating that the right hemisphere does have knowledge about the world, even though it has no control over speech output (Gazzaniga *et al.*, 1962).

Subsequent findings indicated that although mute, the right hemisphere has some albeit limited linguistic capacity. It can read most concrete words (i.e. words that represent real objects in the world), and it can make simple grammatical comparisons (e.g. differentiate between 'The boy went to the store' and 'The boy did not go to the store') (e.g. Zaidel, 1990). However, it cannot process more complicated grammatical constructions in which word order is important (e.g. 'The dog that the cat chased ran under the table behind the garage that had been condemned by the sheriff last week') (Zaidel, 1978), and it cannot perform phonological processing (e.g. Levy and Trevarthen, 1977), which is the ability to break down words into their constituent sounds.

In contrast, the right hemisphere excels at tasks that are spatial and non-verbal in nature. For example, when given blocks that must be arranged to form a pattern, the right hand (left hemisphere) performs in a hapless and disorganized manner, whereas the left hand (right hemisphere) performs the task rapidly and accurately. In addition, the left hand can depict three-dimensional structures in a two-dimensional plane, such as is required when a cube must be drawn on a piece of paper, but the right hand can not (e.g. Gazzaniga, 1970). The right hemisphere also excels at processes such as recognizing faces, non-algebraic aspects of geometry, and so forth. Findings of differences between the hemispheres in mental functioning have been confirmed not only in patients with unilateral lesions but also in neurologically intact individuals (see Banich, 2003, Chapter 4 for a longer discussion of these results).

Whereas earlier models suggested that the hemispheres differed in the kinds of information they each process (e.g. spatial *v*. verbal), more recent research suggests that the hemispheres differ in *how* they process information (see Banich and Heller, 1998). These studies suggest that the hemispheres have different modes of processing (e.g. holistic *v*. piecemeal), and that certain materials or tasks are handled better by one mode than the other. Although many dichotomies have been suggested to describe the differences between the hemispheres, they are summed up well by saying that the left hemisphere processes information in a piecemeal and analytic fashion, with a special emphasis on temporal relationships, whereas the right hemisphere processes information in a gestalt and holistic fashion, with a special emphasis on the spatial relationships. From this viewpoint, language is processed better by the left hemisphere because it relies on distinctions of fine temporal ordering in the comprehension and production of speech sounds, and the gestalt processing of the right is well suited for tasks such as face recognition.

Some researchers posit that the hemispheres selectively filter different aspects of basic sensory features, and that this selective filtering of sensory information underlies hemispheric differences for more complicated cognitive tasks. This viewpoint posits that although both hemispheres are equivalent in their receipt of sensory information, the left hemisphere filters information so that it preferentially processes information of relatively higher frequency, whereas the right hemisphere filters information of relatively lower frequency. (In the visual modality, frequency refers to how quickly information shifts from dark to light, so that information of higher spatial frequency provides the detail, and that of lower spatial frequency provides gross form.) This asymmetry is relative, so that information processed preferentially by the left hemisphere in one context (i.e. when it constitutes the higher-frequency information) may be processed by the right hemisphere in another context (i.e. when it constitutes the lower-frequency information). (For a book-length description of this theory, see Ivry and Robertson, 1998.)

The concept that the hemispheres are specialized for different modes of processing implies that both hemispheres can contribute simultaneously to performance. For example, in face processing, the right hemisphere is involved in processing the overall configuration or gestalt of the face, while the left hemisphere is engaged in processing the details, such as the shape of mouth. This parallel processing brings an important issue to the fore — that of how the hemispheres end up coordinating processing to provide the seamless mental experience that we all have. Recent work suggests that interaction between the hemispheres not only merges together these two modes of processing but also serves an important role in attentional regulation. When attentional or task demands are low, the hemispheres work independently, as coordinating their activity imposes a communication 'overhead'. But as demands increase, their processing becomes increasingly coupled. In this manner, more brain 'power' can be brought to bear on a task, and the cost of communication is relatively small in comparison to the additional computational power provided by an additional hemisphere. Interestingly, a number of clinical disorders, including schizophrenia (e.g. Mohr *et al.*, 2000), multiple sclerosis (Pelletier *et al.*, 1993), and closed head injury (Vuilleumier and Assal, 1995), are characterized by atypical or disrupted interhemispheric interaction and are also associated with attentional difficulties (For a review of the role of interhemispheric interaction in cognitive processing, especially attention, see Banich (2002).

Association Areas

Association areas, where information from multiple sensory modalities converges, are responsible for those abilities that we tend to think of as distinctly human, such as language, compassion and foresight. Because it is involved mainly in processing visual information, the occipital lobe does not serve as large an associative function as the other three major lobes of the brain (frontal, parietal and temporal).

The Frontal Lobe

In discussing the frontal lobes, researchers and clinicians generally describe it as having three distinct regions: the primary motor region (discussed previously), the premotor region, and the prefrontal region. Prefrontal regions are often divided further into dorsolateral, orbital and medial regions. The distinction among these regions is based on major cytoarchitectonic subdivisions. Recent evidence suggests that these regions may play very different roles in mental functioning. Although we will discuss these subdivisions in more detail later, as an overview, dorsolateral regions have been implicated in memory and attentional processing, orbital regions have been implicated in reward processes and decision making, and medial regions have been implicated in judgement and the detection of errors.

Frontal regions are often thought of as the source of some of the most uniquely human abilities. A good generalization about the role of frontal regions is that they are associated with the planning, guidance and evaluation of behaviour. Just as the head of a corporation oversees its day-to-day operations and plans its long-term goals, the frontal lobes are considered to be the 'executive' of the brain. Not only are the frontal regions important for organizing behaviour coherently, but research also suggests that they may

allow us to extrapolate forward in time, enabling us to realize the future consequences of our current behaviour.

The abilities that are destroyed by frontal lobe damage are not categorized easily under a simple rubric, but the loss of these abilities can nonetheless be profound. For example, individuals with frontal lobe dysfunction may exhibit little decrement in performance when given standardized IQ tests that assess fact knowledge and academic skills, such as knowing the definitions of words, knowing how to solve arithmetic problems, knowing how to put together jigsaw puzzles, and so forth. Impairments in functioning may nonetheless be severe. Disruptions may occur in any or all of the following areas: the ability to organize and sequence behaviour; the ability to modulate behaviour, especially its initiation or its cessation; the ability to generate an appropriate emotional response; and the ability to use strategies and tags for retrieving memories.

People with frontal lobe damage generally have difficulty knowing how to organize behaviour to reach a goal. Although they may know the components or steps in a process, they are unable to put them together in a coherent manner to reach a goal. For example, if they go to change a light bulb that has burned out, they will go to the cabinet where they typically store light bulbs. But if a bulb is not there, they may have difficulty organizing themselves to find the keys to the car, drive to the store, purchase new light bulbs, and then come back and replace the burned out bulb, although under other circumstances they are perfectly capable of finding their keys, driving to the store and back, and making a purchase.

Another problem observed in individuals with frontal lobe damage is an increase in 'psychological inertia', the force that must be overcome to either initiate or stop a process. Individuals with frontal lobe damage have an inability to overcome the inertia required to initiate a new behaviour or to cease the task in which they are engaged. This handicap may take many forms. For example, people with frontal lobe damage may not bathe and change their clothes each day on their own volition, but they will do so if directed by another individual; or an individual with frontal lobe damage may sit on a couch for hours without initiating any behaviour. Conversely, once involved in a behaviour, an individual with frontal lobe damage may find it impossible to stop acting in a particular manner. Such patients are likely to perseverate, i.e. perform the same behaviour repeatedly. There is now evidence that obsessive–compulsive disorders, which are characterized by people who engage in the same stereotyped motor behaviour to ward off some danger (e.g. constantly washing hands to prevent infection by germs), result from dysfunction of the frontal lobe, specifically the orbitomedial areas and subcortical regions to which they connect (e.g. Saxena *et al.*, 1998; Tallis, 1997).

Because the frontal lobes are relatively immature in young children, they tend to exhibit perseverative tendencies. If you hide a child's favourite toy behind one of many pillows, the young child will reach out and move the pillow behind which he or she believes the toy to be, but then sees that the toy is not there. Rather than moving another pillow, the child moves the same pillow, which still does not conceal the toy. The child is likely to repeat this behaviour many times. Although the child appears to forget where the toy is hidden, research suggests that very young babies (2–2.5 months old) can remember the location of an object, even when it is hidden behind another (e.g. Baillargeon, 1994). The problem is not so much one of memory but rather that the child seems to be locked into a perseverative behavioural loop in which the only way to look for the toy is to reach out and move that one particular pillow. This sort of behavioural loop is exactly the type of perseverative behaviour that may be exhibited after frontal lobe damage (Diamond, 1990).

Individuals with frontal lobe damage also have more general difficulties in modulating behaviour. For example, patients with frontal lobe damage are often socially uninhibited and inappropriate. They may make unwanted sexual advances to medical personnel, tell jokes at inappropriate times, be insensitive to the social context in which they find themselves, and so forth. This inability to modulate behaviour leads to the paradoxical effect that at certain times individuals with frontal lobe damage are insensitive to their social surroundings, whereas at other times they are unduly swayed by them. For example, by talking about depressing topics, physicians and other medical personnel may find an individual with frontal lobe damage moved to tears, but they can reverse the effect and put him or her in an ecstatic mood within minutes by talking about the person's favourite possessions or activities.

Frontal regions of the brain are also involved in 'metamemory functions', which can be thought of as the abilities that allow for the strategic use, deployment and retrieval of memories. These functions are clearly related to memory, but they do not involve actually remembering a particular item, individual or fact. In general, the difficulties in metamemory observed after frontal lobe damage are problems with the temporal sequencing or tagging of memories. For example, individuals with frontal damage are unable to determine which of two items in a sequence occurred more recently (Milner *et al.*, 1991), even though they can clearly distinguish between items that appeared in a sequence and those that did not (Milner and Petrides, 1984). Moreover, if we show individuals with frontal lobe damage a series of items in which some items appear randomly on multiple occasions (e.g. three times, five times, seven times), these people have difficulty in estimating how often an item occurred although they have no difficulty in discerning whether an item was viewed previously (Smith and Milner, 1988). Finally, individuals with frontal lobe damage have trouble knowing the source of a memory (e.g. remembering that they learned in a travel guide that Rome had a million inhabitants in AD 100) (Janowsky *et al.*, 1989). These types of deficits are often observed in the dementias associated with neurological disorders such as Parkinson's disease and Huntington's disease, because they compromise the integrity of basal ganglia–frontal connections (e.g. Cummings and Benson, 1988). In such cases, recognition memory (e.g. 'Was Churchill the leader of England during the Second World War II?') tends to be intact because the individual need not organize an effortful search through memory. In contrast, effortful retrieval of information (e.g. recall) or metamemory functioning is compromised (e.g. Ivory *et al.*, 1999).

Frontal regions, especially prefrontal areas, are also considered important for keeping memory information online to be used in giving a response, also known as working memory. Working memory is memory that has a limited capacity (7 ± 2 items) and that can be retained without rehearsal for only a short period of time (e.g. 10 s). The role of the prefrontal region in this function is well established, coming from various sources, including work with monkeys (e.g. Goldman-Rakic, 1990) young infants (Diamond, 1990) and adults (e.g. Belger *et al.*, 1998). Some researchers have suggested that ventrolateral regions are important for the storage of information in the working memory buffer, whereas more dorsolateral regions are important for manipulating the contents of working memory (e.g. Petrides, 1998; Wagner, 1999) or for selecting the contents of working memory (see Smith and Jonides, 1999 for a short review of this work). In addition, the prefrontal region seems especially important for creating an attentional 'set', i.e. holding online what it is that one must attend to (Banich *et al.*, 2000b). Dysfunction of the dorsolateral prefrontal region with concomitant disruptions in working memory has been implicated specifically in schizophrenia (e.g. Callicott *et al.*, 2000). If one cannot hold information online or select what is relevant for task performance, then serious disruption in mental processing is likely to ensue.

Damage to frontal regions can have profound effects on personality. Often, the family and other loved ones of an individual who has sustained frontal lobe damage will comment that the individual does not seem to like him- or herself any more. A formerly quiet and peaceful person may be described as argumentative and prone

to outbursts, a previously conscientious and hard-working person may be characterized as irresponsible and lazy, and a previously kind and considerate person may appear to be selfish and uncaring. One of the most famous early cases in which such changes were documented was that of Phineas Gage, a railroad worker. While clearing a way for the railroad in 1848, an explosion blew a steel rod through his skull, damaging sections of his frontal cortex. Family and friends complained that he 'was no longer Gage', and that although his body was the same, the man they knew seemed to have vanished.

More recent research suggests that frontal lobe functioning not only influences personality, a characteristic considered to be constant over time, but that such functioning can also influence a person's internal emotional state or mood, which can vary over time from happy to sad, from calm to frustrated, from peaceful to agitated. Certain aspects of mood are related to the difference in activation between the right and left frontal regions. In particular, relatively higher activation of the left frontal region compared with that of the right is associated with positive mood. In contrast, relatively higher activation of the right frontal region compared with that of the left is generally associated with negative or dysphoric mood (e.g. Davidson, 1992). For example, after damage to left frontal regions, activation of such regions is clearly lower than that of right frontal regions — an imbalance associated with depressed mood. In fact, more than half of individuals with damage to left frontal regions due to stroke fit psychiatric definitions of either major or minor depression (Starkstein and Robinson, 1999). It is notable that the extent of the depression does not depend on the severity of the person's cognitive deficits, but rather is related to the location of the lesion within the left frontal lobe. Because it is an imbalance of frontal regions, rTMS over the left frontal regions, which has the effect of stimulating these regions by increasing regional cerebral blood flow, is therapeutically useful. However, if low-frequency rTMS is employed, which has the effect of decreasing regional cerebral blood, the symptoms of depression actually increase (Speer *et al.*, 2000).

Recent research has suggested that the orbitofrontal cortex plays a major role in decision making, especially that involving the evaluation of rewards and punishment. This region of the brain is the place where neural pathways connect limbic, visceral and autonomically responsive areas of the brain with higher cortical centres in the prefrontal cortex. Individuals with lesions to orbitofrontal regions will pick a deck of cards that can provide a big individual pay-off but on average yields a loss over that which provides smaller individual pay-offs but on average yields a gain (e.g. Bechera *et al.*, 2000). Likewise, activation of these regions as assessed via PET predicts performance on a gambling task (Grant *et al.*, 1999). Given the linkage of the orbitofrontal cortex to the evaluation of reward, it is not surprising that this brain region has been implicated in substance abuse (e.g. Volkow and Fowler, 2000).

Medial frontal regions, especially the anterior cingulate, have been implicated in error detection and monitoring. In particular, there is an ERP component known as the error-related negativity (ERN) that occurs 80–150 milliseconds after the production of an incorrect response (Gehring *et al.*, 1993), whose source appears to be the anterior cingulate (DeHaene *et al.*, 1994). This component is reduced in individuals with obsessive–compulsive disorder (Gehring *et al.*, 2000) and may be heightened in individuals with negative affect (e.g. Luu *et al.*, 2000).

As this chapter illustrates, the frontal regions of the brain are involved in a vast array of behaviours. Rather than being important for specific domains of cognitive activity, such as language, spatial processing or object recognition, frontal regions provide us with executive capabilities that are used across a vast number of domains and allow for flexible and adaptive behaviour.

The Parietal Lobe

The parietal lobe of the cortex plays a role in (1) integrating information from various sensory modalities, (2) integrating information from the sensory world with information stored in memory, and (3) integrating information about an individual's internal state with information from the external sensory world. Because this integrative function can occur in various ways, the deficits observed after parietal lobe damage are often diverse and difficult to conceptualize as all falling under the same rubric. However, if the role of the parietal lobe is conceptualized as associating different forms of information, then the array of functions performed by the parietal lobe will not seem so disjointed. As an example, single-cell recordings in monkeys indicate activity in parietal areas when a conjunction of conditions occurs. For example, a cell in the parietal lobe might fire only when a banana is in view *and* that banana is within the monkey's reach. Alternatively, another cell in the parietal lobe might not fire at the sight of the banana alone but would fire only if the animal was also hungry. Thus, in both cases the cell would fire in response to some conjunction of attributes: the visual stimulus of the banana and its position in space, or the visual stimulus of the banana and the animal's internal state (e.g. Lynch, 1980).

In humans, the role of the parietal lobe in multimodal integration is seen in many syndromes that occur after damage to this region, including agnosia, alexia, agraphia and apraxia. Agnosia is a modality-specific deficit in recognizing objects, meaning that the individual cannot recognize an object in one sensory modality but can recognize it in other modalities. For example, if an individual has a visual agnosia, he or she will be unable to identify an item as a rose merely by looking at it. However, if the person is pricked by a thorn or smells the flower, he or she will recognize it instantly. An important point to note about agnosia is that the deficit can be attributed neither to the inability to perform basic sensory processing nor to a memory deficit. Persons with visual agnosia are not blind. They can distinguish light from dark and they can discriminate basic shapes (e.g. square from rectangle) (Warrington and James, 1988). So, for example, when looking at a rose, a person with visual agnosia can see that an object is there, describe its colour, and maybe even crudely describe its shape, but they cannot use this information to gather a visual impression of a rose. Furthermore, memory for the item is intact. So, for example, if asked what kinds of flowers compose the garland that is placed around the neck of the horse that wins the Kentucky Derby, or which popular flower with thorns is associated with romance, then the person with visual agnosia could easily answer 'rose'.

Agnosias can occur in all modalities. In auditory agnosia, an individual knows that a sound has occurred but they do not know its significance; for example, they cannot identify a particular sound as a car horn, even though he or she knows that some sound has just occurred. Likewise, in tactile agnosia, objects cannot be recognized by touch.

What is common to all these agnosias is that basic sensory processing in the affected modality is intact, as are memory processes. Tactile agnosia is most often associated with parietal damage, visual agnosia with parieto-temporal damage, and auditory agnosia with temporal lobe damage.

Two other deficits common after parietal lobe injury are alexia and agraphia, which are, respectively, the inability to read and the inability to write as a result of brain damage. A parietal locus for these functions is consistent with the operations that are involved in reading or writing. Psychological research has suggested that there are two distinct manners by which reading and writing occur. In the phonological route, a linkage is made between each letter and a sound (e.g. 'bat' ⇒ /ba/ /a/ /ta/), and then the sound pattern is linked to information stored in memory (/ba/ /a/ ta/ ⇒ 'a mammal that flies around and eats insects; seen most often at dusk'). The

alternative route bypasses sound entirely because a pattern of letters is linked directly with meaning (e.g. 'dog' ⇒ a favourite household pet). For both routes, a person must take a visual form and arrive at meaning via association. These deficits, as might be expected, are observed only after left, not right, hemisphere damage.

Notice that the localization of these written language functions is quite distinct from those that produce aphasia (the inability to produce spoken language). As discussed earlier, Broca's aphasia, which is characterized by an inability to produce fluent output in the face of intact production, is associated with damage to frontal regions (the frontal operculum, or Brodmann area 44), while Wernicke's aphasia, which is characterized by an inability to comprehend language in spite of fluent output, is associated with damage to the parieto-temporal junction. Hence, the neural machines that control spoken and written language are quite distinct. Interestingly, it also appears that the neural substrates for reading written language are distinct from those required to read music (e.g. Sergent, 1993). Musical notation relies more on the appreciation of spatial relationships between symbols than do standard language systems.

Still another deficit observed after damage to parietal regions is apraxia, which is the inability to perform skilled motor movement in an abstract manner. Basic motor control is intact, and the individual is not paralysed, yet these people have trouble linking motor movement to a representation. People with apraxia can usually make certain voluntary movements without difficulty, but they cannot pantomime them. For example, an individual with apraxia might be able to put a spoonful of sugar into his or her coffee cup, but when asked to pantomime the same gesture, they might use one finger to represent the spoon rather than positioning the hand as appropriate for stirring sugar into coffee. Apparently, individuals with apraxia lack the capacity to programme the motor sequences that allow for the representation of an act, but these people have the capacity to perform the act itself. Apraxia may also involve the inability to perform gestures that have symbolic significance. For example, an individual may not be able to make the sign of the cross, the victory symbol or the 'OK' sign. Once again, these deficits are most prominent after left hemisphere damage.

Other abilities affected by parietal lobe damage include disturbances in spatial processing. Damage to parietal regions disrupts the ability to localize points in space, to know the angle of lines, and to understand spatial relations between items. Parietal regions of the brain appear to contain the map of space that we use for navigation, for placing our limbs in the correct position for the manipulation of objects, and for knowing what part of space to explore. It was originally thought that most aspects of spatial processing are performed by the right hemisphere. However, more recently it has been noted that the right hemisphere may be involved in those spatial processes involved in the metric or distance aspects of spatial processing (e.g. knowing that two items are 5 cm apart), whereas the left hemisphere may be more involved in spatial processing that involves categorization of spatial relations (e.g. knowing that the glass is to the left of the pen) (Chabris and Kosslyn, 1998). Notice that knowing the distance between two items provides no information on their categorical relationship (e.g. which is to the left and which is to the right), nor does their categorical relationship provide information about the distance that separates them. This is but another example of how the hemispheres may work in parallel in service of cognitive processes.

Right parietal regions have also been implicated in overall arousal and attention. Damage to parietal regions, more so than damage to other regions of the brain, leads to disruption in attention and attentional regulation. This can vary from disruptions in mood states (e.g. decreased arousal in depression; e.g. Heller *et al.*, 1995) to disruptions in the ability to attend to more than place in the visual world (i.e. Balint's syndrome). Typically, such deficits are observed after right, rather than left, hemisphere damage. Probably the most common manifestation of dysregulation in attention is that of hemi-neglect, which typically occurs after a stroke to the right parietal regions. Individuals with this disorder will ignore information on the contralateral side (typically the left); they will forget to eat food on the left side of the plate, ignore people on their left, not shave the left side of the face, and so forth. It can be demonstrated that when stimuli are particularly potent (e.g. a loud noise), individuals can process information contralesionally. Thus, they do not have a sensory deficit that impedes their ability to process the information; rather, they have a limited arena of space to which they can direct their attention, as it is restricted to only one side. In the most severe form of hemi-neglect, almost all contralateral information is ignored. As the neglect abates, as typically occurs with time from onset, the ability to attend to contralesional information improves. Yet, if there is competition between information on the contralesional and ipsilesional side (i.e. bilateral stimulation), then only the ipsilesional information is apprehended whereas that situated contralesionally is extinguished. It has been suggested that this extinction phenomenon occurs because attention gets captured by ipsilesional stimuli and cannot be disengaged to process contralesional stimuli. Support for such a notion comes from studies demonstrating that disrupting activation of the intact hemisphere by TMS or other means ameliorates the hemi-neglect (e.g. Olivieri *et al.*, 1999).

As evidenced by this chapter, damage to the parietal regions can cause a heterogeneous array of syndromes. In general, however, they are all syndromes in which sensory information cannot be integrated across modalities and/or with internal representations or memories.

The Temporal Lobe

Temporal regions of the brain are associated with four main functions: memory, visual item recognition, auditory processing and emotion. Classically, the temporal lobes have been associated with memory function, as documented most clearly in the famous case of H.M., who in early adulthood underwent bilateral removal of anterior portions of the temporal lobe for the relief of intractable epilepsy. Although the surgery was successful in reducing his seizures, he was left with the inability to learn almost all types of new information, even though most of his memories from the years before the operation were intact. This case was pivotal in demonstrating that specific regions within the temporal lobe, most notably the hippocampus, are critical for the formation of new long-term memories. Additional research by Milner and colleagues demonstrated that the memory deficit tends to be greater for verbal material after removal of only the left temporal lobe (e.g. Frisk and Milner, 1990) and greater for spatial information after removal of only the right temporal lobe (Smith and Milner, 1981).

In addition to being important for the formation of new long-term memories, temporal regions of the brain play important roles in visual processing, contributing to visual item recognition. Electrical recordings from single cells in the inferior temporal lobes of monkeys have revealed that these cells respond only to highly specific visual stimuli. Unlike cells in the primary visual cortex, which respond to bars of light oriented at particular angles and moving in particular directions, the cells of the inferior temporal lobe respond to very specific shapes, such as a hand, a brush or a face (Gross *et al.*, 1972). In fact, some of the cells may respond only to the faces of particular people or certain features on a face (e.g. eyes) (Perrett *et al.*, 1987). This specificity of visual processing in temporal regions appears to be a characteristic of the mammalian nervous system. For example, certain cells in the temporal cortex of sheep respond to horned sheep but not unhorned sheep, whereas other cells respond only to sheepdogs but not wolves or dogs with pointed ears (because they resemble wolves) (Kendrick and

Baldwin, 1987). In humans, damage to temporal regions can lead to deficits such as the inability to recognize common objects like cars or chairs (Farah and Feinberg, 2000) or that a given face belongs to a specific individual (De Renzi, 2000). Thus, at least for visual items, temporal regions appear to be important for item identification.

This specialization of temporal regions for visual item processing reflects a segregation of the processing of visual information in the mammalian brain into two streams or systems. On the basis of neuroanatomical, neurophysiological and behavioural work with animals, Ungerleider and Mishkin (1982) suggested that visual information leaving primary occipital areas bifurcates into two pathways, one of which courses dorsally to the parietal lobe, which is important for processing the locations of items, and the other of which travels ventrally to the temporal lobe, which is important for processing the shapes of items.

Because auditory processing areas are located in the temporal lobe, damage to this region of the brain can have consequences for the processing of auditory material. For example, damage in the temporal lobe can lead to auditory agnosia or to difficulties in the appreciation of certain aspects of music, such as pitch (e.g. Zatorre, 1998). Brain-imaging studies also indicate activation of temporal regions, especially that of the right hemisphere, when a tune is running through someone's mind (e.g. Halpern and Zatorre, 1999).

Temporal regions of the brain have also been implicated in the processing of emotional information. The temporal lobe contains structures that are portions of the limbic system, which act to integrate information from the sensory world with internal urges (e.g. urges for food, sex, etc.). One prominent structure in the limbic system located in the temporal lobe is that of the amygdala, which has been implicated in modulating fear responses, especially when incoming information is ambiguous (e.g. Whalen, 1998). It is also implicated in anxiety disorders (e.g. Rosen and Schulkin, 1998), such as panic disorder (e.g. Goddard and Charney, 1997). Moreover, disruptions of temporal lobe functioning can have emotional consequences. For example, some investigators have suggested that temporal regions may be dysfunctional in a certain proportion of people with schizophrenia, most notably those suffering from delusions (Schroder *et al.*, 1995).

SUMMARY

Neuropsychology has much to contribute to understanding a broad number of psychiatric disorders. Damage or dysfunction of a specific brain region has multifaceted consequences, some of which affect mainly cognitive processes while others affect emotional processes. It is the interrelationship between these two sets of consequences that has many implications for our understanding of psychiatric disorders, ranging from depression (e.g. Heller and Nitschke, 1997) to substance abuse (Volkow and Fowler, 2000). The classic approach borrowed from neuropsychology to understanding psychiatric disorders has been that of the lesion method, which makes linkages between dysfunction of specific regions of brain tissue and particular mental consequences. Although such an approach has been fruitful for certain disorders, there are many psychiatric disorders that are produced by more diffuse rather than focal brain dysregulation, schizophrenia being a good example. Nonetheless, neuropsychology will continue to play an important role in understanding the mechanisms of psychiatric disorders and the evaluation of the efficacy of new treatments due to a plethora of new methodologies that can be used singly or in tandem. Evaluation of drug therapies via fMRI, treatment of depression with rTMS, and insights into obsessive–compulsive disorders with ERP recordings are but a few examples of the promise that a neuropsychological approach holds for psychiatry.

XI

Brain Imaging

Steven Laureys, Philippe Peigneux and Serge Goldman

INTRODUCTION

While philosophers have, for centuries, pondered upon the relation between mind and brain, neuroscientists have only recently been able to explore the connection analytically — to peer inside the black box. This ability stems from recent advances in technology and emerging neuroimaging modalities. It is now possible not only to produce remarkably detailed images of the brain's structure (i.e. anatomical imaging) but also to capture images of the physiology associated with mental processes (i.e. functional imaging). We are able to see how specific regions of the brain 'light up' when activities such as reading this book are performed, and how our neurons and their elaborate cast of supporting cells organize and coordinate their tasks. As demonstrated in the other chapters of this book, the mapping of the human mind (mostly by measuring regional changes in blood flow, initially by positron emission tomography (PET) and recently by functional magnetic resonance imaging or (fMRI)) has provided insight into the functional neuroanatomy of neuropsychiatric diseases.

Amazingly, the idea that regional cerebral blood flow (rCBF) is related intimately to brain function goes back more than a century. As is often the case in science, this idea was initially the result of unexpected observations. The Italian physiologist Angelo Mosso first expressed the idea while studying pulsations of the living human brain that keep pace with the heartbeat (Mosso, 1881). These brain pulsations can be observed on the surface of the fontanelles in newborn children. Mosso believed that they reflected blood flow to the brain. He observed similar pulsations in an adult with a post-traumatic skull defect over the frontal lobes. While studying this subject, a peasant named Bertino, Mosso observed a sudden increase in the magnitude of the 'brain's heartbeats' when the church bells signalled 12 o'clock, the time for a required prayer. The changes in brain pulsations occurred independently of any change in pulsations in the forearm. Mosso understood that the bells had reminded Bertino of his obligation to say a silent Ave Maria. Intrigued by this observation, Mosso then asked Bertino to perform a mental calculation; again, he observed an increase in pulsations and, presumably, blood flow as the subject began the calculation and a second rise just as he answered. This was the first study ever to suggest that measurement of cerebral blood flow might be a way of assessing human cognition.

Charles Roy and Charles Sherrington characterized this relationship further at Cambridge University. Based on animal experiments, they suggested that 'the brain possesses an intrinsic mechanism by which its vascular supply can be varied locally in correspondence with local variations of functional activity'. Their observations were fundamental, and their brilliant deductions have dominated the brain-imaging field since. One of the most extraordinary examples of the relationship posited by Roy and Sherrington was observed in Walter K., a German-American sailor who consulted Dr John Fulton at Boston's neurosurgery clinic for headache and failing vision. Walter also reported to hear a humming noise in his head. Fulton, when listening with a stethoscope at the back of his patient's head, confirmed this bruit and organized an exploratory intervention. Dr Harvey Cushing performed the neurosurgery and found a large arteriovenous malformation overlying the visual cortex. An attempt to remove the vascular malformation failed and left Walter with a bony defect overlying his visual cortex. His physicians could now hear the bruit even more clearly. During the course of his stay, Walter mentioned that the noise in his head became louder when he was using his eyes. As Fulton (1928) published later in the journal *Brain*:

> It was not difficult to convince ourselves that when the patient suddenly began to use his eyes after a prolonged period of rest in a dark room, there was a prompt and noticeable increase in the intensity of his bruit . . . Activity of his other sense organs, moreover, had no effect upon his bruit. Thus, smelling tobacco or vanilla did not influence it, straining to hear the ticking of a distant watch produced no effect, and ordinary quiet conversation was without demonstrable influence.

In order to document his remarkable observations for others to appreciate, Fulton recorded the sounds of the bruit while his patient 'was allowed to lie on his stomach in a comfortable position, with his chin resting on the edge of a chaise-longue in such a way that he could close his eyes and open them to read a newspaper lying on the floor'. Within 20–30 seconds after Walter began to use his eyes to read the newspaper, there was a noticeable increase in the intensity of the bruit. If the lights were put out, the bruit continued for nearly a minute afterward; then it gradually subsided, and at the end of two minutes it had returned almost to resting level. Recent research capable of recording changes in blood flow within milliseconds has provided remarkable confirmation of these pioneer observations made with only a stethoscope and a simple recording device. After many such studies, Fulton 'gained the impression' that it was the effort of trying to discern objects that were just at the limit of his patient's acuity that brought on the increases of the bruit. Merely shining light into his eyes when he was making no mental effort had no effect. This was, indeed, a remarkable observation, the significance of which would not be appreciated for many years. It was probably the first ever recorded result of top-down influences on sensory processing (Posner and Raichle, 1994).

In what follows, we will introduce the vast area of anatomical brain imaging (X-ray computed tomography (CT) and magnetic resonance imaging (MRI)) and functional brain imaging (PET, single-photon emission tomography (SPECT), fMRI, electroencephalography (EEG), event-related potentials (ERPs), magnetoencephalography (MEG), magnetic resonance spectroscopy (MRS),

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

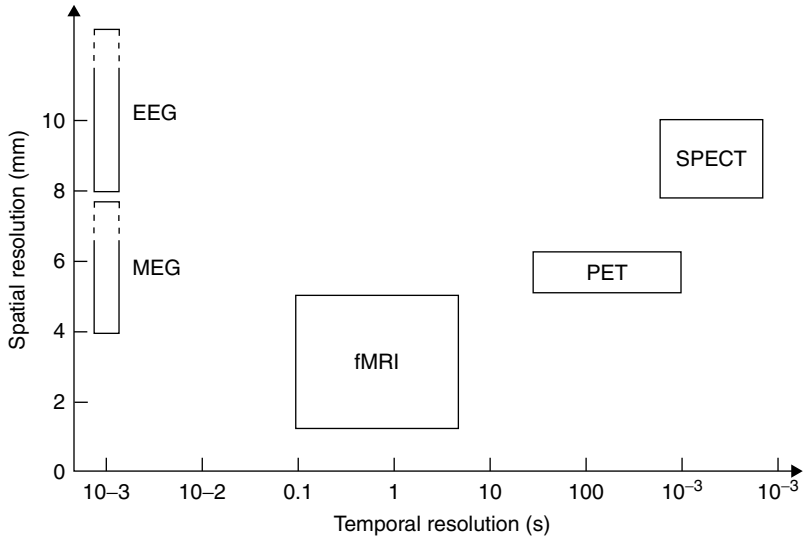

Figure XI.1 Approximation of the resolution in time and space of the most commonly employed functional neuroimaging techniques based on measurements of haemodynamic (fMRI, PET, SPECT) and electrical (EEG, MEG) activity of the brain

transcranial magnetic stimulation (TMS), and near-infrared spectroscopy (NIRS)). Each technique provides different information and has its own advantages and disadvantages in terms of cost, safety and temporal and spatial resolution (Figure XI.1). After briefly discussing their history and basic principles, we will present a short overview of study design and methods to process and analyse functional neuroimaging data.

COMPUTERIZED TOMOGRAPHY

History

The modern era of medical imaging began in the early 1970s, with the introduction of a remarkable technique called X-ray computed axial tomography, now known as CAT, X-ray CT or just CT. The theories that underlie tomographic imaging have existed since 1917, when the German mathematician Radon published his work dealing with reconstruction from image projections. Extension of this work by the South African physicist Allan Cormack in the early 1960s, and its practical applications by the British engineer Sir Godfrey Hounsfield, resulted in the construction of the first CT scanner. Both investigators received the Nobel Prize in 1979 for their independent contributions. Crucial in the development of X-ray CT was the emergence of clever computing and mathematical techniques to process the vast amounts of data necessary to reconstruct the images.

The development of X-ray CT had two consequences. First, it changed forever the practice of medicine because, for the first time, clinicians could non-invasively clearly view living human tissue such as the brain (standard X-rays reveal only bone and some surrounding tissues). Second, it immediately stimulated engineers and scientists to consider alternative ways of creating images of the body's interior using similar mathematical and computerized strategies for image reconstruction (e.g. SPECT and PET) (Posner and Raichle, 1994).

Despite its wide availability, CT has been replaced by the more sensitive MRI as the procedure of choice for cerebral imaging. CT is useful mainly when rapid information about the state of the brain is desired. In particular, it helps in making the choice between surgical and medical management of patients with sudden onset of neurological symptoms; such conditions include head trauma and stroke (where a differentiation between haemorrhage and infarction is important). CT is also used widely for the evaluation of lesions that involve bone (e.g. fractures or bone metastases) and calcifications within lesions of the brain.

Basic Principles

X-rays (i.e. a form of electromagnetic radiation travelling at the speed of light and carrying a large amount of energy) are capable of knocking an electron out of its orbit, therefore they are a form of ionizing radiation. A CT scanner delivers a narrow beam of X-rays that pass through the head. The exiting beam is then collected by a set of detectors, converted into digital data, and fed into a computer for image reconstruction. As the beam travels through the brain, it undergoes attenuation due to interaction with the various tissues it encounters. The degree of attenuation depends on the tissue density: very dense tissue, such as bone, attenuates lots of X-rays, cerebral grey matter attenuates some X-rays, and fluid attenuates even fewer. X-ray detectors positioned in a circle around the head collect attenuation readings as the beam is delivered from multiple angles. A computerized algorithm reconstructs a slice from these multiple readings. Thus, the contrast in a CT image is due to differences in X-ray attenuation among various tissues.

The use of exogenous contrast media in CT (and MRI) of the brain improves the sensitivity of detection and delineation of pathological structures, such as tumours, inflammation and ischaemia. CT contrast agents, like all commonly employed radiographic contrast agents, utilize substances with a high electron density (typically iodated agents) to absorb X-rays and thus produce a contrast effect. In both CT and MRI, a disruption of the blood–brain barrier results in accumulation of the intravenously administered contrast material in the extravascular space, leading to signal enhancement.

MAGNETIC RESONANCE IMAGING

History

MRI comprises a vast and varied array of techniques that use no ionizing radiation and provide an enormous range of information.

From an established ability to provide high-quality structural information, magnetic resonance techniques are advancing rapidly and providing other clinically relevant physiological information, such as spectroscopic studies illuminating the details of biochemical status (MRS; see below), blood oxygenation level allowing functional activation studies (fMRI; see below), cerebral blood compartment (magnetic resonance angiography or (MRA)); perfusion (perfusion-weighted imaging (PWI)), water molecular diffusion (diffusion-weighted imaging (DWI)), cerebral microstructure and fibre tracking (using diffusion anisotropy effects measured by diffusion tensor imaging (DTI)), magnetization transfer imaging, etc.

MRI derives from a potent laboratory technique, nuclear magnetic resonance (NMR), which was designed to explore detailed chemical features of molecules. In 1946, Felix Bloch of Stanford University and Edward Purcell of Harvard University discovered independently the phenomenon of NMR. They were awarded the Nobel Prize 6 years later. In the period between 1950 and 1970, the use of NMR was limited to chemical and physical molecular analysis. In 1971, Raymond Damadian showed that the nuclear magnetic relaxation times of tissues and tumours differed, thus motivating scientists to consider magnetic resonance for the detection of disease. NMR moved from the laboratory to the clinic when Paul Lauterbur found that it could form images by detecting protons. He used a back-projection technique similar to that used in X-ray CT to generate these images. Protons are interesting because they are abundant in the human body; by acting as little compass needles, they respond sensitively to magnetic fields. In 1975, Richard Ernst proposed MRI using phase and frequency encoding and the Fourier transform. This technique is the basis of current MRI techniques. It resulted in excellent images of the anatomy of the brain and other organs that far surpassed in detail those produced by CT. Six years later, Ernst was rewarded the Nobel Prize. In 1977, Peter Mansfield developed the echo-planar imaging (EPI) technique, which would permit the production of images at video rates (30 ms per image). By 1986, the NMR microscope was developed, allowing 10-mm resolution. In 1987, Charles Dumoulin perfected MRA, which could image flowing blood without the use of contrast agents. fMRI was developed in 1993 (see below). Clearly, the magnetic resonance technique is powerful and continuously expanding. Because of the negative connotations associated with the word 'nuclear' in the late 1970s, NMR is now commonly known as magnetic resonance imaging.

At present, MRI is the procedure of choice for the structural imaging of the brain. However, it is susceptible to movement artefacts, and patients who are on life-support systems, have gunshot wounds, or who have implanted MRI-incompatible material (pacemakers, prostheses, etc.) still represent problems. The main limit on the wealth of diagnostic information that can be obtained for each patient is in the duration of the procedure. Approximately 1 hour of magnetic resonance examination time is the practical limit of patient discomfort and cooperation for routine clinical studies. As scan times decrease through the use of new sequencing techniques, the available examination time can be used to improve the quality of the data or to obtain additional types of data. A range of magnetic resonance physiological measurement techniques is poised to fill any reclaimed imaging time. It is expected that further refinements of fMRI, MRA, MRS, PWI, DWI, DTI and other magnetic resonance techniques will allow them to fit into routine clinical practice.

Basic Principles

Some atoms, such as hydrogen (^{1}H), behave like spinning charges. Spinning nuclei will induce microscopic loops of electric current. As a result, they generate a very small magnetic field. MRI depends on the fact that these spinning atoms (mainly hydrogen nuclei, i.e. protons) act as little compass needles in the presence of a magnetic field. A strong magnetic field (approximately 10 000 times stronger than the earth's magnetic field) can align most of the atoms. By applying radiowave pulses to the tissue, the atoms can be perturbed in a precise manner. As a result, they emit detectable radio signals unique to the number and state of the particular atoms in the tissue. The strength of the MRI signal (i.e. the signal emitted when nuclei return to their equilibrium state) depends primarily on three parameters: the proton density in a tissue (the higher the density of protons, the larger the signal), the T_1 relaxation time (longitudinal magnetization), and the T_2 relaxation time (transverse magnetization). These properties are variable among tissues and are the predominant factors responsible for contrast among tissues. The signal intensity of one tissue compared with another (contrast) can be manipulated by varying the time elapsed between application of the radiofrequency pulse and sampling of the emitted signal (Pykett, 1982). The signal in magnetic resonance images is high or low (bright or dark) depending on the pulse sequence used and the type of tissue under study. On a T_1-weighted image, fat, subacute haemorrhage, melanin protein-rich fluid, slowly flowing blood, and paramagnetic substances (e.g. gadolinium) will appear bright. On a T_2-weighted image, increased water, as in oedema, tumour, infarction, inflammation, infection or subdural collection will appear bright (dark on T_1-weighted images). MRI contrast involves the use of relatively non-toxic paramagnetic agents, such as gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA). Unlike CT contrast agents, MRI contrast enhancement is indirect. Indeed, paramagnetic substances will act as relaxation centres for other nuclei in the local microenvironment and shorten the magnetic relaxation times of the surrounding hydrogen nuclei. MRI is a more sensitive method of detection of contrast, requiring dosages in the range of one-twentieth of that for CT.

The techniques used in MRI of the brain depend on the primary goal of its procedure (e.g. anatomical detail is best obtained using T_1 sequences, while inflammation and oedema are better visualized using T_2 sequences). As mentioned previously, MRI can provide a wealth of information not only about intrinsic T_1 and T_2 relaxation properties and spin density but also regarding blood and cerebrospinal fluid flow, bulk motion, diffusion, diffusion anisotropy, perfusion, local oxygenation, local iron content, membrane permeability, temporal dynamics of contrast agent interaction, etc.

POSITRON EMISSION TOMOGRAPHY

History

PET has its roots in tissue autoradiography, a method used for many years in animal studies to investigate organ metabolism and blood flow. In tissue autoradiography, a radioactively labelled compound is injected into a vein. After the compound has accumulated in the organ under interest (such as the brain), the animal is sacrificed and the organ removed for study. The organ is sectioned carefully and the individual slices are laid on a piece of film sensitive to radioactivity. This X-ray film records the distribution of radioactively labelled compound on each slice of tissue. After film development, a picture of the distribution of radioactivity within the organ is obtained, hence regional information on the organ's specific functions can be deduced. The injected radioactive compound determines the type of information. Radioactively labelled water, for example, measures cerebral blood flow. In the late 1940s, Seymour Kety developed this technique for autoradiography in laboratory animals. Accumulation of a radioactively labelled form of glucose measures cerebral metabolism because glucose is the primary source of energy for neurons. In 1977, thanks to such a tracer, Louis Sokoloff introduced a now widely used autoradiographic method for the regional investigation of neuronal activity.

Researchers in the field of tissue autoradiography became fascinated when CT was introduced in the 1970s. They realized that if the anatomy of an organ could be reconstructed by passing an X-ray beam through it, then the distribution of a previously administered radioisotope could also be reconstructed *in vivo*. They simply had to measure the emission of radioactivity from the body section. With this insight was born the idea of autoradiography of living human subjects. A crucial element was the choice of the radioisotope. A class of radioisotopes was selected that emitted positrons (i.e. particles identical to electrons, except that they carry a positive charge). A positron will combine immediately with a nearby electron. They will annihilate each other, emitting two gamma rays in the process. Because the gamma rays travel in opposite directions, detectors around the sample can detect the gamma rays and locate their origin. The crucial role of positrons in human autoradiography gave rise to the name positron emission tomography (Ter-Pogossian *et al.*, 1980).

Throughout the late 1970s and early 1980s, PET was developed rapidly to measure various activities in the brain, such as glucose metabolism, blood flow (see below), oxygen consumption, and uptake of drugs. Although PET is primarily a research tool for brain imaging, its increasing availability in medical centres for oncology and cardiac imaging makes likely its more widespread application to neuropsychiatric diseases. The most frequently performed PET studies measure resting regional cerebral metabolic rates for glucose (rCMRGlu) or changes in rCBF as indirect indices of neural synaptic activity (Magistretti and Pellerin, 1999). Recent developments are PET/CT combined imaging (offering improved attenuation correction and co-registration or fusion of the functional PET image with a high-anatomic-resolution CT image) and improved detector materials, such as lutetium oxyorthosilicate (LSO) scintillators (offering higher stopping power and counting rates).

Basic Principles

PET scanning involves the administration of positron-emitting radionuclides with short half-lives in which particle disintegration is captured by multiple sensors positioned around the head. The radiotracer is administered into a vein in the arm and is taken up by the brain through the bloodstream. After a course of a few millimetres, the positron will interact with an electron in the brain tissue and produce two high-energy photons at approximately 180 degrees apart from each other. In the PET scanner, a ring of detectors around the patient's head can detect these coincident photons. As the radioactive compound accumulates in different regions of the brain, and positron annihilations occur, the scanner detects the coincident rays produced at all positions outside the head and reconstructs an image that depicts the location and concentration of the radioisotope within a plane of the brain. This emission scan is then corrected by comparison with the attenuation image made from a transmission scan of the subject's head. PET studies involve the use of a cyclotron to produce the radioactive tracers. The type of information on the PET image is determined by the administered radiolabelled compound. Oxygen-15, fluorine-18, carbon-11 and nitrogen-13 are common radioisotopes that can combine with other elements to create organic molecules that can substitute for natural substances, such as water, glucose, levodopa (L-dopa), benzodiazepine-receptor ligands, etc. Using different compounds, PET can assess regional blood flow, oxygen and glucose metabolism, and neurotransmitter and drug uptake in the tissues of the working brain. PET can sample all parts of the brain with equal resolution and sensitivity. Typically, it can locate changes in activity with an accuracy of about 6 mm. PET measurements of radioligand binding are discussed elsewhere (see Chapter XIX.10).

Cerebral Metabolic Rate for Glucose

To study regional cerebral glucose utilization, a positron-labelled deoxyglucose tracer is used, [^{18}F]fluorodeoxyglucose (FDG) (Huang *et al.*, 1980). This tracer is taken up by active brain regions as if it was glucose. However, once inside the cell, FDG is phosphorylated by hexokinase to FDG-6-phosphate, which is not a substrate for glucose transport and cannot be metabolized by phosphohexoseisomerase, the next enzyme in the glucose metabolic pathway. Thus, labelled FDG-6-phosphate becomes metabolically trapped within the intracellular compartment. The amount of radioactive label that eventually remains in each discrete region of the brain is related to the glucose uptake and metabolism of that particular region. An FDG-PET scan summates approximately 30 minutes of cerebral glucose metabolism and allows assessment of regional variations. However, given the half-life of ^{18}F (2 h), it is less suited for brain-activation studies.

Cerebral Blood Flow

Most PET activation studies rely on the administration of radioactively labelled water, specifically hydrogen combined with oxygen-15, a radioactive isotope of oxygen ($H_2{}^{15}O$). The labelled water emits copious numbers of positrons as it decays (hydrogen isotopes cannot be used because they do not emit positrons). In just over a minute after intravenous injection, the radioactive water accumulates in the brain, forming an image of blood flow. The radioactivity of the water produces no deleterious effects. Oxygen-15 has a half-life of only 2 minutes, and an entire sample decays almost completely in about 10 minutes (five half-lives) into a nonradioactive form. The rapid decay substantially reduces the exposure of subjects to the potentially harmful effects of radiation. Moreover, only low doses of the radioactive label are necessary. The fast decay and small amounts permit many measures of blood flow to be made in a single experiment. In this way, $H_2{}^{15}O$-PET can take multiple pictures of the brain at work in different experimental conditions. Each picture represents the average neural activity of about 45 seconds. The total number of scans that can be made per subject (typically about 12 images) is limited by the exposure to radiation.

In the last decade, PET has been the technique used most widely to assess the neural substrates of cognitive processes at the macroscopic level. At present, it is superseded by fMRI for many applications (see below). It remains, however, a powerful tool in receptor imaging (e.g. assessment of neurotransmitter or drug uptake) and molecular imaging (e.g. assessment of gene expression or protein synthesis) in both normal and pathological states (Phelps, 2000).

SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY

History

The history of SPECT parallels that of PET. The development of nuclear tomographic techniques paralleled the advances in X-ray CT in the early 1970s (see above). In 1977, Keyes constructed the first rotating gamma camera SPECT system. In this technique, multiple angular projections are accumulated as the camera turns in orbit around the subject's head. (The mathematically equivalent technique of holding a gamma camera head steady while rotating the patient in a chair in front of the camera has been tried successfully but has not caught on commercially.) Hybrid SPECT systems, including coincidence cameras (which can perform both SPECT and PET imaging), and hybrids that incorporate a CT

scanner along with a SPECT system (which offer improved attenuation correction and perfect co-registration or fusion of the SPECT scan with a high-anatomical-resolution CT scan), are currently being developed (Groch and Erwin, 2001).

In general, SPECT tracers are more limited than PET tracers in the kinds of brain activity they can monitor, but they are longer lasting. Thus, SPECT does not require an on-site cyclotron. However, most SPECT technology is relatively nonquantitative, does not permit measured attenuation correction, and has a spatial resolution inferior to that of PET. On the other hand, SPECT is less expensive and more widely available.

Basic Principles

Similar to PET, SPECT also uses radioactive tracers, but it involves the detection of individual photons (low-energy gamma rays) rather than positrons emitted at random from the radionuclide to be imaged. A SPECT scanner uses two or three cameras that rotate around the patient to record data at different angles. Images of active brain regions are then reconstructed by combining a finite number of projections. Typical radionuclides include technetium-99m (^{99m}Tc) and iodine-123 (^{123}I) with half-lives of 6 and 13 hours, respectively. On average, SPECT acquisition times are 20–30 minutes.

Frequently used radiolabelled agents for brain perfusion SPECT are: (1) Tc-99m-hexamethyl propylamine oxime (Tc-99m-HMPAO), a lipid-soluble macrocyclic amine with a rapid brain uptake (reaches its maximum within 10 min of injection, and its distribution remains constant for many hours post-injection); (2) Tc-99m-bicisate ethyl cysteinate dimer (Tc-99m-ECD), with rapid uptake and very slow clearance from the brain (blood clearance is also rapid, resulting in high brain-to-soft-tissue activity ratios); (3) I-123-isopropyliodoamphetamine (I-123-IMP); and (4) the inert gas xenon-133, which permits the quantitative measurement of rCBF without the need for arterial sampling (however, this requires a technically difficult inhalation technique, and it has a poor spatial resolution). The long half-life, rapid brain uptake and slow clearance of most radiolabelled agents for brain perfusion SPECT offer the opportunity to inject the tracer at a time when scanning is impossible (e.g. during an epileptic crisis) and to scan (post-event) the associated distribution of activated brain regions.

In addition to their use in determining perfusion, radiotracers can also be used to determine biochemical interactions, such as receptor binding. Iodine-123-labelled ligands, such as iodo-hydroxy-methoxy-N-[(ethyl-pyrrolidinyl) methyl]-benzamide (IBZM), have been developed for imaging the dopamine receptor system and are used in studies of movement disorders and schizophrenia (IBZM is a D2 receptor agonist that shows high uptake in the striatum and can be displaced by haloperidol). Iodine-123-quinuclidinyl-iodobenzilate (I-123-QNB), an acetylcholine muscarinic antagonist, has been used to image these receptors in the brains of normal subjects and patients with Alzheimer's disease. Other iodine-123 labelled ligands have been used for imaging the benzodiazapine and serotonin receptors. These radiotracers, however, have not yet reached the stage of routine clinical practice, as a consensus on measuring receptor binding using single-photon tracers has not yet been reached, nor have diagnostic clinical strategies been identified.

FUNCTIONAL MAGNETIC RESONANCE IMAGING

History

In 1935, Nobel Laureate Linus Pauling discovered that the amount of oxygen carried by haemoglobin affects its magnetic properties. In 1990, Sejji Ogawa and his colleagues at AT&T Bell Laboratories demonstrated that MRI could detect these small magnetic fluctuations. Several research groups realized immediately the importance of this observation. By the middle of 1991, it was shown that MRI could detect the functionally induced changes in blood oxygenation in the human brain. This ability has led to the term 'functional MRI'. The ability of fMRI to monitor the oxygen signal in real time is limited not by technique but by physiology. Indeed, the stumbling block is the speed of neural activity with the rate of change of oxygenation levels. Signals from one part of the brain can travel to another in 10 ms or less. Unfortunately, changes in blood flow and blood oxygenation are much slower, occurring hundreds of milliseconds to several seconds later. Hence, fMRI is not able to keep up with the 'conversations' between brain areas. For the time being, the only methods that respond quickly enough are electrical recording techniques such as EEG and MEG (see below).

fMRI is taking the place of ^{15}O-labelled-water-PET as the procedure of choice for haemodynamic functional activation measurements. It has several advantages over PET activation studies. First, it does not require the injection of radioactive tracers as the signal comes directly from functionally induced changes in brain tissue (i.e. changes in venous oxygen concentration). Second, the spatial resolution is better, distinguishing parts as small as 1 or 2 mm (better than the PET resolution of about 6 mm). Third, the temporal resolution is better, monitoring changes in blood-flow-induced oxygen signal in real time, using echo-planar imaging (better than $H_2{}^{15}O$-PET resolution of about 45 s). Fourth, MRI provides both anatomical and functional information in each subject, hence permitting a more accurate structural identification of the active regions.

Some concerns have been raised about the intensity of the magnetic field to which the tissues are exposed in MRI, but so far there are no known harmful biological effects. The largest limiting factor is the claustrophobia some subjects may suffer as in most instrument designs the entire body must be inserted into a relatively narrow tunnel. Other limiting drawbacks are its susceptibility to the subject's movement artefacts and artefacts related to the use of metal-containing devices in the magnet (e.g. EEG electrodes, electrical wires).

Basic Principles

fMRI can detect an increase in oxygen that occurs in an area of heightened neuronal activity. The basis for this capacity comes from the way neurons make use of oxygen. Functionally induced increases in blood flow are accompanied by alterations in the amount of glucose the brain consumes but not in the amount of oxygen it uses. Indeed, despite the presence of abundant oxygen, the normal brain resorts to anaerobic metabolism during spurts of neuronal activity. Apparently, this physiological behaviour relies on tactics similar to those present in a sprinter's muscles. It is not understood fully why the brain acts in this way. Additional blood flow to the brain without a concomitant increase in oxygen consumption leads to a heightened concentration of oxygen in the small veins, draining the active neural centres. The reason for this is that supply has increased but the demand has not. Therefore, the extra oxygen delivered to the active part of brain simply returns to the general circulation by way of the draining veins.

The commonest form of fMRI is blood-oxygenation-level-dependent (BOLD) imaging (Ogawa *et al.*, 1990). The BOLD signal depends on the ratio of oxygenated to deoxygenated haemoglobin. In regions of neuronal activity, this ratio changes as increased flow of oxygenated blood temporarily surpasses consumption, decreasing the level of paramagnetic deoxyhaemoglobin. These localized changes cause increases in the magnetic resonance signal, which are used as markers of functional activation. Ultrafast scanning can measure these changes in the signal, which are mapped directly on to a high-resolution scan of the subject's anatomy. fMRI studies require magnets with field strengths superior to 1 tesla.

ELECTROENCEPHALOGRAPHY

History

EEG detects spontaneous brain electrical activity from the scalp. In 1848, the German physiologist Dubois-Reymond demonstrated that an externally recordable electrical signal occurred concomitantly with passage of a nerve impulse along a peripheral nerve. This discovery led the English physiologist Richard Caton to explore the possibility that nerve impulses flowing within brain cells might also produce electrical signals. In 1875, Caton published in the *British Medical Journal*, 'feeble currents of varying direction pass through the multiplier when one electrode is placed on the grey matter and one on the surface of the skull'. Caton demonstrated that the cerebral cortex had a tonic level of oscillatory electrical activity, and that additional phasic electrical activity could be evoked in response to peripheral sensory stimulation. The diagnostic potential of EEG was first hinted at in 1912 by the discovery of Kaufman that abnormal neuroelectric discharges could be recorded in experimentally induced epilepsy in animals. Despite the exciting developments in animal EEG, it was not until 1929 that Hans Berger, a German neuropsychiatrist, recorded the first human EEG. Hereafter, there was an explosion of human EEG studies with (of particular interest) the discovery of 'the EEG in epilepsy and in conditions of impaired consciousness' (Gibbs *et al.*, 1935). Today, EEG is considered a routine clinical procedure of substantial diagnostic value in neurology, neurosurgery and psychiatry, and it is proving to be a useful measure of brain physiology in neuroscientific research.

EEG provides temporal resolution in the millisecond range. However, traditional EEG technology and practice provide insufficient spatial detail to identify relationships between brain electrical events and structures and functions visualized by fMRI or PET. Recent advances help to overcome this problem by recording EEGs from more electrodes (experimental laboratories use 32–64 or even 120 or more electrodes), by registering EEG data with anatomical images, and by correcting the distortion caused by volume conduction of EEG signals through the skull and scalp. In addition, statistical measurements of sub-second interdependences between EEG time series recorded from different locations can help to generate hypotheses about the instantaneous functional networks that form between different cortical regions during mental processing. Physiological and instrumental artefacts (e.g. subject's eye or head movements, heartbeats, poor electrode contacts) can contaminate the EEG (and MEG), so care must be taken to correct or eliminate such artefacts before further analyses are performed.

Basic Principles

Scalp-recorded EEGs in the waking state in healthy adults normally range from several to about 75 μV. The EEG signal is largely attributable to graded postsynaptic potentials of the cell body and large dendrites of vertically oriented pyramidal cells in cortical layers 3 to 5. These are synchronized by rhythmic discharges from thalamic nuclei, with the degree of synchronization of the underlying cortical activity reflected in the amplitude of the EEG. Most of the EEG signal originates in cortical regions near the recording electrode. The columnar structure of the cerebral cortex facilitates a large degree of their electrical summation rather than mutual cancellation. Thus, the EEG recorded at the scalp represents the passive conduction of currents produced by summating activity over large neuronal aggregates. Regional desynchronization of the EEG reflects increased mutual interaction of a subset of the population engaging in 'cooperative activity' and is associated with decreases in amplitude.

To measure the EEG, electrodes are attached to the scalp with a conducting paste. Each electrode is connected with an electrically neutral lead attached to the ear, nose, chin or chest (i.e. reference montage) or with an active lead located over a different scalp area (i.e. bipolar montage). Differential amplifiers are used to record voltage changes over time at each electrode. These signals are then digitized with 12 or more bits of precision, and are sampled at a rate high enough to prevent aliasing of the signals of interest. EEGs are conventionally described as patterns of activity in five frequency ranges: delta (less than 4 Hz), theta (4–7 Hz), alpha (8–12 Hz), beta (13–35 Hz; sometimes subdivided into beta1 at 13–20 Hz and beta2 at 21–35 Hz), and gamma (above about 35 Hz).

EVOKED POTENTIALS

History

An evoked potential (EP) or ERP is the time-locked average of the EEG in response to a specific sensory, motor or cognitive event. Because of their low amplitudes, especially in relation to the background EEG activity, a number of stimuli have to be recorded and averaged with a computer in order to permit their recognition and definition. The background EEG activity, which has no fixed temporal relationship to the stimulus, will be averaged out by this procedure. As mentioned above, Richard Caton reported a clear reactivity of rabbit EEG to sensory stimuli in the form of a cortical-event-related response in 1875.

Basic Principles

Sensory evoked or 'exogenous' potentials are recordings of cerebral or spinal potentials elicited by stimulation of specific sensory pathways, e.g. visual evoked potentials (VEPs) elicited by monocular stimulation with a reversing chequerboard pattern; brainstem auditory evoked potentials (BAEPs) elicited by monaural stimulation with repetitive clicks; and somatosensory evoked potentials (SEPs) elicited by electrical stimulation of a peripheral nerve. They are an important and routinely used means of monitoring the functional integrity of these pathways.

Certain EP components depend on the mental attention of the subject and the setting in which the stimulus occurs, rather than simply on the physical characteristics of the stimulus. Such 'event-related' or 'endogenous' potentials are related in some manner to the cognitive aspects of distinguishing an infrequently occurring target stimulus from other stimuli occurring more frequently. For clinical purposes, attention has been directed particularly at the so-called P_{300} or P_3 component of the ERP (named after its positive polarity and latency of approximately 300–400 ms after onset of an auditory target stimulus).

As a research tool, ERPs can provide valuable information about the precise timing and cortical distribution of the neuroelectrical activity generated during mental activity. An averaged EP waveform consists of a series of positive and negative waves; a significant difference in latency, amplitude, duration or topography of one or more of these waves between experimental conditions that differ in one specific cognitive factor is assumed to reflect the mass neural activity associated with that cognitive factor. Measurements of changes in the amplitudes and timings of peaks in the series of EP waves allows inferences to be made about the sequence and timing of task-associated processes, such as prestimulus preparation, encoding of stimulus features, operations such as matching or comparison of stimulus codes and memory codes, evaluation of the meaning of the stimulus, and response selection and execution. However, it is important to bear in mind that the averaged EP method assumes that the component subprocesses comprising a cognitive behaviour do not vary in time from trial to trial (Gevins, 1998).

MAGNETOENCEPHALOGRAPHY

History

MEG and magnetic source imaging (MSI) measure the magnetic fields generated by electrical activity within the brain. In the early nineteenth century, Hans Christian Oersted, a Danish physicist, discovered that electrical currents generate magnetic fields. The first measure of magnetic fields generated by human bioelectric currents was a magnetocardiogram recorded by a 2-million-turn hand-wound induction coil magnetometer at room temperature (Baule and McFee, 1963). Five years later, using a similar conduction coil and signal-averaging techniques, the brain's alpha rhythm (generating a magnetic field 100 times weaker than that of the heart) was recorded in a specially designed magnetically shielded room constructed at the Massachusetts Institute of Technology (MIT) (Cohen, 1968). The subsequent development of point-contact superconducting quantum interference devices (SQUIDs), operating at liquid helium temperatures of -269°C, improved the sensitivity of the magnetometers, and the first stimulus-elicited cerebral magnetic fields could be recorded (Brenner *et al.*, 1975). The early technical difficulties were overcome in the late 1980s, such that instruments covering the whole scalp and containing more than 100 channels are now available commercially. Nowadays, magnetic field tomography (MFT), a technique based on distributed source analysis of MEG data, makes possible the three-dimensional reconstruction of dynamic brain activity in humans with a temporal resolution better than 1 ms and a spatial accuracy of 2–5 mm at the cortical level (which deteriorates to 1–3 cm at depths of 6 cm or more) (Ribary *et al.*, 1991).

The major advantage of techniques based on the measurements of cerebral electrical activity (i.e. EEG and MEG) is their uncompromised time resolution. Their major drawback, however, is their limited spatial resolution. Indeed, accurate localization of the source of brain activity remains difficult. Furthermore, the resolution becomes poorer the deeper into the brain we attempt to image. The main advantages of MEG over EEG are its superior spatial accuracy and ease of use, particularly when a large number of channels are involved. On the other hand, EEG complements MEG in detecting source components not detected by MEG (i.e. radially oriented sources) (Naatanen *et al.*, 1994). For the time being, MEG, MFT and MSI remain expensive and largely experimental research tools unavailable to most clinical settings.

Basic Principles

Electric currents in the brain produce a change in the magnetic field that can be detected outside the head by SQUID magnetometers. The signals measured can be used to compute the distribution of cerebral activity as a function of time. This method is related closely to EEG, in which the electric field pattern on the scalp is measured.

Electrical currents generate magnetic fields. The direction of the magnetic field is described by a simple right-hand rule. When the thumb of the right hand is pointed in the direction of current flow, the fingers curl in the direction of the surrounding magnetic field. This is true not only for currents flowing within power lines but also for all bioelectric currents, such as those flowing within neurons. Biomagnetic fields directly reflect electrophysiological events of the brain and pass through the skull without distortion. Hence, currents initiated at the synapses, and guided postsynaptically by cell structure, produce the magnetic field detectable outside the head. Magnetic field lines encircle the flow path of this primary current, extending outside the skull. Because pyramidal cells are predominantly oriented perpendicular to the cortex, the direction of the primary current is also perpendicular to the cortex. MEG is therefore most sensitive to activity in the fissural cortex, where the current is oriented parallel to the skull, whereas it does not detect sources that are oriented exactly radially to the skull. Because MEG detects only the tangential component of the primary current, amplitude comparison between differently oriented sources is possible only if source orientations can be estimated, e.g. on the basis of MRI.

The average electromagnetoencephalogram is about 10 picotesla (10^{-12}T) in amplitude, nine orders of magnitude smaller than the earth's steady magnetic field and seven orders of magnitude smaller than the magnetic fields generated by power lines, cars and elevators. The magnetic field produced by a single postsynaptic potential is too weak to be detected outside the head. Instead, what is detected is the macroscopic coherent activity of thousands of neurons. Still, cerebral magnetic fields are so weak that measurements are preferably performed inside magnetically shielded rooms. Sensitivity to such weak signals requires the use of cryogenic technologies. Current MEG instruments consist of an induction loop of niobium wire, which becomes superconducting (i.e. loses its resistivity to the flow of electrical currents) at approximately -258°C. Recording neuromagnetic signals has been compared to listening for the footsteps of an ant in the middle of a rock concert. Noise cancellation is improved by measuring gradients of the magnetic field instead of the field itself. In quiet environments, disturbances can be compensated for sufficiently by using elaborated compensation methods to enable MEG studies to be carried out even without shielded rooms.

Inverse Problem

As for EEG, MEG data have to be subjected to an inverse problem algorithm to obtain an estimate for the distribution of the activity in the brain. Similar to PET, fMRI and EEG, these can then be displayed on cross-sectional anatomical images (obtained by MRI) of the same subject. The inverse problem relates to the difficulty of determining internal sources on the basis of measurements performed outside the head. The most common way to tackle this problem is to determine the single-source current element (dipole) that explains most completely the EEG or MEG pattern. This can be done with a computer algorithm that starts from a random dipole position and orientation and keeps changing these parameters as long as the field pattern computed from the dipole keeps approaching the observed EEG or MEG pattern. When no further improvement is obtained, a minimum in the cost function has been reached; a source corresponding to this solution is called the equivalent current dipole (ECD). In most cases, however, the EEG or MEG data pattern cannot be explained accurately by a single source. In these cases, two or more dipoles could be used to explain the data, but this leads to computational difficulties in trying to determine the best multisource solution. Alternatively, continuous solutions, such as the minimum norm estimate, might also be constructed (Nenonen *et al.*, 1994). When interpreting EEG or MEG results, it should be borne in mind that the inverse problem is fundamentally non-unique. This means that even if the complete electric and magnetic field around the head could be measured precisely, an infinite number of current distributions in the brain could still be constructed that would explain the measured fields. It is always possible that some sources are missed, whatever the measurement set-up. For example, MEG alone is insensitive to radially oriented sources, but even when combined with EEG, silent sources are possible. Full use of available techniques requires the use of estimation theory to derive optimal solutions based on all available information, including MRI, PET and fMRI.

TRANSCRANIAL MAGNETIC STIMULATION

History

TMS is a tool for the non-invasive stimulation of the superficial cortex. In 1980, Merton and Morton surprised neuroscientists by

showing that it was possible to stimulate the motor areas of the human brain electrically through the intact scalp (transcranial electrical stimulation (TES)). They used a brief, high-voltage electric shock to activate the motor cortex and produce a relatively synchronous muscle response, the motor evoked potential (MEP). The problem was that TES was painful because of activation of pain fibres in the scalp. In 1985, Barker and colleagues showed that it was possible to stimulate both nerve and brain using external magnetic stimulation (TMS) with little or no pain. TMS is now used commonly in clinical neurology to study central motor conduction time. Depending on stimulation parameters, TMS can excite or inhibit the arbitrary sites of the superficial cortex, allowing functional mapping and creation of transient functional lesions (Hallett, 2000).

In neuropsychology, the classical paradigm is that of studying the effects of brain lesions on behaviour. With TMS, this paradigm can be applied in spatially and temporally restricted fashion to healthy volunteers. It is now used widely as a research tool to study aspects of human brain physiology, including motor function, vision, language, and the pathophysiology of brain disorders. Combined with other brain-imaging techniques, such as PET, EEG and fMRI, it can be used to evaluate cortical excitability and connectivity (Paus, 1999). It may also be useful in treating various neuropsychiatric disorders, most notably depression.

TMS is still a relatively young technique, and questions remain unanswered regarding its impact on brain function. Nonetheless, recent work with TMS has demonstrated that it allows the investigation of the relationship between focal cortical activity and behaviour to trace the timing at which activity in a particular cortical region contributes to a given task, and to map the functional connectivity between brain regions (Pascual-Leone *et al.*, 2000).

Basic Principles

A brief, high-current pulse is produced in a coil of wire, called the magnetic coil, placed above the scalp. A magnetic field is produced, with lines of flux passing perpendicular to the plane of the coil. An electric field is induced perpendicular to the magnetic field. Magnetic coils may have different shapes: round coils are relatively powerful; figure-of-eight-shaped coils are more focal, producing maximal current at the intersection of the two round components. The precise extent of neuronal activation is not known, but it varies with the intensity of stimulation. Ordinarily, TMS does not activate corticospinal neurons directly; rather, it activates them indirectly through synaptic inputs. Single-pulse TMS, which is very safe, has been used most commonly. Devices are now available that can deliver high-frequency (1–30 Hz), repetitive TMS (rTMS). This has greater effects than single-pulse TMS, but it also has the potential to cause seizures, even in normal individuals. Intracortical inhibition (ICI) and intracortical facilitation (ICF) are obtained using paired-pulse studies, and reflect the activity of interneurons in the cortex. Safety guidelines have been published that should prevent problems (Wassermann, 1998).

rTMS can produce effects that last after the stimulation period. The mechanisms of these changes are not clear, but the analogies to long-term potentiation (LTP) and long-term depression (LTD) of individual synapses in the central nervous system are apparent. Therapeutic effectiveness depends on the exact site of stimulation, intensity, and the precise pattern of pulses, including rate, train length, intertrain interval, and number of trains. This is clearly difficult to clarify and is currently an active area of psychiatric research (George *et al.*, 1999).

MAGNETIC RESONANCE SPECTROSCOPY

History

The fundamentals of NMR spectroscopy were studied and developed at least 30 years before being extended to clinical imaging. During this time, it was a major tool in physical and organic chemistry for determining molecular structure. As MRS technology evolved to allow the study of larger samples at higher field strengths, a logical step was to compare the spectral characteristics of normal and pathological tissue specimens. Following the discovery that normal and cancerous tissue samples had different NMR signals (Damadian, 1971), the first clinical NMR scanning machine was patented in the early 1970s. Hence, MRS has been in use much longer than clinical proton MRI. MRI is generally associated with the signals from hydrogen nuclei (i.e. protons) because of the large amounts of hydrogen atoms in human tissue and brain and the strong signals they provide. However, MRS makes measurements not only of protons but also of nuclei, such as phosphorus (^{31}P), carbon (^{13}C) and fluorine (^{19}F) (Dacey *et al.*, 1991). MRS offers the potential of assessing brain function at metabolic and molecular levels. At present, much of the work in this area is experimental.

Basic Principles

This technique uses natural emissions from atomic nuclei activated by magnetic fields to measure the concentration of endogenous molecules. Potential nuclei include ^{31}P, ^{13}C, ^{23}Na and ^{7}Li, in addition to ^{1}H. The ^{31}P magnetic resonance spectrum can detect tissue concentrations of the phosphomonoesters phosphocholine and inorganic orthophosphate, the phosphodiesters glycerol-3-phosphoethanolamine and glycerol-3-phosphocholine, the triphosphate adenosine triphosphate (ATP), and other phosphorus-containing molecules, including phosphocreatinine. ^{1}H spectroscopy offers the ability to measure lactate concentrations and neuronal markers such as *N*-acetyl aspartate. MRS permits quantitative analysis of these compounds *in vivo*, with the potential of three-dimensional resolution within the brain.

NEAR-INFRARED SPECTROSCOPY

History

NIRS and event-related optical signals (EROS) are relatively new methods to measure *in vivo* changes in cerebral haemodynamics and oxygenation. Changes in the intrinsic optical properties of the tissue are associated with changes in the level of physiological activity in neuronal tissue. As a consequence, it is possible to optically monitor neuronal activity without the use of dyes or other contrast-enhancing agents. Such optical techniques have been applied in the laboratory for more than 50 years. In previous studies of exposed brain tissue, optical imaging of brain activity has been achieved at high temporal and microscopical spatial resolution. Now, using near-infrared light, which can penetrate biological tissue reasonably well, it has become possible to assess brain activity in human subjects through the intact skull non-invasively. Recent developments in NIRS and intraoperative optical imaging have suggested a number of clinically important applications of this technology. After early studies employing single-site NIRS, first near-infrared imaging devices are being applied successfully for low-resolution functional brain imaging (Villringer and Chance, 1997).

Basic Principles

Brain activity is associated with changes in optical properties of brain tissue. Optical measurements during brain activation can assess haemoglobin oxygenation, cytochrome-c-oxidase redox state, and two types of changes in light scattering, reflecting either membrane potential (fast signal) or cell swelling (slow signal). The physiological basis of the most common form of NIRS is wavelength-specific absorption of photons by oxygenated and deoxygenated haemoglobin. Thus, the contrast mechanism for NIRS signals is related closely to that of intrinsic optical imaging of exposed cortex using visible light. The much lower baseline absorption levels at the longer wavelengths used in NIRS allow the light to travel further through skin, skull and brain tissue, thus allowing non-invasive imaging of haemodynamics, albeit with lower spatial resolution. Although it is possible to sample optical signals quite rapidly (>1 kHz), the effective temporal resolution is limited by the indirect nature of the coupling of the haemodynamic processes affecting the optical signals and the underlying neuronal electrical activity. However, there is some evidence that it may be possible to detect optical signals related more directly to neuronal activation (i.e. EROS). The physiological basis of EROS is not well understood, but it may include cell swelling or membrane polarization associated with neuronal activity, resulting in local light-scattering changes. Thus, optical imaging may provide insights into both the electrophysiological (fast) and haemodynamic (slow) processes underlying other brain-imaging signals. However, the spatial resolution afforded by optical methods alone is limited by the diffuse nature of photon transport through tissues.

Although promising, the application of NIRS in functional brain imaging is in an early experimental state. Advantages of the optical methods include biochemical specificity, a temporal resolution in the millisecond range, the potential of measuring intracellular and intravascular events simultaneously, and the portability of the devices enabling bedside examinations. Caveats of cerebral NIRS include insufficient light shielding, optode displacement, and a sample volume including muscle or the frontal sinus mucous membrane.

FUNCTIONAL NEUROIMAGING STUDY DESIGN

History

Mapping the human brain is distinct from the assumptions held by phrenologists of the nineteenth century. According to the German physician Franz Josef Gall, thought processes are localized in single brain areas identified by bumps on the skull. Gall posited that complex behavioural traits (e.g. ideality, cautiousness, imitation, self-esteem, calculation) could be related to the size of these bumps. Although the 'bumps theory' was fanciful, the idea of a functional segregation of the brain was not. In 1861, by carefully studying the brain of a man who had lost the faculty of speech after a left inferior frontal lesion, Paul Broca became convinced that different functions could be localized in different parts of the cerebrum. Now, more than a century of neuropsychological investigations in brain-damaged patients has confirmed that a cortical area can be specialized for some aspects of perceptual or sensorimotor processing, and that this specialization is segregated anatomically in the cortex. In our current vision on brain function, however, functional segregation holds for simple processes rather than for complex behaviours or traits, such as those described by phrenologists. Now, the view is that the cortical infrastructure supporting a single function (and a fortiori a complex behaviour) may involve many specialized areas that combine resources by functional integration between them. Hence, functional integration is mediated by the interactions between functionally segregated areas, and functional segregation is meaningful only in the context of functional integration, and vice versa.

In this framework, the foundation for most functional neuroimaging studies is that complex behaviours can be broken down into a set of constituent mental operations. In order to read this book, for example, you must recognize that a string of letters is a word; then recognize the meanings of words, phrases and sentences; and finally create mental images. The methodological challenge is first to separate each of these tasks from a cognitive perspective, and second to determine those parts of the brain that are active and those that are dormant during their performance. In the past, cognitive neuroscientists have relied on studies of laboratory animals and patients with localized brain lesions to gain insight into the brain's functions. Imaging techniques, however, permit us to visualize, safely, the anatomy and the function of the human brain in both normal and pathological conditions.

It is amazing that the strategy used most widely for functional neuroimaging over the past 15 years is based on an idea first introduced to psychology in 1868. Indeed, Franciscus C. Donders, a Dutch ophthalmologist and physiologist, then proposed a general method to estimate cognitive processes based on a simple logic. He subtracted the time needed to respond to a light (with, say, a press of a key) from the time needed to respond to a particular colour of light. He found that discriminating colour required about 50 ms more than simply responding to the light. In this way, Donders (1969) was the first to isolate a basic mental process and to obtain a measure of the time needed by the brain to perform this specific process.

Basic Approaches

The current strategy in functional neuroimaging is designed to accomplish a similar subtraction but in terms of the brain areas implementing the mental process. In particular, images of neural activity (be it blood flow measured by PET or fMRI or electrical activity measured by EEG or MEG) taken before a task is begun can be compared with those obtained when the brain is engaged in that task. The two periods are referred to as the control state and the task state. It is important to choose carefully each state so as to isolate as best as possible a limited number of operations. Subtracting neural activity measurements made in the control state from each task indicates those parts of the brain active during a particular task. To achieve reliable data, averages are made of many experimental trials in the same person (e.g. fMRI) or of responses across many individual subjects (e.g. PET). Averaging enables the detection of changes in neural activity associated with mental activity that would otherwise be confused easily with spurious shifts resulting from noise.

It is important to stress that this methodological approach, known as the cognitive subtraction paradigm, has an important drawback. Indeed, in order to isolate the neural substrate of a given cognitive component of interest, it must be assumed that the only difference between the control state and the task state is the component of interest to the exception of any other stimulus- or task-related processes. Unfortunately, this cannot always be guaranteed easily and fully. Analytic strategies, however, have been devised to circumvent this problem (see below), and cognitive subtraction designs remain the foundation of most functional neuroimaging experiments.

ANALYSING BRAIN IMAGING DATA

History

Regional differences among brain scans have long been characterized thanks to hand-drawn regions of interest (ROIs). This approach reduced the information from hundreds of thousands of voxels (volume elements that in three dimensions correspond to a pixel with a given slice thickness) to a handful of ROI measurements, with a somewhat imprecise anatomical validity. The development of more powerful voxel-based statistical methods has made these ROI analyses obsolete. Although several solutions are in use in neuroscience laboratories, one of the most popular methods for the analysis of neuroimaging data is statistical parametric mapping (SPM). This is a standardized method that refers to the construction and assessment of spatially extended statistical processes used to test hypotheses about neuroimaging data (mainly PET, SPECT and fMRI). Statistical parametric maps can be thought of as 'X-rays' of the significance of an effect, which can be projected on a three-dimensional representation of the brain. These ideas have been instantiated in software (version SPM99 at time of going to press) by Karl Friston and coworkers at the Wellcome Department of Cognitive Neurology in London (http//www.fil.ion.ucl.ac.uk/spm). SPM has become the most widely used and validated method for analysing functional neuroimaging data. Since its first description in 1990, over 1500 citations now refer to its use.

Basic Approaches

As described above, there are two basic approaches when analysing and interpreting functional neuroimaging data. They are based on the distinction between functional segregation and integration.

Functional Segregation

Using a functional specialization concept of the brain, the following sets of approaches are based on detecting focal differences. They generally fall into one of three broad categories: (1) The subtractive or categorical designs are predicted on the assumption that the difference between two tasks can be formulated as a separable cognitive or sensorimotor component, and that the regionally specific differences in brain activity identify the corresponding functional area (i.e. the cognitive subtraction paradigm). Its utilization ranges from the functional anatomy of word processing to the functional specialization in visual cortex, an application that has been validated by electrophysiological studies in monkeys (Zeki, 1993). (2) The parametric or dimensional design assumes that regional physiology will vary systematically with the degree of cognitive or sensorimotor processing. Parametric designs may avoid many of the shortcomings of 'cognitive subtraction'. A fundamental difference between subtractive and parametric designs lies in treating a cognitive process not as a categorical invariant but as a dimension that can be expressed to a greater or lesser extent in relation to the brain's regional activity. (3) Factorial or interaction designs are also well suited to avoiding the drawbacks of simple subtraction paradigms. Two or more factors can be combined in the same experiment, and the interaction term will assess the effect of one factor while excluding the effect of the other.

Functional Integration

The functional role played by any component (e.g. a neuron or a specific brain area) of a connected system (e.g. the brain) is defined largely by its connections. Connectionist approaches to understanding the integration of brain functions are well established (Hebb, 1964). The nature and organizational principles of intracortical (Goldman-Rakic, 1988) and subcortical (Mesulam, 1990) connections have provided a basis for mechanistic descriptions of brain function, referring to parallel, massively distributed and interconnected (sub)cortical areas. Anatomical connectivity, determined mainly by neuroanatomic tracer experiments in animals, is a necessary underpinning for these models. The concepts of functional and effective connectivity were developed in the analysis of separable spike trains obtained from multi-unit electrode recordings. However, the neurophysiological measurements obtained from functional neuroimaging have a very different timescale (seconds versus milliseconds) and nature (metabolic or haemodynamic versus spike trains) than those obtained from electrophysiological studies.

Only recently have analytical tools become available to assess the functional or effective connectivity between distant cerebral areas (Friston *et al.*, 1997). Functional connectivity is defined as the temporal correlation of a neurophysiological index (e.g. blood flow) measured in different remote brain areas, whereas effective connectivity is defined as the influence that one neural system exerts over another (Buchel and Friston, 1997). In this context, a psychophysiological interaction can be assessed in the framework of the general linear model, as employed by SPM (Friston *et al.*, 1997), to explain the activity in one cortical area in terms of an interaction between the influences of another area in a given experimental context. Put simply, the statistical analysis will identify brain regions that show condition-dependent differences in the way their activity relates to the activity in another (chosen) area.

Preprocessing the Data

Voxel-based analyses require the data to be in the same anatomical space. This is obtained by realigning the data. Indeed, in functional neuroimaging experiments, movement-related variance components represent one of the most serious confounds. Therefore, scans from each subject are realigned using an optimization procedure minimizing the residual sum of squares (Friston *et al.*, 1995).

In a second step, the realigned images are normalized. They are subject to nonlinear warping so that they match a template that already conforms to a standard anatomical space approximating those described by Talairach and Tournoux (1988). Pooling neuroimaging data from grossly different individual brains requires a procedure to spatially normalize the individual brains to an idealized or standard brain for the purpose of achieving overlap between corresponding anatomical and functional areas in different subjects. The Talairach and Tournoux atlas was initially developed — and has proven very useful — for anatomical normalization required for neurosurgical procedures, particularly those at brain sites close to the origin of the reference system (e.g. the anterior and posterior commisures). Each point within Talairach space into which brains are transformed is defined using three coordinates (expressed in millimetres). The first coordinate defines the position in x, i.e. from left (negative) to right (positive), with 0 mm corresponding to the interhemispheric line. The second coordinate defines the position in y, i.e. from posterior (negative) to anterior (positive), with 0 mm corresponding to the anterior commisure. The third coordinate defines the position in z, i.e. from bottom (negative) to top (positive), with 0 mm corresponding to the plane through the anterior and posterior commisures. This standard coordinate system facilitates the reporting of results in a conventional way, and facilitates comparisons between peak voxels obtained in experiments from different laboratories.

After spatial normalization, images need to be smoothed (i.e. convolved with an isotropic Gaussian kernel). Smoothing individual

images before a statistical analysis offers (1) an improved signal-to-noise ratio; (2) conditioning of the data, so that they conform more closely to the Gaussian field model, which lies at the basis of the correction procedure for multiple statistical comparisons; and (3) a better overlap between the localization of anatomical and functional brain areas from different subjects, which permits intersubject averaging.

Statistical Analysis

The data obtained after preprocessing consist of a matrix of many hundred-thousandths of voxels for each subject and for each condition. Each of these voxels is characterized by the x, y and z spatial coordinates in the standard space and a value representing the functional activity in that voxel (e.g. blood flow, glucose metabolism, BOLD signal). The statistical analysis corresponds to modelling the data in order to partition observed neurophysiological states or responses into components of interest, confounds of no interest, and an error term. This partitioning is effected using the framework of the general linear model to estimate the components in terms of parameters associated with the design matrix. The analysis of regionally specific effects uses the general linear model to assess differences among parameter estimates (specified by a contrast) in a univariate sense, by referring to the error variance. The significance of each contrast is assessed with a statistic with a Student's t distribution under the null hypothesis for each and every voxel (i.e. SPM{t}). The SPM{t} is transformed to the unit normal distribution to give a Gaussian field or SPM{Z}.

Statistical Inference

The final stage is to make statistical inferences on the basis of the SPM and characterize the responses observed using the fitted responses or parameter estimates. On one hand, with an a priori anatomically constrained hypothesis about effects in a particular brain location, the Z value in that region in the SPM{Z} can be used to test the hypothesis (i.e. uncorrected P value). On the other hand, if an anatomical site cannot be predicted a priori, a correction for multiple non-independent comparisons is required. Therefore, the theory of Gaussian fields (Friston, 1997) provides a way for correcting the P value for the multiple non-independent comparisons implicit in the analysis. This correction depends on the search volume, the residual degrees of freedom due to error, and the final image smoothness estimate. The obtained corrected and uncorrected P values pertain to different levels of inference in terms of (1) the significance of the effect in a particular voxel, (2) the significance of the coactivation of a cluster of voxels in a specific region, and (3) the significance of the coactivation of several clusters in the whole brain. Importantly, only in cases of well-documented prior neuroanatomical knowledge about the expected result can uncorrected P values be accepted. By specifying different contrasts, one can test for the variety of effects described above, and the significance values above a chosen threshold are represented comprehensively in an SPM map, where each voxel is represented at its proper location on the brain template, and where the T value in this voxel for a given contrast is represented by use of a colour-intensity code.

FUTURE DIRECTIONS: MULTIMODALITY INTEGRATION

As discussed above, fMRI and $H_2{}^{15}O$-PET measure local changes in brain haemodynamics induced by cognitive or perceptual tasks. These measures have a uniformly high spatial resolution of millimetres or less but poor temporal resolution (about 1 s at best). Conversely, EEG and MEG measure instantaneously the current flows induced by synaptic activity, but the accurate localization of these current flows remains an unsolved problem. Recently, techniques have been developed that, in the context of brain anatomy visualized with structural MRI, use both haemodynamic and electromagnetic measures to get estimates of brain activation with higher spatial and temporal resolution. These methods range from simple juxtaposition to simultaneous integrated techniques. However, further advances in multimodality integration will require an improved understanding of the coupling between the physiological phenomena underlying the different signal modalities (Dale and Halgren, 2001).

The combination of TMS with PET or EEG permits the assessment of connectivity and excitability of the human cerebral cortex. PET and fMRI, working in a combination yet to be determined, can define the anatomy of the circuits underlying a behaviour of interest; electrical recording techniques can reveal the course of temporal events in these spatially defined circuits. Parallel information from different imaging modalities is beginning to be used to constrain the EEG or MEG inverse solutions discussed above to limited regions of the cerebrum. This approach provides optimal combined spatial and temporal resolution by exploiting the best aspects of each technology. Combining various techniques offers a more complete characterization of the different aspects of brain activity during cognitive processing. This is even more so regarding our understanding of transitory neuropsychiatric phenomena (e.g. single hallucinations).

Regardless of the particular mix of technologies that will ultimately be used to image human brain function, the field demands extraordinary resources. MRI, PET and MEG equipment cost from €1–4 million, require large teams to be run, and are expensive to maintain. Furthermore, success requires close collaboration within multidisciplinary teams of scientists gathering knowledge and expertise in basic sciences (physics, informatics, chemistry, mathematics, etc.) and neuroscience (neurology, psychiatry, psychology, neuropharmacology, neurobiology, etc.). Few institutions are fortunate enough to have the technical and human resources necessary to master these technologies. Such institutions should optimally make them available to all expert scientists with valid questions in order to increase our knowledge of all aspects of human mental activity. In contrast, EEG data can be collected with a modest amount of compact, lightweight and easy-to-use equipment. Clinical EEG recordings from ambulatory subjects have been made routinely for many years. In the future, then, it appears likely that EEG will become an important tool for studying the neurophysiology of cognition outside the laboratory in naturalistic settings.

Functional neuroimaging experiments provide a vast amount of information. Recent efforts to create neuroscience databases could organize and disseminate quickly such a repository of data. As demonstrated in many chapters of this book, wise use of these powerful tools and the information they produce can aid our understanding and management of many neuropsychiatric diseases. Clearly, neuroimaging is heading us towards a much richer grasp of the relation between the human mind and the brain.

Neurogenetics

Anita Thapar and Michael O'Donovan

INTRODUCTION

Technological advances have revolutionized modern genetics, and completion of the Human Genome Project will undoubtedly represent a historical landmark. The aim of this chapter is to outline and explain the key areas of genetics that are most relevant to psychiatry. We begin by dealing with the theoretical background to quantitative and then molecular genetics, before moving on to discuss the main research methods that are being used to understand the genetic basis of psychiatric disorders. We end by discussing current molecular genetic techniques and new technologies.

THEORETICAL BACKGROUND

Although it is only relatively recently that molecular methods have allowed us to identify specific genes, the concept of a gene as a basic unit of inheritance long predated these technological advances. Gregor Mendel, an Augustinian monk, originally developed a particulate theory of inheritance. Although Mendel's experiments on pea plants and the rules of inheritance that he deduced by observation are now well recognized, his work published in 1866 was ignored during his lifetime. It was only much later at the beginning of the twentieth century that scientists recognized the importance of Mendel's findings. We now know that the units of inheritance described by Mendel are genes, that alternative forms of a gene are alleles, and that genes lie along chromosomes. It was around this time that the term 'genotype' was used to describe the genetic endowment according to the combination of alleles; the observed characteristic was described as the 'phenotype'.

Patterns of Inheritance

Mendel's Laws of Heredity

Mendel's laws are based on the observations he made from his experiments on pea plants. Mendel studied the transmission of dichotomous characteristics, such as whether the seeds were smooth or wrinkled skinned. He first noted that when plants with smooth seeds were crossed with plants characterized by having wrinkled seeds, the offspring or first generation (F1) all had smooth seeds rather than showing an intermediate phenotype. Mendel then found that when the F1 generation was intercrossed, wrinkled seeds reappeared in the subsequent offspring or second generation (F2). The ratio of plants with smooth seeds to those with wrinkled seeds was three to one.

From these results, Mendel deduced that the uniformity in the F1 offspring was the result of a unit of inheritance for each characteristic being inherited from each parent, with one being dominant and the other being recessive. We now term the different forms of these units 'alleles' and can label the dominant allele as 'A' and the recessive allele as 'a'. Those plants with two of the same alleles (AA or aa) are homozygotes, and those with two different alleles (Aa) are heterozygotes. Mendel concluded that when the F1 heterozygotes were interbred, the F2 generation consisted of AA, Aa, aA and aa plants (Figure XII.1). Thus, for a dominant characteristic, only one dominant unit or allele is needed to display the trait, whereas for a recessive trait to be manifest, both alleles have to be recessive. This is Mendel's law of segregation. He also found that the pattern of inheritance for one trait was not affected by the transmission of another trait, i.e. they show independent assortment. We now know that when genes for two traits are located near to each other on a chromosome, there is not independent assortment, and it is this phenomenon of linkage that is utilized in the search for genes (see later).

Patterns of Inheritance for Human Traits and Disorders

Single-Gene Inheritance

The group of disorders that are transmitted in a predictable fashion according to Mendel's laws are sometimes termed 'Mendelian' or 'Mendelizing' disorders. These disorders are characterized by single-gene defects, which, although rare in the general population, are usually associated with severe clinical consequences. Only one copy of the defective gene is required for autosomal dominant disorders such as Huntington's disease to manifest clinically. That is, both heterozygotes (who carry one disease allele) and homozygotes (who carry two copies of the disease allele) will be clinically affected. Thus, if one parent has an autosomal disorder, half of the offspring will be affected and half will be unaffected (Figure XII.2). Genes for many of these conditions, including Huntington's disease, have been located. Thus, it is now possible to test specifically for whether an individual carries the defective gene.

Individuals affected by autosomal recessive disorders such as cystic fibrosis inherit two copies of the gene abnormality. Carriers for these disorders may be fairly common in the general population, but both parents must be carriers for there to be a risk of the disorder manifesting in the offspring. On average, one in four of the offspring of two heterozygote parents will be clinically affected, half will be unaffected carriers, and one in four will be unaffected (Figure XII.2). Autosomal recessive disorders occur more commonly among offspring of consanguineous (genetically related) relationships, as the risk of both parents carrying the same recessive genes is increased.

The final group of single-gene disorders consists of sex-linked disorders. Strictly speaking, these disorders do not appear to show a typical pattern of Mendelian inheritance. However, we now understand that this is because of the inheritance of sex chromosomes. X-linked disorders, such as fragile X syndrome,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

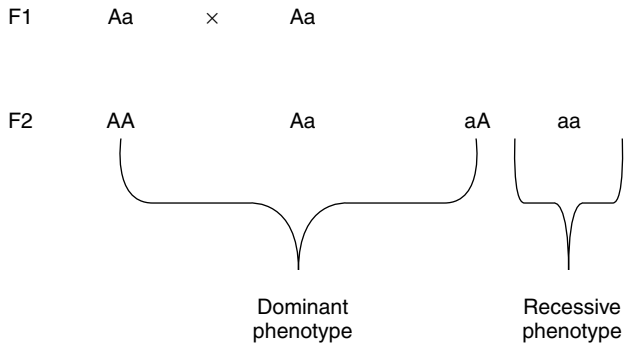

Figure XII.1 Mendel's law of segregation

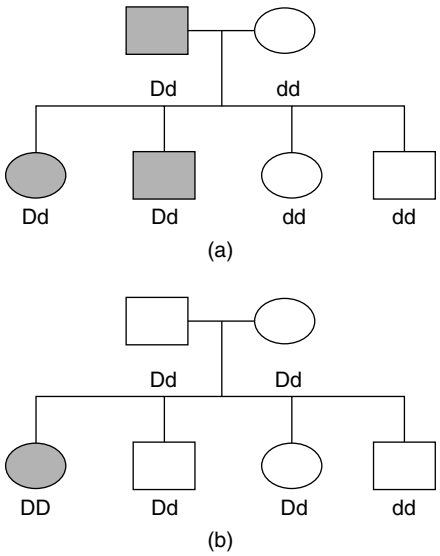

Figure XII.2 Single-gene inheritance. (a) Autosomal dominant inheritance; (b) autosomal recessive inheritance D, disease allele; d, non-disease allele

occur more commonly in males. Males inherit one X chromosome from their mother and one Y chromosome from their father (XY), whereas females have two copies of the X chromosome (XX). Thus, for X-linked recessive conditions, if a father is affected, then all the daughters will be carriers. If a mother is a carrier (X*X) and the father is unaffected, then because the sons must inherit their X chromosomes from their mother, half of the sons will be affected (X*Y) and half will be unaffected (XY). Half of the daughters would be unaffected carriers (X*X).

Atypical Patterns of Mendelian Inheritance

Although these disorders show classical patterns of Mendelian inheritance, the clinical manifestation and severity of many single-gene disorders can vary enormously due to variable expression. For example, conditions such as neurofibromatosis, an autosomal dominant disorder, can manifest with either full-blown clinical symptoms or simply a few café au lait spots. Penetrance is the probability that a particular phenotypic characteristic of a disorder will be manifested, given a specific genotype. Although for Mendelian disorders this should be 1 or 0, single-gene disorders can show an irregular pattern of inheritance due to incomplete penetrance. Penetrance also varies with the definition of disorder.

Variable expression and penetrance have been used to explain the observed clinical manifestations of single-gene disorders. Interestingly, molecular genetic techniques are now providing explanations for other atypical patterns of inheritance for disorders that are otherwise due to single-gene defects. In this section, we focus on the atypical patterns of inheritance. The molecular genetic bases of these observed phenomena are explained later in the chapter.

Heritable Unstable Nucleotide Repeat Sequences

Disorders such as Huntington's disease and fragile X syndrome had previously been observed to show greater clinical severity and an earlier age of onset in subsequent generations, a phenomenon known as anticipation. These are examples of disorders caused by heritable unstable nucleotide repeat sequences. These are unstable repeat sequences of DNA (deoxyribonucleic acid, the molecule that encodes genetic information; see later) that expand in length when transmitted from parent to offspring and manifest as a clinical disorder when the sequence reaches a critical length.

Imprinting

Imprinting is another phenomenon that results in an atypical pattern of inheritance. Here, the phenotypic manifestation of a genetic defect varies according to whether it originates from the mother or father. Angelman syndrome and Prader–Willi syndrome are examples of imprinted disorders where it appears that although most cases are accounted for by a deletion in the same region on chromosome 15 (15q11-13), very different clinical manifestations arise depending on whether the deletion originates from mother or father. Angelman syndrome is characterized by severe mental retardation, ataxia (awkward gait), seizures and a cheerful sociable affect; the deletion originates from the mother. In contrast, Prader–Willi syndrome is characterized by mild mental retardation, short stature, almond-shaped eyes, a high palate, hypogonadism, overeating (hyperphagia) associated with obesity, and increased rates of behavioural difficulties, such as temper tantrums, skin picking and hyperactivity; the deletion is inherited from the father.

Chromosomal Anomalies

Finally, an important group of disorders are explained by chromosomal changes. Humans carry their genetic information on 23 pairs of chromosomes, and medical disorders and mental retardation can arise from anomalies of specific chromosomes. Further explanations are given later in the section on molecular genetics. Until recently, cytogenetic techniques enabled us to detect major chromosomal anomalies such as Down's syndrome, characterized by an additional chromosome 21 (trisomy 21), and Turner's syndrome, in which there is an absence of one of the X chromosomes (XO). High-resolution methods such as fluorescent *in situ* hybridization (FISH) are now available to detect more subtle chromosomal deletions. Microdeletion syndromes include disorders such as velo-cardio-facial syndrome (chromosome 22q11 microdeletion), Angelman syndrome and Prader–Willi syndrome. Some of these syndromes that are known to be associated with increased rates of psychiatric disorders (e.g. velo-cardio-facial syndrome and psychosis) are of particular interest, as they may provide clues about potential susceptibility genes, i.e. genes within the deleted region are potential candidate genes for molecular genetic studies. Although chromosomal anomalies such as Down's syndrome are clearly genetic, they are not inherited and most arise spontaneously.

Polygenic Inheritance

So far, we have considered Mendel's laws, which were based on observations of discrete characteristics (i.e. smooth *v.* wrinkled seeds) influenced by a single gene, and we have briefly discussed disorders caused by single genes. Clearly, many human characteristics, such as height and blood pressure, are distributed continuously

Figure XII.3 Phenotype measured on a continuous scale that results from a single gene with two alleles, A1 and A2. © Oxford University Press 2000. Reprinted from *New Oxford Textbook of Psychiatry*, Volume 1 edited by M.G. Gelder, Juan J. López-Ibor Jr., and Nancy C. Andersen (2000) by permission of Oxford University Press

in the population rather than being simple discrete phenotypes. Moreover, the majority of human traits and diseases, including psychiatric disorders, do not appear to be attributable to single-gene defects. Does this mean that Mendel's laws do not apply for such traits and disorders? This does not appear to be the case.

Let us begin by considering the influence of a single gene A with two alleles A1 and A2 on a trait measured on a continuous scale (Figure XII.3). There are three possible genotypes, A_1A_1, A_1A_2 and A_2A_2. If we describe the phenotypes of each of these genotypes in terms of scores on a continuous scale, then A_1A_1 has a value of $-a$, A_2A_2 has a value of $+a$, and the heterozygote A_1A_2 shows a value of d. When d is equal to zero, then the contribution of A_1 and A_2 is additive, thus the phenotype of A1A2 lies exactly halfway between that of A1A1 and A2A2. When $d = +a$, then A2 is dominant to A1, and when $d = -a$, then A2 is recessive to A1.

In a given population, if we assume that there are no dominance effects, selection, migration, inbreeding or selection, and that p is the frequency of allele A1, q is the frequency of allele A2, and $p + q = 1$, then the frequency of genotypes will be as follows:

A_1A_1	A_1A_2	A_2A_2
p^2	$2pq$	q^2

This is known as Hardy–Weinberg equilibrium. Simplifying further so that $p = q = 0.5$, then we can see that the phenotypic values of A_1A_1, A_1A_2 and A_2A_2 would be distributed in the ratio of $1:2:1$. What happens when we allow for the effect of multiple genes? We next consider a phenotypic trait that results from two genes that have an additive action and two alleles of equal frequency. Now there are five possible phenotype values with relative frequencies of $1:4:6:4:1$. Thus, it can be seen that as the number of genes (n) increases, the number of phenotype values also increases ($2n + 1$), and the distribution of phenotypes begins to approximate a normal distribution. Clearly, Mendel's laws can be applicable for traits that show a continuous distribution. It is thought that the transmission of most of these traits will prove to be explained by the additive action of many genes. This is known as polygenic inheritance.

In general, it is assumed that in most instances, such traits are influenced by the action of multiple genes and environmental factors, otherwise termed as a multifactorial mode of inheritance.

Multifactorial/Polygenic Liability Threshold Models

Most common human diseases, including psychiatric disorders, are considered to be complex disorders, in that they are not transmitted in a classical Mendelian fashion. Although we have shown the effects that multiple genes can have on the distribution of phenotype values, many complex disorders must be considered not as continuous variables but rather as 'present' or "absent". Nevertheless, for those who are affected, clinical severity may be considered along a continuum. A liability threshold model allows us to extend this further by assuming that there is an underlying liability to the disorder that is distributed continuously in the general population; if this liability is influenced by multiple genes, then we can assume that the distribution will be distributed approximately normally. The clinical features of the condition are manifest beyond a particular threshold (Figure XII.4). The liability distribution of relatives of those affected by the disorder will be shifted to the right compared with that of the general population, and a greater proportion of relatives will lie above the threshold. This sort of model can be used to calculate the correlation in liability between pairs of relatives (see the section on twin studies later).

Figure XII.4 Polygenic or multifactorial liability threshold model. © Oxford University Press 2000. Reprinted from *New Oxford Textbook of Psychiatry*, Volume 1 edited by M.G. Gelder, Juan J. López-Ibor Jr., and Nancy C. Andersen (2000) by permission of Oxford University Press

So far, we have assumed that psychiatric disorders are inherited in a multifactorial, polygenic fashion. With the advent of molecular genetic studies, we now know that for some seemingly complex disorders, e.g. Alzheimer's disease and familial breast cancer, Mendelian subforms exist. Although these disorders appear to show a mixed model of inheritance, for most psychiatric disorders it has become increasingly evident that if Mendelian subforms exist, then they are extremely rare. Oligogenic models assume the coaction of a small number of genes, and provide a plausible model of transmission for many psychiatric disorders. These issues can now be addressed directly by molecular genetic studies.

Human Variation and its Components

Quantitative genetics focuses on the observed variation of a given trait (phenotype) within a specified population. This is known as phenotypic variation (V_P); we will next consider the influence of genes and environment on this variation. We begin by assuming a simple model in which phenotypic variation can be partitioned into a proportion explained by genetic factors (V_g) and a component accounted for by environmental influences (V_e):

$$V_p = V_g + V_e$$

Environmental variance can be subdivided further into those influences that result in family members becoming more alike, known as common or shared environmental variance (V_c), and a remaining proportion, termed non-shared environmental variance (V_e). The non-shared environment component includes those environmental influences that serve to make family members dissimilar as well as error variance.

Genetic variance can also be separated further into additive genetic influences (V_a) and dominance effects (V_d). A term that is commonly used to describe genetic variance is 'heritability'. Strictly speaking, heritability describes the proportion of total variance attributable to genetic factors (V_g/V_p). More commonly, the term is used to describe 'narrow-sense heritability', which is the proportion of total phenotype variance explained by additive genetic variance:

$$h_n^2 = V_A/V_P$$

Although heritability and variance explained by shared and non-shared environments provide useful estimates, the limitations of these terms also need to be appreciated. First, heritability and environmental variance estimates apply to populations rather than individuals; for example, a heritability of 50% for antisocial behaviour does not mean that half of a particular individual's antisocial behaviour is accounted for by genes.

Second, heritability estimates refer only to the population that has been studied, and do not apply to different populations or age groups; for example, the magnitude of genetic influences on traits such as IQ and antisocial behaviour appears to be greater in adults than in children (Plomin *et al.*, 2001). Similarly estimates of heritability and environmental variance are likely to have little meaning for selected groups, e.g. those exposed to severe environmental adversity may not be represented in the study sample.

Third, heritability estimates do not account for changes in a given trait over time. Thus, for example, although height has been shown to be highly heritable, there is clear evidence that in the last century, there has been a marked increase in the height of the general population, which is clearly attributable to environmental factors, such as a better diet, rather than to a sudden change in genes.

Finally, in common with other epidemiological study methods, association cannot be equated with cause. Clearly the proportions of variance attributable to genetic and environmental factors cannot tell us about underlying mechanisms and pathways to specific disorders.

These limitations must be brought to mind to avoid overinterpretation of findings. Nevertheless, although there has been much criticism of the concept of heritability, the estimates of genetic and environmental variance provide a useful initial guide for the researcher as to whether genes influence a given trait and to indicate the relative contribution of genes and environment.

Other Influences that Contribute to Phenotypic Variation

Non-Additive Genetic Effects

So far, we have made the simplistic assumption that genes and environment act in a additive fashion. We have already discussed genetic dominance, whereby different alleles within a given locus have a differential effect. The effect of one gene can also have an non-addictive effect when combined with the effects of another locus. This is known as gene–gene interaction or epistasis.

Gene–Environment Interaction

Gene–environment interaction is another important influence that needs to be taken account of by those interested in psychopathology (see Chapter XIII for further discussion). It is well established that not only do mice reared in a favourable environment perform better on tasks than those reared in a less enriched environment, but that this environmental effect will vary depending on the genotype of the mouse. Examples of this type of gene–environment interaction are beginning to emerge in the field of human psychopathology. For example, there is evidence that environmental adversity has a much stronger effect on antisocial behaviour where there is also a background of high genetic risk for such behaviours (Bohman, 1996). Similarly, in both adults and children, the impact of life's stresses on depression varies according to genetic susceptibility (Kendler *et al.*, 1995; Silberg *et al.*, 2001).

Gene–Environment Correlation

So far, we have considered genes and environment as distinct influences. There is increasing evidence that this does not appear to be the case. Gene–environment correlation is observed when a person's genotype is correlated with their environment. There are three forms of gene–environment correlation: passive, active and evocative. Passive gene–environment correlation arises where the parents not only pass on genes to their offspring that increase the likelihood of a particular trait, but also provide an environment that is correlated with the parental genetic make-up. For example, sociable parents may endow their children not only with genes that predispose them to being sociable but also with an environment that increases the likelihood that they will show sociable behaviour. Active gene–environment correlation arises where, for example, a child actively seeks out situations that serve to make him or her more sociable. Finally, evocative gene–environment correlation occurs where responses evoked in others or the environment are correlated with the individual's genotype, e.g. a sociable child who evokes friendly responses in others.

The interesting point about gene–environment correlation is that even where traits or disorders are found to be highly heritable, environmental influences may still be important mediating factors. Again, there are examples from adoption studies of antisocial behaviour that suggest that observed adversity, such as negative parenting, may be due in part to the child's genetic make-up. For example, two studies have found that adoptive parents appear to show increased negative parenting when their adopted children have an increased genetic risk of antisocial behaviour (i.e. their biological parents showed antisocial behaviour) (Ge *et al.*, 1996; O'Connor *et al.*, 1998).

Assortative Mating

Quantitative genetics theory assumes random mating. This, of course, may not hold true for many human traits where like may be attracted to like. This is known as positive assortative mating. Negative assortative mating occurs where opposites attract. There is some evidence that to some extent there is positive assortment for height and, to a lesser extent, cognitive ability.

There has also been reasonably consistent evidence that assortative mating also occurs with antisocial behaviour. Assortative mating may be influenced by social factors, e.g. finding a partner of similar cognitive ability at university, or meeting with an antisocial partner within a delinquent peer group.

The net result of positive assortative mating for twin studies is that genetic similarity amongst the parents leads to increased genetic sharing amongst siblings. This results in an inflated fraternal twin correlation, which would lead to an inflated estimate of the shared environment component. However, so far this has not been shown to cause a serious problem to twin studies.

MOLECULAR GENETICS

So far, we have focused on quantitative genetic theory without considering the molecular basis to inheritance. We now know that genetic information is encrypted in a macromolecule called DNA. The purpose of this section is to explain the organization and structure of DNA, and how information is encrypted within, decoded from, and transmitted by this molecule.

Chromosomes

In humans, DNA is organized into 23 pairs of chromosomes, each of which has a unique appearance. One pair consists of the sex chromosomes, which, as mentioned earlier, come in two forms, X and Y. Females carry two copies of X while males carry one X and one Y. The Y form determines gender, resulting in male differentiation. The other pairs are called autosomes, numbered 1 through to 22. Each chromosome has two arms joined by a central region known as the centromere. The centromere is not positioned exactly in the middle of the chromosome, which therefore appears

to have a long and a short arm, called q and p, respectively. The free end of each arm is called a telomere. The arms are divided further into numbered regions, with those nearest the centromere (cen) having smaller numbers than those near the telomere (tel). Thus, 22q1 designates a region on the long arm of chromosome 22, which is nearer the centromere than 22q2.

The term 'karyotype' is used to describe the chromosome content of a cell. The normal male karyotype is 46,XY and the normal female karyotype is 46,XX. However, occasionally there are abnormalities of chromosome number. Thus, the Turner's syndrome (females with only a single X chromosome) karyotype is 45,X, while the Klinefelter's syndrome karyotype (males with an extra X) is 47,XXY. The usual karyotype of males with Down's syndrome is 47,XY,+21, where +21 indicates an extra copy of chromosome 21. Autosomes are each present in duplicate, with one complete set inherited from each parent. Pairs of the same type are called homologous chromosomes, and each member of a pair is virtually identical at the DNA level.

DNA

The microstructure of DNA is largely responsible for carrying genetic information. DNA is a polymer consisting of a chain of sugar monomers each linked by a phosphate bridge. There are four types of monomer, which differ according to the type of base molecule anchored to each sugar: these are adenine (A), guanine (G), cytosine (C) and thymine (T). A sequence of DNA is usually described by the order of bases in a 5′–3′ direction (5′ and 3′ describe the start and end of the molecule, respectively, as it is synthesized). Thus, a stretch of DNA may be represented as 5′-AGCTTTGGCA-3′.

The entire DNA content of an organism is called its genome, and the complete sequence of the human genome is defined by around 3×10^9 bases. DNA in its natural state usually exists as a double-stranded structure (dsDNA) consisting of two linear DNA molecules held together by hydrogen bonding between the bases in the opposing strands. Pairs of bases in opposite strands do not align randomly. Thus, the adenine is always paired with thymine, and cytosine with guanine. This is called base complementarity, and two strands displaying this property are said to be complementary. Consequently, if the sequence of bases in one strand of DNA is known, then the complementary sequence of bases in the other strand is also known, according to the above simple rule. This permits the dsDNA sequence to be described by one of the two strands. Thus, the dsDNA sequence above would be:

5′-AGCTTTGGCA-3′

3′-TCGAAACCGT-5′

Cell Division

At conception, we begin with a single cell containing 46 chromosomes. By adulthood, each of us consists of around 10^{14} cells. This increase in cell number occurs by mitosis. The production of gametes (sperm and eggs/ova) arises from a rather different process called meiosis.

During meiosis, pairs of homologous chromosomes migrate within the cell to lie together side by side to form a structure called a bivalent (Figure XII.5). Each chromosome is replicated to form pairs of sister chromatids. Because homologues are aligned and each homologue consists of a pair of sister chromatids, each bivalent contains four dsDNA molecules. Chromosomal material is then exchanged almost randomly between homologues, a process called recombination (Figure XII.5). After recombination, the chromosomes are therefore no longer identical to those originally

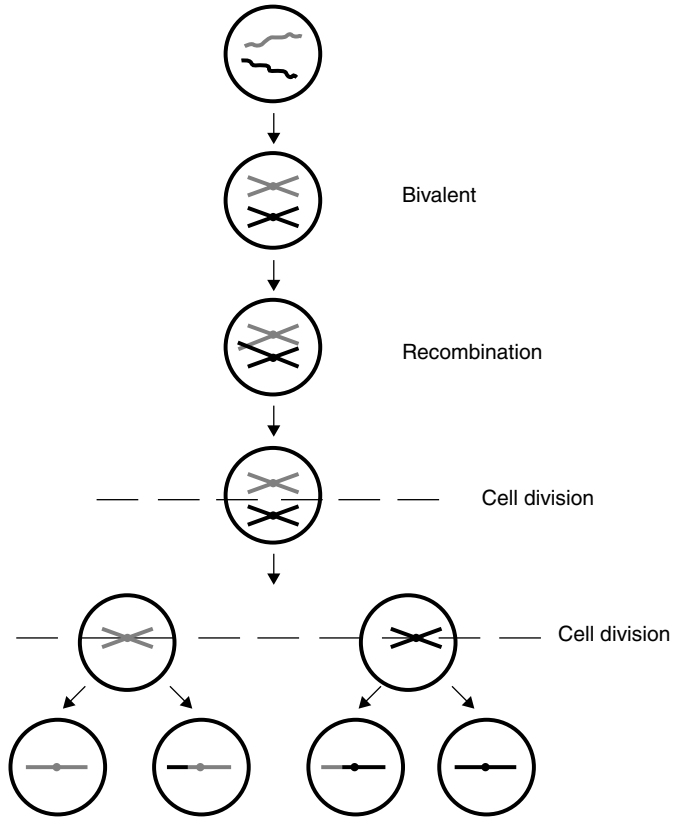

Figure XII.5 Meiosis

inherited from the parents. Furthermore, pairs of sister chromatids are not identical. Instead, each contains a different mixture of genetic material originating from the father and the mother. Recombination is central to the understanding of genetics, particularly of studies that make use of the phenomena of linkage and association (see later).

After recombination, a series of cell divisions occurs, with the final result that each gamete contains only a single copy of each chromosome. Thus, in spermatogenesis, instead of a diploid 46,XY karyotype, each of the four spermatozoa has a haploid 23,X or 23,Y chromosome complement. Furthermore, because of recombination, each sperm is genetically distinct. By a similar process, the product of oogenesis is one large haploid 23,X egg gamete.

Storage of Information in DNA

DNA molecules are organized as genes, which are the stretches of sequence carrying the information required to synthesize RNA (ribonucleic acid) molecules, which in turn code for amino acids that constitute proteins. Only a small proportion of the genome contains this kind of genetic information (~1%). However, there are other functional elements of DNA, including sequences that alter gene expression. In order to express the information encoded in genes, DNA must first be transcribed. During transcription, a segment of DNA corresponding to a gene acts as a template for the synthesis of a complementary strand of messenger RNA (mRNA). In order to initiate transcription, a number of transcription factors bind to DNA at the 5′ end of the gene at a region called the promoter. Whereas the promoter region is located in the immediate region flanking the 5′ end of the gene, there are other regions that can either enhance or repress the rate of transcription. These

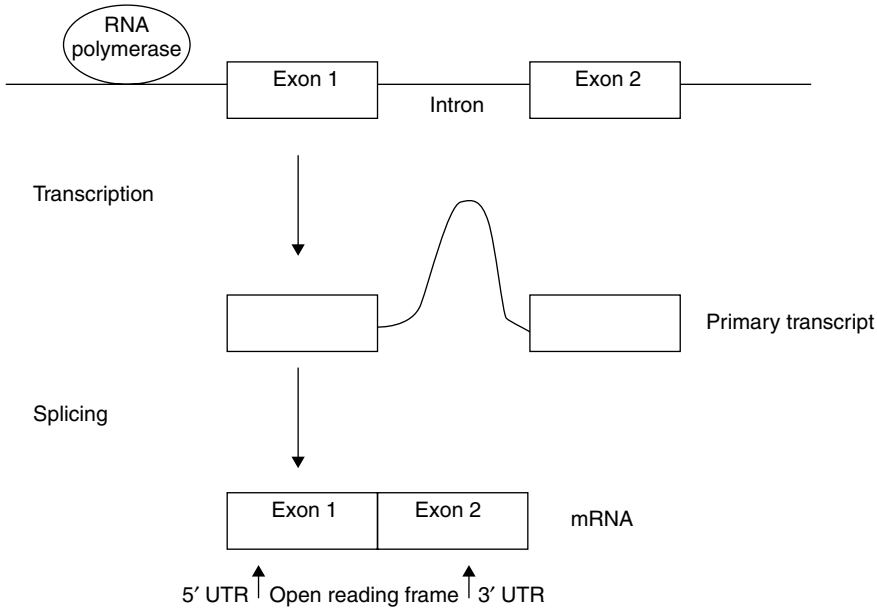

Figure XII.6 Formation of mRNA

are called enhancers and silencers, respectively; unlike promoter elements, their position relative to the gene is unpredictable. The immediate product of transcription does not constitute a functional mRNA molecule. Instead, this primary transcript must be subjected to post-transcriptional processing. There are many post-transcriptional steps, but for our purposes the most important of these is RNA splicing (Figure XII.6).

In humans, the sequence in a gene that is represented by complementarity in a mature mRNA molecule is interrupted by stretches of DNA sequence that is not. These coding and non-coding sequences are called exons and introns, respectively. The intron sequence is removed from the primary transcript by a process called RNA splicing. RNA splicing is of importance for several reasons. First, by altering the pattern of splicing, a single gene may yield several different mRNAs containing different exons and that therefore encode different polypeptides (constituents of proteins). Many genes encoding neuro-receptors display this. Second, mutations in the gene sequence may cause either failure of splicing (read-through) or excessive splicing (exon skipping). Clearly, this can alter the sequence of the mature mRNA and may result in disease.

Codons, Amino Acids and Polypeptides

The amino acid sequence of any given protein is specified by the sequence of bases in the mRNA transcribed from the gene encoding that protein. The unit of information in mRNA encoding an individual amino acid is the codon, which consists of three adjacent bases. The order of codons in the mRNA molecule serially code for each amino acid in its corresponding protein. For example, the amino acid threonine is encoded by the codon ACA, while CAG encodes glutamine. Thus, the sequence ACACAG will specify a segment of a protein where the adjacent amino acids are containing threonine and glutamine. The process of assembling a polypeptide (the units of which are amino acids) based upon the information encoded in mRNA is called translation.

During translation, mRNA molecules first bind to ribosomes, which are large complexes of ribosomal RNA (rRNA) and protein. Another species of RNA called transfer RNA (tRNA) is then responsible for actually reading the genetic code of the mRNA and bringing together the specific sequence of amino acids that is coded for.

Specific subspecies of tRNA bind specific amino acids. Each species of tRNA also has a specific three-base anticodon sequence at one end, which reads the genetic code by binding to the codons of mRNA according to the rules of complementarity. Thus, specific tRNA molecules (and therefore amino acids) base-pair with any given mRNA in an order or sequence that is specific to that mRNA. After base-pairing, the tRNAs yield their captive amino acid for inclusion in the lengthening protein. This is the mechanism by which linear genetic information encoded in DNA results in linear information encoded in a polypeptide (sequence of amino acids; the constituents of proteins).

In addition to encoding specific amino acids, a specific codon sequence (ATG) initiates translation; the sequences TAA, TAG and TGA terminate translation. mRNA species are also preceded by a number of bases that are not translated, called the 5′ UTR (untranslated region), and several hundred bases at the 3′ end that are also not translated (3′UTR). The exonic sequence between these sequences that actually encodes amino acids is called an open reading frame (ORF) because it contains no termination codons.

The codon sequence that is actually translated is called the reading frame. Any stretch of sequence in an mRNA molecule has three potential reading frames, depending on whether the first complete codon begins at base 1, 2 or 3 (see example below).

ACC AGG AUG GGG CAG CUG = thr arg met gly gln leu

A CCA GGA UGG GGC AGC UG = pro gly trp gly ser

AC CAG GAU GGG GCA GCU G = gln asp gly ala ala

Clearly, the order of amino acids specified is dependent on which base forms the start of a codon unit. This is an important concept to grasp because mutations that alter the reading frame can have profound functional consequences.

Just as primary transcripts are modified to produce mature mRNA, so polypeptide products of translation are often modified

before a functional protein is produced. Common modifications include the removal of an *N*-terminal signal sequence, glycosylation, phosphorylation and cleavage.

Genes, Chromosomes and Variation

In 2000, the Human Genome Project delivered the first complete rough draft, covering about 90% of the human genome. Since the information is still incomplete, we can only estimate the total number of genes in the human genome. However, best estimates based on the number of unique mRNA molecules detected so far place this at around 30 000–40 000.

The sequence of any given chromosome is virtually identical in all humans (barring major chromosomal anomalies). However, although they are similar, they are not identical. The science of genetics is essentially the study of this variation. Without DNA variation, every human would carry identical genetic information. All phenotypic (i.e. observable) variation would therefore be due to the effects of the environment.

The term 'locus' is used to describe a sequence at a defined position on a chromosome. If the DNA sequence at a given locus shows variation, then the locus is polymorphic, and each variant of that polymorphism is called an allele. As described earlier, if an individual contains the same pair of alleles at a given locus in a pair of homologous chromosomes, then that person is said to be homozygous at that locus. If an individual carries different allelic forms at a given locus, then that individual is described as heterozygous at that locus. Females are also homozygous or heterozygous at X chromosomal loci because they have two copies of X. However, males are hemizygous because they carry only a single copy of each sex chromosome.

Sequence Variation

The most common types of variation are single-base substitutions (replacement of one base by another) and single-base insertions and deletions (gain or loss of one or more bases relative to a reference sequence). These are often termed single-nucleotide polymorphisms (SNPs). Such changes are extremely common in the human genome. On average, the sequence in a pair of homologous chromosomes carried by any individual is expected have an SNP every 1000 bases, most of which occur in 'junk DNA' and are therefore without phenotypic consequences. Mutations in coding sequence are, however, much more likely to have phenotypic effects. These can be classified as follows:

- *Nonsense mutations* change an amino acid codon to a termination codon, resulting in a truncated protein. Such changes can often be expected to have a dramatic effect, at least on the protein.
- *Missense mutations* change the amino acid specified by a single codon. These are also called non-synonymous substitutions.
- *Silent substitutions* do not alter the amino acid specified by a codon. These are also called synonymous substitutions.
- *Frameshift mutations* are small insertions and deletions in coding sequences, which may have dramatic phenotypic consequences. Because the genetic code is based on the three-base codon system, the deletion or insertion of a single base will cause the entire downstream sequence to be read out of frame, resulting in a dramatically different polypeptide.

Most variation outside coding sequence is expected to have no phenotypic effect, but this is not always so. Variants in promoters, enhancers, repressors, UTRs and introns may result in altered gene expression. Other silent changes may alter mRNA processing. Thus, it should not be assumed that just because a variant does not result in a change in amino acid, it has no phenotypic consequences.

Chromosomal Abnormalities

The most common numerical increases in chromosomal number result from possession of an extra copy of a single chromosome. This is called trisomy; the best known example of this is trisomy 21 or Down's syndrome (male karyotype 47,XY,+21). The converse situation, in which an entire chromosome is missing, is called monosomy; with the exception of Turner's syndrome females, who carry only a single X chromosome (45,X), monosomy of an entire chromosome is lethal and is therefore not found.

If the chromosomal abnormality arises by the failure of a pair of homologous chromosomes to separate during cell division in embryogenesis rather than in the production of sperm and eggs, some cells in the body will have a normal chromosomal number while others will not. This is called mosaicism; the phenotypic consequences of this can vary dramatically, depending on the proportion of cells with the abnormal number of chromosomes.

Other chromosomal abnormalities occur as a result of breakage of chromosomes. These include (1) deletion, in which a large stretch of DNA is lost; (2) inversion, in which a piece of chromosome breaks and becomes reattached in the opposite orientation (consequently, there is no loss of DNA, although individual genes may be interrupted); (3) duplication, in which a segment of chromosome is duplicated; and (4) translocation of segments from one chromosome to another (non-homologous) chromosome. Translocations can be categorized into balanced or unbalanced. For example, if an individual has part of chromosome 1 attached to chromosome 2, and vice versa, then the offspring may be phenotypically normal if both abnormal chromosomes are transmitted simultaneously; this is said to be a balanced translocation. The situation in which offspring receive only one of the abnormal chromosomes is unbalanced, and will result in simultaneous partial monosomy and partial trisomy.

Occasionally, both members of a pair of homologues carried by an individual with a normal karyotype originate from the same parent, rather than one being passed on from the mother and the other from father. This is called uniparental disomy. It might be thought that if a child possesses a pair of chromosomes from a phenotypically normal parent, then this should not pose a problem; however, this is not the case because regions of chromosomes are sometimes 'marked' or imprinted as they are transmitted from a parent to the offspring. Where this occurs, the chromosomes from the mother are not equivalent to those from the father. Abnormalities can then occur when an individual does not receive an imprinted sequence from both parents. Classic examples of relevance in psychiatry are Prader–Willi syndrome and Angelman's syndrome. We have already discussed how these syndromes arise from microdeletions on chromosome 15. These disorders can also arise in the absence of a microdeletion but when both copies of chromosome 15 originate from the mother or the father.

The Mitochondrial Genome

So far, we have focused on chromosomal DNA. However, mitochondria contain their own small genome of around 16 500 bases, which encodes a small number of proteins and RNA molecules required for oxidative phosphorylation. Sperm contribute mitochondria only very rarely during fertilization and, consequently, diseases of the mitochondrial genome are almost always transmitted maternally. There are several thousand mitochondrial DNA molecules per cell rather than two homologous chromosomes, therefore the concepts of homo-, hemi- and heterozygosity do not apply. Instead, what is relevant is the proportion of DNA molecules carrying a variant mutation. This may be 100%, 0% (homoplasmy) or any intermediate ratio (heteroplasmy). Furthermore, because mitochondria are dispersed randomly into daughter cells during cell division, the ratios of heteroplasmy can vary between mother and child and

between individual cells. This has an impact on the severity of the phenotype of diseases caused by mitochondrial mutations.

Mitochondrial DNA has a particularly high mutation rate, therefore mutations commonly accumulate in an individual's somatic cells, leading to a reduction in the efficiency of oxidative phosphorylation. This has been proposed to be important in the aetiology of some neurodegenerative diseases, in particular Parkinson's disease and Alzheimer's disease.

Unstable DNA

We tend to think of DNA as a relatively stable structure that is transmitted reliably from parent to offspring and from cell to cell. However, as mentioned earlier, DNA sequences containing repetitive sequences are often unstable and are prone to extremely high rates of mutation, which may be pathogenic. A particular class of repeat — the trinucleotide repeat — has emerged as playing an important role in human neurological disorders. Trinucleotide repeats are repeat elements in which the unit of DNA sequence that is repeated consists of three bases, e.g. CAGCAGCAG. At a given locus, trinucleotide repeat sequences are often polymorphic in repeat number; when they are located within genes, possession of a relatively large copy number of repeats (called an expanded trinucleotide repeat) can sometimes lead to disease. Expanded trinucleotide repeats were first identified as pathogenic in classic fragile X syndrome; since this discovery, many other disorders have been attributed to expanded trinucleotide repeats, including Huntington's disease and numerous forms of ataxia.

The mechanisms by which trinucleotide repeats lead to disease are still not understood. Some with very large repeats in the promoter, untranslated region or intronic regions appear to exert their effects by silencing transcription. However, the largest group of identified trinucleotide repeat diseases are neurodegenerative disorders (e.g. Huntington's disease) caused by moderate-sized CAG repeats encoding polyglutamine sequences. The pathogenic mechanisms of this group are essentially unknown, and although neurones in people with these diseases have characteristic protein deposits called nuclear inclusions, these are unlikely to provide a primary explanation (Cummings and Zoghbi, 2000).

Progression in age at onset and/or phenotypic severity as a disease transmits through a pedigree is called anticipation. This only known genetic mechanism for anticipation is the propensity of pathogenic expanded repeats to increase in size during transmission from parent to child. As age at onset and/or severity are often related to the repeat size, unstable transmission results in anticipation. Many modern studies generally note that patterns of transmission of major mental disorders are consistent with anticipation, and although biases cannot be ruled out, this has led to the hypothesis that schizophrenia, bipolar affective disorder and even anxiety disorders may, at least in part, be attributed to one or more pathogenic trinucleotide repeats. However, to date, the evidence for this is entirely circumstantial.

Methylation, Imprinting and Epigenetic Inheritance

So far, our discussion has concerned the genetic information carried by the linear DNA sequence. However, there are mechanisms by which variation in the rate at which a gene is expressed (i.e. mRNA is produced) can be inherited in the absence of a change in the primary DNA sequence. This is often referred to as epigenetic inheritance. Although our understanding of epigenetic phenomena is rudimentary, we do have a limited understanding of several important mechanisms. One involves methylation of bases at the 5′ end of genes. This leads to changes in chromatin structure that make the DNA unavailable for transcription and thus silence the methylated gene.

The DNA surrounding some genes is in a different state of methylation in sperm and eggs. This results in a variation in the activity of even identical copies of a gene, depending on the transmitting parent. This phenomenon is called imprinting. Genetic information can also be altered by other influences. For example, gene activity can be dependent upon the precise chromosomal localization of the gene (position effects), and therefore the activity of a gene may be altered by translocation, even if the gene itself is not disrupted by the chromosomal breakage.

METHODS IN PSYCHIATRIC GENETICS

Family, Twin and Adoption Studies

Family Studies

The family study design involves examining whether the rate of disorder is increased amongst relatives of affected individuals compared with the rate amongst relatives of those with either no disorder or some other psychiatric disorder. Thus, family study findings inform us as to whether a disorder is familial. Familial clustering of a disorder can, of course, be explained by environmental influences shared by different family members as well as by genetic factors. Nevertheless the relative risk to first-degree relatives (λ_r) is often used not only as a measure of familiality but also when considering how worthwhile molecular genetic studies may be.

There are two types of family study methods. The family history method involves obtaining information on relatives from the proband (affected individual). Although this is a practical and economical method, given that many individuals may know little about their relatives' health, this type of study can result in an underestimate of the rate of diagnoses in relatives. A preferable, although expensive, method is the family study method, which involves direct interviews with all relatives.

It is rarely possible to include all affected individuals from a defined population (complete ascertainment), and most family studies are, by necessity, based on selected samples, e.g. patients that have been referred to hospital. The selection processes and factors influencing referral patterns, such as comorbidity and help seeking, should ideally be taken into consideration when analysing the data. Similarly, all probands in a family study should be ascertained in an independent fashion, although for common disorders it may arise that different members of the same family are included. This is known as multiple ascertainment. Another difficulty that needs to be considered by those carrying out family studies is that the rate of disorder will depend on the age of the individual, and whether they have passed through the risk period for the disorder being studied. Some relatives will not have reached the age of risk, some will become affected at a later point in time, and others may have died before becoming affected. Thus, the rate of disorder in relatives has to be adjusted using an age correction, and must be expressed as the morbid risk or lifetime expectancy.

Twin Studies

Twin studies allow for the disentangling of genetic and shared environmental effects. Genetically identical or monozygotic (MZ) twins arise from the same fertilized egg and thus share 100% of their genes in common. Non-identical or dizygotic (DZ) twins come from two fertilized eggs and, like full biological siblings, share on average 50% of their genes.

Given certain assumptions (see later), where there is greater MZ twin similarity compared with DZ twin similarity for a given trait or disorder, this suggests a genetic contribution. For continuous

traits, such as height, weight and IQ test score, similarity between the twins is stated as an intraclass correlation coefficient that can be expressed in terms of heritability and shared environmental variance:

$$r_{mz} = h^2 + c^2$$
$$r_{dz} = 0.5\ h^2 + c^2$$

Although we can calculate h^2 and c^2 by solving these simultaneous equations, and e^2 is the remaining variance $(1 - h^2 - c^2)$, most researchers now use formal methods of model fitting (see later).

For categorically defined characteristics, e.g. those with a disorder and those who are unaffected, similarities are expressed as concordance rates. The pairwise concordance rate is calculated by dividing the total number of twin pairs who both have the disorder by the total number of pairs. Proband-wise concordance rates are used when the twins have been ascertained systematically, e.g. from a twin register. Here, we calculate the concordance rate as the number of affected twins divided by the total number of co-twins.

Equal Environments Assumption

The twin study design is based on the assumption that MZ and DZ twins share environment to the same extent. There has been much criticism of this assumption, and indeed where questionnaire measures of environmental sharing had been used, there is evidence of greater MZ environmental sharing than DZ twin sharing.

However, greater MZ environmental similarity may arise as a consequence of their greater genetic similarity. Criticisms of the equal environments assumption have been examined in three main ways. First, some studies have used questionnaire measures of environmental sharing that include items such as whether the twins were dressed alike as children, were treated alike, shared a room and shared friends. It is then examined whether the greater MZ twin environmental sharing is associated with increased MZ twin phenotypic similarity. Studies that have used this approach suggest that greater similarity in childhood environment does not account for greater MZ twin similarity in cognitive ability, personality, depressive symptoms or depressive disorder.

Another method has been to examine twins who have been mistaken about their zygosity. Again, studies that have used this method suggest that perception of zygosity appears to have little influence on twin similarity.

The most powerful method of examining this issue is to investigate reared-apart twins. This allows for examining the effects of environmental sharing apart from those factors that are influential when the twins are very young or when they are in the womb. Although reared-apart twin studies have inevitably been based on highly selected samples, they have yielded findings that are consistent with those of reared-together twins and shown a genetic contribution for traits such as cognitive ability, personality and psychosis.

Comparability of Twins

Another important criticism of the twin method is that twins may not be representative of the general population in that they differ from singletons in some important respects. DZ twinning is influenced by factors such as maternal age, multiparity, family history of twins, and the use of fertility drugs. Twins experience greater intrauterine and perinatal adversity and are clearly unusual in their experience of being brought up as a twin. Moreover, there is also some evidence to suggest that depression is more common in mothers of young twins than in mothers of singletons. However, twins do not appear to differ markedly from singletons for most types of behaviours and disorders, other than showing increased rates of early language delay.

Ascertainment

Many of the older twins studies suffered from bias in that they were based on affected twins referred to the study or on volunteer samples. These groups tend to include more female monozygotic twins who are concordant. More recent studies have been based on either hospital registers or population-based samples. Hospital registers have the advantage of including those with definite disorders, but clearly findings for some disorders may be biased given the process of selection for referral.

Population-based samples overcome these difficulties, but clearly extremely large numbers are required to study less prevalent disorders.

Zygosity

Ideally, zygosity should be assigned utilizing genotyping methods. However, this may be impractical and too expensive for very large population-based studies. Twin similarity questionnaires are used widely in research; they include questions on hair colour and eye colour, and whether the twins look alike and are mixed up by family and strangers. This simple method has over 95% accuracy in distinguishing between MZ and DZ twin pairs.

Adoption Studies

Adoption studies, like twin studies, allow for disentangling the effects of genes and shared environment. They provide a particularly powerful method for examining gene–environment interaction and gene–environment correlation. The basis of the method involves examining the similarity between individuals who have been adopted and their adoptive relatives and biological relatives. This type of method has added to twin evidence in demonstrating the contribution of genetic effects to disorders such as schizophrenia and traits such as IQ.

There are three main types of study design. First, the adoptee study involves examining the rate of disorder among the adopted-away offspring of affected biological parents and comparing this with the rate among controls consisting of adopted-away individuals whose biological parents are unaffected. The second type of study is the adoptee's family study. Here, the adoptee is affected by a specific disorder and the rate of disorder in the biological and adoptive relatives is compared. Finally, the cross-fostering study involves a more complex design but allows for further examination of gene–environment interaction. The rate of disorder in adoptees with affected biological parents and unaffected adoptive parents (high genetic risk, low environmental risk) is compared with the rate of disorder in adoptees with well biological parents and affected adoptive parents (low genetic risk, high environmental risk).

Adoption studies are becoming increasingly difficult to conduct, and they clearly suffer from a number of drawbacks. Adoption is an unusual event, and adoptees are not placed randomly. Adoption may occur more commonly where there is increased early environmental and perinatal adversity, and where there is increased genetic risk for some disorders. Moreover, recent work suggests that adoption studies may lack power in identifying important environmental influences due to a 'restricted range' of environments (Stoolmiller, 2000). Nevertheless, adoption studies have yielded important findings and, in particular, have provided empirical evidence of gene–environment correlation. For example, as mentioned earlier, two adoption studies have shown that the adoptive parents of children with an increased genetic risk of antisocial behaviour (because the biological parents showed antisocial behaviour) show increased rates of negative parenting (Ge *et al.*, 1996; O'Connor *et al.*, 1998).

Similarly adoption study findings have demonstrated evidence of gene–environment interaction, whereby the effects of environmental adversity are increased when there is also genetic susceptibility. In an adoption study of criminality (Bohman, 1996), the

rate of criminality amongst adoptees was 6.7% in those exposed to increased environmental risk alone and 12.1% in those at increased genetic risk. This rate rose to 40% in adoptees with a background of both genetic and environmental adversity.

Other Designs

Finally, an increasing number of mixed designs are being used to examine the contribution of genetic and environmental factors to behavioural traits and psychiatric disorders. Studies involving combinations of twins, siblings and stepfamilies have been used. These all utilize the same principle of examining the phenotypic similarity of pairs of relatives who are biologically related to a different degree and those who are biologically unrelated.

Methods of Statistical Analysis used in Family, Twin and Adoption Studies

Path Analysis

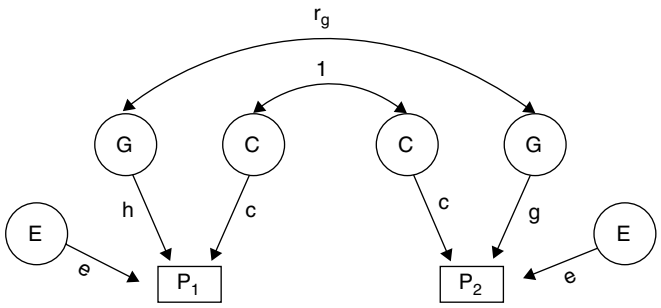
Earlier, we described the resemblance between twin pairs in terms of the proportions of variance attributable to genetic and environmental effects. The resemblance between relatives can be shown diagrammatically using a path diagram (Figure XII.7). It can be seen that the phenotype variance for each relative (P) is influenced by a genetic path (h), a common environmental path (c) and a non-shared environmental path (e), where h, c and e are path coefficients. Path analysis provides a simple method for deriving the equations we presented previously. Using the tracing rules of path analysis (see Li, 1986), the correlation between the relatives (r_{rel}) is obtained by identifying all the connecting paths and multiplying the path coefficients for each of the connecting paths. From Figure XII.7, we obtain two connecting paths: a genetic path, $h \times r_g \times h$, and a common environment path, $c \times c$.

The correlation is then obtained by summing these coefficients, so that:

$$r_{rel} = h^2 r_g + c^2$$

For monozygotic twins, $r_g = 1$, and for full biological siblings and dizygotic twins, $r_g = 0.5$. Thus, we obtain the equations that we presented earlier:

$$r_{mz} = h^2 + c^2$$
$$r_{dz} = 0.5h^2 + c^2$$



C, common/shared environment; E, non-shared environment; G, genotype; P_1, twin 1 phenotype; P_2, twin 2 phenotype; r_g, genetic correlation, 1 for MZ twins, 0.5 for DZ twins.

Figure XII.7 Basic path model of the sources of variance and resemblance between twins

Genetic Model Fitting

Although we can solve the equations presented above to obtain the different components of phenotype variance, most family and twin studies now utilize structural equation model-fitting techniques. This method has the advantage of allowing us to test formally the goodness of fit of a specific model, compare different models, and analyse more complex data sets.

Computer packages such as Mx (Neale, 1997) involve the investigator providing the raw observed data and initial starting values for the unknown parameters (h, c and e for a basic ACE model, incorporating additive genetic (A), shared environmental (C) and non-shared environmental (E) influences). The program iterates using different parameter estimates until expected values are obtained that result in the optimization of fit (i.e. minimizing the difference between the observed and expected values). Different fit functions, such as the maximum likelihood function, are available (see Neale and Cardon, 1991 for details). Acceptability of the tested model is then assessed, usually on the grounds of goodness of fit and parsimony (accepting the simplest model). One method of assessing fit is to examine the chi-squared goodness of fit, where a smaller value indicates a more satisfactory fit. The fit of reduced models, in which the additive genetic influence is dropped (CE), the common environmental influence is dropped (AE), or both A and C are dropped (E), can then be compared against the full ACE. We can subtract the chi-squared value of the full model (χ^2_f) from the reduced model (χ^2_r), and if there is no significant change in goodness of fit (i.e. $P > 0.05$), then we can select the more parsimonious model. Akaike's information criterion (AIC) provides a measure of both goodness of fit and parsimony, and models can be chosen using this method whereby the model with the most negative AIC value is chosen as providing the most satisfactory explanation of the data (Neale and Cardon, 1991).

More complex models incorporating other parameter estimates, such as dominance effects, rater contrast effects, and sibling interaction, as well as measured variables, e.g. marital conflict, can also be examined, provided that the number of unknown parameters does not exceed the number of equations.

So far, we have considered analysis of a single phenotype, which is known as univariate genetic analysis. Multivariate model fitting allows for examining the genetic and environmental influences on two or more observed phenotypes. For example, if we examined anxiety and depression and found that the cross-twin cross-trait correlation was higher in MZ than DZ twins, then this would suggest a common genetic influence on these two phenotypes. Indeed, twin studies utilizing multivariate model fitting have shown that common genetic factors account for much of the overlap of anxiety and depression symptoms and disorder (Kendler *et al.*, 1987; Thapar and McGuffin, 1997; Eley and Stevenson, 1999). Multivariate genetic methods are also being used increasingly to examine longitudinal data and the relationship between environmental risk factors and psychopathology.

DeFries and Fulker Twin Regression Analysis

A simple but elegant method of analysing continuously distributed twin data is based on simple regression analysis. This is commonly known as the DeFries–Fulker (DF) analysis. The method is particularly useful in that it can be used to test whether the genetic aetiology of extreme scores differs from aetiological influences across the normal range. For a trait that is influenced genetically, we will expect the MZ co-twins of the proband to regress less towards the population mean than the DZ co-twins of affected DZ probands. Using regression analysis, estimates of heritability and shared environment for individual differences (across the normal range), as well as for extremes, can be obtained. DF analysis

from several twin studies has, for example, suggested that attention deficit hyperactivity disorder (ADHD) behaves as a continuum, with genetic influences being as important for high scores as for across the range (Thapar *et al.*, 1999).

MOLECULAR GENETIC RESEARCH METHODS

The key technologies in molecular genetic analysis are those that aim to detect and measure DNA sequence variation. How are these techniques used to map susceptibility genes for human disease? The two methods of mapping genes are linkage and association studies. In this section, we will explain linkage and association methods that involve examining whether specific DNA variants (polymorphisms/markers) can be identified as being related to a given disorder. An outline of how DNA sequence variation is measured in the laboratory is then given.

Linkage Studies

Linkage studies involve examining the co-inheritance of the disease and a set of genetic markers within families. Where the disease susceptibility locus and marker locus are located close together on a chromosome, they will tend to be co-transmitted more often than expected by chance. This phenomenon is known as linkage. The estimated distance between the marker and disease locus is defined in terms of the recombination fraction θ. Where there is independent assortment of two loci, $\theta = \frac{1}{2}$; where the two loci are close so that recombination occurs infrequently, θ approaches zero. The advantage of linkage methods is that they can be used for hypothesis-free research. That is, no knowledge of disease pathogenesis is required, as it is feasible to undertake whole genome linkage studies rather than focusing on candidate genes. The main drawback is that unlike association methods (see later), this approach only detects genes of moderate to large effect size. The two main linkage study methods are the lod score method and the affected sib pair method.

Lod Score Method

The traditional approach of linkage analysis for mapping Mendelian disorders is the lod score method. This involves the collection of families with multiply affected individuals, and calculating lod scores for a range of values for θ. The lod score is calculated as follows:

$$\text{lod} = \log_{10} \frac{\text{probability that } \theta = \theta'}{\text{probability that } \theta = 0.5}$$

where θ' is a given value of θ. The final estimate of θ is obtained when the maximum lod score is achieved. A lod score of 3 or more is taken as indicating significant linkage.

The main problem with this method is that specific models and the mode of inheritance need to be specified. Although single-gene subforms exist for some complex disorders, e.g. Alzheimer's disease, it is becoming increasingly apparent that for most psychiatric disorders, major genes do not exist or at least are extremely rare. Thus, there has been more interest in non-parametric methods of linkage analysis.

Affected Sib Pair Method

This approach involves collecting pairs of siblings of whom both are affected by the disorder. The approach is being used widely as a strategy for mapping susceptibility genes for disorders such as schizophrenia, bipolar disorder and autism. If a marker allele is linked to the disorder, then we would expect affected siblings to share that particular allele more often than would be expected. Given that the probabilities of siblings sharing 0, 1 or 2 alleles that are identical by descent from the parents should be $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{1}{4}$, then we can test formally for statistically significant departures from these expected proportions. The affected sib pair method does not require specification of the mode of transmission, and it is thus better suited to mapping susceptibility genes for complex disorders.

The sib pair method has also been adopted for studies of quantitative (continuously distributed) traits, such as reading disability. Several approaches based, for example, on regression and variance components methods (Sham, 1998) have been developed, although extremely large sample sizes (thousands) are required to detect genes of moderate effect size. Nevertheless, strategies such as sampling sibling pairs who are highly discordant and highly concordant for scores on a particular trait measure and including a greater number of siblings can increase power. This method has been used for identifying quantitative trait loci (QTL) for reading disability, but given the increasing appreciation of the importance of genes of small effect size, association approaches also need to be considered.

Association Studies

Association studies are like case–control studies, in that they involve comparing a group of affected individuals with a control group consisting of people without the disorder. The frequencies of alleles for a given marker among cases and controls are then compared using contingency table analysis. If one particular marker allele is significantly more common among cases, then this suggests that the allele is associated with the disorder. The strength of the association is usually expressed as an odds ratio or relative risk. There are three main explanations of association. First, it may be that the polymorphism itself is contributing to susceptibility to the disease. Alternatively, the polymorphism may be extremely close to the disease susceptibility locus, with resulting linkage disequilibrium. Finally, association may arise for spurious reasons if the cases and controls differ in terms of allele frequencies for some other reason (e.g. ethnically distinct groups); this is known as population stratification. This potential for yielding false positive results has been used as an argument by some for not using case–control association studies. Although careful matching of controls is undoubtedly important, another way of overcoming these criticisms is to use family-based association study designs, whereby genetic information from the parents is used to generate an 'internal' control group. The two most commonly used methods are the haplotype relative risk (HRR) method and the transmission disequilibrium test (TDT) (Spielman *et al.*, 1993). The TDT, which requires the collection of DNA from the affected offspring and both parents, is now used widely and is a test of linkage in the presence of association. TDT analysis involves examining families where at least one of the parents is a heterozygote for the polymorphism that is being tested. If a specific allele is associated with the disorder, then we would expect this allele to be transmitted more frequently to the affected offspring than expected. The number of transmissions and non-transmissions for the two alleles are compared statistically using a simple McNemar chi-squared test. The TDT has now been developed further to allow for testing multiple alleles (so far, we have considered a biallelic polymorphism), utilizing siblings when parents are unavailable, and examining quantitative traits.

Association studies provide a statistically more powerful method of detecting genes of small effect size compared with linkage methods. So far, this type of study design has been used when examining polymorphisms within or near candidate genes. These are genes that encode for proteins that are thought to be involved in the aetiology of the disorder. This clearly poses a problem in psychiatry, where the pathogenesis of most disorders remains unknown. Nevertheless, meta-analyses of findings from association studies have

yielded significant findings of association of polymorphisms in the dopamine DRD4 receptor gene with ADHD, and the 5-HT2a receptor with schizophrenia, although effect sizes appear to be small. The alternative approach is to undertake a whole genome linkage disequilibrium or association study, whereby thousands of evenly spaced markers are tested. Although it has been suggested that this represents a useful way forward, at present there are many reservations about the practicality of such an approach, particularly with regard to the issue of multiple statistical testing and the feasibility of such large-scale genotyping. However, techniques such as DNA pooling and high-throughput genotyping may mean that whole genome association studies will become a feasible strategy for the future.

BASIC TECHNIQUES IN MOLECULAR GENETICS

The Polymerase Chain Reaction

Most molecular genetic studies employ the polymerase chain reaction (PCR). This is a method for replication of a small sequence of DNA, typically 200–1000 bases in size. The first step in PCR is to identify the sequence that defines the DNA fragment of interest. A pair of synthetic, single-stranded DNA molecules called primers are then designed. The two primers are identical to the two 5′ extremes of the DNA fragment of interest and are used to prime synthesis of DNA. Genomic DNA is mixed with the primers, a heat-stable DNA polymerase (an enzyme that catalyses the formation of DNA, e.g. Taq polymerase), and a mixture of the individual monomeric nucleotides (A, T, C and G, often referred to as dNTPs). The dsDNA is converted into single-stranded DNA (or denatured) by heating, and then cooled to allow the primers to bind to the single-stranded genomic DNA by base-pairing, a process known as hybridization. Catalysed by the Taq polymerase, primers are then extended from their 3′ ends according to the rule of complementarity by the sequential addition of the appropriately paired dNTPs. This results in a larger DNA molecule that is complementary to the original DNA strand to which the primer is bound. The whole process (denature, hybridize, extend) is repeated many times, with each cycle exponentially increasing the number of copies of the target sequence. At the end of the process, the starting concentration of the target fragment has been increased by $\sim 10^5 - 10^6$ to a concentration that can be detected easily by several techniques (see below).

Genotyping Polymorphisms that Alter the Size of Fragments

Genotyping is the process of determining which alleles are carried by an individual at a given locus. A class of polymorphism commonly used in genetic studies is the short tandem repeat polymorphism (STRP). These contain a certain sequence repeated several times, but the exact number of times a sequence is repeated varies in the population. The repeat is often a dinucleotide repeat, containing multiple copies of the sequence CA. Genotyping is then simply a case of measuring the size of the repeat. This is achieved by first amplifying genomic DNA by PCR in the presence of primers that flank the repeat. One of the primers is usually tagged with a radioisotope or a fluorescent dye. The PCR products are then separated by size by gel electrophoresis. The DNA molecules are placed at one end of a gel-like substance and subjected to a voltage gradient. This causes the PCR products to migrate along the gradient towards the positive terminal at a rate that is related inversely to size. The DNA fragments in the gel can then be visualized by the use of one of several DNA-staining techniques or, if fluorescent dyes or radioisotopes have been used, by a fluorescence scanning device or autoragiography respectively. This allows the size of the amplified molecules to be determined and therefore the alleles present to be identified.

Genotyping Single-Nucleotide Polymorphisms

SNPs are the most common types of polymorphism, and are increasingly thought of as the polymorphisms of choice for genetic studies. At the time of writing, the most common method for genotyping SNPs is based upon enzymes called restriction endonucleases. Such enzymes recognize and cut dsDNA at specific stretches of the DNA sequence of usually between four and eight bases. If a polymorphism changes the recognition sequence for one of these enzymes, then one allelic variant will be cleaved but the other not. After PCR, the reaction products are digested with an appropriate enzyme, which results in two smaller fragments in the presence of the allele that is cleaved by the enzyme, or one large fragment in the presence of an allele that is not cleaved. Polymorphisms like these are called restriction fragment length polymorphisms (RFLPs). As the assay is now based upon fragment size, the genotype can be determined by a process of electrophoresis.

Emerging Methods for Genotyping

There are numerous new techniques on the horizon for genotyping SNPs, some of which have already been installed in a number of laboratories. It is not yet clear which technique will emerge as the method of choice. Here, we consider briefly a few of the most promising techniques.

Mini-Sequencing/Primer Extension

After PCR, a third primer (the extension primer) is added. This extension primer is designed so that it anneals to one of the strands of the PCR product immediately adjacent to the polymorphic base. A second reaction is then performed, which permits the primer to be extended by only a single base. The specific base that is added to the primer will be the base that is complementary to the base at the polymorphic site. If the polymorphism at a given site is either an A or a C, then by complementarity, either a T or a G will be incorporated, respectively. The nature of the incorporated base can then be detected by a variety of methods, including mobility in a gel, fluorescence or mass.

Micro-Arrays (or DNA Chips)

Genotyping by DNA chips may be based on primer extension or allele-specific hybridization. In general terms, a DNA sequence that is a perfect match to another DNA sequence will hybridize more efficiently to that sequence than to a very similar sequence. In the case of the SNP above, amplified alleles containing an A at the polymorphic site will hybridize to a complementary DNA molecule containing a T in the correct position in preference to a molecule that is identical in all respects other than it contains a G instead of a T. The opposite is true for alleles containing a C. This is the principle of allele-specific hybridization.

In one application of allele-specific hybridization, PCR products from a single locus from thousands of subjects are spotted out (arrayed) individually in an area approximately the size of a postage stamp. This micro-array can then be hybridized with two short synthetic DNA molecules, each of which is perfectly complementary to one of the two possible alleles, and each tagged with a different fluorescent dye. After hybridization, the micro-array is analysed by a confocal laser system to determine the colour of the oligonucleotide bound to each spot, which therefore defines the genotype of that individual at that locus. Alternatively, instead of arraying PCR products from thousands of individuals, each spot on

the micro-array can contain a different oligonucleotide, with pairs of spots representing a pair of possible alleles at a given locus. Under this scenario, a chip can be constructed that will allow thousands of loci to be arrayed on a single micro-array. Different PCR products representing thousands of different loci from an individual can then be used to probe the micro-array, and the pattern of binding at each pair of spots then yields the genotype at each locus.

Detecting Unknown DNA Variation

The term 'mutation detection' describes the process of identifying unknown population variation in a defined stretch of DNA. There are currently numerous mutation-detection techniques available. The definitive method is DNA sequencing, which is the process of identifying the complete sequence in a fragment of DNA. Thus, one method for looking for population variation is to sequence the same stretch of DNA in many different people. However, sequencing is expensive and, outside the major public and private genome centres, it is labour intensive. For this reason, prior to sequencing, most laboratories first undertake mutation scanning to identify fragments that are likely to contain variants.

One of the simplest and most widely used of these is single-strand conformation analysis (SSCA) (Orita *et al.*, 1989). Even a single-base change in a single-stranded PCR product can alter its three-dimensional folding pattern (or its secondary structure), particularly if the DNA molecule is small (around 200 bases). This can be detected as altered migration of single-stranded PCR products during electrophoresis. Polymorphisms detected in this way are sometimes called single-stranded conformation polymorphisms (SSCP), and the technique is sometimes also known as SSCP. There are many more mutation-scanning techniques (Cotton, 1997), and the degree of automation is evolving rapidly. For example, in more highly automated laboratories, mutation-scanning analysis is often performed using high-performance liquid chromatography (HPLC) rather than a gel. With this method (called denaturing HPLC or DHPLC), and other semi-automated technologies, (including improvements in sequencing) whereas a few years ago screening a single gene for polymorphisms was a fairly labour-intensive process, it is now possible to contemplate screening hundreds or even thousands of genes in a single laboratory.

Information Technology and Positional Cloning

Positional cloning refers to a set of techniques by which disease-related genes are identified on the basis of their chromosomal location. Classically, positional cloning is achieved by first identifying the approximate chromosomal location of a disease gene by linkage (see earlier). This process is simplified greatly by the availability of fairly detailed 'maps' of polymorphisms called DNA markers, which are sequence variants known to reside at particular locations in the genome. The next step is to identify the specific sequence variations in that region that confer susceptibility to disease. A number of strategies may be used. However, the classic approach requires the creation in the test tube of a complete representation of the linked region in a series of small contiguous cloned fragments of DNA. The next stages are to identify the relatively small proportion of the DNA within the region corresponding to genes, screen these for sequence mutations/polymorphisms, and then test whether any of the detected variants are more common in patients with the disease compared with people who are unaffected. This process involves a great deal of cost and labour, such that analyses of even relatively small genomic regions of 1–2 million bases are large undertakings.

Fortunately, as a consequence of the Human Genome Project, most of these techniques are now in the process of being replaced by cloning 'in silico'. Increasingly, genomic sequence, gene sequence, and even the identification of some polymorphisms can all be obtained by searching computer databases. Thus, genetic researchers increasingly depend at least as much upon expertise with bioinformatics as they do upon 'wet' laboratory experiments.

Candidate Gene and Positional Candidate Gene Analysis

A major benefit of the positional cloning approach is that genes can be identified without any knowledge of disease pathophysiology. However, as we discussed earlier, where there are good clues to the pathophysiology of disease, or where the genetic effects are so small that they are difficult to detect by (at least today's) positional cloning technologies, hypothesis-driven candidate gene approaches are appropriate. Essentially, the task of the candidate gene approach in the laboratory is to select genes with plausible a priori roles in the disease pathogenesis (called functional candidate genes), screen the candidate gene sequences for DNA sequence variation, and test populations of affected and unaffected subjects for evidence that variants in the candidate gene are more commonly associated with affected status. As mentioned above, the technologies that make this approach possible (availability of gene sequence, mutation detection and genotyping) are all undergoing rapid improvements, and whereas testing a single candidate gene was rather time consuming in the past, it is now possible to test many candidate gene hypotheses in relatively short periods of time. Furthermore, although some considerable distance in the future, a catalogue of every human polymorphism in every gene will eventually become available, making the mutation-screening step at least partially obsolete. Ultimately, one can envisage the possibility of buying micro-arrays with either every known common polymorphism represented, or using specific chips that will allow whole systems of candidate genes (e.g. the genes known to be involved in neurotransmission or neurodevelopment) to be tested for association with disease. However, with multiple testing on such a large scale on the horizon, appropriate statistical techniques and adequate sample sizes will clearly be required.

Gene Expression

The function of a cell depends upon its pattern of gene expression, and it follows that altered function as part of a disease process is likely to be accompanied by alteration in the gene-expression profile. This offers the possibility of identifying the pathophysiological pathways or genes involved in a disease process by looking for differences in gene expression in tissues from individuals with and without that disease. Many readers will already be familiar with this broad approach, which is analogous to more traditional studies looking at differences in metabolic enzyme activities or neuroreceptor densities in patients versus controls. Indeed, many of our hypotheses concerning the aetiology of mental disorders have been provided by these methods. The recent development of technology allowing virtually every protein or mRNA in a tissue to be assayed is likely to provide important opportunities for developing new hypotheses concerning the aetiology of mental disorders.

Gene expression can be quantitated at the level of mRNA or the level of translated protein. There are many methods that permit individual mRNA species to be quantitated (e.g. Northern Blotting), but technological advances in the last 5 years have changed beyond recognition the rate at which expression data can be extracted. For example, it is now possible to measure the expression levels of thousands of genes simultaneously using gene-expression chips. These chips are simply micro-arrays containing thousands of DNA sequences, each of which is individually complementary to a different species of mRNA. Total RNA from a cell type or a tissue is reverse-transcribed in the presence of a fluorescent dye to create a complex cDNA mix. This is then hybridized to the micro-array.

Each different arrayed sequence binds a specific mRNA species, and the amount that is bound gives an indication of the abundance of that specific mRNA. By comparing the patterns of hybridization from either different tissues or different individuals, it is possible to create a profile of the genes that are differentially expressed either in different tissues or between subjects. Analogous technologies are also available for quantitating proteins, and technologies are under development that will even allow the function of thousands of proteins to be analysed simultaneously.

XIII

Gene–Environment Interactions

D.I. Boomsma and N.G. Martin

INTRODUCTION

Most genetic-epidemiological approaches used in the study of the aetiology of individual differences in psychiatric disease in humans assume that the effects of genes and environment are additive. That is, it is assumed that the effect of an environmental risk factor does not depend on the genotype of the individual, or, stated differently, that the expression of the genotype does not depend on the subject's environment. Kendler and Eaves (1986) discuss several models for the joint effects of genes and environment on the liability to psychiatric illness that extend this simple additive approach. In addition to the additive effects of genes and environment, they consider models for the genetic control of sensitivity to the environment (gene–environment interaction) and models for the genetic control of exposure to the environment (gene–environment correlation). We begin this chapter by briefly introducing the ideas of Kendler and Eaves, and by considering the predictions for risk of illness in relatives when for both probands and relatives their environmental exposure can be assessed. Next, we focus in more detail on genotype $\times$ environment ($G \times E$) interaction, and present some designs, using twin data, to assess its significance. We illustrate these models with published data on depression, disinhibition and alcohol use in Australian and Dutch twins.

Kendler and Eaves (1986; see also Eaves, 1982 and Eaves, 1984) describe three basic models that represent how genes and environment may jointly influence the liability to psychiatric disorder. Liability to psychiatric disorder is considered a quantitative dimension that is unobserved, or latent, and that underlies the probability of becoming affected. Individuals with a high liability have a high probability of illness, while individuals who score low on the liability scale have a low probability. Many traits that vary in a discontinuous manner, but do not show a pattern of simple Mendelian inheritance, may have an underlying continuous liability scale with a threshold that imposes a discontinuity (e.g. affected or unaffected for the disorder) on the visible expression. The variation in liability may be caused by both genetic and environmental influences (Falconer, 1989).

Kendler and Eaves (1986) propose three models that explain variation in liability:

1. Genes and environment contribute additively to liability of a disorder.
2. Genes and environment interact; this interaction model can be thought of as genes controlling sensitivity to the environment, or as the environment controlling gene expression.
3. Genes and environment are correlated: genes alter the exposure to relevant environmental risk factors.

These explanations for the variation in disease liability are not mutually exclusive; part of the variance may be explained by the additive actions of genes and environment and another part by their interaction. The properties of such complex models are a mixture of the characteristics of the three basic models, and we limit ourselves to the presentation of these basic models. In discussing some of the predictions based on these models, it is assumed that the environment can be dichotomized into 'protective' or 'predisposing', and that environmental risk can be assessed in the proband (the index case or patient from whom other family members are identified) and in his or her relatives.

In the additive model (model 1), an individual's liability to disorder is the sum of the contributions of genes and environment. Under this model, the effect of a given environment is the same, regardless of genotype. The risk to relatives to become affected is highest when an affected proband is or was exposed to a protective environment. The risk of developing the disorder is always higher in monozygotic co-twins of probands (who share all their genetic material with the proband) than in their siblings or other first-degree relatives (who share, on average, 50% of their genetic material with the proband).

When there is $G \times E$ interaction (model 2), genes determine the degree to which a subject is sensitive to the environment. Individuals with a 'sensitive' genotype have the greatest increase in scores on the liability scale in the predisposing environment and the largest decrease in the protective environment. In individuals with an 'insensitive' genotype, their scores on the liability scale do not change, or change to a lesser extent, as a function of their environment. *The risk to relatives of affected probands randomly distributed over environments is modestly greater than in the general population*. Under this model, familial resemblance is, in general, lower than under an additive model, especially when the predisposing environment is relatively rare. The risk to relatives is highest when both proband and relative have been exposed to a predisposing environment and risk is higher in monozygotic co-twins than in siblings only when both proband and relative have been exposed to the same kind of environment. If, for example, the proband is exposed to a protective environment and the relative to a predisposing environment, then the risk to siblings may be higher than the risk to monozygotic co-twins.

Genetic control to environmental exposure (model 3) implies that the heritability of illness can be explained (entirely or to a certain extent) by an indirect path of genetic influence on the probability of exposure to a predisposing environment. If the heritability of the disorder is explained entirely by this mechanism, then the liability of disease does not depend on genotype once environmental exposure is taken into account. If this mechanism operates, then it will be very difficult to distinguish it from a pure genetic model (Eaves *et al.*, 1977).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

A CLOSER LOOK AT GENOTYPE × ENVIRONMENT INTERACTION

The models outlined by Kendler and Eaves (1986) offer a first conceptualization of the joint effects of genotype and environment on psychiatric disease liability or on a (quantitative) psychiatric phenotype. We now take a closer look at G × E interaction. As stated above, G × E interaction can be thought of as the effect of an environmental risk factor depending on the genotype of the individual, or as the expression of the genotype depending on the subject's environment. Measures of either the subject's genotype or of a relevant aspect of their environment are therefore required to assess the significance of G × E interaction (Martin *et al.*, 1987). With respect to measures of the genotype that are possibly relevant to the development of psychiatric disease, no strong empirical findings have yet emerged that unambiguously identify susceptibility loci for psychiatric disorder. This is not for lack of trying. Polymorphisms in large numbers of candidate genes have been tested in genetic association studies. These include polymorphisms in pathways of neurotransmitters, such as serotonin, dopamine, noradrenaline and γ-aminobutyric acid (GABA). Not all variants that have been tested, however, have yet been shown to be functional at the transcription or enzyme activity level (Stoltenberg and Burmeister, 2000). Terwilliger and Weiss (1998) present an overview of the results obtained in association studies of candidate genes and psychiatric disorder published in *American Journal of Medical Genetics (Neuropsychiatric Genetics)* and *Psychiatric Genetics* in 1997. The distribution of the 261 reported significance levels is almost uniform between 0 and 1, which leads Terwilliger and Weiss to conclude: 'even the significant results may not be real, as there are just as many P values that are too large as those that are too significant.' The published P values are consistent with the absence of gene effects in all published analyses. It may be that for some candidate genes that have been studied, the relevant variants have not yet been investigated. For example, for both the serotonin transporter gene (SERT) and the dopamine transporter gene (DAT), it has recently been reported that they contain many more variants than the simple repeat polymorphisms that, until now, were used in genetic association studies (Nakamura *et al.*, 2000; Miller *et al.*, 2001). Another possibility to explain the absence of any strong findings of risk genotypes for psychiatric disorder is population stratification. If in case–control studies investigating candidate genes the effect of stratification is in the opposite direction to the effect of a genuine candidate gene, this will lead to false negative results (Cardon, personal communication). Alternative approaches to model the effects of candidate genes that test the association of particular alleles and disorders both between and within families (Fulker *et al.*, 1999) overcome the problem of stratification but have rarely been applied to the study of psychiatric disorders. One example is the study of Lesch *et al.* (1996). In this study, the association between SERT and neuroticism was shown to be equally strong in a sample of unrelated individuals as in a sample of siblings (brothers) with different genotypes for the short/long polymorphism in the transcriptional control region upstream of the SERT coding sequence. Therefore, the association cannot be explained by mechanisms such as population stratification, because siblings belong to the same stratum.

In the absence of solid findings of candidate genotypes increasing susceptibility for psychiatric disorder, we explore the presence of G × E interaction by looking at the expression of unidentified genetic influences conditional on environmental exposure. The approaches suggested by Eaves (1982) to test for the presence of G × E interaction involving a measured dichotomous environmental variable (e.g. presence or absence of a risk factor) and Falconer (1989), involving a longitudinal study design, will be introduced and illustrated with some empirical examples.

In the approach suggested by Eaves (see also Heath *et al.*, 1989 and Heath *et al.*, 1998), the relative influences of genotype (heritability) and environment on a trait are estimated conditional upon environmental exposure. When there is no G × E interaction, the influence of genetic and environmental factors should not differ between subjects with different degrees of exposure. If genetic effects are modified by exposure, such that heritabilities differ significantly between exposure-positive and exposure-negative groups, then this constitutes evidence for G × E interaction. Thus, this type of interaction is detected by testing whether the amount of variance explained by genetic factors differs between exposure-positive and exposure-negative groups. In addition to G × E interactions as indexed by differences in heritabilities between groups, there may also be differences in the amount of variance explained by environmental factors. This phenomenon is called heteroscedasticity (e.g. Heath *et al.*, 1989).

A true difference in heritabilities between subjects from groups differing in environmental exposure constitutes evidence for G × E interaction, but it does not tell us whether the same or different genes are expressed in the different groups. To address this issue, data from twins discordant for environmental exposure or longitudinal data from twins (or other genetically related subjects), are required. If in a longitudinal design the same subjects can be measured under different environmental conditions, then the extent to which the same genes are expressed in different environments can be assessed. Falconer (1989) (see also Lynch and Walsh, 1998) proposed that the same character measured on the same subjects in two different environments can be treated as two different traits. G × E interaction can then be detected in a bivariate genetic analysis from the genetic correlation between the two traits. If the genetic correlation is high, then trait values in two different environments are very nearly determined by the same set of genes. If the genetic correlation is low, then the trait is influenced by different sets of genes in different environments, and this provides evidence for G × E interaction. A genetic correlation across environments of unity need not imply the absence of G × E interaction, because, as was discussed above, this still leaves open the possibility that the relative importance of genetic factors in explaining individual differences is a function of environmental exposure.

Not all traits can be studied in a longitudinal design. Lynch and Walsh (1998) distinguish between 'labile' and 'nonlabile' traits. Labile traits are those for which phenotypic expression can adjust within individuals, through physiological and/or behavioural means, to changes in the environment, e.g. behavioural traits in the presence of competitors or mates, blood pressure or cortisol in response to stress (Boomsma *et al.*, 1998), and behavioural and emotional problems during development (Van der Valk *et al.*, 2001). Nonlabile traits become fixed during some sensitive period of development (e.g. height, age at first major depression) and thus cannot be studied in a longitudinal design that requires the same subjects to participate under different environmental conditions. Both labile and nonlabile traits can show G × E interaction, but whereas for a labile trait the entire reaction norm can be determined at the individual level by measuring the same individual in a number of environments, for nonlabile traits, different individuals need to be studied in different environments. A particularly informative design for nonlabile traits is one that includes twin pairs who are concordant and discordant for a certain environmental exposure. The extent to which the resemblance (expressed as a correlation between trait values of twin 1 and twin 2) in discordant twins differs from the correlation predicted from the correlations in concordant twin pairs gives an estimate of the extent to which the genetic correlation differs from unity. In the next section, we present a brief introduction to the estimation of genetic and environmental parameters (e.g. heritabilities and correlations) and to formal testing of G × E interaction.

STATISTICAL APPROACH

In analysing G × E interaction, we will use structural equation modelling (SEM) or genetic covariance structure modelling (GCSM) to obtain estimates of parameters and to carry out hypothesis testing. These techniques provide a general and flexible framework for the analysis of data gathered in genetically informative samples. In applying GCSM, genetic and environmental effects are modelled as the contribution of latent (unmeasured) variables to the phenotypic individual differences, or to a liability dimension, which itself is also unobserved (e.g. Martin and Eaves, 1977; Neale and Cardon, 1992). The latent genetic and environmental factors represent the effects of many unidentified influences. In the case of a genetic factor, these effects are due to a possibly large, but unknown, number of genes (polygenes). The latent environmental factors can be distinguished into environmental influences common to family members and environmental influences specific to an individual. The contributions of the latent variables are estimated as regression coefficients in the linear regression of the observed phenotype on the latent variables. Given an appropriate design providing sufficient information to identify these coefficients, actual estimates may be obtained using a number of well-known computer programs, such as LISREL (Joreskog and Sorbom, 1995), or Mx (Neale, 1997).

Identification of genetic models, especially the identification of the effect of shared family environment versus shared genes, can be achieved by several designs, such as adoption or twin designs. We focus on the classical twin design (Martin *et al.*, 1997), which includes monozygotic (MZ) and dizygotic (DZ) twins. MZ twins are genetically identical, while DZ twins (and siblings) share on average 50% of their segregating genes. If MZ twins resemble each other more than DZ twins do, then this is evidence for the importance of genetic influences on the trait under consideration. One advantage of structural equation modelling is that this approach is easily generalized to multivariate and longitudinal data. Twin data are used to decompose the variance for a single trait into a genetic and a non-genetic part. Likewise, bi- and multivariate twin data can be used to decompose the covariance between traits, or between repeated measures of the same trait, into a part due to correlated genetic influences and a part due to correlated environmental influences (Martin and Eaves, 1977; Boomsma and Molenaar, 1986). The flexibility of GCSM is also evident in the relative ease with which measured genotypic (e.g. DNA marker data) or environmental information can be incorporated into the analysis.

In both univariate and multivariate genetic analysis, the identification of genetic and environmental parameters depends on a multigroup analysis in which data from MZ and DZ twins are analysed simultaneously. For a univariate phenotype, the phenotype (P) can be expressed as a function of an individual's genotype (G), the environment common to family members (C), and the environment unique to the individual (E):

$$\mathrm{P}_i = g\mathrm{G}_i + c\mathrm{C}_i + e\mathrm{E}_i$$

where $i = 1, \ldots N$ individuals.

The coefficients g, c and e are population parameters that represent the strength of the relation between the measured phenotype and the latent (unmeasured) factors G, C and E. The latent genetic and common environmental factors are correlated in family members. In MZ twins, the genetic factors are correlated 1, and in DZ twins the correlation is 0.5. The common environmental factors are correlated 1 in both MZ and DZ twins, unless the twins are of opposite sex. For DZ opposite-sex (DOS) twins, the correlation of their common environmental factors may be less than 1 if the family environment exerts a different influence on boys and girls. Likewise, the correlation between genetic factors may be less than 0.5 in DOS twins if different genes are expressed in males and females.

Assuming that all latent variables have been standardized to have unit variance, and that the latent factors are uncorrelated (no gene–environment correlation), then the variance of P may be written as:

$$V(P) = g^2 + c^2 + e^2$$

where $V(P)$ is the variance of the phenotype, and g^2, c^2 and e^2 represent the genetic, common environmental and unique environmental variances. The standardized genetic variance (i.e. g^2 divided by the phenotypic variance $V(P)$) is called the heritability of the phenotype, often symbolized by h^2.

The parameters g, c and e may be estimated by maximum likelihood, implemented in, for example, LISREL or Mx. Their significance can be assessed by likelihood ratio tests. For example, the goodness of fit of a model that constrains the genetic variance to be zero can be compared with a model in which the genetic variance is estimated freely. The difference in goodness-of-fit parameters then provides a test of significance for the genetic effect. In multigroup designs with, for example, MZ and DZ twins who were assessed in a protective or a predisposing environment, equality of parameter estimates across exposure groups can also be assessed by likelihood ratio tests (Neale and Cardon, 1992).

Estimates of the genetic correlation between two traits (or between values of the same trait assessed twice in the same twins under different environmental conditions) can be obtained from the bivariate generalization of this model. The correlation (r_p) between two phenotypes P1 and P2 is given by:

$$r_p = h_1 h_2 r_g + c_1 c_2 r_c + e_1 e_2 r_e$$

where r_g, r_c and r_e are the correlations between genetic, common and unique environmental factors that influence phenotype 1 and phenotype 2 (or the same trait measured in environment 1 and environment 2). These correlations are weighted by the square roots of the standardized heritabilities for trait 1 and 2 (h_1 and h_2, respectively) and the square roots of the standardized environmentalities (Plomin *et al.*, 2001). The significance of these correlations may also be tested by likelihood ratio tests, comparing the likelihood of a more restricted model (e.g. $r_g = 0$) with the likelihood of a less restricted model (in which r_g is estimated).

EMPIRICAL EXAMPLES

Information on personality, anxiety and depression, alcohol initiation and several aspects of religion was collected by mailed survey in 1974 Dutch families consisting of adolescent and young adult twins and their parents (Boomsma *et al.*, 1999; Koopmans *et al.*, 1999). These data were used to explore the influence of religion on personality traits and alcohol initiation. First, the influence of different aspects of religion on average scores for personality characteristics, such as neuroticism, extraversion and sensation seeking, and for depression and anxiety was investigated. Several traits were associated significantly with religion. The association between religion and personality was found to be especially strong for the disinhibition scale of the sensation seeking questionnaire (Zuckerman, 1971; Feij *et al.*, 1997). Therefore, this scale was selected to look at the genetic architecture of disinhibition in male and female twins with and without a religious upbringing. The familial resemblance for different aspects of religion — upbringing, religious affiliation and active participation — was large, and genetic factors did not contribute to this familial resemblance.

We tested whether in addition to an effect on means, there was any evidence for an interaction between genotype and environment (G × E) on disinhibition scores. When there is no interaction, the influence of genetic and environmental factors should not differ

Table XIII.1 Twin correlations for disinhibition and alcohol use as a function of religious upbringing in adolescent and young adult Dutch twins

	Disinhibition					Alcohol use				
	MZM	DZM	MZF	DZF	DOS	MZM	DZM	MZF	DZF	DOS
Religious	0.62	0.62	0.61	0.50	0.38	0.93	0.82	0.87	0.90	0.75
Non-religious	0.62	0.35	0.58	0.35	0.30	0.88	0.61	0.95	0.72	0.75

DZF, dizygotic female; DZM, dizygotic male; MZF, monozygotic female; MZM, monozygotic male
Religious: MZM, 149 pairs; DZM, 124 pairs; MZF, 227 pairs; DZF, 169 pairs; DOS, 259 pairs
Non-religious: MZM, 143 pairs; DZM, 123 pairs; MZF, 188 pairs; DZF, 151 pairs; DOS, 214 pairs

Table XIII.2 Percentage of variance in disinhibition and alcohol use explained by genetic factors (G), common environment (C) and unique environment (E) for males (M) and females (F) as a function of religious upbringing. Parameter estimates with 95% confidence intervals in parentheses

	Disinhibition			Alcohol use		
	G	C	E	G	C	E
F, religious	37 (22–55)	25 (9–37)	38 (32–46)	25 (7–48)	67 (46–82)	7 (3–16)
F, non-religious	61 (7–67)	0 (0–48)	39 (32–51)	40 (5–69)	47 (20–76)	13 (6–26)
M, Religious	0 (0–22)	62 (43–69)	38 (31–45)	0 (0–17)	88 (72–92)	12 (7–19)
M, Non–religious	49 (14–69)	11 (0–40)	40 (32–51)	39 (14–66)	56 (29–78)	5 (2–11)

between twins with and without a religious upbringing. If genetic effects are modified by religious upbringing (differ significantly between the religious and non-religious groups), then this constitutes evidence for G × E interaction. In these analyses, religious upbringing is thus considered to be the shared environment, and disinhibition and alcohol use are the phenotype. Table XIII.1 presents the correlations between twins for disinhibition and for alcohol use conditional on religious upbringing. Both for disinhibition and alcohol use, the MZ and DZ correlations do not differ, or differ very little, from each other in twin pairs from a religious background. In contrast, in the twin pairs who were brought up in a non-religious environment, MZ correlations are larger than DZ correlations, though more so for disinhibition than for alcohol use. Table XIII.2 gives the estimates for heritability and the amounts of variance explained by common environmental factors shared by family members and by unique (or idiosyncratic) environmental factors (Boomsma *et al.*, 1999; Koopmans *et al.*, 1999). In males, the difference in heritabilities between religious and non-religious groups is significant for both variables. In females, the differences between religious and non-religious groups are in the same direction as for males, but they are not statistically significant. In subjects with a religious upbringing, the influence of their genotype on disinhibition and alcohol use is much lower than in subjects from a non-religious background. Indeed, in religious males, the point estimates for heritability are zero. These findings suggest that in subjects raised in a religious home environment, the expression of genetic factors is restricted. The influence of genetic factors is larger in adolescents and young adults who have been brought up without religion.

Further examples suggest that the environmental dichotomy of married/partnered versus having no life partner is a powerful modifying factor on expression of genetic variation for a number of traits in females, including alcohol consumption (Heath *et al.*, 1989) and depression (Heath *et al.*, 1998), although since being married successfully is itself under partial genetic control (Jockin *et al.*, 1996), these may not be straightforward cases of G × E interaction. Our first example did not include any twin pairs who were discordant for religious upbringing (all pairs grew up in the same family), but the study on alcohol consumption in adult Australian twins includes a group of older females discordant for marital status. In comparison to the concordant groups, MZ female twins who are discordant for being married resemble each other less. The correlation for alcohol use in discordant DZ twins is near zero, but a similar low correlation was observed in concordant unmarried DZ females. Due to the small number of pairs in some of the groups, a statistically based discrimination between different models of G × E interaction was not possible, but all analyses pointed to the conclusion that the importance of genetic factors is larger in older, unmarried respondents. The estimate for the genetic correlation between alcohol consumption in the married and in the unmarried state was 0.59, indicating that different genes may be expressed under these two conditions.

POWER

The number of twin pairs needed to detect a statistically significant difference in heritabilities between two groups may be quite large. The number depends on the size of the heritabilities in the two groups, on the significance level, and on the power chosen by the researcher. We investigated through simulation (e.g. Neale and Cardon, 1992) the sample sizes required to detect G × E interaction in the classical MZ/DZ twin design. Some results are presented in Table XIII.3 The standardized heritability of the trait was always 60% in one of the exposure groups, and was smaller in the second group (between 0% and 40%). In the second group, there could be an additional contribution of common environment, accounting for 20–60% of the variance. The left-hand part of Table XIII.3 gives the results for the situation in which there is always contribution of common environment to trait variance (in this case, the MZ correlations in both exposure groups are always 0.6, and only the DZ correlations differ, e.g. when $h^2 = c^2 = 0.3$, the DZ correlation is 0.45). The right-hand part of Table XIII.3 gives the required sample sizes when heritabilities differ between groups, but when there is no contribution of common environment. In this case, both MZ and DZ correlations differ from those in the group where $h^2 = 0.6$. The columns labelled N1 give the required number of twin pairs for a design in which the sample consists of equal numbers of MZ and DZ pairs, and the columns labelled N2 for a design in which the sample consists of 40% MZ and 60% DZ pairs, for power equal to 50, 80 or 90%. The test of significant differences in genetic architecture

Table XIII.3 Number of twin pairs required to detect a significant difference in heritability between two groups differing in exposure to an environmental risk factor (df = 3, $P = 0.05$, power = 50, 80 or 90%) for samples consisting of 50% MZ and DZ 50% (N1) pairs and of 40% MZ and 60% DZ (N2) pairs

Group 1: $h^2 = 0.6$ and $c^2 = 0$				Group 1: $h^2 = 0.6$ and $c^2 = 0$			
Group 2:	Power(%)	N1	N2	Group 2:	Power(%)	N1	N2
$h^2 = 0.4$ and $c^2 = 0.2$	50	3169	2639	$h^2 = 0.4$ and $c^2 = 0.0$	50	451	533
	80	5998	4994		80	854	1009
	90	7796	6491		90	1110	1311
$h^2 = 0.3$ and $c^2 = 0.3$	50	1329	1103	$h^2 = 0.3$ and $c^2 = 0.0$	50	229	269
	80	2507	2087		80	433	509
	90	3258	2713		90	563	661
$h^2 = 0.0$ and $c^2 = 0.6$	50	263	219	$h^2 = 0.0$ and $c^2 = 0.0$	50	76	88
	80	498	414		80	143	166
	90	647	539		90	186	215

between groups had three degrees of freedom (df), allowing for differences in the contributions of genetic, common and unique environmental factors, although it could be argued that a 2 df test is more appropriate (which would require smaller sample sizes), because the type of G × E interaction of interest does not include a difference between groups in the contribution of unique environmental factors.

Table XIII.3 shows that for a power of 80% and for relatively small differences in heritabilities between groups (0.3 or smaller), large samples are needed, especially if there is also a contribution of common environment to familial resemblance. When this is the case, a design with 40% MZ pairs and 60% DZ pairs has more power than a design with equal numbers of MZ and DZ pairs (e.g. when for the second group $h^2 = c^2 = 0.3$, a study with an equal number of MZ and DZ pairs requires 2507 pairs, i.e. more than 5000 individuals, whereas an N2 design requires 2087 pairs).

Fewer twin pairs are needed to detect a significant difference in heritabilities between exposure groups, when genes are the only source of familial resemblance and there is no contribution of common environment. In this case, as shown in the right-hand part of Table XIII.3, a design with an equal distribution of MZ and DZ twins has the highest power.

LEVEL GENES AND VARIABILITY GENES

It is possible that there are genes that have no effect on the mean expression level of a trait but, depending on environmental circumstances, have a greater or lesser variance of expression. It is not difficult to think of molecular mechanisms, e.g. promoters of different binding efficiency, to explain the existence of such variability genes. MZ twins offer a unique opportunity to test for the presence of such genes if a measured genotype is available. Most readers will be familiar with the ABO and Rh blood groups, which are polymorphisms in proteins of the red blood cells determined by genes on chromosomes 9 and 1, respectively. The MN blood group is another such polymorphism in a cell-surface protein, which is coded for by a gene on chromosome 4. Magnus *et al.* (1981) showed that the intrapair variance for cholesterol in MZ pairs who were blood group M− (i.e. blood group N) was significantly greater than in MZ pairs who were M+ (i.e. blood groups M and MN); this was replicated by Martin *et al.* (1983). From this observation, Berg *et al.* (1989) introduced the idea of 'variability genes' as opposed to 'level genes'. Level genes affect the mean expression of a trait, or prevalence in the case of a disease, and are the usual target of association studies. Variability genes do not need to influence trait levels, but they determine the influence of the environment on intra-individual variability. Thus, Birley *et al.* (1997) were able to predict from these results that blood group N subjects would have a greater drop in serum cholesterol levels in response to a low-fat diet than MN heterozygotes, and indeed this was observed. Potentially, variability genes can be even more important than level genes. An allele that increases environmental variance by 50% (the approximate effect size of the N allele on cholesterol variability) will increase the proportion of cases above the second standard deviation by more than two-fold, and those above the third standard deviation by more than five-fold. Unfortunately, however, the power of the variance ratio test to detect heterogeneity of variances is not large (Martin, 2000).

If the genes that contribute to sensitivity to the environment are correlated (distribution or action) with genes affecting the mean expression of a trait, then MZ twins offer an opportunity to detect G × E, without the requirement that they are genotyped (Jinks and Fulker, 1970; Eaves *et al.*, 1977). The difference in trait values between MZ twins is an estimate of the environmental effect, whereas the sum of MZ twins' scores is a function of their (shared) genetic deviation and their family environmental deviation. Assuming that there is some genetic contribution to the trait — as evidenced by a greater MZ than DZ correlation — any relationship between the absolute trait differences of MZ pairs and their corresponding sums is evidence of G × E interaction. Jinks and Fulker (1970) suggested that as a preliminary step to any biometrical genetic analysis of twin data, one should therefore regress the MZ absolute pair differences on their pair sums to check for G × E interaction. In practice, this form of G × E is often predictable as a function of the non-normality of the scale distribution and can be removed by an appropriate transformation of the scale of measurement. Thus, positive skewness (tail to the right) produces positive correlations between MZ differences and sums, and negative skewness produces a negative correlation. The often observed 'basement–ceiling' effect in psychometric scales, where there is good discrimination of differences in the middle of the range but a bunching at the low and high extremities, produces an inverse U-shaped quadratic relationship of means and intrapair differences.

DISCUSSION

'No aspect of human behavior genetics has caused more confusion and generated more obscurantism than the analysis and interpretation of the various types of non-additivity and non-independence of gene and environmental action and interaction . . .' (Eaves *et al.*, 1977). This statement is as true today as when it was written. Often, the term 'G × E interaction' is used simply to denote that both

genes and environment are important. A better term to describe this situation is 'genotype–environment coaction' (Martin, 2000). We should reserve the term 'G × E interaction' for its statistical sense of different genotypes responding differently to the same environment, or, viewed from the other end, some genotypes being more sensitive to changes in the environment than others (different reaction ranges). From the extensive literature on crops and domesticated animals, the overwhelming message regarding G × E interaction is that it is extremely common (Lynch and Walsh, 1998), although it may explain only a relatively small proportion of the total trait variance. There are, however, still few data on its significance in natural populations. In a review of gene-mapping strategies, Tanksley (1993) discusses some of the first empirical results for Environment by quantitative trait loci (QTL; genes that influence quantitative traits) interactions in plants. QTLs affecting quantitative traits in maize and tomato in one environment (e.g. the USA) are often active in other environments (e.g. the Middle East) as well. QTLs showing the largest effects in one environment seemed more likely to also be detected in other environments, suggesting little environment by QTL interaction. QTLs with minor effects seemed more likely to show interactions with the environment. If similar results would apply to QTLs influencing personality traits and psychiatric disorders in humans, then this might conceivably explain the sometimes inconsistent results observed in candidate gene studies, in which genes of minor effect are tested. Examples of candidate genes that fail to show consistent replication across different populations include the dopamine receptor DRD4 (Plomin and Caspi, 1998), the SERT polymorphism in the serotonin transporter promotor region (Ebstein *et al.*, 2000), and the NOTCH4 gene in schizophrenia (McGinnis *et al.*, 2001; Sklar *et al.*, 2001). These are all examples of QTLs that, when found to be associated significantly with personality or psychiatric disorder, explain only a small proportion of the variance and can be considered minor QTLs.

We have shown how the analysis of G × E interaction can be conducted in the classical MZ/DZ twin design, using measures of environmental exposure or direct measures of the genotype. If measures of either environment or genotype are not available, i.e. in the majority of the quantitative genetic studies of metric human phenotypes, then the detection of G × E interaction is more difficult. One test for G × E interaction is the test suggested by Jinks and Fulker (1970) discussed above, involving examination of the association between the means and differences of MZ twin pairs. Another approach to test for genotype–environment interaction when measures of the environment or the genotype are not available is based on the analysis of the higher-order moments of genetic and environmental factor scores. Molenaar and Boomsma (1987) and Molenaar *et al.* (1990, 1999) have shown that the effects of certain types of interaction cannot be detected at the level of second-order moments (i.e. variances and covariances), but that they do lead to specific values of the third- and fourth-order moments (i.e. skewness and kurtosis) of genetic and environmental factor scores. These methods do not require measurements of the environment or the genotype, but require multiple indicators of the phenotype for the calculation of factor scores (Boomsma *et al.*, 1990) and the estimation of the higher-order moments of these factor scores. This approach to the detection of interaction factors hinges on the estimation of fourth-order moments. Unfortunately, the sampling variability of these estimates is very high, therefore large samples of phenotypic values are needed in order to secure the reliability of the detection tests. In simulation studies (where it is certain that the generated phenotypic values constitute a homogeneous sample), it was found that estimates of fourth-order moments depend strongly on the extreme phenotypic values in a sample, and that removal of these extreme observations (which are often interpreted as outliers in empirical studies) could lead to severe bias.

When G × E is present, but not modelled explicitly (e.g. because no measures of environmental exposure or genetic sensitivity are available), the interaction terms will be confounded with other terms in the model. For example, an interaction of genotype with unique environmental factors will be confounded with the unique environmental influences and cannot be separated from it in an analysis of second-degree statistics (Eaves *et al.*, 1977). Likewise, an interaction between genes and common environmental factors will be confounded with genetic effects. This might explain why it is so rare to observe a main effect of common environment shared by family members on psychiatric disorders (or many other traits). If the effects of parental rearing style and the shared family environment depend on the genetic constitution of an individual, then these will show up in most analyses as pure genetic effects.

The phenomenon of G × E interaction was introduced in this chapter in a statistical manner. Kandel (1998) outlines some of the biological phenomena underlying gene structure and function that may explain genetic sensitivity to the environment. Genes have dual functions: their template function guarantees reliable replication, and their transcriptional function regulates gene expression in the cell. Although almost all cells of the body contain all genes, in any given cell only a small proportion of genes is expressed. The expression of genetic information takes place when RNA is synthesized from DNA. RNA specifies the synthesis of polypeptides, which form proteins. The manufacture of specific proteins by a subset of genes in any given cell is thus highly regulated, and this regulation of gene expression is responsive to environmental factors. Learning, social interaction, stress and hormones (Strachan and Read, 1999) can alter the binding of transcriptional regulators to enhancer elements of genes, which, together with the promoter, usually lie upstream of a gene's coding region. After transcriptional regulators have bound to the promotor region, RNA synthesis is initiated. As demonstrated by studies of learning in simple animals, environmental triggers and experience can produce sustained changes in neural connections by altering gene expression. Certain environments may produce alterations in gene expression that produce structural changes in the brain, which may underlie psychiatric disorder. It remains an intriguing question as to what causes some individuals to experience more of such environmental triggers than others. As already pointed out by Kendler and Eaves (1986), exposure to certain environments may itself be under genetic control.

In conclusion, one might observe that G × E interaction has been the topic of much loose speculation over the years, with extravagant claims made for its potential importance, and precious few well-documented examples, at least in the human domain. Those presented above are some of the few we know of. One of the most exciting prospects now that we have the human genome sequence, and are on the brink of identifying QTLs for many complex traits, is that we shall at last be able to see just how widespread and important a phenomenon it really is.

Gender Issues in Brain Structures and Functions and Their Relevance for Psychopathology

D.F. Swaab

SEX DIFFERENCES IN THE PREVALENCE OF NEUROLOGICAL AND PSYCHIATRIC DISEASES

Sex differences in brain and hormone levels are not only of importance for sexual behaviour, but are also thought to be the structural and functional basis of the often pronounced sex differences in the prevalence of neurological and psychiatric diseases. The proportions of cases range from more than 75% women in Rett syndrome, lymphocytic hypophysitis, anorexia and bulimia nervosa, and hypnic headache syndrome to more than 75% men in dyslexia, attention deficit hyperactivity disorder (ADHD), autism, sleep apnoea, Gilles de la Tourette syndrome, rabies, Kallmann syndrome and Kleine–Levin syndrome (Table XIV.1). Women are more prone to anxiety disorders than men (Seeman, 1997). Not only might the number of cases of disorders show clear sex differences, but the signs and symptoms and the course of the disease might also differ. Male schizophrenic patients have more severe enlargement of the lateral ventricles (Nopoulos *et al.*, 1997). Men suffer from schizophrenia 2.7 times more often than women; they are also prone to a more severe form of this disorder, have a poorer premorbid functioning experience, have an earlier onset, experience more negative symptoms and cognitive defects, and exhibit a greater number of structural brain abnormalities. Relapses are more severe, and their response to neuroleptic medication is less favourable. Women, by contrast, display more affective symptoms, auditory hallucinations and persecutory delusions (Castle and Murray, 1991; Leung and Chue, 2000). Moreover, an interaction with gender was observed in the second trimester of pregnancy when prenatal exposure to maternal stress was studied as a risk factor for schizophrenia (Van Os and Selten, 1998). There may also be a strong effect of age on sex differences in the prevalence of disorders: in depression up to the age of 54, the women : men ratio is 61 : 39, while after the age of 54, the ratio reverses to 35 : 65 (Bebbington *et al.*, 1998). Other examples of sex differences in neurological disease are those following restricted left-hemisphere lesions: 41% of men and 11% of women developed aphasia, whereas manual apraxia was found in 6% of the women and 42% of the men (Kimura and Harshman, 1984). The prevalence of cluster headache in men, and the fact that it is extremely rare before adolescence, indicates that sex hormones circulating in adulthood might be involved in the pathogenetic mechanism (Leone and Bussone, 1993). Changes over the years have also been reported. The men : women ratio of cluster headache decreases from 6.2 : 1 for patients with an onset before 1960 to 2.1 : 1 for patients with an onset in the 1990s. Changes in lifestyle, in particular in employment rate and smoking habits of women, are held responsible for this change (Manzoni, 1998). On the other hand, men still commit 89% of all murders and 99% of all sexual crimes (Spratt, 2000).

There is an excess of men with mental retardation (Turner, 1996). However, middle-aged women with Down's syndrome have an earlier onset of dementia than their male counterparts, and a more severe form of Alzheimer's disease, which correlates with the number of neocortical neurofibrillary tangles rather than density of senile plaques (Raghaven *et al.*, 1994). Age-related sex differences are now reported throughout the brain. Women run a higher risk of developing dementia after the age of 80 than men (Letenneur *et al.*, 1999; Launer *et al.*, 1999; Seeman, 1997). Very pronounced neurofibrillary Alzheimer changes are found in the infundibular nucleus and adjacent median eminence in 80% of the men over 60 years of age and in only 6% of the women (Schultz *et al.*, 1996). With advancing age, there is a loss of neurons in the pars cerebellaris loci coeruli that begins in women around age 40 and in men already at age 20 (Wree *et al.*, 1980).

Whether sex differences in the brain that arise in development ('organizing effects') are indeed the basis for the sex difference in neurological or psychiatric diseases still has to be established. In ADHD, an association with androgen receptor haplotypes was found (Comings *et al.*, 1999). Alternative mechanisms that are mentioned are the immediate effects of differences in circulating sex hormone levels ('activating effects'), caused by sex-hormone-stimulated gene transcription (Torpy *et al.*, 1997), as presumed in, for example, sleep apnoea (see Table XIV.1). A number of the diseases listed in Table XIV.1 are related to changes in catecholaminergic neurons, which are influenced during development by direct somatic effects of sex-specific genes (Pilgrim and Reisert, 1992). In a recent Dutch study, a higher prevalence of various psychiatric disorders was found in homosexual people compared with heterosexual people. These differences seem to be gender specific, with a higher prevalence of substance-use disorders in homosexual women and a higher prevalence of mood and anxiety disorders in homosexual men, both as compared with their heterosexual counterparts. It is not clear at present whether these differences result from biological or social factors (Sandfort *et al.*, 2001), but it does mean that sexual orientation should be included as a possible factor in the study of prevalence in psychiatric and neurological diseases.

SEX DIFFERENCES IN HYPOTHALAMIC STRUCTURES

The Hypothalamus as our Sexiest Part

There is an increasing amount of data concerning morphological and functional sex differences, especially in the various nuclei of the hypothalamus, which we will focus on in this review (Figures XIV.1 and XIV.2). The hypothalamus contains a number of structurally sexually dimorphic structures (Figure XIV.3), such

as the sexually dimorphic nucleus of the preoptic area (SDN-POA), which was first described in the rat brain by Gorski *et al.* (1978). Due to differences in perinatal steroid levels, the SDN-POA in the male rat is three to eight times larger than in the female rat (Jacobson *et al.*, 1980). The SDN-POA is located between the dorsolateral supraoptic nucleus (SON) and the mediorostral pole of the paraventricular nucleus (PVN), at the same rostro-caudal level as the suprachiasmatic nucleus. Morphometric analysis revealed that there is a striking sexual dimorphism in the size and cell number in the SDN-POA (Swaab and Hofman, 1984; Swaab and Fliers, 1985; Hofman and Swaab, 1989). Sexual differentiation of the human SDN-POA occurs 4 years postnatally, and only after this age does the nucleus differentiate according to sex (see below). This is due to a decrease in both volume and cell number in women, whereas in men volume and cell number remain unaltered up to the fifth decade, after which a marked decrease in cell number is also observed (see below). Sexual differentiation has also been reported for two other cell groups in the preoptic anterior hypothalamus (INAH2 and 3) (Allen *et al.*, 1989b). These areas (Figure XIV.1) were found to be larger in men than in women, and this was later partly confirmed by LeVay (1991) and Byne *et al.* (2000). Other brain regions with a larger volume in men than in women are the darkly staining posteromedial part of the bed nucleus of the stria terminalis (BST-DSPM), described by Allen *et al.* (1989a), and the central nucleus of the BST (Zhou *et al.*, 1995c). The sex difference in the number of vasoactive intestinal polypeptide (VIP) expressing neurons in the suprachiasmatic nucleus (SCN) is age dependent (Zhou *et al.*, 1995b). The infundibular nucleus shows sex-dependent Alzheimer changes (Schultz *et al.*, 1996), and the size of the anterior commissure is sexually dimorphic (Allen and Gorski, 1991). 5-Hydroxyindoleacetic acid (5-HIAA) levels in the hypothalamus of men were lower than those in women, indicating a higher turnover rate of 5-hydroxytryptamine (5-HT) in the female brain (Gottfries *et al.*, 1974). In addition, we found clear age-dependent sex differences in the activity of the vasopressinergic neurons of the supraoptic nucleus (Ishunina *et al.*, 2000a).

The Sexually Dimorphic Nucleus of the Preoptic Area

There are indications that the SDN-POA area is involved in sexual behaviour. Electrical stimulation of the median preoptic area in the rat induces highly exaggerated stimulation-bound sexual behaviour (Merari and Ginton, 1975). Following lesions of the medial preoptic area, mounting, intromission and ejaculation are eliminated, but the animals do not lose the ability to achieve an erection. Although the median preoptic area does not seem to organize copulatory behaviour, it is crucial for the recognition of sensory stimuli as appropriate sexual targets, and for the integration of this recognition with sexual motivation and copulatory motor programmes. The PVN receives extensive input from the medial preoptic area. The parvocellular oxytocinergic neurons of the PVN project to the spinal cord and synapse on neurons that innervate the penis (McKenna, 1998). However, the exact role of the SDN-POA in these functions of the preoptic area is unclear. Electrophysiological experiments in the rat that showed increased multiple unit activity in the preoptic area during mounting, both in intact males and females (Kartha and Ramakrishna, 1996), do not clarify the exact contribution of the SDN-POA to these activity changes. Also, lesion experiments in rats have indicated that the SDN-POA may be involved in aspects of male sexual behaviour, i.e. mounting, intromission and ejaculation (Turkenburg *et al.*, 1988; De Jonge *et al.*, 1989). However, since the effects of lesions on sexual behaviour were only slight, it might well be that the major functions of the SDN-POA are still unknown at present. Penile erection following medial preoptic area

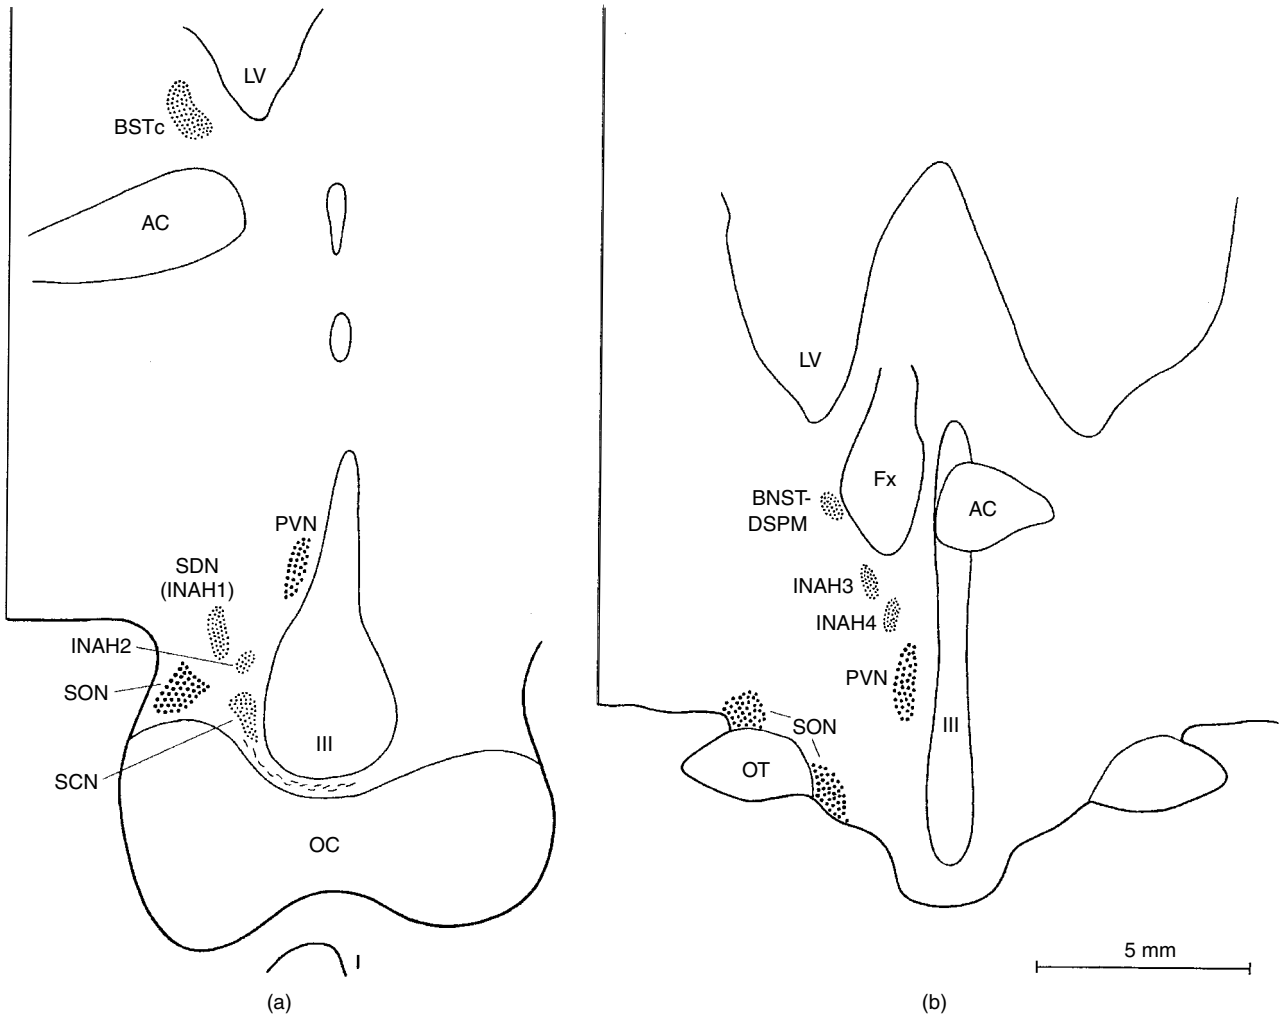

Figure XIV.1 Topography of the sexually dimorphic structures in the human hypothalamus. (a) is a more rostral view than (b). The AC, BSTc, BNST-DSPM, INAH2, 3 and 4, SCN and SDN vary according to sex. stimulation in the monkey and the rat, as reported by Giuliano *et al.* (1996), is considered to be one of such putative functions by some authors, but following lesions of the medial preoptic area, rats do not lose the ability to achieve an erection (McKenna, 1998). On the basis of animal experiments, the SDN-POA area is also presumed to be involved in sexual orientation. Lesions of the area of the SDN-POA in the ferret caused a significant shift in the males' preference from oestrous females to stud males, i.e. from a male-typical pattern of sexual behaviour to a more female-typical pattern (Kindon *et al.*, 1996; Paredes and Baum, 1995). Intact female rats show a preference for interaction with males and a tendency for males to interact with females. After lesion of the medial preoptic area of the anterior hypothalamus (mPOA), the females' preference was not modified. However, mPOA-lesioned male rats changed their partner preference after the lesion, and the coital behaviour of these males was reduced significantly after the lesion (Paredes *et al.*, 1998). Although in our studies of the human SDN-POA we did not find differences in size or cell numbers of this nucleus in relation to sexual orientation (Swaab and Hofman, 1990), this does not exclude a functional involvement of this structure in sexual orientation.

Nomenclature and Homology to the Rat Sexually Dimorphic Nucleus of the Preoptic Area

The SDN-POA in the young adult human brain is twice as large in men ($0.20\,mm^3$) than in women ($0.10\,mm^3$) on one side and contains twice as many cells (Swaab and Fliers, 1985; Figures XIV.3 and XIV.4). The original observations on 13 men and 18 women were extended and confirmed in a subsequent study of 42 men and 38 women (Swaab and Hofman, 1988) and in another independent study (Braak and Braak, 1992). The SDN-POA is also present in rhesus monkey (Braak and Braak, 1992). However, the fact that Byne (1998), who called this nucleus 'the lateroanterior nucleus of the rhesus monkey' did not find a sex difference in its volume makes this comparison complex. Daniel and Prichard (1975) used the term 'preoptic nucleus' for the human SDN-POA, but this name has not been used in the literature since. The SDN-POA is also identical to the 'intermediate nucleus' described by Brockhaus (1942) and Braak and Braak (1987), and to the 'interstitial nucleus of the anterior hypothalamus-1 (INAH1)' of Allen *et al.* (1989b). The term 'intermediate nucleus'

is, however, controversial, since Feremutsch (1948) called the scattered vasopressin or oxytocin cells and islands between the SON and PVN the 'intermediate nucleus', and Morton (1961) used this name, by mistake, for the clusters of accessory SON cells, but now referring to the 1942 Brockhaus paper. Judging by the sex differences in the human SDN-POA in size and cell number, rostro-caudal position, cytoarchitecture, peptide and γ-aminobutyric acid (GABA) content (see below), this nucleus is probably homologous to the SDN-POA in the rat of Gorski *et al.* (1978), despite the fact that the rat SDN-POA is located in a more medial position than its human counterpart.

The SDN-POA contains galanin (Gai *et al.*, 1990), named after its N-terminal residual glycine and its C-terminal alanine (Tatemoto *et al.*, 1983), galanin mRNA (Bonnefond *et al.*, 1990), thyrotropin-releasing hormone (TRH) neurons (Fliers *et al.*, 1994), and glutamic acid decarboxylase (GAD) 65 and 67 (Gao and Moore, 1996a; Gao and Moore, 1996b). This supports the possible homology with the SDN in the rat, in which these peptide- and GABA-containing neurons have also been described (Bloch *et al.*, 1993; Gao and Moore, 1996a; Gao and Moore, 1996b). In addition, some scattered substance P neurons are present in the human SDN-POA (Chawla *et al.*, 1997), and moderate substance P cell numbers were found in this area in rat (Simerley *et al.*, 1986). Although we believe that all the data favour the homology between the human and the rat SDN-POA, it should be noted that others have claimed, on the basis of the presence of a sex difference, a possible homology between the rat SDN-POA and the human INAH3 (Allen *et al.*, 1989b; LeVay, 1991; Byne *et al.*, 2000). However, this claim

did not take into account a homology in neuropeptide and GABA content of those nuclei. In men, we recently found a more intense staining than in women for the androgen receptor and for the oestrogen receptor (alpha) in the SDN-POA, further supporting the presence of a sex difference in this nucleus (Fernández-Guasti *et al.*, 2000; Kruijver *et al.*, 2001). Concerning the presence of oestrogen receptors in the SDN-POA, it is relevant to note that an oestrogen response element has been found within the human galanin gene (Howard *et al.*, 1997). It should also be noted that microinjection of galanin into the medial preoptic nucleus facilitates female-typical and male-typical sexual behaviours in the female rat (Bloch *et al.*, 1996).

Development, Sexual Differentiation, Ageing and Alzheimer's Disease

Sexual dimorphism does not seem to be present in the human SDN-POA at the time of birth. At that moment, total cell numbers are still similar in boys and girls, and the SDN-POA contains no more than some 20% of the total cell number found between 2 and 4 years of age. From birth up to this age, cell numbers increase equally rapidly in both sexes (Figure XIV.5). A sex difference in the SDN-POA does not occur until about the fourth year postnatally, when cell numbers start to decrease in girls, whereas in boys the cell numbers in the SDN-POA remain stable until their rapid decrease at approximately 50 years of age. In women, a second phase of marked cell loss sets in after the age of 70 (Figure XIV.4; Swaab and Hofman, 1988; Hofman and Swaab, 1989). The sharp decrease in cell numbers in the SDN-POA later in life might be related to the dramatic hormonal changes that accompany both male and female senescence (Hofman and Swaab, 1989), and to the decrease in male sexual activity around 50 (Vermeulen, 1990). However, it is not clear whether the hormonal changes are related directly to these changes in various functions, either as cause or as effect of the observed cell loss in this nucleus.

The sex difference in the pattern of ageing, and the fact that sexual differentiation in the human SDN-POA only occurs after the fourth year of age (Swaab and Hofman, 1988; Figure XIV.5) might explain why Allen *et al.* (1989b), who had a sample of human adults biased for aged individuals, did not find a significant sex difference in the size of the SDN-POA, which they called INAH1 (Swaab *et al.*, 1992). The age distribution, however, does not explain why LeVay (1991) and Byne *et al.* (2000) could not find a sex difference in the volume of INAH1. Although the numbers of subjects they studied were much smaller than those in our study (Swaab and Hofman, 1988), technical differences such as section thickness may be a possible explanation for the controversy. The finding that nuclear androgen (Figure XIV.6) and oestrogen receptor α staining in the SDN-POA was more intense in men than in women (Fernández-Guasti *et al.*, 2000; Kruijver *et al.*, 2002, submitted) supports the presence of a sex difference in this nucleus.

A prominent theory is that sexual orientation develops as a result of interaction between the developing brain and sex hormones (Dörner, 1988; Gladue *et al.*, 1984). According to Dörner's hypothesis, homosexual men would have a female differentiation of the hypothalamus. Although LeVay's (1991) data on the small female-sized INAH3 in homosexual men are in agreement with this theory, this idea was not supported by our data on the SDN-POA in homosexual men. Neither the SDN-POA volume nor the cell number of homosexual men (Figure XIV.7) who died of AIDS differed from those of the male reference groups in the same age range, nor from those of heterosexuals also suffering from AIDS (Swaab and Hofman, 1988; Swaab and Hofman, 1990). The fact that no difference in SDN-POA cell number was observed between homosexual and heterosexual men, and the large SCN found in homosexual men (Swaab and Hofman, 1990), refutes the general formulation of Dörner's hypothesis that homosexual men would have 'a female hypothalamus' and favours the idea that homosexual men are a 'third sex', i.e. different from heterosexual men and women.

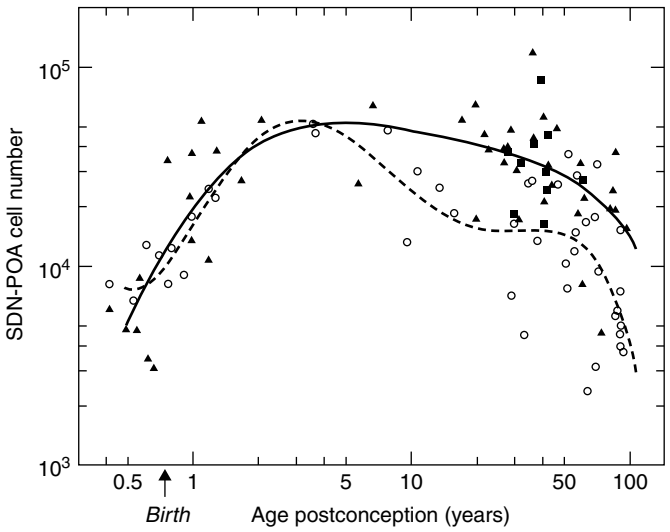

Figure XIV.5 Developmental and sexual differentiation of the human SDN-POA in 99 subjects; (log–log scale). Note that at the moment of birth, the SDN-POA is equally small in boys (▲) and girls (○) and contains about 20% of the cell numbers found at 2–4 years of age. Cell numbers reach a peak value around 2–4 years postnatally, after which a sexual differentiation occurs in the SDN : there is to a decrease in cell number in the SDN of women, whereas the cell number in men remains approximately unchanged up to the age of 50. The SDN-POA cell number in homosexual men (■) does not differ from that in the male reference group. The curves are quintic polynomial functions fitted to the original data for men (full line) and women (dashed line). Adapted, with permission from Swaab, D.F. and Hofman, M.A., 1988. *Dev Brain Res* 44, 314–318

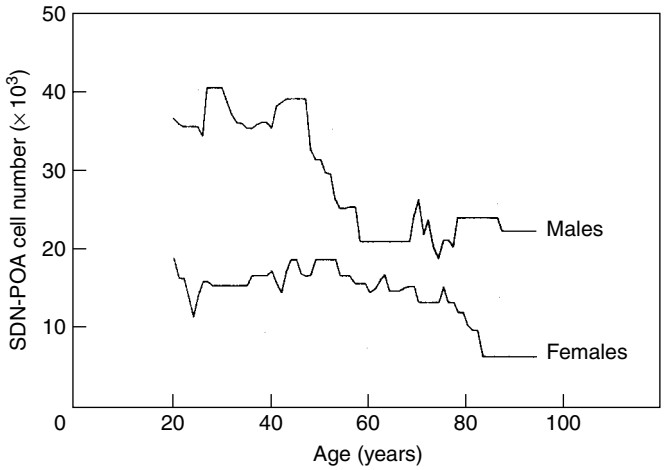

Figure XIV.4 Age-related changes in the total cell number of the SDN-POA in the human hypothalamus. The general trend in the data is enhanced by using smoothed growth curves. Note that in men, the SDN cell number declines steeply between the ages of 50 and 70 years, whereas in women, a more gradual cell loss is observed around the age of 80 years. These curves demonstrate that the reduction in cell number in the human SDN in the course of ageing is a nonlinear, sex-dependent process. Figure XIV.7 (a) Volume of the human SCN and SDN as measured in three groups of adult subjects: (1) male reference group ($n = 18$); (2) male homosexuals who died of AIDS ($n = 10$); and (3) heterosexuals who died of AIDS ($n = 6$; 4 men, 2 women). The values indicate medians and the standard deviation of the median. The differences in the volume of the SCN between homosexuals and the subjects from both other groups are statistically significant (Kruskal–Wallis multiple comparison test, $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$). Note that none of the parameters measured in the SDN (a,b) showed significant differences among the three groups (P always > 0.4). (b) Total number of cells in the human SCN and SDN. The SCN in homosexual men contains 2.1 times as many cells as the SCN in the reference group of male subjects, and 2.4 times as many cells as the SCN in heterosexual AIDS patients. (c) The number of vasopressin neurons in the human SCN (the SDN does not contain vasopressin-producing cells). The SCN in homosexual men contains, on average, 1.9 times as many vasopressin neurons as the SCN in heterosexual AIDS patients. Notice that the SCN of heterosexual individuals who died of AIDS contains fewer vasopressin cells than the SCN of the subjects from the reference group. The Suprachiasmatic Nucleus in Relation to Sex and Sexual Orientation

Sex Differences in Sleep

The sex differences in the shape of the vasopressinergic SCN and in the numbers of VIP-expressing cells (Swaab *et al.*, 1985; Swaab *et al.*, 1994; Zhou *et al.*, 1995b) suggest the possibility of sex differences in circadian patterns. Moreover, in the human SCN, nuclear androgen receptor staining was more apparent in men than in women (Fernández-Guasti *et al.*, 2000), which may be one of the mechanisms causing functional sex differences in this nucleus. Indeed, sex differences have been reported in sleep patterns that may be related to SCN sex differences. Women have

higher percentages of slow-wave sleep and lower percentages of stage 1 sleep than men (Van Hilten *et al.*, 1994). Women have about twice as many sleep spindles as men, and they tend to spend more time sleeping than men in a free-running environment. In addition, middle-aged women display more slow-wave sleep than middle-aged men. The period of free-running circadian rhythm is shorter and the fraction of sleep significantly larger in women than in men (Wever, 1984). In addition, testosterone has relatively specific and discrete effects on sleep and hormonal rhythms in men (Leibenluft *et al.*, 1997). In healthy elderly women and men, differences in entrained circadian temperature rhythms and sleep patterns exist that indicate that ageing may affect the circadian timing system in a sexually dimorphic way (Campbell *et al.*, 1989; Moe *et al.*, 1991). Animal experiments indicate that only part of the sex differences in paradoxical sleep are dependent on circulating hormones (Fang and Fishbein, 1996).

In the rat SCN, there is a sex-specific circadian pattern in VIP mRNA but not in vasopressin mRNA (Krajnak *et al.*, 1998).

The Suprachiasmatic Nucleus, Sexual Behaviour and Reproduction

In addition to its possible involvement in reproduction (see below), the SCN might also play a role in sexual orientation. In fact, the first difference in the human brain in relation to sexual orientation was observed in the SCN. Morphometric analysis of the SCN of ten homosexual men revealed that the volume of this nucleus was 1.7 times larger than that of a reference group of 18 presumed heterosexual men, and that it contained 2.1 times as many cells (Figure XIV.7; Swaab and Hofman, 1990). The same high number of SCN vasopressin neurons as observed in 1–2-year-old children (Swaab *et al.*, 1990) were also found in homosexual men. It seems as if the programmed postnatal cell death, which appears to begin in the SCN between 13 and 16 months after birth, does not occur to the same extent in homosexual men. The increased number of vasopressin-expressing neurons in the SCN of homosexual men appeared to be quite specific for this subgroup of neurons, since the number of VIP-expressing neurons was not changed. However, in both the vasopressin, and the VIP neurons in the SCN, a reduced nuclear diameter was observed in homosexual men, suggesting metabolic alterations in the SCN in relation to sexual orientation (Zhou *et al.*, 1995a).

There are a number of experimental data and observations on human material that indicate that the SCN is involved in aspects of sexual behaviour and reproduction. In the early 1970s, postcoital ultrastructural changes indicating neuronal activation were reported in the SCN of the female rabbit (Clattenburg *et al.*, 1972). Also important is the fact that the activity of SCN neurons increases suddenly around puberty (Anderson, 1981), indicating the addition of a reproductive function to the already mature circadian functions of the SCN. In addition, efferents of the SCN innervate the preoptic area that is involved in reproductive behaviours. Extensive lesioning of the SCN area results in failure of ovulation in the female rat (Brown-Grant and Raisman, 1977). The ovarian reproductive cycle is controlled by the SCN, probably through a direct monosynaptic innervation of luteinizing hormone-releasing hormone (LHRH) neurons by VIP fibres (Van der Beek *et al.*, 1993; Van der Beek *et al.*, 1997). Several morphological sex differences have been reported that support putative reproductive functions. The SCN of male rats contains a larger amount of axospinal synapses, postsynaptic density material and asymmetrical synapses, and their neurons contain more nucleoli than those of female rats (Güldner, 1982; Güldner, 1983). The sex differences in synaptic numbers in the rat SCN depend on androgens in development (le Blond *et al.*, 1982). In gerbils, the volume of the SCN is sexually dimorphic (Holman and Hutchison, 1991), as is the organization of astroglia in the SCN (Collado *et al.*, 1995).

A sex difference was found in the shape of the vasopressin subdivision of the human SCN (Swaab *et al.*, 1985), and a sex difference was observed in the number of VIP-containing neurons in the human SCN. The number of VIP-expressing neurons in the SCN is larger in men aged 10–40 years and women aged 41–65 years (Swaab *et al.*, 1994b; Zhou *et al.*, 1995b). These observations are also consistent with sexually dimorphic functions of the SCN that are still awaiting better definition. It is interesting to note that the pineal hormone 5-methoxytryptophol shows significant sex differences: plasma concentrations increase in boys and decrease in girls after the age of 8 years (Molin-Carballo *et al.*, 1996).

In seasonal breeders, VIP immunoreactivity in the SCN changes in relation to seasonal fluctuations in sexual activity (Lakhdar-Ghazal *et al.*, 1992). The activation of c-fos in the SCN by sexual stimulation also points to a role of the SCN in reproduction (Pfaus *et al.*, 1993). Bakker *et al.* (1993) have found that male rats treated neonatally with the aromatase inhibitor 1,4,6-androstratriene-3,17-dione (ATD) showed a clear sexual partner preference for females when tested in the late dark phase. When tested in the early dark phase, however, they showed a lesser preference for the female, or no preference at all. This is the first indication of the involvement of the clock, i.e. the SCN, in sexual orientation. The number of vasopressin-expressing neurons in the SCNs of these ATD-treated bisexual animals was increased (Swaab *et al.*, 1995), something that was also found in homosexual men (Swaab and Hofman, 1990). This observation supports the possibility that the increased number of vasopressin-expressing neurons in the SCN of adult homosexual men reflects a difference in the early stages of development in the brain.

Other Sexually Dimorphic Hypothalamic Structures

Interstitial Nuclei of the Anterior Hypothalamus-1 and -2

In addition to the sex differences observed in the SCN, the SDN-POA and the BST, Allen *et al.* (1989b) described two other cell groups, the INAH2 and INAH3), that were larger in the male brain than in the female brain (Figure XIV.1). Moreover, LeVay (1991) found that INAH3 was twice as large in heterosexual men as in homosexual men. INAH2 in the human hypothalamus is said to correspond to the anterocentral nucleus and INAH3 to the dorsocentral portion of the anterior hypothalamic nucleus in the rhesus monkey (Byne, 1998). Since nothing is known about their neurotransmitter content, it is unclear which nuclei in the rat or rhesus monkey are homologous to the human INAH2 and INAH3. Recently, we found galanin-containing cells and fibres not only in INAH1 (SDN-POA) but also in INAH2; the question was raised whether INAH1 and INAH2 are indeed two separate nuclei or whether they are both part of a continuous horseshoe-shaped structure. As no chemical marker is known for INAH3, it is not yet clear whether this nucleus has to be considered as a perifornical cell group, islands of the PVN or the BST, or a separate anatomical entity. There is a discrepancy in the literature concerning the sex difference in the size of INAH2 as described by Allen *et al.* (1989b) that could not be confirmed by LeVay (1991) or Byne *et al.* (2000). The fact that LeVay did not observe a smaller INAH2 in women was proposed to be explained by an age-related sex difference in this nucleus. INAH2 shows this sex difference only after the childbearing age, with one exception: a 44-year-old woman who had a hysterectomy with ovarian removal 3 years before her death and who had a small INAH2 (Allen *et al.*, 1989b). The sex difference in INAH2 thus seems to come to expression only after menopause, when circulating oestrogens are absent. This would also explain why LeVay could not confirm the difference in INAH2 in his group of young patients. The sex difference in INAH2 was considered to be the first human example of a sex difference

depending on circulating levels of sex hormones, i.e. a difference based on a lack of activating effects of sex hormones in menopause rather than on organizing effects of sex hormones in development. However, Byne *et al.* (2000) could not confirm the relationship between INAH2 and reproductive status as suggested by the data of Allen *et al.* (1989b). A second example of a functional sex difference can be found in the supraoptic nucleus and PVN (see later). INAH4 is not sexually dimorphic (Allen *et al.*, 1989b).

The Anterior Commissure, Interthalamic Adhesion and Third Ventricle

The anterior commissure appears as early as gestational day 47 (Hori, 1997) and contains about seven million fibres. It connects anteriorly two-thirds of the right and left temporal neocortices and the posterior part of the orbital aspect of the frontal lobes (Demeter *et al.*, 1988). The anterior commissure was investigated in humans with circumscribed hemispheric lesions. The largest contingent of commissural axons appeared, from this study, to originate in the inferior part of the temporal lobe. In addition, axons originating from the inferior part of the occipital lobe, occipital convexity, central fissure and prefrontal convexity were found to cross the anterior commissure (Di Virgilio *et al.*, 1999). There is also a small olfactory part rostrally (Sylvester, 1986).

The anterior commissure was found to be 12% larger in women than in men (Allen and Gorski, 1991). In an earlier study, only a trend towards such a sex difference was noted (Demeter *et al.*, 1988). However, Higley *et al.* (1999) found a greater number of fibres in women than in men. A sex difference in the size of the commissure was also observed in people with Down's syndrome (Sylvester, 1986). These observations point to a greater connectivity between the cerebral hemispheres of women. Allen and Gorski (1992) found that the anterior commissure was larger in homosexual men than in heterosexual men. Sexual dimorphism in the anterior commissure is presumed to underlie sex differences in cognitive skills, developmental language disorders, and functional asymmetries. The anterior commissure mediates interhemispheric transfer of visual information, including the visual recall of dreams, auditory and olfactory information (Allen and Gorski, 1991; Martin, 1985; Botez-Marquard and Botez, 1992; Risse *et al.*, 1978).

In rats, the anterior commissure is larger in females than in males. Prenatal stress, known to disrupt both sexual differentiation and sexual behaviour, causes a disappearance of the sex difference in the size of the anterior commissure (Jones *et al.*, 1997).

Allen and Gorski (1991) found that the interthalamic adhesion, a grey structure that crosses the third ventricle between the two thalami, was present in more women (78%) than men (68%), confirming the old study by Morel (1947). In a comparison between ten control women and eight men, all with a mean age of 79 years, magnetic resonance imaging (MRI) measurements showed that the third ventricle volume was 67% larger in men than in women (Wahlund *et al.*, 1993).

Sex Hormone Receptor Distribution

In most hypothalamic areas that contain androgen receptor staining, nuclear staining in particular is less intense in women than in men (Figure XIV.6). The strongest sex differences were found in the lateral and the medial mammillary nucleus (Fernández-Guasti *et al.*, 2000). The mammillary body complex is known to be involved in several aspects of sexual behaviour. In addition, a sex difference in androgen receptor staining was present in the horizontal diagonal band of Broca, SDN-POA, medial preoptic area, the dorsal and ventral zone of the periventricular nucleus, PVN, supraoptic nucleus, ventromedial hypothalamic nucleus, and the infundibular nucleus. However, no sex differences were observed in androgen receptor staining in the BST, the nucleus basalis of Meynert, or the island of Calleja (Fernández-Guasti *et al.*, 2000). Nuclear androgen receptor activity in the mammillary complex of heterosexual men did not differ from that of homosexual men, but it was significantly stronger than in women. A female-like pattern was found in 26- and 53-year-old castrated men and in intact old men. These data indicate that the amount of nuclear receptor staining in the mammillary complex is dependent on the circulating levels of androgens, rather than on gender identity or sexual orientation. This idea is supported by the finding that a male-like pattern of androgen receptor staining was found in a 36-year-old bisexual non-castrated male-to-female transsexual and a heterosexual virilized woman aged 46 years (Kruijver *et al.*, 2001).

The Bed Nucleus of the Stria Terminalis

The BST is situated at the junction of the hypothalamus, septum and amygdala (Lesur *et al.*, 1989; Walter *et al.*, 1991; Figure XIV.1). It plays an essential part in rodent sexual behaviour (Liu *et al.*, 1997). Oestrogen and androgen receptors have been found in the human BST (Fernández-Guasti *et al.*, 2000; Kruijver *et al.*, 2002, submitted), and it is a major aromatization centre in the developing rat brain, i.e. converting androgens into oestrogens. The BST in rat receives projections mainly from the amygdala, and provides a strong input in the preoptic-hypothalamic region. Reciprocal connections between the hypothalamus, BST and amygdala are well documented in experimental animals (Zhou *et al.*, 1995c; Liu *et al.*, 1997). There is a strong innervation of galanin fibres in the BST, and galanin receptors have also been shown in this structure (Mufson *et al.*, 1998). The BST and centromedial amygdala have common cyto- and chemoarchitectonic characteristics, and these regions are considered to be two components of one distinct neuronal complex. Neurons in the substantia innominata form cellular bridges between the BST and amygdala (Martin *et al.*, 1991; Heimer, 2000; Lesur *et al.*, 1989; Walter *et al.*, 1991). In most mammals, including humans, the extended amygdala presents itself as a ring of neurons encircling the internal capsule and the basal ganglia (Heimer *et al.*, 1997). The BST–amygdala continuum contains, for example, LHRH neurons (Rance *et al.*, 1994).

Five principal sectors have been identified in the BST, including a 'darkly staining posteromedial component (dspm) of the BST' (Allen *et al.*, 1989a; Lesur *et al.*, 1989; Kruijver *et al.*, 2000; Martin *et al.*, 1991). This part of the BST is situated in the dorsolateral zone of the fornix (Figure XIV.1) and is sexually dimorphic (Figure XIV.8). This sex difference does not seem to occur before adulthood. Its chemical composition and relationship to the other four principal BST sectors (see above) is unknown. Although the BST contains nuclear androgen receptors, no sex differences in the staining of this receptor were observed (Fernández-Guasti *et al.*, 2000; Figure XIV.6).

Reversed Sex Differences in the Bed Nucleus of the Stria Terminalis in Transsexuals

The volume of the BST-dspm is 2.5 times larger in men than in women (Allen *et al.*, 1989a). We have found that the central nucleus of the BST (the BSTc), which was defined by its dense VIP innervation (Figure XIV.8), probably originating in the amygdala or by its somatostatin fibres and neurons, is sexually dimorphic. The BSTc is 40% smaller and also contains some 40% fewer somatostatin neurons in women compared with men (Figure XIV.9). No relationship was observed between BSTc volume or somatostatin cell number and sexual orientation: in the heterosexual male reference group and a group of homosexual men, similar BSTc volume and somatostatin cell number were observed. The size and somatostatin cell number of the BSTc were, moreover, not influenced by abnormal hormone levels in adulthood. However, a remarkably small

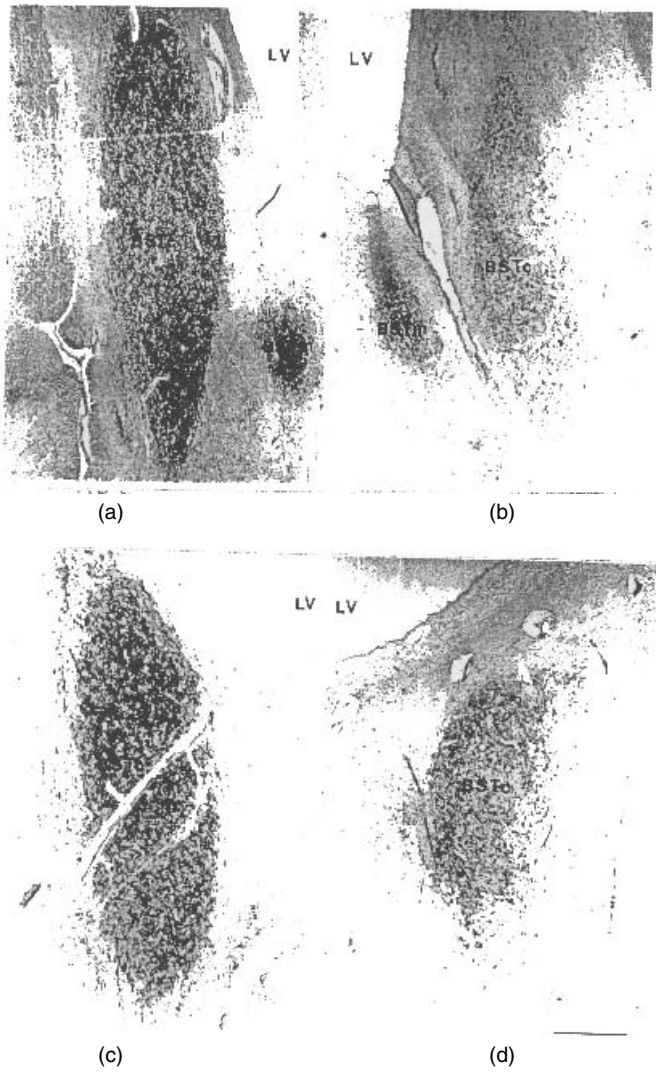

Figure XIV.8 Representative sections of the BSTc innervated by VIP. (a) Heterosexual man, (b) heterosexual woman, (c) homosexual man, (d) male-to-female transsexual. Scale bar, 0.5 mm. Note that there are two parts of the BST in (a) and (b): small medial subdivision (BSTm) and large, oval-sized central subdivision (BSTc). A female volume was observed in genetically male (male-to-female) transsexuals. There was no difference according to sexual orientation. LV, lateral ventricle

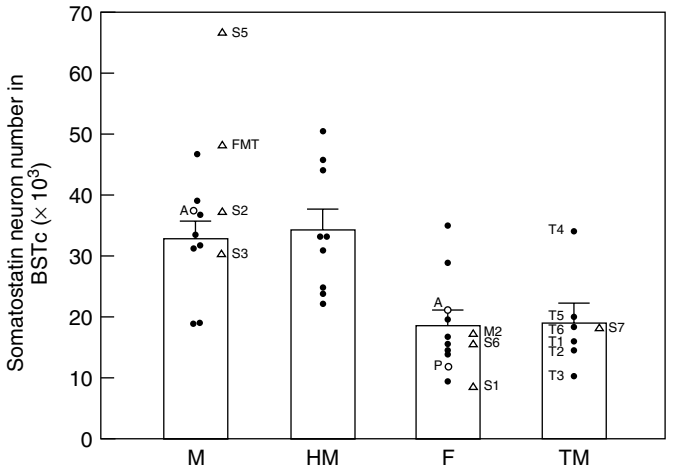

Figure XIV.9 Distribution of the BSTc neuron numbers among the different groups according to sex, sexual orientation and gender identity. M, heterosexual male reference group; HM, homosexual male group; F, female group; TM, male-to-female transsexuals. The sex hormone disorder patients S1, S2, S3, S5, S6 and M2 indicate that changes in sex hormone levels in adulthood do not change the neuron numbers of the BSTc. The difference between the M and the TM group ($P < 0.04$) also becomes statistically significant according to the sequential Bonferonni method if S2, S3 and S5 are included in the M group, or if S7 is included in the TM group ($P \leq 0.01$). Note that the number of neurons of the female-to-male transsexual (FMT) is fully in the male range. A, AIDS patient. The BSTc number of neurons in the heterosexual man and woman with AIDS remained well within the corresponding reference group (see Figure XIV.1), so AIDS did not seem to affect the somatostatin neuron numbers in the BSTc. P, postmenopausal woman. S1 (25 years of age): Turner syndrome (45,X0; ovarian hypoplasia). M2 (73 years of age): postmenopausal status. Reproduced by permission from Kruijver, F.P.M., Zhou, J.N., Pool, C.W., Hofman, M.A., Gooren, L.J.G. and Swaab, D.F., 2000. *J Clin Endocrinol Metabol* 85, 2034–2041

BSTc (40% of the male reference volume and somatostatin neuron number) was observed in a group of six male-to-female transsexuals (Figures XIV.8 and XIV.9). These data suggest that the female size of this nucleus in male-to-female transsexuals was established during development, and that the BSTc is part of a network that might be involved in gender, i.e. the feeling of being either a man or a woman (Zhou *et al.*, 1995c; Kruijver *et al.*, 2000).

Sex Differences in the Supraoptic and Paraventricular Nuclei

Although we did not find a sex difference in vasopressin neuron numbers, a sex difference was reported in vasopressin plasma levels. Men have higher vasopressin levels than women (Van Londen *et al.*, 1997; Asplund and Åberg, 1991). In addition, it was found that the posterior lobe of the pituitary is larger in boys than in girls (Takano *et al.*, 1999). This sex difference is explained by the higher activity we found in vasopressin neurons in the SON in young men compared with women, as determined by the size of the Golgi apparatus. In the course of ageing, probably triggered by the decrease in oestrogen levels, the neuronal activity increases gradually in women but remains stable in men. The sex difference in neuronal activity in the SON thus disappears after the age of 50 years (Ishunina *et al.*, 1999). This is thus an example of a hypothalamic system that does not show a structural sex difference but rather a functional sex difference. It is also an example of a sex difference based on the 'activating' (or, in this case, 'inhibiting') effects of sex hormones.

The activation of neurosecretory vasopressin neurons in postmenopausal women was confirmed by measurement of the cell size as a parameter for neuronal activity. The vasopressin neurons in the SON appeared to be larger in young men than in young women. In elderly women (>50 years old), vasopressin cell size considerably exceeded that of young women. In addition, vasopressin cell size correlated positively with age in women but not in men. Sex differences in the size of the PVN vasopressin neurons were pronounced at the left side and absent at the right side, indicating the presence of functional lateralization of this nucleus. No difference was found in any morphometric parameter of oxytocin neurons in the PVN among the four groups studied. These data demonstrate sex differences in the size of the vasopressin neurons, and thus presumably in their function, that are age- and probably also side-dependent, and the absence of such changes in oxytocin neurons

in the PVN (Ishunina and Swaab, 1999). The activation of vasopressin neurons in postmenopausal women is probably mediated by a decrease in the presence of oestrogen receptor β in these neurons and an increase in oestrogen receptor α nuclear staining (Ishunina *et al.*, 2000a).

The low-affinity neurotrophin receptor p75 ($p75^{NTR}$) may be involved in the mechanism of activation of vasopressin neurons in postmenopausal women. This receptor was found to be expressed in the SON neurons of aged individuals, while $p75^{NTR}$ expression was shown to be suppressed by oestrogens in a cell line. We investigated whether $p75^{NTR}$ immunoreactivity in SON neurons was age- and sex-dependent in post-mortem brains of control patients ranging in age from 29 to 94 years old with an anti-$p75^{NTR}$ antibody and determined the area of $p75^{NTR}$ immunoreactivity per neuron profile using an image analysis system. To study whether the $p75^{NTR}$ might also participate in the activation of SON neurons, we related Golgi apparatus size to the amount of $p75^{NTR}$ in the same patients. We found that $p75^{NTR}$ immunoreactivity did indeed correlate significantly with age and Golgi apparatus size, but only in women and not men. These observations suggest that $p75^{NTR}$ modulates the effects of oestrogens on vasopressinergic neurons in the human SON (Ishunina *et al.*, 2000b).

The sex differences in activity of the SON are consistent with other observations showing oestrogen and progesterone interference with renal actions of vasopressin. Women have a higher turnover than men, and the greatest difference is present during the lateral phase of the menstrual cycle (Claybough *et al.*, 2000).

SEXUAL DIFFERENTIATION OF THE BRAIN AND SEXUAL BEHAVIOUR

> We must remember that all our provisional ideas in psychology will one day be explained on the basis of organic substrates. It seems then probable that there are particular chemical substances and processes that produce the effects of sexuality and permit the perpetuation of individual life.
>
> Sigmund Freud, *On Narcissism*

Mechanism of Sexual Differentiation of the Brain

Sexual differentiation of the brain is thought to be 'imprinted' or 'organized' by hormonal signals from the developing male gonads. On the basis of animal experiments, this process is presumed to be induced by androgens during development following conversion to oestrogens by cytochrome P-450 aromatase. Male sexual differentiation of the human brain is thus probably determined in the two first periods during which sexually dimorphic peaks in gonadal hormone levels are found, i.e. during gestation and during the perinatal period, while from puberty onwards, sex hormones alter the function of previously organized neuronal systems ('activating effects') (for references, see Swaab *et al.*, 1992; De Zegher *et al.*, 1992; Forest, 1989; Tucker Halpern *et al.*, 1998). Testosterone is formed in the foetal Leydig cells in the testicle from about 8 weeks of gestation (Hiort, 2000). The possible importance of the male testosterone surge for sexual differentiation of the brain following aromatization to oestrogens agrees with the observation that girls whose mothers were exposed to diethylstilboestrol during pregnancy have an increased chance of developing bi- or homosexuality (Ehrhardt *et al.*, 1985; Meyer-Bahlburg *et al.*, 1995), while girls with congenital adrenal hyperplasia have a greater chance for becoming homosexual or having gender identity problems (Meyer-Bahlburg *et al.*, 1996; Money *et al.*, 1984; Dittmann *et al.*, 1992; Zucker *et al.*, 1996; (Table XIV.2; see also below) oestrogens produced locally by aromatase are thought to participate in numerous biological functions, including sexual differentiation of the brain. Aromatase is found throughout the adult human brain, with the highest levels in the pons, thalamus, hypothalamus and hippocampus. The amount of aromatase mRNA is also highest in the hypothalamus, thalamus and amygdala. No differences were detected between the four men and two women studied (Sasano *et al.*, 1998). Such a study has, however, not been performed in development. The neonatal peak of testosterone is probably induced not by the hypothalamus of the child but by chorionic gonadotrophins from the placenta, since a normal neonatal increase of testosterone was found in a patient with hypogonadism based upon a DAX-1 gene mutation that causes hypogonadotrophic hypogonadism (Takahashi *et al.*, 1997).

In human neonates at 34–41 weeks of gestation, the testosterone level is ten-fold higher in men than in women (De Zegher *et al.*, 1992). Although the peak in serum testosterone in boys at 1–3 months postnatally approaches the levels seen in adult men, most testosterone is bound to globulin. Yet the amount of free testosterone in male infants is about one order of magnitude larger than that in female infants at this time (Bolton *et al.*, 1989). During the adrenarche, i.e. from 7 years of age to the onset of puberty, the adrenals start to produce more androgens, predominantly dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulphate (DHEAS). After the age of 8 years, testosterone from the adrenals also starts to rise, while a small but significant testicular production of testosterone is also present in prepubertal boys (Forest, 1989). Although the testosterone peak during puberty is generally thought to be involved in activation rather than organization (Forest, 1989), the neuron numbers of the female domestic pig hypothalamus, to our surprise, showed a two-fold increase in a sexually dimorphic hypothalamic nucleus around puberty (Van Eerdenburg and Swaab, 1991), which means that although this phenomenon may have been programmed earlier, late organizational effects cannot, at present, be excluded. Few data are available on the exact period in development when the human brain differentiates according to sex. Brain weight is sexually dimorphic from 2 years postnatally, taking differences in body weight between boys and girls into account (Swaab and Hofman, 1984). As discussed earlier, sexual differentiation of the human SDN-POA becomes apparent between 4 years and puberty (Swaab and Hofman, 1988), and a similar late sexual differentiation was found in the BST (Allen *et al.*, 1989a). Concluding, one might say that the limited evidence that is currently available suggests that sexual differentiation of the human hypothalamus becomes apparent between 2 years of age and puberty, although this may, of course, be based upon processes that were programmed much earlier, e.g. by a peak in sex hormone levels in mid-pregnancy or during the neonatal period (see earlier). On the basis of existing prenatal serum samples from their mothers, it appears that higher androgen exposure in the second trimester of foetal life may masculinize a girl's behaviour (Udry *et al.*, 1995).

Although the process by which oestrogens are derived from testosterone by aromatization is considered to be the major mechanism for androgenization of the brain during development, testosterone itself may also be of importance for sexual differentiation of the brain. The androgen receptor located on the X chromosome at Xq11-12 may be mutated in such a way that the subject has a complete androgen insensitivity syndrome. In spite of normal testis differentiation and androgen biosynthesis, the phenotype has a normal female external and behavioural appearance (Batch *et al.*, 1992). Phenotypic women with complete androgen insensitivity syndrome perceive themselves as highly feminine. They do not have gender problems, and they largely report their sexual attraction, fantasies and experiences as heterosexual women (Wisniewski *et al.*, 2000; Wilson, 1999). This means that for the development of human male gender identity and male heterosexuality, direct androgen action on the brain seems to be of crucial importance, and that the aromatization theory may even be of secondary importance for human sexual differentiation of the brain.

The observation by Macke *et al.* (1993) that DNA sequence variation in the androgen receptor is not a common determinant of sexual orientation seems to be at variance with these data, but it should be noted that the DNA variations in that study did not prevent normal androgenization of the subjects studied, so there was no loss of function of this receptor. This view agrees with the lack of gender problems in a brother and a sister with aromatase deficiency due to a mutation (Morishima *et al.*, 1995). Moreover, a 28-year-old man with oestrogen resistance due to a mutation of the oestrogen receptor gene was described as tall, with continued linear growth in adulthood, incomplete epiphysal closure, and increased oestrogen and gonadotrophin levels. A change in a single base pair in the second exon of the oestrogen receptor gene was found. However, the patient did not report a history of gender identity disorder, he had a strong heterosexual interest, and he had normal male genitalia. The elevated serum oestrogen levels are explained by a possible compensatory increase in aromatase activity in response to oestrogen resistance (Smith *et al.*, 1994). The observations in complete androgen sensitivity syndrome (Wisniewsky *et al.*, 2000) and the male gender heterosexual behaviour of patients with 5-α-reductase-2 or 17β-hydroxy-steroid dehydrogenase-3 deficiency (Imperato-McGinley *et al.*, 1979; Imperato-McGinley *et al.*, 1991; Wilson *et al.*, 1993; Wilson, 1999) indicate that a direct action of testosterone may be more important than dihydrotestosterone for male heterosexual psychosexual development.

Not only sex hormones may affect sexual differentiation of the brain: on the basis of animal experiments, it is expected that all compounds that influence hormone or neurotransmitter metabolism in development may also affect sexual differentiation of the brain (Pilgrim and Reisert, 1992). For example, young adult male mice that were exposed prenatally to alcohol were found to have a decreased preference for female partners and an increased preference for males (Watabe and Endo, 1994). Exposure during development to some drugs (e.g. barbiturates) causes deviations in testosterone levels persisting into adulthood (Ward, 1992). This agrees with the findings of Dessens *et al.* (1999) that children born of mothers who were exposed to anticonvulsants, such as phenobarbital or diphantoin, have an increased probability of transsexuality (see below). Exposure of rats to drugs such as opiates led to behavioural changes despite apparently normal adult gonadal hormone levels (Ward, 1992). Similar observations in human sexual differentiation have not yet been reported.

It is of great interest that there is also recent animal experimental evidence for primary genetic control of sexual differentiation that does not involve sex hormones. Results obtained from cultures of embryonic rat brain indicate that dopaminergic neurons may develop morphological and functional sex differences in the absence of sex steroids (Pilgrim and Reisert, 1992). For such hormone-independent effects, the most likely candidates are those genes located on the non-recombining part of the Y chromosome and believed to be involved in primary sex determination of the organism. Two candidate genes are the two testis-determining factors ZFY and the master switch for differentiation of a testis SRY. Those are putative transcription factors. We have shown that SRY and ZFY are transcribed in the hypothalamus and frontal and temporal cortex of adult men and not in women. It may well be possible that they function as sex-specific, cell-intrinsic signals that are needed for full differentiation of a male human brain, and that continuous expression throughout life may be required to maintain sex-specific structural or functional properties of differentiated male neurons. Sexual differentiation of the human brain may thus be a multifactorial process, although a role of SRY and ZFY in this process still needs to be proved (Mayer *et al.*, 1998). An alternative mechanism could be the actions of an imprinted X-linked locus (Skuse, 1999). Recent clinical studies on human subjects with mutations in genes involved in sexual differentiation also point to the possibility that the interaction between sex hormones and brain development may not be the only mechanism involved in the development of gender and sexual orientation.

The relative contributions of the different sex hormones and other non-hormonal factors on sexual differentiation of the human brain should clearly be a focus for future research.

Sexual Differentiation, the Hypothalamus and the Amygdala

Sex differences in the hypothalamus and other limbic structures are thought to be the basis of sex differences in reproduction (e.g. copulatory behaviour in both sexes, the menstrual cycle in women), gender identity (i.e. the feeling that one is either a man or a woman), gender identity disorders (transsexuality) and sexual orientation (homosexuality, heterosexuality, bisexuality) (Gooren *et al.*, 1990; Swaab *et al.*, 1992; Swaab and Hofman, 1995). The PVN in the rat, in particular its oxytocin neurons, is involved in erectile functions in copula. For penile erections initiated by psychogenic stimuli, the medial amygdala, the PVN and, to a lesser extent, the BST are involved, while medial preoptic lesions in the rat have little, if any, effect on this type of erections (Liu *et al.*, 1997). Sexual arousal and orgasm produce long-lasting alterations in plasma prolactin concentrations in both men and women (Exton *et al.*, 1999), which might be related to postorgasmic loss of arousability (Bancroft, 1999), indicating a role of the medial-basal hypothalamic dopamine neurons.

There is extensive animal experimental literature that shows that the medial preoptic area of the hypothalamus is a key structure for male and female copulatory behaviour (Pilgrim and Reisert, 1992; Yahr *et al.*, 1994; McKenna, 1998) and that the hypothalamus is involved in seminal vesicle contractions at coitus (Cross and Glover, 1958). However, the exact role of its subarea, the SDN-POA, in these functions is not clear, and literature on hypothalamic structures involved in sexual orientation in experimental animals is scarce (Paredes *et al.*, 1998; Kindon *et al.*, 1996). Paredes and Baum (1995) found that lesions of the medial preoptic area/anterior hypothalamus in the male ferret affected not only masculine coital performance but also heterosexual partner preference. Edwards *et al.* (1996) observed a decrease in partner preference in male rats following a lesion of the BST. Perkins *et al.* (1995) showed that testosterone, oestrone and oestradiol plasma concentrations were higher in female-oriented rams than in homosexual rams. In the preoptic area, the aromatase activity was higher in the female-oriented rams than in the male-oriented rams, indicating again the possible importance of the preoptic area in sexual orientation (Resko *et al.*, 1996). The content of oestrogen receptors in the amygdala was found to be similar in both homosexual rams and ewes, but less than the receptor content in heterosexual rams, while the oestrogen receptor content of the hypothalamus, anterior pituitary and preoptic area of these two groups did not differ (Perkins *et al.*, 1995). These data suggest that the amygdala might also play a role in sexual orientation. Indeed, in some Klüver–Bucy syndrome cases due to damage of the temporal lobe, patients were reported to change from heterosexual to homosexual behaviours, indicating that the temporal lobe might be of importance for sexual orientation (Lilly *et al.*, 1983; Marlowe *et al.*, 1975; Terzian and Dalle Ore, 1955). Also, there are a few case histories of changing sexual orientation, from heterosexual to paedophilic or homosexual, on the basis of a lesion in the hypothalamus or the temporal lobe, from which the amygdala has strong connections to the hypothalamus (Miller *et al.*, 1986). There is no information available on the exact nature of the preoptic and amygdala neuronal systems and connections that may be involved in sexual orientation. Data on the hypothalamus in relation to gender identity in animals are, of course, nonexistent.

There are a few studies in the medical literature that implicate the hypothalamus and adjoining structures in various aspects of sexual

behaviour. Direct electrical or chemical stimulation of the septum may induce a sexually motivated state of varying degrees up to penile erection in men and building up to orgasm in both sexes (Heath, 1964). Markedly increased sexual behaviour was observed following the placement of the tip of a ventriculoperitoneal shunt into the septum in two cases (Gorman and Cummings, 1992). Meyers (1961) described a loss of potency following lesion in the septo-fornico-hypothalamic region. Electrical stimulation of the mammillary body in monkeys induced penile erection (MacLean and Ploog, 1962; Poeck and Pilleri, 1965). Precocious puberty and hypersexuality have been reported following lesions in the posterior part of the hypothalamus, and hypogonadism is an early sign of pathology in the anterior part of the hypothalamus (Bauer, 1954; Bauer, 1959; Poeck and Pilleri, 1965). In particular, hamartomas that affect the posterior region of the hypothalamus, i.e. those that are pendulated and attached to the region of the mammillary bodies, may cause precocious puberty (Valdueza *et al.*, 1994). In addition, precocious puberty is found in cases of pineal region tumours that produce gonadotropins.

A German stereotactic psychosurgical study (Müller *et al.*, 1973) reported on 22 mainly paedophilic or ephebophilic (preferring pubertal boys) homosexual men ($n = 14$) and six cases with disturbances of heterosexual behaviour (hypersexuality, exhibitionism or paedophilia). In 12 homosexual patients, a lesion was made in the right ventromedial nucleus of the hypothalamus. In eight patients, homosexual fantasies and impulses disappeared. According to this paper, in six patients a 'vivid desire for full heterosexual contacts' occurred after the operation. In one paedophilic patient, bilateral destruction of the ventromedial nucleus was performed and he lost all interest in sexual activity after the operation. The heterosexual patients reported a significant reduction of their sexual drive. Unilateral ventromedial hypothalamotomy in 14 cases treated for aggressive sexual delinquency caused a decrease in sexual drive (Dieckmann *et al.*, 1988; Albert *et al.*, 1993). Although these studies at first sight appear to suggest that the human hypothalamus is indeed involved in sexual orientation and sexual drive, they are highly controversial from an ethical point of view, and they are methodologically deficient (Heimann, 1979; Schorsch und Schmidt, 1979; Rieber and Sigusch, 1979).

Transsexuality and Other Gender Identity Problems

Transsexuality is a rare condition. The annual incidence of transsexuality in Sweden has been estimated to be 0.17/100 000 inhabitants. The sex ratio (genetic male : female) varies from country to country between 1.4 : 1 and 3 : 1 (Garrels *et al.*, 2000; Landén *et al.*, 1996). There is little information about the factors that may influence gender and cause transsexuality in humans (Table XIV.2). The disparate maternal aunt/uncle ratio in transsexual men, pointing to an X-related heredity, has been hypothesized to be due to genomic imprinting (Green and Keverne, 2000). There are only a few reports that have found chromosomal abnormalities in transsexuals. Six cases of male-to-female transsexuals with 47,XYY chromosome and one female-to-male transsexual with 47,XXX have been reported (Tayfun Turan *et al.*, 2000). Moreover, transsexualism has been reported in a man with Klinefelter's (XXY) syndrome. In addition, pairs of monozygotic female twins have requested sex reassignment, and familial cases of gender identity problems have been reported, suggesting a genetic basis for this disorder (Green, 2000; Sadeghi and Fakhrai, 2000). Although only a minority of the transsexuals has an underlying endocrine abnormality (Meyer *et al.*, 1986), there are some indications of a possible disorder of the hypothalamo-pituitary-gonadal axis in some transsexuals that may have a basis in development, such as a high frequency of polycystic ovaries, oligomenorrhoea and amenorrhoea in female-to-male transsexualism (Sadeghi and Fakhrai, 2000; Futterweit *et al.*, 1986).

Table XIV.2 Factors that influence sexual differentiation of the human brain

Factor	Notes
Gender identity (transsexualism)	
Chromosomal disorders	Rare: 47XYY (male to female), 47XXX (female to male) (Tayfun Turan *et al.*, 2000), monozygotic twin (female; Sadeghi and Fakhrai, 2000), genomic imprinting (Green and Keverne, 2000)
Phenobarbital/diphantoin	Dessens *et al.* (1999)
Hormones	Intersex (Zucker *et al.*, 1987; Reiner, 1996)
	Cloacal extrophy
	5-α-reductase deficiency, 17-β-hydroxy-steroid-dehydrogenase-3 deficiency (Imperato-McGinley *et al.*, 1979; Imperato-McGinley *et al.*, 1991; Wilson, 1999).
	Congenital adrenal hyperplasia girls with gender problems (Meyer-Bahlburg *et al.*, 1996; Zucker *et al.*, 1996)
	More polycystic ovaries, oligomenorrhoea and amenorrhoea are found in transsexuals (Futterweit *et al.*, 1986)
Social factors?	Bradley *et al.* (1998): not effective; John/Joan/John case (Diamond and Sigmundson, 1997)
Sexual orientation	
Genetic factors	Twin studies (Kallmann, 1952; Bailey and Bell, 1993)
	Molecular genetics (Hamer *et al.*, 1993; Hu *et al.*, 1995); but see Rice *et al.* (1999)
Hormones	Congenital adrenal hyperplasia girls (Money *et al.*, 1984; Dittmann *et al.*, 1992; Zucker *et al.*, 1996)
	Diethylstilboestrol (Ehrhardt *et al.*, 1985; Meyer-Bahlburg *et al.*, 1995)
	Male-to-female sex reassignment (Bailey *et al.*, 1999)
	Stress during pregnancy (Ellis *et al.*, 1988; Bailey *et al.*, 1991)
Social factors?	Raising by transsexual or homosexual parents does not affect sexual orientation (Green, 1978; Golombok *et al.*, 1983)

Dessens *et al.* (1999) reported that three children born of a group of 243 women exposed to the anticonvulsants phenobarbital and diphantoin were found to be transsexuals, while in addition there were a few other subjects with gender dysphoria/cross-gender behaviour. Gender problems thus occurred remarkably often in view of the rarity of this disorder. This observation on the effect of compounds that are known to alter steroid levels in animal experiments has to be examined further. In this respect, it is of interest to note that phenobarbital has been used widely as prophylactic treatment in neonatal jaundice and greatly elevated the postnatal rise in testosterone (Forest *et al.*, 1981). In 1996, Meyer-Bahlburg *et al.* reported a gender change from woman to man in four 46,XX individuals with classical congenital adrenal hyperplasia. Congenital adrenal hyperplasia, characterized by high androgen levels during prenatal development, constitutes a risk factor for the development of gender identity problems. Although it should be emphasized that the large majority of women with this disorder do not experience a marked gender identity conflict, the odds ratio that a genetic female with this disease would live as an

adult in the male social role compared with genetic females in the general population was found to be 608 : 1 (Zucker *et al.*, 1996). These observations support the view that intrauterine or perinatal exposure to abnormal levels of sex hormones may permanently affect gender identity.

The concept of sexual neutrality at birth, after which infants differentiate as masculine or feminine as a result of social experiences, was proposed by Money *et al.*, (1955a; Money *et al.*, 1955b). Gender imprinting was presumed to start at the age of 1 year and to be well established by 3–4 years (Money and Erhardt, 1972). Observations on children with male pseudohermaphroditism due to 5-α-reductase-2 deficiency were supposed to support the influence of life experience on psychosexual make-up (Al-Attia, 1996). A classic report that has strongly influenced the opinion that the environment plays a crucial role in gender development was that described by Money of a boy whose penis was accidentally ablated at the age of 8 months during a phemosis repair by cautery and who was subsequently raised as a girl. Orchiectomy followed within a year to facilitate feminization, and further surgery to fashion a full vagina was performed later. Initially, this individual was described as developing into a normally functioning woman. Later, however, it appeared that the patient had rejected the sex of raising and switched at puberty to living as a man again, when he requested male hormone shots, a mastectomy and phalloplasty. At the age of 25, he married a woman and adopted her children. This famous John–Joan–John story, although just one case, illustrates that there is little if any support for the view that individuals are sexually neutral at birth and that normal psychosexual development is dependent on the appearance of the genitals (Diamond and Sigmundson, 1997). In a second case of penile ablation, in which the decision was made to reassign the patient as a girl and raise the baby as a girl, the remainder of the penis and testes were removed at the slightly earlier age of 7 months. Although her sexual orientation was bisexual, and even though she was attracted mainly to women, her gender identity was female. The different outcome as compared with the former case is explained by the authors on the basis of the earlier decision to reassign the sex (Bradley *et al.*, 1998).

Reiner (1996) described a 46,XY child with mixed gonadal dysgenesis, one immature testis, hypoplastic uterus and clitoral hypertrophy, who was raised without stigmatization as a girl but who declared himself male at the age of 14. Following corrective surgery and testosterone substitution, he lived as a boy despite the social factors that were clearly in favour of maintaining the assigned sex. Apparently, the deficient testis had been able to organize the brain during development, even though the hormone levels were prenatally so inadequate that ambiguity of the genitalia was induced.

A child with true hermaphroditism, 45X (13%) 47XYY (87%) sex chromosome mosaic pattern in blood, uterus, fallopian tubes, phallus, testicular tissue and epididymis, was assigned male sex at birth. At 5 weeks, the decision was made to reassign him to female. At 9 months, an operation was performed to make the genitalia female, at 13 months the testicle was removed, and at the age of 5, another operation was carried out to make the genitalia female. The patient was raised as a girl but she had masculine interests, and at about 8 years of age, she declared that 'God had made a mistake' and that she 'should have been a boy'. Apparently, the male sex hormones to which she had been exposed *in utero* had imprinted the male gender, although the authors also presumed postnatal psychosocial factors to have played a role (Zucker *et al.*, 1987).

As described above, we recently found a female-sized central nucleus of the BST in male-to-female transsexuals. These data were confirmed by neuronal counts of somatostatin cells, the major neuron population in the BSTc. Changes in hormone levels could not explain this difference (Zhou *et al.*, 1995c; Kruijver *et al.*, 2000). This supports the hypothesis that gender identity develops as a result of an interaction between the developing brain and sex hormones.

Homosexuality

Xq28–Thanks for the genes, mom

Seen on T-shirts in the USA

Sexual orientation is influenced by a number of genetic and non-genetic factors (Table XIV.2). Genetic factors appear from studies in families and twins, and through molecular genetics (Kallman, 1952; Bailey and Bell, 1993; Hamer *et al.*, 1993; Turner, 1995; Hu *et al.*, 1995; Pillard and Bailey, 1998; Bailey *et al.*, 1999). Hamer and colleagues found linkage between DNA markers on the X chromosome and male sexual orientation. Genetic linkage between the microsatellite markers on the X chromosome, i.e. Xq28, was detected for the families of gay males but not for the families of lesbians (Hamer *et al.*, 1993; Hu *et al.*, 1995). In a follow-up study, Rice *et al.* (1999) studied the sharing of alleles at position Xq28 in 52 Canadian gay male sibling pairs. Allele and haplotype sharing for four markers were not increased more than expected, which did not support the presence of an X-linked gene underlying male homosexuality. In a reaction to this paper, Hamer (1999) stated that (1) the family pedigree data from the Canadian study supported his hypothesis, (2) three other available Xq28 DNA studies found linkage, and (3) the heritability of sexual orientation is supported by substantial evidence independent of the X chromosome data. In a meta-analysis of the four available studies, he found a significant linkage. Rice *et al.* (1999) responded extensively and remained convinced that an X-linked gene could not exist in the population with any sizeable frequency. This controversy will undoubtedly continue.

Sex hormones during development also have an influence on sexual orientation, as appears from the increased proportion of bisexual and homosexual girls with congenital adrenal hyperplasia (Money *et al.*, 1984; Dittmann *et al.*, 1992; Meyer-Bahlberg *et al.*, 1996). Then there is diethylstilboestrol (DES), a compound related to oestrogens that increases the occurrence of bisexuality or homosexuality in girls whose mothers received DES during pregnancy (Ehrhardt *et al.*, 1985; Meyer-Bahlburg *et al.*, 1995) in order to prevent miscarriage (which it does not do). Whether environmental oestrogens from plastics can influence sexual differentiation of the human brain and behaviour is in debate but is certainly not established. In addition, phyto-oestrogens, such as resveratrol, present in grapes and wine and an agonist for the oestrogen receptor, should be considered in this respect (Gehm *et al.*, 1997).

Maternal stress is thought to lead to increased occurrence of homosexuality in boys (Ellis *et al.*, 1988) and girls (Bailey *et al.*, 1991). As interesting case histories of this potentially environmental factor, Weyl (1987) mentions that Marcel Proust's mother was subjected to the overwhelming stress of the Paris commune during the fifth month of her pregnancy in 1871; and Mary, Queen of Scots, the mother of the homosexual King James I of England, towards the end of the fifth month of pregnancy experienced her secretary and special friend Riccio being killed. Although postnatal social factors are generally presumed to be involved in the development of sexual orientation (Byne and Pearson, 1993; Zucker *et al.*, 1996), solid evidence in support of such an effect has not yet been reported. The observation that children raised by lesbian couples or by transsexuals generally have a heterosexual orientation (Green, 1978; Golombok *et al.*, 1983; Kirkpatrick *et al.*, 1981) does not support the possibility of the social environment in which the child is raised as an important factor for determining sexual orientation, nor is there scientific support for the idea that homosexuality has psychoanalytical or other psychological or social learning explanations, or that it would be a 'lifestyle choice' (Ellis, 1996). Various hypothalamic structures are structurally different in relation to sexual orientation, i.e. the suprachiasmatic nucleus, INAH3 and the commissura anterior (see earlier), suggesting that

a difference in hypothalamic neuronal networks that occurs in development may be the basis of differences in sexual orientation.

Disorders of Sexual Behaviour

Hypothalamo-pituitary disorders often interfere with the expression of sexuality. In fact, a decreased sexual desire was significantly present in 72% of adult men with a pituitary tumour. One-third of these patients reported decreased sexual desire, even as the first symptom of the tumour. Decreased sexual drive is the first symptom in 50% of men with pituitary tumours accompanied by hyperprolactinaemia. In addition, sexual desire is absent or decreased in two-thirds of women with hypothalamo-pituitary disorders. This problem was recorded for 84% of women with hyperprolactinaemia and for only 33% of those with normal serum prolactin. Almost all these women had amenorrhoea (Lundberg and Hulter, 1991; Lundberg and Brattberg, 1992). As men age, there is a decrease in total and free testosterone levels and an associated increase in gonadotropin levels, while a decrease in sexual activity is also notable (Davidson *et al.*, 1983). Although the hormonal changes during ageing are generally considered to contribute only to a minor degree to the decline in sexual function in men, there are many studies showing the relationship between testosterone levels and sexual activity. Testosterone does increase the incidence of all types of male sexual activity in hypogonadal men, and the antiandrogen cyproterone acetate inhibits sexual activity (Davidson *et al.*, 1982; Albert *et al.*, 1993; Yates, 2000). There is also clear evidence that testosterone modulates sexual behaviour in women: adrenalectomy decreases sexual activity and testosterone replacement restores it (Albert *et al.*, 1993; Tuiten *et al.*, 2000).

Disturbed sexual behaviour has, moreover, been reported in a number of neurological and psychiatric disorders (Chandler and Brown, 1998), such as rabies (Dutta, 1996), encephalitis lethargica, multiple sclerosis, Wolfram syndrome, Prader–Willi syndrome, anorexia nervosa and bulimia nervosa, Kallmann syndrome, Klinefelter's syndrome, depression, Down's syndrome, Kleine–Levin syndrome and Parkinson's disease. Antipsychotic treatment in schizophrenia results in more sexual disturbances in men than in women (Hummer *et al.*, 1999). In depression, sexual activity *per se* is said not to be reduced during the depressed state. Rather, loss of sexual interest appears to be related to the cognitive set of depressive symptoms, i.e. loss of sexual satisfaction. Nocturnal penile tumescence alterations may be more trait-like than state-like in depression (Nofzinger *et al.*, 1993).

A newly discovered group of neurological and reproductive disturbances is due to mutations in sex hormone receptors or aromatase. Some abnormalities of the androgen receptor result in the syndrome of androgen resistance, which goes together with normal male differentiation. More recently, mutations of the androgen receptor were also described in a form of Kennedy's disease, a motor neuron disease. In Kennedy's disease (X-linked bulbospinal muscular atrophy), a trinucleotide repeat expansion occurs in exon A of the androgen receptor gene (MacLean *et al.*, 1995). People with Kennedy's disease have normal virilization, although progressive gynaecomastia, testicular atrophy and infertility may occur (MacLean *et al.*, 1996). In addition, mutations of the oestrogen receptor may cause oestrogen resistance.

Cases of female pseudohermaphroditism, hypergonadotropic hypogonadism and multicystic ovaries have been reported to be associated with missense mutations in the gene encoding aromatase (P450). In one 14-year-old girl, breast development did not occur, her clitoris was enlarged, and circulating androgens and gonadotrophins were high, causing hyperstimulation of the ovaries (Conte *et al.*, 1994). Female pseudohermaphroditism has also been found to be caused by placental aromatase deficiency. Maternal serum levels of oestrogens were low and those of androgens high in the third trimester, causing maternal virilization and pseudohermaphroditism of the female foetus (Shozu *et al.*, 1991). Another mutation of the human gene encoding for aromatase P450 has been reported in male and female siblings. During both pregnancies, the mother exhibited signs of progressive virilization. The girl had nonadrenal female pseudohermaphroditism at birth, developed progressive virilization at of puberty, and had pubertal failure with no signs of oestrogen action, hypergonadotropic hypogonadism and polycystic ovaries. The girl's brother was 204 cm tall. He was sexually mature and had elevated testosterone levels, low oestrogen levels and high gonadotrophins. Interestingly, the psychosexual orientation of both brother and sister was reported to be appropriate for their phenotypic sex (Morishima *et al.*, 1995). There has also been a publication on two mutations in the CYP19 gene that were responsible for aromatase deficiency in an 18-year-old woman with ambiguous genitalia at birth, primary amenorrhoea, sexual infantilism and polycystic ovaries (Ito *et al.*, 1993). No information is present on the sexual differentiation of the hypothalamus in such subjects.

Stereotactic hypothalamotomy aimed at the ventromedial nucleus has been performed during detention in violent sexual offenders. Sexual drive was reported to be markedly reduced and no relapses occurred. As side effects, a strong feeling of hunger and weight gain were reported (Dieckmann and Hassler, 1977). In one patient, agitation followed by unconsciousness and hemiparesis resulted from a haemorrhage into the third ventricle after removal of the electrode after such an operation. Another patient became unconscious but recovered later (Šramka and Nádvorník, 1975). Stereotactic hypothalamotomy was not only a risky operation but also a controversial one, both from an ethical and scientific point of view.

CONCLUSIONS

Sex differences in the brain and hormone levels are not only of importance for sexual behaviour; they are also thought to be the structural and functional basis of pronounced sex differences in the prevalence of neurological and psychiatric diseases.

There is an increasing amount of literature concerning morphological and functional sex differences in the human brain. Focusing on the hypothalamus, sex differences have been reported in volume and cell numbers of particular areas in neuronal metabolic activity of such areas and in transmitter content. Some of the sex differences seem to be related to age or certain disorders like Alzheimer's disease, others to reproduction, gender identity and sexual orientation. The BSTc, a brain area involved in reproduction, was found to be twice as large in men as in women. In male-to-female transsexuals, this sex difference was found to be reversed. The BSTc of genetically male transsexuals was found to be of female size and neuron number, supporting the idea that this structure may be involved in the feeling of being a man or a woman. The BSTc in transsexuals thus seems to have followed a course of sexual differentiation during development that is opposite to that of the sex organs.

Based on animal experiments, sexual differentiation of the brain is thought to be 'imprinted' or 'organized' by androgens during development, following conversion by aromatase to oestrogens, presumably during gestation or the perinatal period. From puberty onwards, sex hormones alter the function of previously organized neuronal systems. This action is known as 'activating' effects of sex hormones, but such effects may also inhibit neuronal function. However, genetic males with a complete androgen insensitivity syndrome, despite normal testis differentiation and androgen biosynthesis, have a phenotype that is normal female, both externally and behaviourally. They perceive themselves as highly feminine and do not have gender problems. This means that for the development of human male gender identity and male heterosexuality,

direct androgen action on the brain seems to be of crucial importance. The aromatization theory, which emphasizes the importance of oestrogens, may thus be of secondary importance for human sexual differentiation.

Apart from the interactions of hormones and the developing neurons, a number of other factors seem to influence sexual differentiation of the brain and thus influence sexual orientation and gender identity. Chromosomal disorders, genetic factors, stress during pregnancy, and medicines taken by the pregnant woman may play a role. However, postnatal social factors do not seem to be of primary importance for the development of sexual orientation or gender identity.

The interaction between hormones, hypothalamic structures and the amygdala seem to be of the utmost importance for sexual behaviour. Disorders of sexual behaviour may not only go together with decreased hormone levels in elderly people; they may also result from countless neurological, neuroendocrine or psychiatric diseases and therefore demand careful diagnostic attention.

ACKNOWLEDGEMENTS

Animal Models of Cognitive Disorders

Thomas Steckler

INTRODUCTION

Animal models of human cognitive function are required for an understanding of the aetiology of human cognitive disorders, e.g. identifying novel therapeutic targets and the mechanism of action of drug effects on cognitive function. Animal models reflect approximations to the situation to be modelled. Although it should not be assumed that attempts to model a certain aspect of a situation (e.g. the generation of a tau transgenic mouse) will lead to all facets of that situation (i.e. a 'demented' mouse), these models will help to understand part of the complexity of the situation (e.g. tau overexpression leading to neuronal loss) and to evaluate related concepts (e.g. the hypothesis that dysfunction of tau can lead to neurodegeneration and cognitive impairments).

These objectives demand validation of the model (Sarter and Bruno, 2001; van der Staay and Steckler, 2001; van der Staay and Steckler, 2002; Willner, 1991). The focus of validation will depend on the type of model (1) *screening* models, (2) more complex or *simulation* models, and (3) *assay* or mechanistic models (Figure XV-1.1) (Ellenbroek and Cools, 2000; Willner, 1991) (see also Chapters III and XVII-1). It should be noted that there is a certain degree of overlap between these categories. Screening models rely strongly on predictive validity, i.e. on whether a manipulation (e.g. a drug treatment) predicts performance in the condition to be modelled (Willner, 1991). Simulation models attempt to incorporate both the neurobiological and behavioural abnormalities underlying a disorder (see Chapter III); they require assessment of how well a measure of a particular process, trait or state reflects theoretical assumptions (construct validity; Willner, 1991). Moreover, simulation models require face validity, i.e. a high degree of phenomenological similarities between the measure of the model and the condition it simulates (Willner, 1991).

In drug development, there can be a third model, the assay or mechanistic model, which allows easy assessment of whether a compound is active on a target, e.g. a receptor. This can be, but does not have to be, a behavioural assay, but it could be any easily and reliably measurable and specific physiological outcome. Assessment of perioral movements or parasympathetic activation, for example, can serve as indices of *in vivo* cholinergic activity (Salamone *et al.*, 1986). Such models allow fast ranking of compounds according to potency and duration of action, and give first indications as to whether a drug penetrates the brain. Of note, these models are not necessarily related to the desired therapeutic effect of a drug, which needs to be assessed separately in screening and simulation models. Therefore, the mechanistic model will not be further discussed here.

This does not mean that one model category is better or worse. The important point is to use the appropriate model to answer a particular question. Often, conclusions are drawn from mechanistic or screening models prematurely as these types of models lack certain validity aspects. For example, a screening model can give an indication for activity of a compound, but often data are overinterpreted. Conclusions that drug *x* is a cognitive enhancer and will be useful for treatment of dementia cannot be drawn from a screening model, as it poses the risk of many false positives later on in the clinic. It is important to acknowledge the limitations of the model used, and it is advisable to use more than one model to enhance the robustness of the result.

In principle, these model categories can be divided further into *causative* and *symptomatic* models (Figure XV-1.1). A causative model uses an approach that is linked directly to the disease process, such as exposure to the noxious agent known to cause the neuropsychiatric disease itself. For example, chronic ethanol treatment results in both cognitive and structural changes in the brains of rats (Arendt *et al.*, 1988; Savage *et al.*, 2000) and is thought to mimic the effects of alcohol abuse. Likewise, the brain damage and behavioural deficits caused by ischaemia induced by occlusion of the middle cerebral artery (Bederson *et al.*, 1986; Markgraf *et al.*, 1992; Tamura *et al.*, 1985; Van der Staay *et al.*, 1996; Yamamoto *et al.*, 1988) constitute a causative model of stroke.

Alternatively, drugs or lesions known to modulate brain systems hypothesized to be involved in the aetiology of neuropsychiatric diseases, but not necessarily being a key factor in the underlying aetiology, can be used. Pyrithiamine-induced thiamine deficiency, for example, has been used as a model of Wernicke–Korsakoff syndrome, which is related to alcohol abuse and is due to the thiamine deficiency seen in alcohol abusers. Treatment with pyrithiamine produces a range of neuropathological and behavioural abnormalities in rodents, which model the cognitive deficits seen in Wernicke–Korsakoff syndrome (Irle and Markowitsch, 1983; Langlais *et al.*, 1992; Mumby *et al.*, 1999; Savage *et al.*, 1999), although it is other dietary issues, not pyrithiamine, that cause the thiamine deficiency in alcohol-dependent patients.

Another example derives from the field of psychosis: chronic phencyclidine (PCP) administration has been proposed to model psychosis, although the tool itself is not aetiologically relevant (most schizophrenic patients do not take PCP, although *N*-methyl-D-aspartate (NMDA) antagonists can worsen their symptoms; Lahti *et al.*, 2001). Both pyrithiamine and PCP models have to be considered as symptomatic models. At times of course, there is overlap, and a symptomatic model can turn into a causative model and vice versa, depending on whether a process can be linked aetiologically to a disease.

Note that the fact that the tool is not related causally does not necessarily reduce the validity of the model. For example, NMDA antagonists such as PCP or ketamine produce a range of schizophrenia-like positive and negative symptoms in humans (Krystal *et al.*, 2000; Lahti *et al.*, 2001). Long-term exposure to PCP produces prefrontal cortical cognitive and dopaminergic dysfunction in rats and monkeys, even after discontinuation of drug treatment (Jentsch *et al.*, 1997a; Jentsch *et al.*, 1997b; Jentsch *et al.*, 1999; Jentsch and Taylor, 2001), and can lead to neurodegeneration in

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

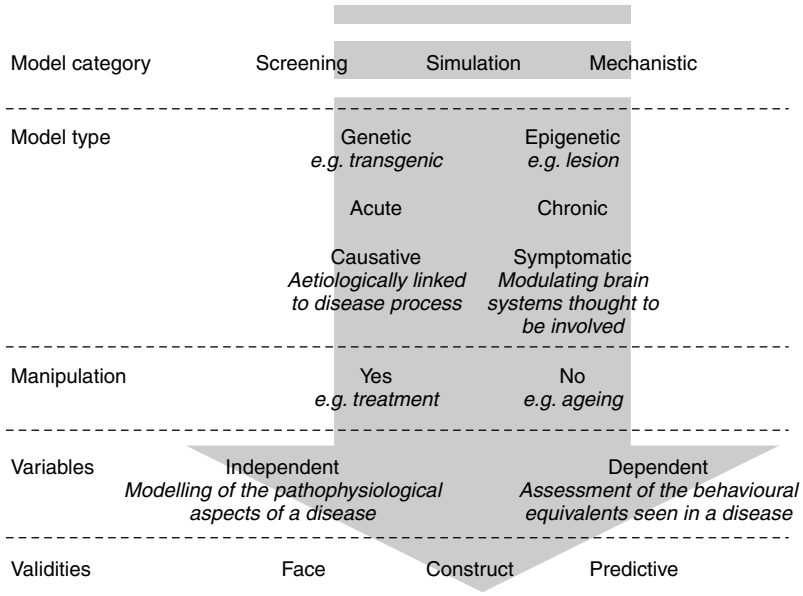

Figure XV-1.1 Classification of animal models of human cognitive dysfunction

certain brain areas, including various cortical areas (Ellison, 1995). These symptomatic similarities give this model high face validity, and the dopaminergic changes indicate good construct validity. Moreover, the cognitive impairments induced by subchronic PCP administration in rats can be reversed by antipsychotic drugs such as risperidone (Schroeder *et al.*, 2000). This suggests that (sub)chronic PCP administration may also be a model with good predictive validity for treatment of cognitive symptoms in psychosis.

Within these model categories, we can further define independent and dependent variables (Figure XV-1.1). First, different aspects of a condition (e.g. a disease state) can be modelled, such as genetic (e.g. tau mutations) and epigenetic (e.g. ageing, pharmacological challenge) phenomena. Models may be based on naturally occurring features (e.g. old animals) or on experimental manipulation (e.g. transgenic mice and brain-specific lesions), or they can consist of combinations thereof. These aspects of a model, by definition, constitute independent variables. Second, the independent variables have both neurobiological and behavioural consequences, which make up the dependent variables. Both variables will be viewed separately in this chapter, as the number of possible combinations are enormous.

This does not mean, however, that independent and dependent variables have no bearing on each other. Ultimately, the validity of a model will depend on both the independent variables (i.e. the physiological manipulation) and the dependent variables (i.e. the outcome measure, such as performance in a cognitive task), and the model has to be judged in total. Failure to take all these aspects into account poses the risk to generate invalid results.

Neuropathological features of Alzheimer's disease, for example, include widespread cerebral atrophy, neuronal loss, deposition of β-amyloid (Aβ) peptide in extracellular neuritic plaques (derived by endoproteolysis from amyloid precursor protein (APP)), and intracellular neurofibrillary tangles (comprised mainly of hyperphosphorylated forms of the microtubule-associated protein tau; Selkoe, 1991). Furthermore, a wide range of neurotransmitter abnormalities occurs in Alzheimer's disease, involving catecholamines and neuropeptides. Among these neurotransmitter alterations, possibly the most significant changes can be seen in the cortical projection from the nucleus basalis of Meynert, which undergoes extensive degeneration, leading to cholinergic hypofunction (Perry, 1986; Perry *et al.*, 1978). Behaviourally, patients suffering from Alzheimer's disease do not have a non-specific memory decline but are particularly impaired in certain aspects of mnemonic function, while other parts are relatively spared. They seem to have particular difficulties with encoding and acquisition, leading to declarative memory impairments, including recall and recognition, and a rapid rate of forgetting, while procedural memory is preserved (Brandt and Rich, 1995). An animal model of Alzheimer's disease should aim to model the neuropathological/neurochemical, molecular and behavioural/cognitive features.

From the examples given so far, it is already obvious that not only neurodegenerative disorders, such as Alzheimer's disease, but also other psychiatric disorders, such as attention deficit hyperactivity disorder (ADHD), schizophrenia and depression, stroke and drug abuse, and the normal ageing process are associated with significant cognitive dysfunction, and that amelioration of this dysfunction would be beneficial for long-term outcome in all of these disorders. Thus, talking about animal models of human cognitive function inevitably will cover a wide range of different human psychiatric and neurological diseases, although the focus is probably on animal models of dementia. It cannot be the aim of this chapter to review all these models in detail; rather, I will give some relevant examples, which can then be used to illustrate general principles and which hopefully can be extrapolated to other, newly developed models in the future. Although the cognitive deficits seen in the various neuropsychiatric disorders are specific (see the example of Alzheimer's disease, above), it is also of note that there is overlap between the disorders. For example, executive functions, such as concept formation, problem solving and set shifting, such as on the Wisconsin Card Sorting Test (WCST), are impaired in Alzheimer's disease (Whitehouse *et al.*, 1993). WCST performance is also impaired in schizophrenic patients (Goldberg and Gold, 1995). Thus, a behavioural model assessing executive functions in an animal, and using a task comparable to the WCST, would be useful as a model for both human disorders, i.e. there is also overlap between models. However, an Alzheimer model may approach the issue by using a manipulation of amyloid deposition, while a psychosis model may focus on chronic PCP treatment, for example.

MAKING THE MODEL: A SURVEY OF THE INDEPENDENT VARIABLES

Looking at the independent variables of an animal model of cognitive dysfunction, we can distinguish epigenetic and genetic, and unmanipulated and experimentally manipulated models. The wide range of different approaches used to model a particular disease can be illustrated, for example, in the field of Alzheimer's disease. Here, animal models used in the past included unmanipulated adult animals, old rodents or non-human primates (epigenetic, unmanipulated), selectively bred strains, such as senescent-accelerated prone (SAMP) mice (genetic, unmanipulated), acute pharmacological systemic or local challenge (e.g. with scopolamine or hemicholinium-3; epigenetic, acute symptomatic manipulation), basal forebrain lesions using various toxins (epigenetic, chronic symptomatic manipulation), Aβ infusions (epigenetic, chronic causative manipulation), and APP, tau or other transgenics (genetic, chronic causative manipulation), to mention just a few. Advantages and disadvantages of these models will be addressed in the following sections.

Epigenetic Models of Dementia with Naturally Occurring Features

The Unmanipulated Adult Laboratory Rodent

Seemingly, one of the most simple and straightforward approaches to investigating the effects of manipulations on cognitive function is the use of normal, not further manipulated animals. This is standard practice, for example, when looking at the side-effect profile of a drug in a screen for drug-induced cognitive deficits. This approach has also been employed to look explicitly at cognitive enhancement, but here it makes the assumption that animals function at a suboptimal level. It is well known, however, that animals can learn to respond with high accuracy in a wide variety of cognitive tasks. Therefore, the chances of failing to see drug-induced changes due to ceiling effects, e.g. in spatial learning tasks, are high, although there are exceptions (see below).

These models primarily fulfil the characteristics of screening models as they may have predictive validity for cognitive effects of a manipulation in humans (e.g. as part of a side-effect profile of a drug), but most of them have neither face nor construct validity for human disease states associated with cognitive impairment.

A modification of this approach has been to use the naturally occurring variation amongst rodents, to segregate individuals into poor and good performers, and to then use poor performers as a model for cognitive dysfunction, e.g. to model ADHD (Puumala *et al.*, 1996; Puumala *et al.*, 1997). This approach, however, is also flawed, as it assumes either that the cognitive process under investigation is also intact in the human condition and just reflects the extreme of a normal variation, or that some laboratory rats exhibit some uncontrolled pathological features. In the absence of a clear neurobiological correlate, the construct and face validities of the independent variable of such a model must be considered poor, even if behavioural assessment is done in highly relevant paradigms with high validity of the dependent variable. Similar dissociations between good and poor performers have also been carried out in old animals, but here the deficits are also accompanied with age-related pathology (see below).

Possible exceptions to these restrictions are the latent inhibition and the prepulse inhibition (PPI) models of schizophrenia, which are also based on unmanipulated animals (see Chapter XVII-1 in this book for extensive discussions of these models). Latent inhibition is a cognitive process that refers to the detrimental effects of prior stimulus pre-exposure on subsequent conditioning to that stimulus (Lubow, 1989). PPI is a measure of sensorimotor gating and is related to the startle response, characterized by a reduction in startle amplitude following prior presentation of another stimulus of lower intensity, which is unable to elicit a response on its own (Graham, 1975). Both latent inhibition and PPI are highly conserved across species, the brain circuits are similar in animals and humans, both phenomena can be assessed in animals and humans with highly comparable methods, and both phenomena are impaired in schizophrenia (Koch, 1999; Lubow, 1989; Moser *et al.*, 2000; Swerdlow and Geyer, 1998; Weiner and Feldon, 1997).

Both phenomena may also tax comparable processes, as both latent inhibition and sensorimotor gating may serve to allocate attentional resources to relevant stimuli. Altered information processing has been viewed as a core cognitive symptom in schizophrenia (Cadenhead and Braff, 2000; Callaway and Naghdy, 1982), and this may form the basis of the latent inhibition and PPI impairments in these patients. Moreover, both latent inhibition and PPI can be potentiated in animals by antipsychotic drugs and have been claimed to have good predictive validity for antipsychotic activity in patients (Moser *et al.*, 2000; Swerdlow and Geyer, 1998; but see Depoortere *et al.*, 1997a and Depoortere *et al.*, 1997b for a different view on the predictive validity of PPI). Because of these points, both latent inhibition and PPI have also been suggested to model schizophrenia with high face and construct validity. However, this applies for the dependent variable only (i.e. for the behaviour under investigation). Assessment of latent inhibition and PPI in the otherwise not manipulated animal is of limited construct and face validity with respect to the independent variable. To model a disease process with high face and/or construct validity, it would be necessary to introduce at least some of the changes that may form the pathophysiological basis underlying the (cognitive) symptoms of that disease.

The Unmanipulated Aged Laboratory Rodent

The chances of detecting cognitive improvement following intervention are better in animals with predetermined cognitive dysfunction, i.e. in deficiency models, such as old, lesioned, transgenic or otherwise compromised animals.

Old animals have been suggested to represent good models for human aging (Barnes, 1990; Decker, 1995; Gallagher and Pelleymounter, 1988). Amongst rodents, rats have been the model of choice, but there is an increasing interest in mouse models of age-related neurobiological and behavioural function (Ingram and Jucker, 1999). Importantly, ageing is not just a function of time; there is also a clear effect of genotype interacting with age: strains differ in the vulnerability to ageing, develop different degrees of age-related behavioural, neurochemical and anatomical impairments, and show pronounced differences in longevity (Ingram and Jucker, 1999; Wyss *et al.*, 2000). This can also be seen at the behavioural level, as strains can adopt different strategies to solve a behavioural paradigm at different ages (Wyss *et al.*, 2000), which may hamper comparability of data across studies.

Often, there are individual differences within aged animal populations in both behavioural and neurochemical measures (Lee *et al.*, 1994), and it may be advisable to separate old good from poor performers as drug effects may require a deficient group (Caprioli *et al.*, 1995; Quirion *et al.*, 1995). As a caveat, however, it needs to be stressed that some of the age-related effects may be due to poorly controlled unspecific age-related confounds, such as cataracts, which impair visual acuity, cardiovascular insufficiency, thermoregulation and stress reactivity (Andrews, 1996; Lindner and Gribkoff, 1991). In particular, when it comes to drug studies, age-related changes in pharmacokinetic and pharmacodynamic parameters must be taken into consideration (Mares *et al.*, 1994; Yang *et al.*, 1984). Motivational factors have also been reported to change with age (Blokland and Raaijmakers, 1993). Moreover, aged rodents often have a very different history of housing compared with young controls, which could in principle interfere with performance. These factors need strict control as they will compromise the validity of the model.

In general, however, rodent spatial memory deficits have been suggested to constitute a good model for age-related human cognitive decline (Gallagher and Nicolle, 1993; Ingram *et al.*, 1994), and age-related impairments in spatial performance have been correlated with measures of central nervous system activity, such as cholinergic function (Dunbar *et al.*, 1993; Fischer *et al.*, 1989). Aged rodents have also been used as models of dementia, and results obtained with potential cognitive enhancers have been extrapolated rather liberally to the demented patient in the past. At face validity, it is normal ageing that is modelled in aged rats and mice. However, aged rodents do not mimic the neuropathological features of dementia. Unless one assumes a continuum between ageing and neurodegenerative disorders, such as Alzheimer's disease, then their value for the understanding of these disorders is limited to the part of the disease contributed by the aging process *per se*. This suggests that studies using aged rodents as animal models of dementia use a suboptimal model. Following this logic, it may not come as a big surprise that the literature is repleted with drugs showing cognitive enhancement in the aged animal but failing in the patient.

The aged monkey may represent a better model for dementia. In contrast to the rodent, aged non-human primates develop not only cognitive impairment but also neuropathological changes more comparable to those seen in dementia, including neuronal loss, cholinergic impairment, amyloidosis, senile plaques and tau-immunoreactive neurofibrillary tangles (Cork *et al.*, 1990; Price *et al.*, 1991; Struble *et al.*, 1982; Struble *et al.*, 1985; Walker *et al.*, 1987; Walker *et al.*, 1990). They represent a model with better face validity for dementia. However, their availability is limited for both practical (low reproductive rate, long generation time, etc.) and ethical reasons (Price *et al.*, 1998a).

Genetic Models of Dementia with Naturally Occurring Features

Breeding of selected lines of rodents has led to animals with an accelerated ageing process. Although selection of extreme phenotypes can already be considered an experimental manipulation, it is done on the basis of naturally occurring alleles, and the neurobiological and behavioural changes seen in these lines can be considered a naturally occurring feature, equivalent to a comparison between strains of rats or mice. The SAMP mouse, for example, shows an earlier and faster ageing process and earlier onset of cognitive deficits than its normal counterpart, the senescent-accelerated resistant mouse (SAMR), which ages at normal rates (Miyamoto *et al.*, 1986; Takeda *et al.*, 1981; Takeda, 1999). At least 14 SAMP inbred strains and four SAMR inbred strains have been generated on the basis of longevity, and incidence and degree of age-associated dysfunction through selective breeding from the AKR/J inbred mouse strain (Takeda, 1999). In particular, sublines SAMP-8 and SAMP-10 have been reported to show early-onset learning and memory impairments, and SAMP-10 also exhibits age-related cerebral atrophy, hippocampal cholinergic dysfunction, altered intracellular signalling (a reduction in hippocampal protein kinase C level) and hippocampal overexpression of APP (Flood and Morley, 1992; Jeong *et al.*, 1997; Markowska *et al.*, 1998; Miyamoto *et al.*, 1992; Okuyama *et al.*, 2000; Shimada, 1999; Shimada *et al.*, 1994; Takeda *et al.*, 1997). However, SAMP-8 mice also suffer from age-related changes in blood pressure (Han *et al.*, 1998) and altered emotionality (Markowska *et al.*, 1998; Miyamoto *et al.*, 1992), both of which could confound cognitive performance. SAMP mice bear the same restrictions as normally aged animals: primarily, they model ageing, not neurodegenerative disease processes, although the finding of amyloidosis in some sublines favours this model over simply aged rodents if used as a model of dementia.

Experimentally Induced Epigenetic Models of Dementia

Acute Manipulations

Drugs acting at neurotransmitter systems known or at least suggested to play an important role in neuropsychiatric disorders have been employed in a wide range of studies to mimic the neurochemical alterations seen in these disorders. Several drugs are known to impair cognitive performance in both animals and humans, and a prominent role has been attributed to the effects of cholinergic blockade.

The cholinergic hypothesis of dementia predicts that many of the cognitive deficits seen in patients are due to degeneration and consequent hypofunction of the cholinergic basal forebrain (Perry *et al.*, 1978; Perry, 1986). One of the most frequently employed drugs to mimic this hypofunction is the muscarinic antagonist scopolamine, alone or in combination with other treatments, such as nicotinic blockade or serotonergic or noradrenergic manipulations (Dawson *et al.*, 1992; Decker *et al.*, 1990; Levin *et al.*, 1991; Steckler and Sahgal, 1995). The scopolamine model has been proposed to resemble the cholinergic dysfunction seen in Alzheimer's disease (Bartus, 1978).

However, scopolamine treatment produces only some of the cognitive deficits seen in Alzheimer's disease if tested in healthy volunteers (Beatty *et al.*, 1986; Ebert and Kirch, 1998; Litvan *et al.*, 1995), and, in fact, the model may mimic the cognitive changes seen in normal ageing more closely than those seen in dementia. This is possibly not surprising, given that the neuropathological and neurochemical alterations seen in dementia encompass much more than just a cholinergic deficit. Although this can be taken into consideration by combining the scopolamine model with manipulations in other neurotransmitter systems (Decker *et al.*, 1990; Levin *et al.*, 1991; Steckler and Sahgal, 1995), there are additional limitations to the scopolamine model: for example, it can be criticized for its acute effects, while dementia is a chronically progressing disorder, which allows for compensation and other secondary changes to occur. Moreover, systemic injections of scopolamine, as is most frequently done, will affect all cholinergic systems, both centrally and peripherally. Therefore, scopolamine causes a wide range of non-specific deficits in animals, which can easily overshadow any specific effect on cognitive function.

One possibility to overcoming these non-specific effects would be to infuse scopolamine directly into selected brain areas, such as the hippocampus (e.g. Dunnett *et al.*, 1990; Ragozzino and Kesner, 1998). That way, it could be argued, one has a model at hand that, at face validity, mimics one specific aspect of dementia, namely cholinergic dysfunction. However, construct validity must be considered low as the induction of this deficit (acute, systemic, postsynaptic effects) and its mode of action (muscarinic receptor blockade) is very different from that seen in dementia (chronic, brain-specific degeneration of certain presynaptic cholinergic projections, especially those of the basal forebrain). Likewise, predictive validity is limited: numerous studies investigating potential cognitive enhancers in the scopolamine model reported stunning beneficial effects of these compounds to reverse scopolamine-induced behavioural deficits in animals, but almost all of these compounds failed at later stages of drug development (see Sarter *et al.*, 1992a and Sarter *et al.*, 1992b for overview). Part of the poor predictive validity could be the use of inappropriate behavioural tests, as will be discussed below. However, part of it might also be the limitations of the scopolamine model *per se*, which may be best suited to predicting beneficial effects of drugs developed within a cholinergic programme. Indeed, all drugs currently marketed for the treatment of Alzheimer's disease (galantamine, donepezil, rivastigmine, tacrine, idebenone) are cholinomimetics. They block acetylcholinesterase and thereby inhibit the breakdown of acetylcholine. All these drugs also show

good and possibly most consistent activity in the scopolamine model (Ballard and McAllister, 1999; Bejar *et al.*, 1999; Bores *et al.*, 1996; Chopin and Briley, 1992; Harder and Kelly, 1997; Kirkby *et al.*, 1996; Ogura *et al.*, 2000; Wang *et al.*, 2000; Yamazaki *et al.*, 1989), but this also applies to antagonism of the non-cognitive effects of scopolamine (Baraka and Harik, 1977; Dokla and Rydelek-Fitzgerald, 1991; Shannon and Peters, 1990). Of note, all these drugs represent only symptomatic improvement, and they are able to only partially improve memory and slow down further deterioration in dementia, but none of them leads to complete restitution or stops progression of the illness.

Thus, it could be argued that the scopolamine model may be a good model for hypocholinergic disease states, including ageing and dementia, but it must be realized that it does not necessarily represent a good model for the other aspects of dementia. Notwithstanding these shortcomings, the scopolamine model still enjoys popularity for evaluation of potential cognition-enhancing therapies.

The hemicholinium model also targets the cholinergic system, but it has been suggested to be of higher construct validity than the scopolamine model because hemicholinium-3 (HC-3) primarily affects presynaptic cholinergic function (Salamone, 1991). HC-3 blocks the high-affinity choline uptake into the presynaptic neuron. Compared with the ease with which many other drugs can be administered peripherally, the model is limited by the fact that it has to be administered intracerebroventricularly (ICV) or directly into the brain as it is unable to pass the blood–brain barrier. Naturally, however, ICV HC-3 also avoids the problems inherent in the peripheral administration of cholinergic antagonists. ICV HC-3 has been reported to impair attention (Muir *et al.*, 1992) and spatial learning (Hagan *et al.*, 1989, 1990), and to disrupt delayed (non)matching to position performance in rats (Andrews *et al.*, 1994; Steckler *et al.*, 1995). At least some of these deficits can be reversed with cholinomimetics (Hagan *et al.*, 1989; Hagan *et al.*, 1990). Although the hemicholinium model has a number of advantages over the scopolamine model, it will still target all cholinergic brain systems, including those that are relatively unaffected in disease states such as dementia.

Taken together, a common theme of both the scopolamine and the hemicholinium models is their attempt to acutely shift the activity in brain systems that have been suggested to be related causally to the cognitive abnormalities seen in the disease state. As such, these models already present with better face and construct validity than the naturally occurring models for neuropsychiatric disorders. However, limitations of these models are also obvious. These limitations can be reduced by refinements of the model, which improve face and construct validity further (compare peripheral versus central administration of scopolamine, or the scopolamine versus the HC-3 models). Despite these improvements, however, there is no clear evidence that these models have better predictive validity over models using unmanipulated animals.

Chronic Manipulations

Animal models of human cognitive dysfunction using chronic manipulations are, in principle, covered by two main approaches: chronic drug administration and, in particular, the huge field of lesion studies.

Probably the most frequently used chronic symptomatic model in the field of Alzheimer's disease is the cholinergic basal forebrain lesion model, especially lesions of the nucleus basalis magnocellularis (NBM), the animal homologue of the human nucleus basalis of Meynert, which lead to cholinergic cortical deafferentiation. Compared with the scopolamine and HC-3 models, these lesion models have the advantage that they are chronic, leading to region-specific degeneration of presynaptic cholinergic projections arising in the basal forebrain.

Original approaches employed electrolytic lesions (LoConte *et al.*, 1982), excitotoxic lesions with kainic acid, quisqualic acid, ibotenic acid, NMDA or α-amino-3-hydroxy-5-methyl-isoxazole-4-proprionic acid (AMPA) (Dunnett, 1985; Etherington *et al.*, 1987; Lerer *et al.*, 1985; Wenk *et al.*, 1984), or lesions induced with ethylcholine mustard aziridinium ion (AF64A) (Fisher and Hanin, 1986). However, all these approaches suffer substantial non-specific toxic damage to different degrees (Dunnett and Barth, 1991; Fibiger, 1991; McGurk *et al.*, 1987).

Lesion specificity, however, constitutes an important factor for the validity of an animal model of cholinergic dysfunction. This can be illustrated by findings that quisqualic acid lesions or lesions with AMPA, which produce more cholinergic but less non-cholinergic damage than ibotenic acid, have fewer effects on mnemonic performance than ibotenic acid in some tasks (Dunnett *et al.*, 1991; Etherington *et al.*, 1987). This indicates that there is a substantial, but unintended, non-cholinergic component that contributes to the lesion-induced deficit following administration of excitotoxins such as ibotenic acid. However, comparable behavioural effects can also be induced by the different excitotoxins under certain circumstances, despite different non-cholinergic damage. For example, Robbins *et al.* (1989) showed that ibotenic acid- and quisqualic acid-induced lesions of the NBM produced comparable effects in an attentional paradigm, which suggests that the deficit seen in this task was mediated cholinergically. This in turn suggests that the cholinergic deficit seen in dementia contributes to the attentional impairment of these patients, and that cholinergic basal forebrain lesions may have particularly good face validity as animal models of dementia in combination with attentional paradigms, but that their value can be less in combination with other types of behaviour.

More recently, the immunotoxins 192 IgG-saporin for rodents and ME 20.4 IgG-saporin for primates have been developed, which bind to the low-affinity p75 nerve growth factor receptor expressed by cholinergic basal forebrain neurons and lead to selective damage of the cholinergic basal forebrain if administered locally (Book *et al.*, 1994; Fine *et al.*, 1997; Heckers *et al.*, 1994; Wiley, 1992; Wiley *et al.*, 1991). Both immunotoxins can also be administered ICV, but this will lead to additional cerebellar damage, as Purkinje cells also express the p75 receptor (Berger-Sweeney *et al.*, 1994; Heckers *et al.*, 1994). In agreement with the findings from the more selective excitotoxic lesion studies with quisqualic acid or AMPA, the effects of 192 IgG-saporin-induced cholinergic lesions in rats are relatively subtle despite substantial cholinergic damage, but involvement of cholinergic basal forebrain projections in cognitive processes, including attentional functions, mnemonic functions and conditional learning, were clearly seen after such lesions (Fine *et al.*, 1997; McGaughy *et al.*, 1996; McGaughy *et al.*, 2000; Steckler *et al.*, 1995; Torres *et al.*, 1994; Wrenn and Wiley, 1998).

Interestingly, an upregulation of APP expression has also been reported in the cortex and hippocampus following 192 IgG-saporin lesions (Leanza, 1998; Lin *et al.*, 1998). As mentioned before, overexpression and aberrant processing of APP are key features of Alzheimer's disease. This not only adds to the face validity of the model, but also suggests that the cholinergic cortical and hippocampal projections from the basal forebrain may be required for maintenance of physiological APP levels.

The immunotoxin models have an advantage over pharmacological or other lesion models in that they selectively target those parts of the cholinergic system that also undergo degeneration in dementia. As a caveat, however, it has been noted that the cholinergic projection from the basal forebrain to the amygdala is spared following 192 IgG-saporin lesions (Heckers *et al.*, 1994), a cholinergic projection clearly affected in Alzheimer's disease (Fishman *et al.*, 1986; Shinotoh *et al.*, 2000). Moreover, some methodological issues

can contribute to variability of results, such as exact stereotactic coordinates, volume and concentration of the toxin, and hence the exact site and the degree of cholinergic depletion (Wrenn and Wiley, 1998).

In any case, the lesion models must be considered symptomatic. Do chronic causal models of Alzheimer's disease exist? An early approach trying to model the pathophysiology of Alzheimer's dementia more closely was the aluminium toxicity model. In the original study, administration of aluminium salts was shown to lead to delayed neurofibrillary degeneration in rabbits (Klatzo *et al.*, 1965), although comparable effects in rats were lacking (King *et al.*, 1975). The aluminium model was based on the hypothesis that exposure to aluminium could serve as a risk factor for the development of dementia (Rifat and Eastwood, 1994). However, the aluminium-induced tangles in animals are structurally different from those seen in Alzheimer's patients (Selkoe *et al.*, 1979), and there is accumulating evidence questioning a role for aluminium in the aetiology of dementia (Forster *et al.*, 1995; Makjanic *et al.*, 1998; Reusche *et al.*, 2001; Rifat and Eastwood, 1994). Given this more recent evidence, the aluminium model must be considered to be of low face and construct validity.

A possibly more promising approach for the development of an animal model of dementia is the infusion of β-amyloid peptides directly into the brain. The principal component of these amyloid deposits is Aβ, which is derived from proteolytic processing of APP. Two major C-terminal variants of Aβ exist (Aβ40 and Aβ42), which differ in length. Aβ42 is the principal component in amyloid plaques (Iwatsubo *et al.*, 1994). In the rat brain, intracerebral injection with Aβ40 and Aβ42 led to the formation of aggregates, with Aβ40 aggregates containing fibrillar structures similar to the amyloid fibrils seen in Alzheimer's disease (Shin *et al.*, 1997). Thus, current evidence suggests that this model has good face and construct validity. Moreover, chronic ICV infusions with Aβ peptides led to a reduction in cortical and hippocampal cholinergic activity and impaired mnemonic function (Nakamura *et al.*, 2001; Yamada *et al.*, 1998), adding further evidence in favour of this model. Alternative techniques that allow investigation of the effects of Aβ or APP in the brain include the overexpression of these peptides by adenovirus-mediated gene transfer (Masamura *et al.*, 2000; Nishimura *et al.*, 1998) or transgenesis (e.g. Holcomb *et al.*, 1998; Hsiao *et al.*, 1996; Nalbantoglu *et al.*, 1997), which leads us to the experimentally induced genetic models. In contrast, ICV administration of secreted forms of APP (APPs751 and APPs695) has been reported to enhance performance of mice tested on visual discrimination or lever-press learning tasks (Meziane *et al.*, 1998).

Experimentally Induced Genetic Models of Dementia

Experimentally induced genetic models can comprise transgenic animals, which have an extra gene added to their genome, or knockout animals, which have a selective inactivation or deletion of specific genes. Knockdown models, on the other hand, have a downregulation of the gene product following infusion of antisense oligodeoxynucleotides (ODNs) complementary to a specific sequence of mRNA, which interfere with translational processes. Moreover, genes can be transferred into brain cells using viral vectors. These models can give new insights into the pathophysiological processes underlying neurodegenerative diseases, such as Alzheimer's disease, or other disorders associated with cognitive dysfunction (Duff, 1997; Higgins and Cornell, 1995; Price *et al.*, 1998b.)

Genetic models of Aβ amyloidosis include transgenic mice that express wild-type APP, fragments of APP, mutated familiar Alzheimer APP variants or Aβ (Bronfman *et al.*, 2000; Buxbaum *et al.*, 1993; Games *et al.*, 1995; Irizarry *et al.*, 1997; Holcomb *et al.*, 1998; Hsiao *et al.*, 1996; Kammesheidt *et al.*, 1992; LaFerla *et al.*, 1995; Moran *et al.*, 1995; Nalbantoglu *et al.*, 1997; Riekkinen *et al.*, 1998). Most of these studies have focused on transgenes linked to familiar early-onset Alzheimer's disease rather than sporadic cases (Seabrook and Rosahl, 1999). The 'Swedish' mutation K670N/M671L shows primarily overproduction of Aβ40, while the mutations V717F and V717I, and the 'London' mutation V642I, result in predominance of Aβ42 (Maruyama *et al.*, 1996; Moechars *et al.*, 1999; Thinakaran *et al.*, 1996).

These models show amyloidosis and plaque formation to varying degrees. Early models failed to produce plaques, but plaque formation was achieved by using models with high enough expression of Aβ, using appropriate promoters (Games *et al.*, 1995; Hsiao *et al.*, 1996). The neuropathological features such as amyloid deposition and plaque formation develop with age, but they can be speeded up by combination with other transgenes (e.g. Holcomb *et al.*, 1998). The development of progressive neuropathology adds strongly to the face validity of these models.

APP transgenics have been studied on their own and in combination with other mutations, e.g. in the presenilin 1 (PS1) gene. Mutations of the PS1 gene have been suggested to cause up to 50% of all early-onset familiar Alzheimer's disease cases (Alzheimer's Disease Collaborative Group, 1995; Sherrington *et al.*, 1995). Several mutations that have been reported to cause Alzheimer's disease are located in the related PS2 gene (Li *et al.*, 1995; Rogaev *et al.*, 1995). Mutations in the PS1 and PS2 genes have been linked to strong deposits of Aβ42 in human brain and periphery (Lemere *et al.*, 1996; Scheuner *et al.*, 1996). Transgenic mice expressing mutated PS1 show increases in the Aβ42 : Aβ40 ratio, suggesting increased concentrations of Aβ42 (Citron *et al.*, 1997; Duff *et al.*, 1996), but they do not develop plaques. However, the amyloid deposition is enhanced in mice coexpressing PS1 and mutated APP together with dystrophic neuritis and astrocytosis (Borchelt *et al.*, 1997). Despite this strong amyloid deposition, even PS1/APP double-transgenic mice fail to show significant neurodegeneration in hippocampus or cortical areas (Takeuchi *et al.*, 2000).

Colocalization of amyloid plaques with acetylcholinesterase and dystrophic cholinergic neurites has been reported in APP transgenics (Stürchler-Pierrat *et al.*, 1997), and a reduction in size of cortical and hippocampal cholinergic boutons was observed in double-transgenic mice overexpressing APP and PS1 (Wong *et al.*, 1999). More recently, association of APP overexpression with cholinergic deafferentiation and cholinergic cell shrinkage has been shown in the 'London' mutation (Bronfman *et al.*, 2000). This indicates that these transgenic models show not only the amyloidosis associated with Alzheimer's disease but also the cholinergic dysfunction. Together with findings that APP expression is upregulated following basal forebrain lesions (Leanza, 1998; Lin *et al.*, 1998), one could speculate about a self-perpetuating circle in which amyloidosis leads to cholinergic damage, which enhances amyloidosis further.

Although a number of different Aβ amyloidosis and PS1 transgenics have been developed, cognitive testing has centred around a handful of paradigms, most frequently the water-maze place-navigation task. The limited number of behavioural tests is one of the major drawbacks of the transgenic approach compared with the rat experiments. In general, the deficits seen in these mutants have been reported to be age related (Arendash *et al.*, 2001; Berger-Sweeney *et al.*, 1999; Chapman *et al.*, 1999; Moran *et al.*, 1995; Morgan *et al.*, 2000), thus having the advantage over previously discussed models that cognitive alterations also develop gradually. Some studies have linked the memory deficits seen in these mice with the accumulation of amyloid in the brain (Arendash *et al.*, 2001; Dodard *et al.*, 2000; Gordon *et al.*, 2001; Hsiao *et al.*, 1996), while others have described performance deficits in memory tasks without the occurrence of amyloid deposition (Dodard *et al.*, 1999; D'Hooge *et al.*, 1996; Holcomb *et al.*, 1999; Kumar-Singh *et al.*, 2000; Moechars *et al.*, 1999; Yamaguchi *et al.*, 1991). A

few studies have also used more extensive test batteries and were able to dissociate the deficit seen in these mutants further. For example, Arendash *et al.* (2001) reported impaired circular or radial water-maze acquisition, but spared water-maze retention, circular platform performance, and Y-maze alternation in transgenic animals overexpressing APP and PS1. However, impairments in sensorimotor performance (Arendash *et al.*, 2001; Tremml *et al.*, 1998), increased stress responsivity and hypoglycaemia (Pedersen *et al.*, 1999), altered aggression, neophobia (Moechars *et al.*, 1998), and reduced exploratory activity (Tremml *et al.*, 1998) have also been reported in some APP or PS1/APP double-transgenic lines. This indicates the need to clearly dissociate mnemonic and non-mnemonic alterations in APP transgenics, a goal that can be difficult to achieve using some of the standard murine paradigms for testing cognitive function, as will be discussed below.

Moreover, APP transgenic mice do not develop tau filaments, another hallmark of Alzheimer's disease (Games *et al.*, 1995). Although no mutation has been identified in the tau gene in Alzheimer's disease, mutations of this gene in frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) have shown that dysfunction of tau can also lead to dementia and neurodegeneration (Hutton *et al.*, 1998). Transgenic mice expressing different human tau isoforms or tau mutations have been developed (Brion *et al.*, 1999; Götz *et al.*, 1995; Ishihara *et al.*, 1999; Lewis *et al.*, 2000; Probst *et al.*, 2000; Spittaels *et al.*, 1999). Mice carrying tau mutations develop neurofibrillary tangles (Lewis *et al.*, 2000; Lewis *et al.*, 2001) but instead lack other features of Alzheimer's disease, such as amyloidosis. Therefore, Aβ amyloidosis/tau double-transgenics represent an interesting extension of this approach. More recently, such mice were generated and indeed show both features of Alzheimer's disease (Lewis *et al.*, 2001). However, overexpression of tau results in motor deficits, peripheral neuropathy and muscle atrophy in transgenic mice (Ishihara *et al.*, 1999; Lewis *et al.*, 2000; Probst *et al.*, 2000; Spittaels *et al.*, 1999), which renders cognitive testing difficult.

An important genetic risk factor for Alzheimer's disease is the ε4 allele of apolipoprotein E (ApoE) (Corder *et al.*, 1993; Strittmatter *et al.*, 1993). Evidence from ApoE-expressing transgenic and ApoE-lacking knockout mice suggests that ApoE directly influences Aβ deposition in the brain and facilitates the formation of neuritic and cerebrovascular plaques (Bales *et al.*, 1997; Holtzman *et al.*, 1999; Holtzman *et al.*, 2000). Hartman *et al.* (2001) reported that transgenic mice expressing the ApoE4 isoform display deficits in a working-memory radial-arm maze task, while no deficits were seen in water-maze place navigation. Moreover, these mice were described as being 'emotionally more reactive'. Some ApoE4 transgenics have also been reported to develop motor problems, which can be accompanied by muscle wasting, loss of body weight, and premature death (Huber *et al.*, 2000; Tesseur *et al.*, 2000). This again suggests that potential non-specific confounding factors must be controlled strictly when cognitive function is assessed in these mutants.

Despite these shortcomings, mouse mutants with amyloidosis, tau or ApoE4 overexpression must be considered the animal models of dementia with the highest face and construct validities. At present, not enough data have been generated to draw conclusions about the predictive validity of these models, but recent reports are encouraging, showing that immunization with Aβ not only causes a marked reduction in brain amyloid deposits, but also reduces learning deficits in APP transgenic mice (Janus *et al.*, 2000; Morgan *et al.*, 2000). However, it appears feasible to improve the validity of this model even more by using behavioural paradigms that allow a more rigorous control of the different factors that govern performance in cognitive tasks, and that more readily tax those cognitive processes that are affected in dementia (Steckler, 1999; see discussion below).

A number of general issues remain to be addressed when it comes to experimentally induced genetic models, such as the genetic background and flanking genes (Gerlai, 1996; Gerlai, 2001). For example, some mouse strains are characterized by poor visual abilities, poor cognitive function or hypoactivity. Using such strains as background strains to generate a mutation that is expected to cause cognitive impairment asks for problems, as the features of the background strain can interfere with performance on the cognitive task. This has certainly been neglected in some studies in the past. Some of the behavioural alterations seen in conventionally generated mutant mice may be due to peripheral rather than central effects of the transgene. Using brain-specific promoters to generate conditional mutants will reduce this problem. Finally, compensatory processes may take place that could also interact with the effects of a genetic manipulation, although this may be less of a problem for the Alzheimer's disease models discussed above, as here many features develop gradually with age.

Models of Psychosis and Depression Associated with Cognitive Dysfunction

As discussed already, there is evidence for good predictive validity in the latent inhibition and PPI models of schizophrenia using unmanipulated animals, but this is a quality of the dependent, not independent, variables. The next question to address is whether models based on experimental manipulations are any better. Acute drug manipulations have been used to model the latent inhibition deficits seen in schizophrenia (see Chapter XVII-1 of this book for more extensive discussion). Latent inhibition, for example, is impaired by amphetamine; this impairment can be attenuated by antipsychotic drugs (Moran *et al.*, 1996; Moser *et al.*, 1996; Moser *et al.*, 2000; Warburton *et al.*, 1994; Weiner *et al.*, 1994; Weiner *et al.*, 1995; Weiner *et al.*, 1996). Apomorphine- or PCP-induced sensorimotor gating deficits in the prepulse inhibition model of schizophrenia have also been attenuated by antipsychotics (Geyer, 1998; Martinez *et al.*, 2000; Swerdlow *et al.*, 1996). All these models target neurotransmitter systems that might play important roles in schizophrenia (dopamine and glutamate). Hence, the amphetamine, apomorphine and PCP models of latent inhibition impairment are clearly of higher face validity than the latent inhibition models employing normal animals, although predictive validity may be comparable.

The neonatal hippocampus-lesioned rat represents a lesion model of schizophrenia that has gained increasing interest over recent years (Lipska *et al.*, 1993). Neonatal hippocampal lesions not only lead to PPI impairment (Le Pen *et al.*, 2000; Lipska *et al.*, 1995), but also impair avoidance performance and spatial learning and memory when animals are tested as adults (Chambers *et al.*, 1996; Le Pen *et al.*, 2000).

The Flinders sensitive (FSL) rat has been proposed as a model of depression on the basis of its reduced locomotor activity, passive coping strategies in forced swimming, reduced body weight, increased REM sleep, and passive avoidance deficits (Overstreet, 1986; Shiromani *et al.*, 1988; see Chapter XVIII-1 in this book for an extensive discussion of animal models of depression). FSL rats have been generated by genetic selection. Two rat lines were bred to be either sensitive or resistant to pharmacological manipulation of cholinergic activity (Overstreet *et al.*, 1986), with the FSL rats being hypersensitive to cholinergic agonists. However, changes in hypothalamic-pituitary-adrenal (HPA) axis regulation seen in the FSL animals differ markedly from the alterations seen in human depression (Holsboer, 1999), which questions the face validity of this model. Interestingly, no accuracy differences were seen between FSL and their control line, the Flinders resistant (FRL) rats, in an operant delayed matching-to-position/visual discrimination task or in a radial-arm maze paradigm, although

FSL rats responded more slowly than the other rats during acquisition of both tasks. Abnormal performance has been reported in comparable human paradigms in depressed patients, in particular with increasing age (Abas *et al.*, 1990; Deldin *et al.*, 2001; Freedman, 1994; Purcell *et al.*, 1997; Sweeney *et al.*, 2000). Cognitive performance of FSL rats also failed to show altered sensitivity to cholinergic blockade (Bushnell *et al.*, 1995), which is surprising given that these animals were bred explicitly for different sensitivity to cholinergic manipulation and that cholinergic blockade has clear effects on mnemonic function. These limited data sets suggest that the FSL rat is not a good model for the cognitive changes seen in depressed patients.

Furthermore, some transgenic mice have been suggested to resemble changes seen in depression. Functional abnormality of the HPA axis is one of the most prominent features of depression, including impaired mineralocorticoid receptor function, restrained glucocorticoid receptor feedback, raised plasma cortisol level, and increased corticotropin-releasing hormone (CRH) activity. Normalization of the neuroendocrine abnormalities seems to be a prerequisite for stable remission in depressed patients (Steckler *et al.*, 1999a). One possibility to model these changes is the use of mouse mutants with altered HPA axis activity, which show a range of neuroendocrine and behavioural alterations comparable to those seen in depression.

Mice overproducing CRH have been reported to be impaired in forced choice alternation and water-maze place-navigation learning. The place-navigation deficit was attenuated by the benzodiazepine chlordiazepoxide (CDP). However, since CDP has both amnesic and anxiolytic actions, it can be suggested that the place-navigation deficit is possibly confounded by heightened anxiety or overarousal (Heinrichs *et al.*, 1996).

Mutants expressing a glucocorticoid receptor antisense construct show an abnormal response in the dexamethasone suppression test (Barden *et al.*, 1997) and altered stress responses that can be normalized with antidepressant treatment (Montkowski *et al.*, 1995; Steckler *et al.*, 1999a). Spatial allocentric, but not egocentric, learning is impaired in these mice (Rousse *et al.*, 1997; Steckler *et al.*, 1999b; 2001). Moreover, glucocorticoid receptor antisense transgenics exhibited altered impulsive behaviour besides an accuracy deficit in an operant two-choice visual discrimination task (Steckler *et al.*, 2000). However, these animals also display increased dopaminergic system activity compared with controls (Cyr *et al.*, 2001; Sillaber *et al.*, 1998), which might be a major contributor to the performance deficits seen in these mice.

Clearly, many other mutants exist that have been proposed as animal models of human psychiatric and neurological disorders and that show cognitive alterations (Campbell and Gold, 1996; Gold, 1996; Picciotto and Wickman, 1998; Steckler, 2001b). A discussion of all these models is beyond the scope of this chapter.

Another approach that needs to be addressed and that differs fundamentally from the models discussed so far is the use of early developmental manipulations. Here, the animals are manipulated early in life, leading to a number of long-lasting molecular changes that persist into adulthood (Meaney *et al.*, 1995; Steckler, 2001b). These early-life stress models have been used to model both depression and psychosis (the importance of the models for schizophrenia or depression has been suggested to depend at least in part on the exact timing of stress exposure within the early development of the animal). Prenatal or post-natal stress (e.g. maternal deprivation) or social isolation shortly after weaning have been shown to lead to a range of cognitive deficits (Cilia *et al.*, 2001; Ellenbroek and Cools, 2000; Geyer *et al.*, 1993; Jones *et al.*, 1991; Lapiz *et al.*, 2001; Lehmann *et al.*, 1999; Matthews *et al.*, 1996; Oitzl *et al.*, 2000; Rao *et al.*, 1999; Stevens *et al.*, 1997).

These models deserve acknowledgement as they show important cognitive abnormalities that may be used to model the cognitive impairments seen in depression and psychosis.

Models of Attention Deficit Hyperactivity Disorder

A genetic model of ADHD, originating from selective breeding, is the spontaneously hypertensive rat (SHR) (Sagvolden *et al.*, 1992). ADHD is a disorder characterized by inattention, hyperactivity and heightened impulsivity (Sagvolden and Sergeant, 1998). SHR rats were established in 1963 from the Wistar–Kyoto (WKY) outbred strain, but the original selection process focused on hypertension rather than an animal model for ADHD (Okamoto, 1969). Only later was it discovered that SHR rats display hyperactivity, may show attentional deficits, and may be more sensitive to immediate reinforcement, which can be improved with methylphenidate, a common treatment of ADHD (Sagvolden *et al.*, 1992).

ADHD has been suggested to result from dysfunction in reinforcement mechanisms, which may involve mesolimbic catecholaminergic projections (Sagvolden and Archer, 1989; Sagvolden *et al.*, 1998), and allelic polymorphisms for the genes encoding for the dopamine transporter and the dopamine D_4 receptor have been reported in ADHD (Amara, 1993; Swanson *et al.*, 2000). Indeed, changes in dopaminergic activity have also been reported in the SHR rat. Dopaminergic activity is decreased in the frontal cortex of SHR rats when compared with normotensive WKY control rats (Myers *et al.*, 1981; Russell *et al.*, 1998; Russell *et al.*, 2000), while noradrenergic activity is increased (Russell *et al.*, 2000). However, these changes in dopaminergic activity seem to be unrelated to dopamine transporter function (Russell *et al.*, 1998). Moreover, in *in vitro* slice preparations, methylphenidate, which is a standard treatment in children with ADHD, is less potent in inducing dopamine release in prefrontal cortex, accumbens and caudate-putamen from SHR rats compared with slices from WKY rats, while amphetamine is more potent (Russell *et al.*, 1998), i.e. different rank orders in potency were seen with the two drugs in SHR and WKY rats. Since both methylphenidate and amphetamine are used to treat ADHD (Solanto, 1998), both drugs should affect dopaminergic activity in similar directions and to a comparable degree in the SHR model. In addition, amphetamine induces hyperactivity in SHR rats, which is even more pronounced than in WKY rats (McCarthy *et al.*, 1980; Van den Buuse and De Jong, 1989), although amphetamine decreases activity in children with ADHD. These findings led Russell *et al.* (1998) to conclude that the SHR rat 'may not be a perfect model for ADHD'. Adding to this view, Bull *et al.* (2000) also failed to see impaired performance in SHR rats responding on a task of impulsivity, the differential low rate (DRL) 60s schedule. The failure of SHR rats to be more impaired on this task than WKY rats again suggests that the SHR rat is limited as a model for ADHD. Moreover, part of the cognitive deficits seen in SHR rats can be attenuated by antihypertensive treatment (Wyss *et al.*, 1992), indicating that secondary changes induced by increased blood pressure contribute to the effects seen in this model — physiological changes that are not described in ADHD.

Other genetic ADHD models with naturally occurring features are the WKHA rat, an inbred strain developed in the 1970s from the SHR rat, which is normotensive and differs in some neurochemical and behavioural features. Importantly, there is evidence for increased, not reduced, mesocortical dopaminergic activity at the frontal cortex level, at least in female WKHA rats (Hendley, 2000) and behavioural differences include better habituation of the hyperactive response following repeated exposure to an environment in WKHA than in SHR rats (Hendley, 2000). The opposite response would be predicted from a model of ADHD.

The Naples high excitability rat has also been proposed as an ADHD model (Gonzalez-Lima and Sadile, 2000). This rat originates from selective breeding for high activity on spatial tasks. Furthermore, the acallosal inbred mouse strain I/LnJ, which shows a complete penetrance of corpus callosum agenesis, has been considered to be a model for ADHD (Magara *et al.*, 2000). In particular,

Table XV-1.1 Validity of some animal models of cognitive dysfunction focusing on the independent variable

—, (+), +, ++, +++, grades of validity of the model with respect to disease. Note that the predictive validity focuses on cognitive performance only; this will be influenced at least in part by the behavioural paradigm used. ?, no, or no sufficient, data. BF, basal forebrain; PS, presenilin.

acallosal mice have been suggested to model the defective interhemispheric cross-talk that may play a role in ADHD. They show limited evidence for impaired learning, impulsivity and hyperactivity (Magara *et al.*, 2000). However, data are too limited at the moment, and WKHA rats, Naples rats and I/LnJ mice warrant further investigations to prove their utility as animal models of ADHD.

Overview of Animal Models of Cognitive Disorders

Table XV-1.1 provides a summary of the models discussed so far. It is evident that these models differ primarily in their face and construct validity. Predictive validity in general must be considered relatively poor for various reasons. Some models have been tested with a limited range of standard drugs only, where the desired effect was seen but it is too early to conclude from the effects of newer compounds with activity in these models whether these drugs are also active in the clinic. Some models show a high number of false positive results (see the scopolamine model of dementia), while others (e.g. Aβ infusions) have not been tested sufficiently. It is also obvious that there are a number of models at hand with high face and construct validity.

MEASURING IN THE MODEL: A DISCUSSION OF THE DEPENDENT VARIABLES

Whatever the principle of a model, it must be realized that an animal model of human cognitive function can only be as good as it is possible to assess cognition in the animal or to predict cognitive effects in humans from the animal model. Therefore, it is of utmost importance to define a given psychological process and to break down these criteria into components testable in animals (van der Staay and Steckler, 2002).

Animal Cognition is not a Unitary Process

First, it must be acknowledged that different types of cognitive function can be distinguished not only in humans but also in animals. These cognitive processes may entail all processes involved in animal learning, such as discrimination, attention, executive functions, association, encoding, storage, rehearsal, retrieval and response selection. Although intelligence and logic can be subsumed under the heading cognition, this is not part of the definition as used here, as these processes are very difficult to measure in

animals (Steckler, 2001a). Thus, we are faced with processes that may in part run sequentially (e.g. encoding, storage/consolidation, retrieval), in parallel, or possibly in reverberating loops. There is a qualitative component, and different forms of, for example, attention and memory can be distinguished, some of them involving very different brain circuits. There is also a quantitative component, and tasks of different complexity will demand different degrees of processing capacity, and hence will be differentially sensitive to manipulation. Furthermore, these processes are dynamic and will change over time as a result of experience, and more extensive training may result into a shift from more effortful processing to more automatic processing of information (Hasher and Zacks, 1979; Sarter, 1990), both of which will again show different sensitivity to manipulation.

These processes are influenced by non-specific factors, such as stimulus processing, reward-related properties and/or motor output, and it is important for data interpretation to be able to distinguish clearly these non-specific factors from the specific cognitive processes under investigation (Steckler, 1999; Steckler, 2001a).

Measurement of Disease-Relevant Types of Behaviour

Mnemonic Abilities

One frequently employed distinction of mnemonic processes is that between declarative (effortful) and procedural (automatic) processes. In humans, declarative memory includes higher-order processes, such as memory for facts (semantic memory) and memory for events (episodic memory), while procedural memory includes habituation, sensitization and simple classical conditioning. As already pointed out, patients suffering from Alzheimer's disease do not have a non-specific memory decline, but exhibit pronounced declarative memory impairments, while procedural memory is preserved (Brandt and Rich, 1995). Consequently, behavioural paradigms used to test cognitive function in animal models of dementia should also tax declarative-like, not procedural-like, memory in the animal. Concurrent discrimination, for example, is impaired in temporal lobe and diencephalic amnesia (Zola-Morgan and Squire, 1989), and comparable processes can be studied in rats, in which animals are required to learn a number of discriminations simultaneously (Aggleton *et al.*, 1991; Bussey *et al.*, 1994; Rothblat *et al.*, 1993; Wible *et al.*, 1992).

Another frequently employed type of paradigm in humans as well as in rats comprises delayed (non-)matching paradigms, which assess recognition or recency memory (Steckler *et al.*, 1998). In general, subjects have to remember a sample over a certain retention interval, followed by a choice between two or more choice stimuli, one being identical with the previous sample, the other being novel or less recent. A correct matching response constitutes a response to the choice stimulus that matches the sample; a correct non-matching response would be a response to the other stimulus. Two major variants of these tasks can be distinguished: delayed response and delayed comparison, taxing different types of memory and being differentially susceptible to mediating strategies (Pontecorvo *et al.*, 1996; Steckler *et al.*, 1998). In delayed-response tasks, all the information the animal needs to perform correctly is available before the onset of the retention interval. In delayed-comparison paradigms, the information of where to respond is available to the animal only after the delay is over and the comparison stimuli are presented. Therefore, the risk of mediating strategies is higher in delayed-response tasks. Rats have been shown frequently to master both delayed-response and delayed-comparison procedures, and more recently, comparable maze-based and operant procedures have been described for mice (Beracochea and Jaffard, 1999; Cho and Jaffard, 1994; Estape and Steckler, 2001; Steckler *et al.*, 1999b; Ward *et al.*, 2001), which could be of great potential for testing transgenic mouse models of Alzheimer's disease. Moreover, these methods are ideally suited for further analysis using methods such as the mathematical methods of signal detection theory, which allow a distinction between accuracy and bias (Marston, 1996; Pontecorvo *et al.*, 1996; Sahgal, 1987; Steckler, 2001a). These tasks also allow us to study retention of information over time, i.e. a forgetting curve. The slope of this forgetting curve provides information about the mnemonic ability of the subject. Moreover, the tight control of stimulus and response contingencies enables fine-tuning of the procedural parameters, which can help to dissociate further the cognitive processes that may be affected in the model (Steckler *et al.*, 1998; Van Hest and Steckler, 1996).

The Morris water maze is also frequently employed to study the spatial orientation and memory deficit seen in Alzheimer's disease. In particular, for the assessment of mouse mutants, this task has become the gold standard (see the discussion on transgenic models of Alzheimer's disease, above). In this task, a rodent has to swim in a water tank and find an escape platform submerged under the surface of the water. The platform always remains in a stable spatial position relative to extramaze cues surrounding the maze (place navigation). To control for non-specific effects, the most frequently employed control situation is a so-called cue-navigation task, in which the animal can directly see the platform, and which therefore should not require spatial navigation. However, it has been pointed out that not only mnemonic, but also motor, motivational, perceptual and other cognitive factors, such as altered arousal or attention, can influence water-maze performance, and that a deficit in the place-navigation task in combination with intact cue navigation does not allow us to draw conclusions about spatial memory (Steckler, 1999). For example, the latency to find the hidden platform can be confounded easily by motor deficits (Huerta *et al.*, 1996). A motor deficit may not necessarily become apparent in the cued-navigation task, as animals can find the visual platform more easily than the hidden one, therefore they swim less and may be less exhausted. Place navigation involves not only a spatial but also a non-spatial learning component (knowing that there is a hidden platform). Moreover, often superimposed on spatial navigation are search strategies that contribute to performance (Hodges, 1996). Therefore, the so-called probe trial, where the platform is removed and the animal explores the maze freely in search for the platform, is considered by some authors to be more sensitive. A preference for the previous platform location is taken as indication for spatial learning. However, an impairment during the probe trial does not exclude the possibility that this impairment is due to non-specific factors that interfered with performance during the acquisition stage. For example, it has been shown that lesions of the dorsal noradrenergic bundle alter maze performance if rats are tested in cold water, but leave performance unaffected if tested in warm water (Selden *et al.*, 1990), suggesting that anxiogenic and stressful features of the test can influence maze performance. Clearly, animals that are impaired during acquisition due to altered stress responses are likely to be impaired during the probe trial as well. All these factors must be considered when using the water maze (or any other learning and memory paradigm) if the dependent variable of the model should remain valid. It can be concluded that the water maze is a useful paradigm for testing spatial learning and memory in rodents, especially mice, but unfortunately the potential confounding factors often seem to be neglected.

An alternative water-maze paradigm that has been used in both rats and mice is a two-choice spatial-discrimination task, in which animals have to make a choice between two visible platforms. Neither platform can be distinguished on the basis of visual features, but must be discriminated on the basis of spatial cues. One platform is stable, while the other sinks if the animal tries to climb on to it (Arns *et al.*, 1999; Morris *et al.*, 1986; Steckler *et al.*, 1999b). This task allows a dissociation between errors of commission (choice of sinking platform) and errors of omission (no choice of platform at all). This distinction gains relevance from the fact that maze

navigation may be impaired by non-specific factors. Introduction of a choice reduces the influence of these confounds because a probability serves as the critical variable (Arns *et al.*, 1999).

The need to pay attention to investigating mnemonic processes analogous to the cognitive symptoms observed in dementia is often forgotten too easily, which can be illustrated with the example of the passive avoidance paradigm. In passive avoidance, the attempt of an animal to move from one place to another in a test chamber is punished by foot shock. Upon re-exposure to the test chamber without shock, the animal will refrain from executing that movement, given that an association between the place or the movement and the shock had been formed. The time interval from beginning of re-exposure to reinstatement of the response is generally taken as an indicator of memory retention. Many non-specific factors will confound performance on this task, such as pain threshold, motor function and emotionality. Moreover, the type of memory involved in performing such a task may be fundamentally different from the memory impaired in dementia (Steckler and Muir, 1996). Despite these shortcomings, passive avoidance has been, and is being, used rather uncritically as one of the most popular tasks to study rodent animal models of dementia, as validity aspects were widely neglected (Sarter *et al.*, 1992b).

Clearly, when it comes to face and construct validity, paradigms such as delayed (non-)matching paradigms or concurrent discrimination paradigms are more advanced. However, whether they show superior predictive validity remains to be proven, given that all we have to treat Alzheimer's disease patients are cholinomimetics such as galantamine, donepezil, rivastigmine, tacrine and idebenone.

Attentional Function

Another feature of Alzheimer's disease is an attentional and executive dysfunction, in particular in divided attention but also in selective attention (Coslett and Saffran, 1996; Morris, 1996). Different types of attention, such as vigilance/sustained attention, divided attention and selective attention, can also be modelled in the rat (Bushnell, 1998; Muir, 1996; Robbins, 1998; Sarter and Bushnell, 1995; Steckler and Muir, 1996). Tasks bearing good face validity with human tasks of divided attention have been described for rats (McGaughy *et al.*, 1994). In the paradigm used by McGaughy *et al.*, animals were tested in a conditional discrimination paradigm, where they had to discriminate between constant/flashing lights or constant/pulsing tones, the to-be-attended modality being unpredictable for a given trial. Animals were required to respond to one of two levers if a constant light or a pulsing tone was presented, and to respond to the other lever if a flashing light or a constant tone occurred.

Related to the ability to divide attention to stimuli from different modalities is the ability to shift attention either within dimensions (intradimensional shift) or between dimensions (extradimensional shift). Initial studies reported intra- and extradimensional set shifting in rats (Schwartz *et al.*, 1971; Shepp and Eimas, 1964), but only recently was a dissociation between rule-shifting and true shifting of an attentional set in rats achieved (Birrell and Brown, 2000). Here, rats were trained to dig for reward in bowls, which had to be selected on the basis of odour, filling medium, or the texture that covered its surface. Rats had to perform a series of discriminations, including reversals, intradimensional shifts and extradimensional shifts. For intradimensional set shifting, they had to learn a new discrimination within a sensory dimension (e.g. olfaction); for extradimensional set shifting, they were also required to shift between sensory dimensions (e.g. from odour to filling medium). This task bears resemblance to the Wisconsin Card Sorting Test, and could also be useful for the assessment of cognitive functions in animal models of both dementia and schizophrenia.

Selective attention paradigms have also been described for rats (Carli *et al.*, 1983; Cole and Robbins, 1987; Muir *et al.*, 1992) using paradigms that resemble those used in humans (Wilkinson, 1963). In these paradigms, at least two stimuli are employed, with one stimulus serving as a distractor that should be ignored (e.g. a burst of white noise), while the animal has to attend to the relevant stimulus signalling reinforcement. Selective attention has been shown to be impaired following manipulation of the noradrenergic system (Carli *et al.*, 1983; Cole and Robbins, 1987).

Clearly, tasks such as latent inhibition can also be subsumed under this category, as a deficit to attend selectively to the relevant stimulus during the initial stage of the task will interfere with learning during the final stages of the task. However, it can be difficult to dissociate an attentional impairment from other factors, e.g. impaired learning, in this paradigm.

Moreover, tasks measuring sustained attention have been developed for rats and, more recently, mice (Carli *et al.*, 1983; Humby *et al.*, 1999; Marston *et al.*, 2001; McGaughy and Sarter, 1995; McGaughy *et al.*, 1996; Muir *et al.*, 1992; Robbins *et al.*, 1989; Sahgal and Steckler, 1994), some of which also bear strong resemblance to human paradigms of sustained attention (Sahakian *et al.*, 1993). In the five-choice serial reaction time task, rats or mice have to monitor an arc of five holes, one of which is illuminated by a short-lasting light stimulus of less than one second; the animal has to nose poke into that hole in order to get reward (Humby *et al.*, 1999; Marston *et al.*, 2001; Muir *et al.*, 1992; Robbins *et al.*, 1989). This task has been shown, for example, to be highly sensitive to cholinergic drugs and lesions, and both impairment and enhancement of performance have been demonstrated (Grottick and Higgins, 2000; Humby *et al.*, 1999; Mirza and Bright, 2001; Mirza and Stolerman, 1998; Muir *et al.*, 1992; Robbins *et al.*, 1989).

Other Cognitive Functions

Besides mnemonic and attentional functions, there is a range of other cognitive types of behaviour that have been described to undergo changes in certain forms of dementia, such as impulsivity (Lindau *et al.*, 1998) or timing behaviour (Cummings, 1986); these types of behaviour can also be modelled in the animal (Bizot and Thiebot, 1996; Bull *et al.*, 2000; Evenden, 1999a; Evenden, 1999b; Harrison *et al.*, 1997; Meck, 1996; Meck and Church, 1987; Paule *et al.*, 1999; Puumala *et al.*, 1996). In fact, assessing these types of behaviour may be even more relevant in animal models of other psychiatric disorders, such as ADHD, where increased impulsivity is a key symptom (American Psychiatric Association, 1994; Sagvolden and Sergeant, 1998).

Testing Cognitive Function

The final point to address is how to best test cognitive function in an animal. It has been argued that most information may be gained if animals are tested in species-typical societies in natural environments (Gerlai and Clayton, 1999; Würbel, 2002). Although this idea has its merits, the argument is flawed as it remains unclear what constitutes a naturalistic environment for a laboratory animal, e.g. for a transgenic mouse with altered genetic information. Therefore, a natural environment must be considered to be as artificial as every other environmental setting. Moreover, it has been argued that such 'natural' environments are defined less precisely and hence are less amenable to standardization and comparison (Van der Staay and Steckler, 2002). To have a valid animal model (of cognitive disorders), however, it is of utmost relevance to have tasks at hand that, irrespective of the degree of ecological relevance, allow a clear-cut dissociation between the behaviour of interest (e.g. cognitive function) and non-specific factors. It is a basic requirement to be able to differentiate between different types and stages of cognitive function (Steckler, 1999). Only then can we address the relevant questions, using models that tax disease-relevant types of cognitive function and that are comparable

between humans and animals. These are essential prerequisites to improving face and construct and, possibly, the predictive validity of animal models of cognitive disorders.

ANIMAL MODELS OF COGNITIVE DISORDERS: SUMMARY

Over recent years, there has been tremendous development in the field of animal models of cognitive dysfunction, which is probably most advanced in the field of Alzheimer's disease. Models in this area have developed from rather unspecific approaches, such as old animals, progressing to more theory-driven models with improved, though not sufficient, face and construct validity, such as basal forebrain-lesioned animals, and advancing to transgenic models.

Clearly, recent developments, such as the generation of double-transgenic mice, indicate that we have not reached the end of this process, and further improvements are possible. At the same time, there are a number of good behavioural paradigms available to model the cognitive impairment seen in various human disorders. Those are based primarily on work with rats, but murine equivalents are emerging. Importantly, it must be realized that any animal simulation model of cognitive dysfunction is only as good as the cognitive processes measured in the animal. If this does not reflect human cognitive processes accurately, then the value of the data is negligible. This situation changes if one considers screening or mechanistic models, but the ultimate proof will be in models of the simulation type. It is this combination between models with high validity at the level of the independent variable and high validity at the behavioural level that can be expected to advance this field most dramatically and to improve predictive validity and the development of novel treatment strategies for neuropsychiatric disorders associated with cognitive deficits.

Aminergic Transmitter Systems in Cognitive Disorders

John P. Bruno and Martin Sarter

INTRODUCTION

The major categories of cognitive disorders defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) include various types of dementias, deliriums, and amnestic disorders (American Psychiatric Association, 2000). The goal of this chapter is to present a thorough, but certainly not exhaustive, summary of the evidence for dysregulations in aminergic neurotransmitter systems in several representative cognitive disorders. Aminergic transmitter systems include the biogenic amine acetylcholine (ACh), the catecholamines dopamine, noradrenaline and adrenaline, and the indoleamine serotonin (5-hydroxytryptamine; 5-HT). For a more detailed discussion of the neuropharmacology and chemoanatomy of aminergic transmitter systems, the reader is referred to Chapter IV of this book.

Not surprisingly, there is considerable variation in the extent of the literature on the neurochemical dysregulations accompanying delirium, dementia and amnestic disorders. The scope of our review will be limited to several syndromes for which there is considerable evidence implicating specific aminergic transmitter systems to these cognitive disorders. Thus, the discussion of the dementias will be limited to dementia of the Alzheimer's type (DAT) and AIDS-associated dementia (AAD). The discussion of amnestic disorders will be limited to those that accompany chronic alcohol consumption (Korsakoff's syndrome) or administration of the psychostimulant 3,4-Methylenedioxymethamphetamine (MDMA; ecstasy). Finally, the discussion of delirium will focus on the ability of several drugs or toxins to impair aminergic function. This chapter will focus exclusively on clinical populations. However, valuable corroborating evidence for links between certain cognitive dysfunctions and specific aminergic populations can be found in various animal models of these cognitive disorders. Several of these models are discussed in other chapters within this book.

An important issue that permeates any summary and interpretation of the neurochemical dysfunctions accompanying neuropsychiatric disorders is the considerable variation in the methods used to collect such data, and the relative strength of inferences supported by these various methods. A review of the literature reveals neurochemical data collected from post-mortem tissue, biopsy tissue, analysis of cerebrospinal fluid (CSF), neuroimaging techniques with transmitter-selective markers, and finally a 'reverse deduction' on the basis of drug effects (therapeutic or abused). There are obvious limitations to constructing hypotheses about the neurochemical bases of complex cognitive disorders on the basis of each of these types of data. Several of these methods lack the spatial resolution for highlighting regional contributions within distributed neural systems and, more importantly, rarely capture the dynamics and subtleties of chemotransmission likely to be at the heart of many cognitive disorders. As such, the overinterpretation of negative data (i.e., seemingly intact neurotransmitter systems in neuropsychiatric populations) is particularly problematic. In this regard, the use of animal models with more precise neurochemical methods can be invaluable in formulating and testing hypotheses about the neurochemical bases of cognitive disorders (see Chapter III in this book). Throughout this chapter, we will point out the source of the neurochemical evidence supporting the relationship between dysregulation in the aminergic system and the cognitive disorder, along with any concerns surrounding the interpretation of such evidence.

Of course, simply documenting a specific neurochemical impairment in a patient diagnosed with a cognitive disorder is not sufficient evidence to conclude a causal relationship between the neurochemical deficit and the cognitive construct. Extending these correlations into the realm of causality is a difficult task, particularly when it comes to clinical populations. The primary strategy for probing the causal relationship between two variables is to manipulate levels of one of the variables and look for systematic changes in the other variable. While this can be done readily in experimental animals, and in fact should be a critical component of any animal model of neuropsychiatric condition, this is often difficult to achieve in clinical populations. Certainly one can examine, either between subjects or, ideally, within subjects, whether the cognitive impairments worsen as markers of the neurochemical pathology become more severe (i.e., with time since onset in a neurodegenerative condition). A second strategy, and one that is often used in studies of the biological bases of disease, is a type of *post hoc* logic in which the causal relationship between neurochemical pathology and symptom is inferred on the basis of the effectiveness of pharmacotherapeutics. This, however, can be a risky strategy and may lead to both false positives (i.e., the drug does not interact directly with neurochemical systems that are necessary and sufficient for the disease but rather modulates the activity of these systems) and false negatives (i.e., the drug affects the critical neurochemical systems but does not 'replicate', in sufficient physiological fashion, signal processing within this damaged system). We will identify in this chapter those few situations in which such strong relationships exist between the degree of neurochemical dysfunction and the cognitive symptoms.

DEMENTIAS

The DSM-IV defines dementia as a syndrome of multiple cognitive deficits that include memory impairments and at least one of the following: aphasia, apraxia, agnosia and disturbances in executive functions (American Psychiatric Association, 2000). The memory impairment is a necessary feature of the diagnosis, progressing from an early presentation of difficulty in learning new material to eventually an inability to remember previously learned material (memory). The impairments in executive function are related to disorders of the frontal lobe and involve the ability to think abstractly and to plan, initiate, sequence, monitor and inhibit

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

complex behaviour. These cognitive deficits must represent a marked decline from a previous level of functioning, and must also be severe enough to cause significant impairment in social or occupational functioning. There are a number of dementia syndromes, including DAT, frontal lobe dementia (DFL), vascular dementia, dementia of the Lewy Body type (LBD), AAD, dementia associated with Huntington's disease, dementia associated with Pick's disease, dementia due to other general medical conditions, and substance-induced persisting dementia. The two dementias that have received the most attention with respect to possible roles of aminergic transmitter systems are DAT and AAD. Each of these syndromes will be discussed below.

Dementia of the Alzheimer's Type

The search for a neurochemical basis of DAT began in earnest almost 40 years ago with the hope that such an identification would lead to the development of effective pharmacotherapies. This exploration was fuelled by the identification of a dopaminergic component to Parkinson's disease and the ensuing success of L-Dopa-based 'replacement pharmacotherapy'. Over the ensuing decades, a great deal of evidence has revealed aminergic dysfunctions in DAT (summarized below). Unfortunately, the development of efficacious pharmacotherapies for DAT has not met with the same degree of success as seen in the treatment of Parkinson's disease. This probably reflects the fact that a simple replacement strategy designed to elevate tonic levels of deficient neurotransmitters (e.g., ACh), borrowed from our experience with Parkinson's disease, is inconsistent with the normal functions of such systems in information processing (see Sarter and Bruno, 1997, Sarter and Bruno, 1998 and Sarter and Bruno, 1999 for a discussion of this issue).

Most of the attention on the neurochemical bases of dementia has focused on DAT. This is the result of two observations. First, while certainly not homogeneous in nature, DAT reveals the most consistent profile of neurochemical dysregulations of any of the dementias. Second, the cognitive deficits in DAT correlate best with the reduction in various markers of cholinergic transmission (Francis *et al.*, 1985; Lehericy *et al.*, 1993), and the prominent focus on pharmacotherapeutics has occupied considerable attention (Lawrence and Sahakian, 1998; Rogers and Friedhoff, 1996; Sahakian *et al.*, 1989; Sahakian *et al.*, 1993). In addition to deficits in cortical cholinergic transmission, the literature reveals clear and consistent reductions in markers of adrenergic, serotonergic and, to a lesser degree, dopaminergic transmission in DAT. An overview of these findings appears below.

Cholinergic Systems in Alzheimer's Dementia

The earliest and most consistent neurochemical abnormalities to appear in the brains of DAT occur in the cholinergic system. The decline in cholinergic transmission is not uniform throughout the brain. There are significant reductions in the basal forebrain cholinergic system, where there is estimated to be a 30–90% loss of neurons with no loss in other cholinergic-rich areas, particularly the brainstem (Mesulam, 1996). This loss of neurons manifests itself in a reduction in the biosynthetic enzyme choline acetyltransferase (ChAT) in temporal lobes and more moderate reductions in frontal lobes. Biopsy studies suggest that the decline in cortical ChAT activity can occur within 1 year of the onset of clinical signs (Bowen *et al.*, 1983). Consistent with the loss of basal forebrain neurons is an accompanying reduction in the density of (presumably presynaptic) nicotinic receptors in the cortex and parahippocampal gyrus, as measured post-mortem (Perry *et al.*, 1995) and *in vivo* with positron emission tomography (PET) (Nordberg, 1996).

A recent study investigated the relationship between declines in nicotinic receptor (nAChR) binding and vesicular ACh transport sites (vesamicol binding), using autoradiographic methods, in medial temporal cortex in DAT (Sihver *et al.*, 1999). In age-matched controls, binding was particularly high in layers I, III and V. Autopsied tissue analysis revealed that binding was reduced in all layers in DAT by 40–55%. While the loss of nAChR binding correlated well with the reduction in ChAT activity, vesamicol binding was reduced by only 25%, suggesting some compensatory activity within residual cholinergic terminals.

The basis for the selective vulnerability of basal forebrain cholinergic neurons, as opposed to other populations of cholinergic neurons, remains unclear. Autoradiographic studies demonstrate the presence of high-affinity ^{125}I-NGF binding sites (presumably corresponding to tyrosine kinase A, TrkA) in the nucleus basalis of meynert (nMB) and striatum but not in the pedunculopontine nucleus. Immunohistochemical studies have revealed TrkA expression on nBM and the cholinergic interneurons of the striatum. This supports the hypothesis that there is a relationship between the dependence upon NGF and the neuronal vulnerability in DAT. In DAT, the number of neurons expressing TrkA was decreased in nBM, likely as a result of cholinergic neuronal loss (Boissiere *et al.*, 1997). While neither NGF levels or mRNA are altered in DAT, there may still be more subtle problems with receptor function/transduction.

As with any other neurodegenerative disease, early detection is an important goal. The ability to develop an *in vivo* imaging protocol for revealing cholinergic denervation is viewed as paramount in this quest (Volkow *et al.*, 2001). ChAT, the most specific marker expressed by cholinergic neurons, does not have an available tracer for imaging studies. Recently, however, a tracer, C-11-labelled *N*-methyl-4-piperidyl-acetate (C-11-MP4A), has been developed for the catabolic enzyme acetylcholinesterase (AChE). The use of this tracer has revealed that AChE activity is reduced in DAT (Herholz *et al.*, 2000; Kuhl *et al.*, 1999; Geuia and Mesulam, 1996), and that this reduction correlates well with reductions in regional cerebral blood flow or glucose metabolism, particularly in temporolateral regions of the cortex (Herholz *et al.*, 2000).

Finally, it should be stated that the functional consequences of a loss of cortical cholinergic innervation need not be limited to direct changes in interneuronal communication. A double immunocytochemical study for ChAT and reduced nicotinic adenine diphosphate (NADPH) (as a marker for nitric oxide) revealed inputs to cortical microcirculation (Vaucher and Hamel, 1995), raising the possibility that cholinergic denervation will also result in inadequate cortical perfusion. In fact, cortical microvascular abnormalities appear to be related intimately to the pathophysiology of the disease. Regional cholinergic denervation and NADPH have been reported in cortical microvessels in DAT. Moreover, the deficits in cortical perfusion parallel the regional differences in cortical cholinergic denervation (i.e., temporal regions are more affected than primary motor and somatosensory regions). These changes raise the interesting possibility that the cholinergic denervation may compromise the ability to adapt enhanced cortical perfusion to neuronal activity associated with tasks related to arousal and attention (Tong and Hamel, 1999).

Noradrenergic/Adrenergic Systems in Alzheimer's Dementia

There are consistent changes in noradrenergic and, to a lesser extent, adrenergic systems in DAT. The progressive loss of noradrenergic neurons in the locus coeruleus has been documented using post-mortem as well as biopsy tissue samples (see Mann, 1988 for a review). In contrast to the loss of cortical cholinergic inputs discussed above, there is little relationship between the extent of loss of noradrenaline in the locus coeruleus and the cognitive deficits seen in DAT (Palmer *et al.*, 1987a; Palmer *et al.*, 1987b; Palmer and DeKosky, 1993). These losses in noradrenaline may, however, contribute to important noncognitive behavioural

impairments that accompany the syndrome, such as depression and wandering (Zubenko and Moossy, 1988). These noncognitive components represent a disturbing set of complications that contribute to patient suffering, care giver stress and health costs, particularly as these complications may expedite the institutionalization of victims of DAT.

The loss of noradrenergic neurons in the locus coeruleus results in reduced noradrenergic innervation of the cortex. Noradrenaline levels and high-affinity [^{3}H]noradrenaline uptake are consistently reduced in the temporal and parietal cortex. Interestingly, these changes in noradrenaline uptake are seen in patients that have displayed clinical symptoms for less than 2 years, suggesting that such dysfunctions occur rather early in the course of the disease (Palmer *et al.*, 1987a).

The mechanisms underlying the loss of noradrenergic neurons in the locus coeruleus in DAT are not well understood. Recently, it has been speculated that this loss reflects the accumulation of an endogenous neurotoxic compound in DAT. In this regard, a recent study compared levels of the neurotoxic monoamine oxidase A (MAO-A) metabolite of noradrenaline, 3,4-dihydroxyphenylglycolalderhyde (DOPEGAL), in post-mortem tissue samples from DAT victims and age-matched controls (Burke *et al.*, 1999). The authors reported a 2.8–3.6-fold increase, relative to that seen in controls, in DOPEGAL levels in the locus coeruleus from DAT tissue.

As mentioned above for cortical ACh, there is some speculation that compensatory increases in noradrenergic transmission might accompany the loss of noradrenergic neurons in the locus coereleus in DAT. There are higher levels of noradrenaline in the CSF in ageing and in DAT (Raskind *et al.*, 1999). A priori, such increases could reflect increased release of noradrenaline and/or decreased metabolism and clearance. This issue was addressed by comparing the ability of the α_2 antagonist yohimbine to increase noradrenaline release levels in the CSF of young adult controls and DAT patients. Administration of yohimbine led to greater levels of noradrenaline in the CSF in DAT patients than in young controls, consistent with the capacity for greater synthesis/release of noradrenaline following the neuronal loss accompanying the dementia (Raskind *et al.*, 1999).

Post-mortem analyses of adrenergic receptors reveal changes in both number and affinity in DAT. Receptor binding of α_1 (postsynaptic), using [^{3}H]prazosin, revealed a 50% reduction in B_{max} and affinity in the hippocampus with no change in the frontal cortex or nBM. The loss of α_1 sites probably reflects a loss of receptors on glutamatergic neurons. In contrast, receptor binding of α_2 (presynaptic), using [^{3}H]yohimbine, revealed a 50% reduction in B_{max} and a 66% reduction in affinity in nBM, with no changes in the hippocampus or frontal cortex (Shimohama *et al.*, 1986). The loss of α_2 sites may represent the loss of noradrenergic inputs from the locus coeruleus to the basal forebrain. Theoretically, declines in this input could contribute to the cognitive deficits seen in DAT as α_2 receptor activity may positively modulate ACh release in the hippocampus and cortex (Tellez *et al.*, 1999).

There is also evidence indicating changes in brainstem adrenergic systems in DAT. The biosynthetic enzyme phenylethanolamine-*N*-methyl transferase (PNMT) exhibits a progressive loss (50–88%) in the locus coeruleus, frontal cortex, hippocampus and amygdala (all areas with significant neuronal degeneration) but not in the cerebellum or motor cortex (areas with little neuronal degeneration). This pattern has led to the hypothesis that the loss of adrenaline-containing neurons is secondary to some initial degeneration of target neurons and the consequent loss of growth factors that might be critical for the induction of synthetic enzymes within the afferent neurons (Burke *et al.*, 1988). Interestingly, the loss of locus coereleus neurons correlated positively ($r = 0.71$) with the loss of PNMT activity. There was an accompanying loss of mitogenic activity, as measured by brain-derived growth factor (BDGF), consistent with the hypothesized loss of growth factors. Moreover, while there was a significant reduction in PNMT staining in afferents adjacent to the degenerating neurons, there was no change in PNMT staining in projections adjacent to intact blood vessels.

Serotonergic Systems and Alzheimer's Dementia

Although somewhat more variable than the effects seen in adrenergic systems, there are several reports indicating widespread serotonergic dysfunctions in DAT. There is also some suggestion that these impairments may occur relatively early in the disease (Bowen *et al.*, 1983; Palmer *et al.*, 1987c). As is the case with decreases in adrenergic transmission, however, there is little evidence that changes in serotonergic transmission contribute significantly to the cognitive deficits seen in DAT. Rather, dysfunctions in serotonergic transmission are likely to contribute to the affective disorders that accompany DAT (Court and Perry, 1991). Post-mortem analyses reveal significant reductions in 5-HT levels in the frontal cortex (Arai *et al.*, 1984; D'Amato *et al.*, 1987; Palmer *et al.*, 1987b), temporal cortex (Palmer *et al.*, 1987c), hippocampus (Cross *et al.*, 1984), hypothalamus (Sparks *et al.*, 1988), nucleus basalis Meynert (Sparks *et al.*, 1992) and basal ganglia (Sparks *et al.*, 1988). Reductions in the levels of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of 5-HT metabolism, and the number of 5-HT reuptake sites in the cortex (Palmer *et al.*, 1987a) are consistent with the interpretation that there is a loss of serotonergic innervation to the cortex. These autopsy studies have been corroborated by ante-mortem data showing reduced concentrations of 5-HT and 5-HIAA, as well as diminished 5-HT uptake (Palmer *et al.*, 1987b). This decline in presynaptic indices of serotonergic transmission is paralleled by a reduction (30–40%) in the number of 5-HT-positive neurons in the median and dorsal raphe nuclei (Chen *et al.*, 2000).

The mechanisms underlying these reductions in markers of serotonergic transmission are unclear. In this regard, several studies have investigated the relationship between the decline in these markers and more traditional neuropathologies seen in DAT. There is a negative correlation between the number of tangles and 5-HT or 5-HIAA content in the cortex from biopsy tissue samples (Palmer *et al.*, 1987a). Neurofibrillary tangles also appear within the dorsal and medial raphe, but the magnitude of the loss of raphe neurons does not correlate with the density of tangles (Chen *et al.*, 2000).

As is the case with the noradrenergic systems described above, strong evidence supporting a relationship between declines in serotonergic transmission and the cognitive impairments seen in DAT is not available. Declines in cortical and basal forebrain 5-HT content could impact on cortical cholinergic function and, hence, certain cognitive functions. There are clear indications in the animal literature for a 5-HT_2 (Zhelyazkova-Savova *et al.*, 1997) and a 5-HT_4 (Consolo *et al.*, 1994) receptor-mediated release of cortical ACh. On these grounds, the impact of drugs that affect serotonergic transmission on cognitive function in DAT merits additional study.

A role for the deficits in 5-HT function in the agitation syndrome seen in DAT has been substantiated. A recent study examined the relationship between levels of 5-HT activity and the degree of agitation in a group of DAT patients (Mintzer *et al.*, 1998). 5-HT activity was assessed using fenfluramine (an indirect 5-HT agonist) -induced serum prolactin. DAT patients with and without accompanying agitation were challenged with an oral dose of fenfluramine (60 mg). Increases in serum prolactin were larger in the agitated than in the non-agitated group. Moreover, within the agitated group, there was a positive correlation between the degree of agitation and the increase in serum prolactin.

Dopaminergic Systems in Alzheimer's Disease

Changes in the dopaminergic systems in Alzheimer's disease differ from those seen in the cholinergic and noradrenergic systems

in two important ways. First, changes in the dopaminergic systems are more variable than those reported for the other two classes of aminergic transmitter systems. Second, to the extent that there are dysfunctions, changes in the dopaminergic systems appear to be more localized to changes in dopaminergic receptors rather than dopaminergic innervation to critical target regions. Post-mortem concentrations of dopamine have been found repeatedly to be unaltered in the cerebral cortex of patients with DAT (Palmer and DeKosky, 1993). This result has been corroborated with ante-mortem diagnostic craniotomies for dopamine, dihydroxyphenylacetic acid (DOPAC), and homovanillic acid (HVA) levels (Palmer *et al.*, 1987b), although there is a report of reduced levels of HVA and HVA/dopamine ratios from the CSF in DAT (Reinikainen *et al.*, 1990).

Much of the focus on the role of the mesolimbic and mesocortical dopaminergic systems and DAT has been fuelled by the observation that up to 80% of patients with Parkinson's disease manifest some signs of dementia (Brown and Marsden, 1984). Likewise, extrapyramidal motor dysfunctions have been reported in 20–80% of DAT patients (Merello *et al.*, 1994). Caution must be exercised not to overinterpret these data to suggest that the involvement of the striatal dopaminergic system is similar in the two diseases. While one PET study using ^{18}F-fluorodopa revealed no evidence for dysfunction of dopaminergic terminals in DAT patients with parkinsonian features, others have reported markers of degeneration of nigrostriatal systems (see Leverenz and Sumi, 1986). A recent single-photon positron emission tomography (SPET) study compared the specific striatal uptake of the D2 receptor ligand [I-123]*S*-3-iodo-*N*-(1-ethyl-2-pyrolidinyl)methyl-2-hydroxy-6-methoxybenzamide ([^{123}I]-IBZM) in DAT patients without extrapyramidal symptoms with age-matched controls to test the hypothesis that alterations in striatal dopamine may actually be part of a profile in DAT independent of any parkinsonian symptomatology (Pizzolato *et al.*, 1996). The DAT patients exhibited a decrease in D2 receptor ligand binding relative to the controls. The source of this reduced binding cannot be determined from this particular study; reductions could be at the level of cholinergic interneurons, corticostriatal terminals and/or striatopallidal projections.

Joyce and colleagues (1993) have conducted a series of autoradiographic studies on the density and pattern of D2 receptors in post-mortem tissue from subjects with DAT using the highly selective ligand [^{125}I]epidepride. These studies focused on two structures within the medial temporal lobe: the hippocampus (molecular layer of the dentate gyrus) and the amygdala (basolateral area). The binding studies revealed a modular organization of D2 receptors in rostral and mid-levels of temporal cortex (i.e., higher-order association cortex) with high densities in the dentate gyrus, CA3 and subiculum. There is a loss of these modules in tissue from DAT subjects (Joyce *et al.*, 1998). Interestingly, those areas that are affected most by the formation of more traditional neuropathologies (i.e., plaques and tangles) are the regions that appear to be losing the D2 receptor binding. Those regions exhibiting diminished D2 receptor binding also show a reduction in the number of pyramidal neurons staining for D2 mRNA. There was no evidence for a reduced dopaminergic innervation to the hippocampus as measured by changes in the expression of tyrosine hydroxylase.

Dysfunctions in D2 receptor activity in DAT have prompted investigations of a possible relationship between the D2 receptor gene (DRD2), the A1 allele and Alzheimer's disease (Pizzolato *et al.*, 1996; Small *et al.*, 1997). These studies have addressed the hypothesis that the A1 allele, like the APOE4 allele, is a major risk factor in late-onset DAT. The A1 allele is associated with reduced DRD2 binding sites as well as reduced visuospatial function and prolonged P300 latencies, characteristics of DAT. While still an intriguing hypothesis, the initial study found that the A1 allele does not contribute to risk for DAT either alone or in combination with the APOE4 allele. The study also demonstrated that the A1 allele that contains the gene that codes for the DRD2 decreases significantly with ageing in both DAT patients and in controls (Small *et al.*, 1997). Thus, we must be careful to include age-matched controls in future studies exploring relationships between the A1 allele and risk for DAT.

AIDS-Associated Dementia

The pandemic of HIV-1 infection has evolved into a worldwide problem with a preferential affliction of younger adults and children. It has been estimated conservatively that roughly 7–14% of adult HIV-infected people will eventually experience a syndrome of moderate to severe cognitive deficits known as AAD. This dementia presents with attentional impairments, memory deficits and reduced alertness (Sarter and Podell, 2000). In addition, AAD has all the hallmarks of a subcortical dementia, in that there is little evidence for cortical disconnection syndromes (and the attendant apraxias, agnosias, aphasias). It is accompanied, on the other hand, by psychomotor slowing, bradykinesia, and altered posture and gait, mimicking advanced Parkinson's disease (Berger and Arendt, 2000).

The pathophysiology of AAD has remained somewhat elusive. The specification of the underlying neuropathologies, which are undoubtedly complex and multifactorial, is made difficult by the fact that neurons are not infected directly by HIV; rather, it is thought that infected non-neuronal cells secrete diffusable toxic substances (Sarter and Podell, 2000). Two brain regions that appear to be affected preferentially in AAD are the frontal lobes and the basal ganglia (Hall *et al.*, 1996). Radiological data support correlations between tissue loss in the basal ganglia and whether HIV-positive patients are presenting with or without dementia. Children that present with AAD show extensive calcification within the basal ganglia (Berger and Nath, 1997). There is also diminished regional cerebral blood flow (rCBF) in the basal ganglia in patients presenting with AAD (Berger and Arendt, 2000).

The involvement of the dopaminergic system in AAD was suggested early on by the observation that patients were extremely sensitive to the extrapyramidal side effects of dopamine receptor blockers (Berger and Arendt, 2000; Nath *et al.*, 2000). This heightened sensitivity is suggestive of decreased dopamine receptor activity, a scenario similar to that seen in Parkinson's disease. In this regard, stereological studies reveal decreased (25%) neuronal density in SN_{pc}, but without the presence of Lewy bodies as is typically seen in Parkinson's disease. This reduction in neuronal density may be driven by the viral nuclear regulatory protein *Tat*. Preclinical studies in rats demonstrate that intraventricular injections of *Tat* result in oxidative stress in the striatum (Aksenov *et al.*, 2001) and ultimately produce apoptotic cells predominantly in basal ganglia (see Berger and Nath, 1997). Moreover, dopamine-related drugs of abuse (i.e., amphetamine and cocaine) may synergize with viral proteins such as *Tat* to produce enhanced neurotoxicity (Nath *et al.*, 2000). While there is a trend towards lowered concentrations of dopamine and HVA from the caudate at autopsy in AIDS patients relative to controls, these differences become more pronounced and statistically significant if one focuses exclusively on those AIDS patients who manifested dementia (Sardar *et al.*, 1996). These data are also supported by less direct measures of diminished CSF HVA levels in seropositive subjects and preliminary observations suggesting a trend towards a correlation between the decrease in HVA levels and cognitive deficits (Sardar *et al.*, 1996).

MEMORY DISORDERS

The disorders contained within the 'Amnestic disorders' category of the DSM-IV (American Psychiatric Association, 2000) are

characterized by a disturbance in memory that is due to either the direct physiological effects of a general medical condition or the persisting effects of a substance (e.g., a medication, a drug of abuse, or exposure to a toxin). Individuals with amnestic disorders are impaired in their ability to learn new information or are unable to recall previously learned information or past events. These deficits are seen most readily on tasks that require spontaneous recall; they may also become apparent when the person is required to recall stimuli presented at some earlier time. Amnestic disorders may be preceded by an evolving clinical picture that includes disorientation and confusion, and thus the differential diagnosis between delirium and an emerging amnestic disorder merits caution (American Psychiatric Association, 2000).

In this section, we will examine two substance-induced memory disorders. First, we will discuss alcohol-induced persisting amnestic disorder (Korsakoff's syndrome) that is apparently due to the vitamin deficiency associated with prolonged, heavy ingestion of alcohol (Fadda and Rossetti, 1998). While the neuropathology accompanying this syndrome is complex, there is significant evidence for impaired noradrenergic transmission in this amnestic disorder. Second, we will review evidence for a significant and long-lasting memory deficit associated with repeated administration of the illicit recreational drug MDMA (ecstasy). The preclinical and, to a lesser extent, clinical literature indicates that this drug is neurotoxic for serotonergic nerve terminals and collectively raises the possibility that this amnestic syndrome is related to decreases in this aminergic system.

Korsakoff's Syndrome

Korsakoff's syndrome (or disease or psychosis) represents the chronic amnesic phase of the Wernicke–Korsakoff syndrome. The outstanding clinical feature of this amnesia is a selective and permanent anterograde memory loss (McEntee and Mair, 1990; Squire and McKee, 1993) with accompanying impairments in learning. Neuropsychometric data reveal that as a group, Korsakoff patients have average intellectual capabilities (as measured by Wechsler Adult Intelligence Scale (WAIS) IQ) but severe memory impairments, as revealed by the WAIS and Wechsler Memory Scale (WMS). Korsakoff's syndrome is associated with a thiamine deficiency that is secondary to the nutritional deficiencies of alcoholics. Long-lasting alcohol abuse is not a necessary condition, as Korsakoff's syndrome has also been reported in nutritionally depleted non-alcoholics (McEntee and Mair, 1990; Victor *et al.*, 1989).

The syndrome presents with a very characteristic midline diencephalic and brainstem neuropathology. Post-mortem studies reveal small punctate lesions in the periventricular region (along the walls and floor of the third and fourth ventricles) and the periaqueductual regions of the brainstem and diencephalon. There is often, but not always, damage to the mediodorsal nucleus (MDN) of the thalamus and the mammillary bodies (see McEntee and Mair, 1990 for a review). There is a significant amount of controversy surrounding the necessary and sufficient neuropathologies for the amnesic syndrome. Mammillary body lesions are present in most cases, and the frequency of this pathology has led to the speculation that it is a critical condition for the amnesic syndrome. However, there are several cases of such lesions without an accompanying amnesia, suggesting that damage to mammillary bodies may not be sufficient for the syndrome (see McEntee and Mair, 1990 for a discussion of this issue). Others (e.g., Victor *et al.*, 1989) have suggested that lesions of the MDN are crucial for the memory impairments (Markowitsch, 1988). However, there are reported cases of Korsakoff patients with amnesia yet no MDN lesions (although these patients had significant lesions of the mammillary bodies). Thus, it may be that damage to either the MDN or the mammillary bodies is necessary for the memory deficits.

Three observations have prompted a great deal of speculation about the neurochemical basis of Korsakoff's syndrome. First, a number of aminergic systems course through or near the sites of these brain lesions (Fadda and Rossetti, 1998). Second, there is a long history of animal research demonstrating memory impairments following lesions or pharmacological manipulations that disrupt aminergic systems (see Mair and McEntee, 1983 for a discussion of this literature). Finally, there are preclinical neurochemical data demonstrating that conditions of thiamine deficiency can result in altered precursor transport, synthesis and turnover in several aminergic systems (see Witt, 1985, for a review).

Adrenergic Transmission and Korsakoff's Syndrome

The greatest focus on the aminergic components of Korsakoff's amnesia has been directed toward the brainstem locus coeruleus system and noradrenergic projections to the telencephalon. While several reports indicate diminished noradrenergic transmission in Korsakoff's syndrome, the data are by no means consistent. CSF levels of the noradrenaline metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) were reported to be reduced (by 41%) in a large group of Korsakoff's syndrome patients, even when corrected for plasma MHPG concentrations. Importantly, the reductions in MHPG from the CSF correlated with the degree of memory impairments (McEntee *et al.*, 1984). The nucleolar volume of the locus coeruleus (a measure of activity within locus coeruleus neurons) was found to be reduced in the locus coereleus, and post-mortem levels of noradrenaline were diminished in the locus coeruleus and target regions, such as the supraoptic and paraventricular nuclei (Mayes *et al.*, 1988). As was the case with CSF levels of MHPG, the reductions in nucleolar volume in the locus coeruleus were greatest in those patients who were most amnestic.

There are, however, several studies that are not consistent with these findings. Martin *et al.* (1984) did not observe any change in CSF MHPG levels, nor did they find a correlation between MHPG levels and memory function when a larger sample size was studied. More recently, Halliday *et al.* (1992) conducted a quantitative study of locus coeruleus integrity comparing four 'uncomplicated' alcoholics with nine Korsakoff's syndrome patients. The authors report no group differences in the number, morphology or distribution of pigmented locus coeruleus neurons. Moreover, the analysis of locus coeruleus neuronal number reveals a rather marked variability within the control group (standard deviation 20%) and a significant ageing-related decline in neuronal counts. Thus, it may be premature to attribute the source of reductions of presynaptic markers of noradrenergic transmission to a loss of neuronal number within the locus coeruleus. While it would appear that cell loss within the locus coeruleus does not account for the amnesia seen in Korsakoff's syndrome, it still remains possible that other, more subtle changes in adrenergic transmission are critical to the symptoms of this disease. The sources of variation among these collective studies are considerable and may contribute to the inconsistency of findings. First, the various neuroanatomical and neurochemical measures utilized in these studies (nucleolar volume of locus coeruleus, number of locus coeruleus neurons, morphology of locus coeruleus neurons, CSF metabolite levels, post-mortem noradrenaline tissue levels) differ in their capacity to reveal physiologically meaningful alterations in noradrenergic transmission. Second, there is significant variation in the sample sizes in these studies. Given the inherent variability of neuropathology in human disease, studies with considerable differences in sample size will be expected to have very different statistical powers for revealing effects. Finally, the discussion above regarding the profile and distribution of lesions in Korsakoff's syndrome does not support a uniform neuropathology, thus there may be multiple variants of this syndrome that are reflected in differential contributions of particular aminergic systems.

Cholinergic Transmission and Korsakoff's Syndrome

The potential role of dysfunction in cholinergic transmission in Korsakoff's amnesia has received significant attention and is justified by several observations. First, cholinergic blockade in healthy subjects produces memory impairments (Kopelman and Corn, 1988). Second, as described earlier in this chapter, there is a significant correlation between the well-established memory deficits and various markers of impaired cholinergic transmission in Alzheimer's dementia (Francis *et al.*, 1985). This raises the possibility that other syndromes characterized by memory deficits are mediated by dysregulations in cholinergic transmission. Third, basal forebrain lesions accompanying certain vascular insults are accompanied by memory impairments (Damasio *et al.*, 1985). Finally, biochemical data suggest that thiamine deficiency can eventually result in diminished levels of acetyl Cheyney A (acetyl CoA) and reduced turnover of ACh (Barclay *et al.*, 1981; Witt, 1985).

A more direct link between the basal forebrain cholinergic system and Korsakoff's syndrome has been suggested by the observation of a significant reduction (47%) of the number of magnocellular neurons (presumably cholinergic) within the nucleus basalis of Meynert in autopsied brains from three patients (Arendt *et al.*, 1983). However, reductions in basal forebrain neurons in Korsakoff's disease are not reported consistently. Mayes *et al.* (1988) conducted a series of post-mortem morphometric measurements on basal forebrain cholinergic nuclei from patients diagnosed with Korsakoff's before death. They report no reduction in number or nucleolar volume of basalis neurons, although the authors comment on the fact that many of these neurons were shrunken and exhibited a loss of Nissl substance. A more recent and complete analysis compared basal forebrain magnocellular neurons among controls, alcoholics, Wernicke's encephalopathy patients who did not present with amnesia, and Wernicke's patients who later developed a classical Korsakoff's amnesia (Cullen *et al.*, 1997). Cell number (Ch4 cholinergic neurons) did not differ significantly between non-alcoholic controls and alcoholics. Ch4 cell number in the Wernicke's encephalopathy group was modestly but significantly reduced (24%) below control levels. However, cell number was comparably reduced (21%) in the Wernicke's group that developed Korsakoff's syndrome. The authors conclude that nucleus basalis neurons are lost in thiamine-deficient alcoholic patients, but that cell loss is relatively minor and does not account for the profound memory disorder seen in Korsakoff's syndrome. Furthermore, they raise the interesting possibility that this loss in Ch4 cell number might contribute to attentional dysfunctions seen in both Wernicke and Korsakoff patients.

Serotonergic Transmission and Korsakoff's Syndrome

An early study on serotonergic transmission in Korsakoff's syndrome reported abnormally low levels of the 5-HT metabolite 5-HIAA (21% decrease) in some but not all patients (McEntee *et al.*, 1984). Halliday *et al.* (1992) utilized more direct immunohistochemical techniques to compare the number of 5-HT-positive raphe neurons in alcoholics that manifested Korsakoff's syndrome with those that did not. While they report a significant (50%) reduction in the number of 5-HT-positive neurons, this value was similar in both groups of alcoholics. The relative contribution of alcohol toxicity versus thiamine deficiency on serotonergic neurons in the median raphe nucleus was addressed in a more recent report from their laboratory (Baker *et al.*, 1996). The authors report no difference between the number of 5-HT neurons in alcoholics without Korsakoff's syndrome and age-matched controls. However, there was a substantial loss (nearly 70%) of serotonergic neurons in brains from previously diagnosed Korsakoff's patients. These data suggest that the cell loss in the raphe reflects the thiamine deficiency rather than the effects of alcohol *per se*.

Dopaminergic Transmission and Korsakoff's Syndrome

The roles of mesocortical and mesolimbic dopaminergic systems in the memory disorders associated with Korsakoff's syndrome have received little attention. This is somewhat surprising given the observation that chronic alcohol consumption is associated with reductions in rCBF and glucose metabolism in medial frontal lobe (Adams *et al.*, 1993), and that dopaminergic systems exert important modulatory influences on cognitive activity mediated by frontocortical neurons (Dolan *et al.*, 1995). One study reported significant reductions (23%) in CSF levels of the dopamine metabolite HVA in Korsakoff's patients (McEntee *et al.*, 1984). However, these results were not seen consistently in all patients and, unlike several of the reports with the noradrenaline metabolite MHPG, did not correlate strongly with memory impairments.

As discussed earlier, the therapeutic efficacy of drugs with relatively selective actions on specific transmitter systems can provide insights into the contributions, in this case, of aminergic systems to the memory disorders associated with Korsakoff's syndrome. The therapeutic agents studied most extensively for the treatment of Korsakoff's amnesia have been drugs that affect the monoamines, noradrenaline, dopamine and serotonin. McEntee and Mair (1990) compared the effects of twice-daily oral administrations of clonidine (an α_2 noradrenaline agonist), amphetamine (an indirect monoaminergic agonist), L-dopa (an indirect monoaminergic agonist) and adrenaline (an α noradrenaline agonist, with weak amphetamine-like actions) on memory performance in a small population of Korsakoff's syndrome patients. Clonidine treatment produced significant improvement, compared with placebo, on several items on the Wechsler memory scale (memory passages, visual reproduction). A single photon emission computerized tomography (SPECT) imaging study tested the hypothesis that frontal lobe function would be increased by clonidine-induced adrenoreceptor stimulation, and that the ability of clonidine to increase metabolic activity would correlate with the drug's ability to enhance memory function (Moffoot *et al.*, 1994). The acute administration of clonidine increased performance on a verbal fluency task, although this effect was variable and not always distinguishable from the effect of placebo. Nevertheless, the increase in neuropsychological performance was correlated with the increased metabolic activity in the left dorsolateral frontal cortex and, to a lesser extent, in the posterior cingulate cortex and thalamus. However, a clinical trial with a larger group of subjects was unable to demonstrate a therapeutic effect of clonidine (O'Carroll *et al.*, 1993). McEntee and colleagues report smaller, less consistent effects with amphetamine (McEntee and Mair, 1990) and ephedrine (Mair and McEntee, 1986). Similar therapeutic effects on a verbal recall test were seen in six Korsakoff's syndrome patients following a week-long administration of the indirect adrenergic agonist methylphenidate (O'Donnell *et al.*, 1986). The effects of these adrenergic agonists must be viewed cautiously, however, as it is possible that drug-induced changes in attentional processing might account for some of the antiamnesic effects of the drugs (McEntee and Mair, 1990). Finally, a possible role for dysfunctions in serotonergic transmission in Korsakoff's amnesia is supported by a study demonstrating that the 5-HT uptake inhibitor fluvoxamine enhanced memory in a small group of patients. Interestingly, the reported improvements of fluvoxamine correlated with the reductions in the CSF levels of the 5-HT metabolite 5-HIAA (Martin *et al.*, 1989).

MDMA-Induced Memory Deficits

Recreational usage of the illicit drug MDMA first became highly visible in the mid-1980s. Its consumption has evolved worldwide so dramatically since then that it poses serious health risks. Demonstrations of MDMA-induced selective impairment in memory coupled

with suggestions of neurotoxicological damage (particularly to brain serotonin systems) suggest that repeated consumption of MDMA promises to be seen increasingly as a diagnostic group in the future.

Consumption of MDMA is associated with profound effects on mood. Users generally report feelings of elation, energy, confidence and enhanced sociability while on the drug. The period of withdrawal is associated with feelings of depression, lethargy and irritability (Curran and Travill, 1997). A number of studies indicate that the psychological effects of MDMA extend beyond changes in mood to selective impairments in memory. Tests designed to evaluate general information-processing speed (simple reaction time, choice reaction time, Sternberg task response time) and sustained attention reveal no significant differences between MDMA users and various control groups (Krystal *et al.*, 1992; Parrott *et al.*, 1998). However, a number of studies indicate significant impairments in a variety of tasks that assess memory function. MDMA users exhibit mild to moderate decrements when compared with alcohol users (Curran and Travill, 1997) in working memory and the initial and delayed paragraph test of the Wechsler Memory Scale (Krystal *et al.*, 1992), and show deficits in delayed and non-delayed word recall (Morgan, 1999; Parrott and Lasky, 1998).

One difficulty associated with ascribing performance deficits in these laboratory tasks to deficits in memory is that MDMA users rarely report memory impairments. There have been several surveys of recreational MDMA users, and they have not revealed subjective evidence for memory deficits (see Krystal *et al.*, 1992). In this regard, Parrott *et al.* (1998) raise the interesting possibility that perhaps these apparent memory deficits reflect a change in cognitive strategy rather than memory deficits *per se*. After all, MDMA users report a change to a more phenomenological, less verbal style not only when on the drug but for some time thereafter. Thus, future studies on neuropsychological function should be expanded to include a range of non-verbal as well as verbal memory tasks and other measures of cognitive strategy.

The preclinical and clinical neurotoxicological literature suggests serious grounds for concern over repeated use of MDMA. Animal studies reveal damage to several markers of 5-HT-containing neurons (decreased 5-HT and 5-HIAA levels, diminished 5-HT uptake), particularly in the hippocampus (Frederick and Paule, 1997; Steele *et al.*, 1994). The reported impact on the hippocampus is particularly important, given the vast literature implicating its role in memory processes (see Nadel and Bobbot, 2001 for a review). The human neurotoxicology literature, although less extensive, is entirely consistent with the animal studies. Levels of 5-HIAA in the CSF are reduced in subjects who have a history of repeated MDMA use (McCann *et al.*, 1994; Ricaurte *et al.*, 1990). These decreases in CSF 5-HIAA correlate with the extent of memory impairments in abstinent MDMA users (Bolla *et al.*, 1998). A PET imaging study found ecstasy users to have reduced 5-HT transporter binding in a number of brain regions, including the frontal and temporal cortices (Szabo *et al.*, 1997). Little is known about the effects of MDMA usage on postsynaptic 5-HT receptor function. A recent study (Reneman *et al.*, 2000) used SPECT imaging and the 5-HT_{2A} receptor ligand [^{123}I]-5-I-R91150 to assess the density of 5-HT_{2A} receptors and, importantly, to correlate changes in the density of this receptor with performance on a memory recall test. Although the sample sizes are small, there was a significant increase in the density of 5-HT_{2A} binding in the occipital cortex in repeated MDMA users (cumulative consumption of at least 50 tabs) relative to controls. There was a strong negative correlation ($r = -0.98$) between performance on the word recall test and binding in the MDMA group and no significant correlation in the control group. It is important to point out that the MDMA users in this study had been drug abstinent for 2–11 months (mean 4.6 months) before this study.

The demonstration of memory deficits in drug-abstinent MDMA users raises the important issue of the permanency of these neuropsychological deficits. In addition to the SPECT study cited above, the study by Parrott and Lasky (1998) was conducted 2 and 7 days after drug consumption, whereas the study by Krystal *et al.* (1992) tested MDMA users who had not taken the drug for an average of 66 days. Collectively, these investigations suggest that the memory deficits induced by repeated MDMA usage may be long-lasting or even permanent. If so, this leads to the chilling conclusion that the mild to moderate deficits reported in these studies represent only the tip of the iceberg, and that many of these users may remain at high risk for more severe ageing-related memory deficits as they experience an age-related loss of 5-HT-containing neurons.

Future research in the area of MDMA-induced amnestic disorders will have to confront several methodological and interpretational challenges. First, as is the case with any study on an illicit drug, the illegal status of MDMA and its potential neurotoxic effects constrain experiments and preclude the use of more traditional double-blind, placebo-controlled designs. Second, it is often difficult to get predrug baseline performance data on cognitive tasks in the MDMA group (but see Parrott and Lasky, 1998 for an example of baseline performance in the drug group). Third, future studies should identify more carefully appropriate control groups against which to compare the performance of the MDMA group. MDMA users tend to be poly-drug users and, thus, it is important to include control groups that have a history of use of several drugs (e.g., alcohol, cigarettes, cannabis, LSD, cocaine, inhalants) but not of MDMA. The comparison of MDMA users with a poly-drug user control group was accomplished in Morgan (1998). Fourth, it will become important to determine how much MDMA needs to be consumed before the emergence of these memory deficits. This is a difficult issue to address. Parrott and Lasky (1998) state that their 'regular users were comparatively more impaired than the novice users'; however, it is not clear how these two groups were defined. In a different study, Parrott *et al.* (1998) found no differences in memory deficits between users who had consumed more than ten tabs of MDMA versus those that had consumed fewer than ten tabs. Finally, an issue confounding the specification of both the dose sufficient to produce memory deficits and the attribution of MDMA to such syndromes is the fact that MDMA tablets often contain impurities (e.g., ketamine) that affect dose and also impair neuropsychological function in their own right (Parrott *et al.*, 1998).

DELIRIUM

The DSM-IV defines delirium as a general disturbance in consciousness that gives rise to changes in cognition that are not related to an existing or evolving dementia (American Psychiatric Association, 2000). Cognitive changes include disorientation (to time/space), reductions in awareness of the environment, and impairments in the ability to focus, sustain or shift attention. Memory (particularly of recent events) may also be impaired temporarily. The delirious state can also be associated with a number of other disorders, including disturbances in sleep–wake cycles, psychomotor activity and emotion (anxiety, fear, depression, irritability).

Delirium typically develops over a short period of time (hours/days), with a fluctuating presence and severity. The two primary aetiological conditions associated with delirium are general medical conditions (head trauma, vascular diseases, metabolic disturbances) and substance-induced (medications, drugs, toxins). The discussion below will focus on the contributions of aminergic transmitter systems to delirium in elderly patient populations (50% of elderly patients may become delirious upon admission to hospitals) and following various medications (several substances that affect aminergic systems can induce delirium).

Cholinergic Transmission and Delirium

The link between cholinergic transmission and delirium has been fostered by three observations. First, it is generally believed that ACh plays an important role in the global cognitive disruption characteristic of delirium (Perry and Perry, 1995), including decreases in wakefulness (Baghdoyan, 1997) and impairments in attentional processes (Sarter and Bruno, 1997). Second, medications with anticholinergic properties often precipitate episodes of delirium (Trzepacz *et al.*, 1996; also see below). Finally, physostigmine, an indirect cholinergic agonist, has been shown to be effective in the treatment of delirium (Granacher *et al.*, 1976).

A recent empirical study by Han *et al.* (2001) evaluated the longitudinal association between the use of cholinergic medications and the severity of delirium in a large cohort of elderly medical inpatients with diagnosed delirium. They also determined whether this association was modified by the presence of dementia in delirious patients. The results indicated an increase in the severity of delirium associated with several measures of cholinergic medication, but a pre-existing condition of dementia did not increase this association. However, this latter point requires additional study as most of these patients were only mildly demented and, thus, cholinergic deficits may have been less evident in these patients.

Another linkage between cholinergic deficiency and delirium has been revealed using a functional competitive binding assay for serum anticholinergic activity developed by Tune and Coyle (1981). This assay measures the ability of the patient's serum to block central muscarinic receptors. An association between delirium and elevated serum anticholinergic activity has been demonstrated in two studies of elderly medical patients (Flacker *et al.*, 1998). The basis of the serum anticholinergic activity is not known, but it is generally thought to reflect residual levels of medications or their metabolites. It should be pointed out, however, that there is a significant amount of overlap in the serum anticholinergic activity in delirious and nondelirious patients, suggesting the importance of other contributing factors.

In spite of these supporting observations, there are certainly some exceptions to the suggested relationship between cholinergic transmission and delirium (see Han *et al.*, 2001 for a discussion of this issue). There are at least three factors that could account for such discrepant findings. First, different studies utilize different measures of ACh medication exposure (serum ACh level, number and dose of cholinergic medications, aggregate risk score of ACh potency), and the relationship between these measures has not been specified clearly. Second, the effects of cholinergic medications on delirium may be confounded by other risk factors, such as age, dementia and a variety of comorbid conditions. Collectively, the evidence suggests that delirium is viewed adequately as a disorder based on multiple transmitter abnormalities. Additionally, various risk factors interact with neuropathological processes to produce heterogeneous symptoms of delirium (Flacker and Lipsitz, 1999).

Serotonergic Transmission and Delirium

A postulated role for 5-HT in delirium is not surprising, given the evidence from both the animal and human literature linking serotonergic transmission with several of the functions affected by delirium, such as wakefulness, mood and cognition (Meneses, 1999). Interestingly, there are suggestions that delirium can be associated with either excessive activation or reduction in serotonergic transmission. Elevated levels of the 5-HT metabolite 5-HIAA have been reported in ill, delirious, non-demented patients when compared with control populations of healthy subjects as well as when compared with groups of nondelirious alcoholics and patients on antipsychotics (Banki and Vojnik, 1978). Consistent with these CSF findings, the literature contains reports of a 'serotonin syndrome' characterized by confusion, restlessness and tremor. This syndrome can be precipitated by medications that act as 5-HT agonists, such as L-tryptophan, MAO inhibitors, and fluoxetine (Steiner and Fontaine, 1986).

Several reports have linked the occurrence of delirium with reduced serotonergic transmission, or at least with reduced levels of tryptophan. Plasma tryptophan to large neutral amino acid ratios were significantly lower post-surgery in a group of delirious patients (van der Mast *et al.*, 1996). Moreover, a retrospective study demonstrated that patients with early symptoms of delirium tremens exhibited improved mini-mental status exam scores, sleep/wake cycle, and reduced tranquilizer use following daily treatments with L-tryptophan (Hebenstreit *et al.*, 1989).

Dopaminergic Transmission and Delirium

Finally, abnormalities in dopaminergic transmission have also been linked to delirium and acute confusion. Dopamine agonists such as L-Dopa (Birkmayer, 1978), pergolide (Cummings, 1991) and buproprion (Golden *et al.*, 1985) have been reported to lead to delirium. In some cases, dopaminergic antagonists such as haldol are effective in relieving the symptoms of delirium.

CONCLUSIONS

A review of the available clinical literature clearly reveals multiple dysregulations in aminergic transmission accompanying a wide range of cognitive disorders. However, there is considerable variation in the consistency and magnitude of some of these linkages. These discrepancies no doubt reflect at least two interacting variables. First, the individual cognitive disorders are indeed syndromes with multiple neuropathologies and aetiologies. Thus, it is not surprising that transmitter profiles vary within heterogeneous and often small groups of patients. Second, a wide range of methodologies is used to characterize the integrity of aminergic systems accompanying these cognitive disorders. We are constrained when assessing neurochemistry in clinical populations, and care should be taken in comparing data obtained by such discrepant and often indirect measures. Nevertheless, there is little doubt that deficits in adrenergic transmission correlate well with neuropsychological performance in a number of cognitive disorders. The challenge facing us now is to understand better the relationships between damage to a particular transmitter system within a brain region and deficits in the various psychological functions that characterize these cognitive disorders.

Disturbances in the Amino Acid Transmitter Systems in Cognitive Disorders Classified and Diagnosed According to DSM-IV

Theodora Duka

The dementia classification according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 2000) gives four main groups of dementias. This classification does not reflect the separated neuronal mechanisms underlying the dementias, nor does it correspond to a prominent different symptomatology seen in the different dementias. It does, however, allow a categorization according to the most obvious cause (see Table XV-3.1). It is widely accepted that the most common dementia is Alzheimer's dementia, followed by alcohol dementia including Korsakoff's syndrome. The dementia that is most common in young people and children is human immunodeficiency virus (HIV)-related dementia. We will refer mostly to these three types of dementia.

Amino acid neurotransmitters, especially γ-aminobutyric acid (GABA) and glutamate, are thought to play an important role in the cognitive function of the brain. Therefore, it is not surprising that most research efforts to understand how dementias develop have been concentrated on investigating the way that these amino acids influence cognition. GABA represents the main inhibitory amino acid neurotransmitter and glutamate the main excitatory amino acid neurotransmitter in the brain. There are two ways by which these amino acids are implicated in the dementias: firstly, by their direct participation in learning and memory processes, and secondly, by their involvement in neuronal degeneration. More recently, other amino acid neurotransmitters, such as quinolate, glycine and kynurenic acid, have also been implicated in the development of some dementias, although the role of these latter amino acids in normal cognitive function is less clear. In this chapter, the role of GABA receptors and glutamate receptors in the normal cognitive state will be discussed, followed by their role in the different types of dementias. Finally, we will discuss the complex issue of what underlies the function of a damaged brain.

THE ROLE OF AMINO ACID NEUROTRANSMITTERS IN COGNITION

GABA and Cognition

The amino neurotransmitter GABA mediates fast synaptic inhibition in the brain and directly activates chloride-permeable ion channels. GABA ionotropic receptors are divided into GABA-A and GABA-C. The GABA-A receptors are important as they are the target of benzodiazepine and barbiturate drugs. The GABA-A protein subunits can be divided into seven families with multiple isoforms: α (six isoforms), β (three isoforms) and γ (three isoforms), and the newer δ, ε, θ, and π (Mehta and Ticku, 1999; Neelands *et al.*, 1999; Loh and Ball, 2000; Pirker *et al.*, 2000). The receptors lacking the γ-subunit are insensitive to benzodiazepines and have higher agonist affinities.

Table XV-3.1 Classification of cognitive disorders according to DSM-IV

Type of dementia	Main cause
1. Alzheimer's dementia	Neurodegenerative disorder
2. Alcohol-induced persisting dementia	Long-term alcohol use • *Wernicke's encephalopathy*: acute symptoms related to motor balance • *Korsakoff's syndrome*: chronic condition characterized by poor memory
3. Vascular dementia (multi-infarct dementia)	Ischaemia (neurodegeneration)
4. Dementia related to other general medical conditions	HIV (infection) Head trauma (injury) Parkinson's disease (neurogenerative disorder) Huntington's disease (neurogenerative disorder) Pick's disease (neurogenerative disorder) Creutzfeld–Jacob disease (infection)

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Most information on the role of GABAergic activity on cognition is derived from reports on the effects of benzodiazepine ligands on memory. The discovery of betacarbolines, the first ligands at the benzodiazepine site of the GABAergic complex with inverse agonist activities, led to a breakthrough in our understanding of the role that GABA may play in memory. The inverse agonists bind at the benzodiazepine site and are negative modulators of GABAergic activity. They bring about their effects by reducing the frequency of the chloride-channel openings, preventing the entrance of chloride ions into the cell. The spectrum of the behavioural effects of these inverse agonists were the mirror image of the spectrum of effects of the classical agonists, benzodiazepines, and induced anxiety (Dorow *et al.*, 1983) and convulsions (Stephens and Sarter, 1988). Ligands with selective or partial inverse agonist properties at the benzodiazepine binding sites were developed from the betacarbolines and benzodiazepines. They were characterized in several behavioural tests, and it was revealed that they produced the opposite effects of benzodiazepines and betacarbolines with full or partial agonist properties at the benzodiazepine sites (Stephens and Sarter, 1988). Thus, the partial or full inverse agonists demonstrated promnestic effects (Venault *et al.*, 1986), and furthermore, they were able to counteract the disruptive effects of scopolamine on acquisition (Sarter *et al.*, 1988a).

During the late 1980s, Sarter *et al.* (1988b) put forward a hypothesis to explain how the GABAergic system may affect memory, and what its role may be in the development of dementia. Several pharmacological studies at that time had provided evidence that increased GABAergic activity in the basal forebrain would decrease the acetylcholine release in the cortex (Casamenti *et al.*, 1986). In addition, anatomical studies had provided evidence that GABAergic afferent projections from the nucleus accumbens project to cholinergic cell bodies in the basal forebrain (Zaborszky *et al.*, 1986). Thus, on the basis of the pharmacological and anatomical data, it could be suggested that the activity of cortical cholinergic neurons derived from the basal forebrain are under the control of GABAergic input. Based on this evidence, Sarter *et al.* (1988b) hypothesized that in senile dementia of the Alzheimer's type, degeneration of the cholinergic neurons from the basal forebrain to the cortex leads to a reduction of acetylcholine availability in the cortex. Reduced acetylcholine availability is facilitated further by GABAergic inhibitory control, which remains unchanged, on the remaining intact cholinergic cells in the basal forebrain and on the nerve endings in the cortex. Sarter *et al.* (1988b) further suggested the cognition-enhancing potential of compounds with antagonist or partial inverse agonist properties. Such compounds would have a disinhibitory control of the GABAergic input, and would induce an enhancement in acetylcholine release.

Data from recent studies provide further evidence that GABAergic projections to the basal forebrain control the excitability of basal forebrain cholinergic neurons (Moore *et al.*, 1995; Zaborszky *et al.*, 1991). The increase of cortical acetylcholine would mediate the processing of stimuli and associations and the allocation of processing resources for these attentional functions, and would influence memory via these mechanisms (Muir *et al.*, 1992; Robbins *et al.*, 1997). This result, however, may depend on the degree of neuronal loss due to the neuronal degeneration, and indeed experiments using inverse agonists to improve cognitive effects in animals have shown that the effects on cognition appear to be related to the loss of cholinergic input into the cortex; in animals with 50–60% loss, but not 90% loss, treatment with the benzodiazepine inverse agonist alleviated the lesion-induced impairment in measures of attention (Sarter and Bruno, 1997).

This initial hypothesis on the role of GABA in senile dementia provided a reasonable theoretical approach to the development of a new generation of drugs for the treatment of some symptoms of dementia, which has been followed up since by many pharmaceutical companies.

Duka and colleagues (Duka *et al.*, 1988; Duka *et al.*, 1996) were the first to test the idea in humans that a ligand at the benzodiazepine receptor with partial inverse agonist properties at the GABA–benzodiazepine receptor complex would have the opposite effects of a full agonist on memory, i.e. enhance the abilities of the subject to retain memories. Partial agonist properties of such a compound are essential in order to circumvent other unwanted effects, such as anxiety induction and convulsant activity. Such a compound, a β-carboline antagonist with weak partial inverse agonist properties at the benzodiazepine binding site, ZK 93426, was developed in the late 1970s and tested in several preclinical and clinical studies in the 1980s and 1990s. ZK 93426 was never tested in subjects suffering from any cognitive disorder because of its poor kinetics (very low bioavailability), which required administration as an intravenous infusion. The development of a new compound characterized preclinically as a successor of ZK 93426, showing a similar spectrum of effects in preclinical testing and a good oral bioavailability, was introduced in phase I and was administered to healthy participants and subsequently to Alzheimer's patients. However, its weak cognitive-enhancing properties were accompanied by many psychotogenic effects, and the compound was not developed further.

Recent studies with transgenic mice have highlighted the role of GABA–benzodiazepine receptor complex subunits in the different actions of benzodiazepines, including memory. Rudolph *et al.* (1999), using the technique of homologous recombination, engineered mice with the a1 protein subunit mutated (arginine was replaced in the 101 position by histidine), so that there was no $\alpha 1$ benzodiazepine binding site. The otherwise healthy mutants have GABA-A receptors containing only the $\alpha 2$, $\alpha 3$ and $\alpha 5$ subunits for the benzodiazepines to bind. When the mice were given diazepam, the anxiolytic effects, but not the sedating or amnesic effects, of diazepam were seen. Based on these data, it can be suggested that the $\alpha 1$ subunit is the one involved in the mediation of the benzodiazepine effect on memory. However, the tasks used to test the amnestic effects are also known to be sensitive to anxiolytic effects of benzodiazepines, which were present in the mutants; consequently, the data cannot be conclusive (see Wisden and Stephens, 1999). Thus, the role of GABA-A subunits in mediating benzodiazepine-induced amnesia still needs to be investigated. Further studies using similar techniques have suggested that the $\alpha 2$ and not the $\alpha 3$ site is responsible for the anxiolytic effects of benzodiazepine (Low *et al.*, 2000; Crestani *et al.*, 2001), which makes the $\alpha 2$ subunit the most likely to mediate the anxiolytic effects of benzodiazepines and still leaves open the question about amnestic effects.

Zolpidem, a widely used imidazopyridine hypnotic (a non-benzodiazepine sedative-hypnotic) (Praplan-Pahud *et al.*, 1990) has been shown to induce sedation and muscle relaxant activity similar to that induced by other benzodiazepines, while at the same time producing less memory and cognitive impairment. However, the reports in the literature are contradicting, and amnestic effects of zolpidem may be present, depending on the dose and the task used (Evans *et al.*, 1990; Balkin *et al.*, 1992; Wesensten *et al.*, 1995; Berlin *et al.*, 1993). In a more recent study, the effects of triazolam (a benzodiazepine full agonist) were compared with those of zolpidem on specific memory tasks (Mintzer and Griffiths, 1999). Although both compounds had a similar spectrum of effects in several tasks on memory, there were certain memory functions in which their effects were distinctively different. In particular, triazolam impaired, while zolpidem did not, the ability of the subjects to retrieve spatial contextual information (i.e. information about the location where an event occurred). Similarly, in a retrieval of spatial route task (Balkin *et al.*, 1992), zolpidem did not impair performance. Spatial information is an important attribute in the

retrieval of memories and appears to be impaired in patients with cognitive disorders (Carlesimo *et al.*, 1994; Swainson *et al.*, 2001). On the other hand, zolpidem is a sedative drug, and at certain doses sedation can account for impairment in several memory tasks. Thus, similarities between zolpidem and triazolam or other full agonist benzodiazepines in some memory tasks could be understood as a result of the sedation present (Stephens *et al.*, 1991). If, as shown from studies *in vivo*, zolpidem binds with high affinity to $\alpha 1$ (by which its sedative effects are mediated) (Crestani *et al.*, 2000) and intermediate affinity to $\alpha 2$ and $\alpha 3$, but not at all to $\alpha 5$, then we can suggest that $\alpha 5$ subunits may be the benzodiazepine binding site that mediates the amnestic effects. Consistent with this idea, recent studies have shown that novel benzodiazepine receptor ligands, designed using pharmacophore/receptor models and selective for the $\alpha 5\beta 3\gamma 2$ benzodiazepine receptor subtype, enhanced memory when injected directly into the hippocampus in animals (Huang *et al.*, 2000). The ligand used in these studies was an inverse agonist at the $\alpha 5\beta 3\gamma 2$ benzodiazepine receptor subtype. Thus, from these data, and taking into account the discussion at the beginning of this section, it can be suggested further that new benzodiazepine inverse agonist ligands specific for the $\alpha 5$ benzodiazepine receptor subunit may be the future candidates for treating Alzheimer's dementia. These compounds should not present with the type of anxiogenic effects that have been reported previously when the nonspecific benzodiazepine partial inverse agonists were given to humans (Dorow *et al.*, 1983; Dorow *et al.*, 1987; Duka *et al.*, 1987).

Glutamate and Cognition

Glutamate is the principal excitatory neurotransmitter in the brain. It binds to bring about its actions to four types of glutamate receptors: *N*-methyl-D-aspartic acid (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole proprionic acid (AMPA) and kainate, which are ionotropic (all three are named after the pharmacological agents that bind to them), and a fourth metabotropic receptor. There are several glutamate receptor subunits identified: for the NMDA receptor, the subunits NR1, NR2A, NR2B, NR2C and NR2D; for the AMPA receptor, the subunits GluR1, GluR2, GluR3 and GluR4; for the kainate receptor, the subunits GluR5, GluR6, GluR7, KA1 and KA2; and for the metabotropic receptor, the subunits mGluR1, mGluR2, mGluR3, mGluR4, mGluR5, mGluR6 and mGluR7. The result of NMDA binding is to facilitate the calcium conductance. However, in order for this to happen, the neuronal membrane has to be excited already so that magnesium will not bind in the channel. Another important condition to be fulfilled before NMDA can open the calcium channel is that glycine should be present at its binding site. The role of NMDA and glycine receptor activity in cognition will be presented in the following section.

NMDA Receptors

It is now well established that NMDA receptors play a crucial physiological role in various forms of synaptic plasticity, including those involved in learning and memory. NMDA is important for the induction of activity-dependent synaptic modification, so called long-term potentiation (LTP) (Bliss and Collingridge, 1993), a mechanism related to memory formation and learning (Sakimura *et al.*, 1995; Davis *et al.*, 1992).

In animal studies, performance in spatial but also non-spatial memory tasks is found to be impaired in the presence of competitive and non-competitive NMDA blockers. In particular, impairment of both working and reference memories in a radial-arm memory task has been reported after the administration of NMDA antagonists (Maurice *et al.*, 1994; Pitkanen *et al.*, 1995; Zhang *et al.*, 2000). The effects of NMDA antagonists in long-term memory have also been established using a passive avoidance task (Mondadori and Weiskrantz, 1993). Many studies have also reported learning deficits induced by the NMDA antagonist in the Morris water-maze task, a spatial learning task (McNamara and Skelton, 1993; Morris *et al.*, 1986; Morris *et al.*, 1990). From studies with non-human primates, it is suggested that several of the effects of NMDA antagonists on memory reflect impairments on acquisition and encoding of information (Thompson *et al.*, 1987; Buffalo *et al.*, 1994; Morris *et al.*, 1986). Numerous studies with animals have linked the activity of NMDA receptors within the hippocampus to the animal's performance in memory-related tasks (Morris *et al.*, 1986; Morris *et al.*, 1990). Memory tasks that are sensitive to the deficits induced by NMDA antagonists (i.e. the Morris water-maze task), are also affected by hippocampal lesions.

The effects of NMDA antagonists on memory in humans have been explored less due to the psychotogenic effects of the available NMDA antagonists, which limits their use in the laboratory. Early studies with phencyclidine (PCP; a non-competitive NMDA antagonist) aimed at simulating psychotic symptomatology have shown impairment of memory function as well as psychomotor performance and selective attention shortly after its administration (Rosenbaum *et al.*, 1959; Cohen *et al.*, 1962). The structurally related anaesthetic ketamine is known to induce anterograde amnesia, i.e. information acquired after its administration cannot be retrieved later (Pandit *et al.*, 1971). Since the doses used were those used for anaesthesia, it was difficult from these studies to conclude anything about the specificity of ketamine effects on memory. Recent studies with ketamine in subanaesthetic doses have shown ketamine to be an amnestic in tests of delayed recall of words presented at different times after ketamine administration (Krystal *et al.*, 1994; Krystal *et al.*, 1998a). In a more recent study, Newcomer *et al.* (1999) demonstrated a dose-dependent effect of ketamine on tasks of immediate and delayed paragraph recall, as well as in the delayed match-to-sample task. In a word-recognition task, subjects were also found to be impaired in recognizing words presented after ketamine infusion, whereas recognition for words presented before ketamine was not impaired (Hetem *et al.*, 2000). It has also been shown that the effects of ketamine on memory using a visual word-recognition task (subjects had to recognize words as being new (first time shown) or old (seen previously)) are mediated by hippocampal structures (Grunwald *et al.*, 1999). The method used to demonstrate the functional activation of hippocampal structure was an analysis of limbic event-related potentials. Findings such as an increase of cyclic adenosine monophosphate (cAMP) in the hippocampus (CA1 area) by NMDA (Nguyen and Kandel, 1996), and more recently, the finding that the selective inhibitor of a type 4 cAMP-specific phosphodiesterase (PDE4), rolipram, antagonizes the effects of NMDA on memory and learning (Zhang *et al.*, 2000), have led to hypotheses of an important role of cAMP and PDE4 in signal-transduction mechanisms for those NMDA receptors that are involved in learning and memory. Such findings highlight the molecular mechanisms underlying the role of NMDA in memory function. However, as yet there are no useful compounds that interact with the NMDA receptors and that can be used in human studies as tools to understand the role of glutamate on memory.

Glycine Modulatory Site

The glycine B (strychnine-insensitive) site on the NMDA receptor is a modulatory site to which glycine binds, and, in the presence of glutamate, acts synergistically with glutamate to promote channel opening and excitatory neurotransmission. This glycine binding site on the NMDA receptor complex is distinct from the classic strychnine-sensitive receptor, which mediates glycine's inhibitory actions.

D-Cycloserine is a partial glycine agonist. According to the principles of partial agonist effects, it activates the synapse at low concentrations but has an antagonistic effect on endogenous glycine

at high concentrations. In a series of studies, it has been shown that D-cycloserine improves memory in normal (Pussinen *et al.*, 1997; Kishi *et al.*, 1998; Land and Riccio, 1999) and aged animals (Popik and Rygielska, 1999), and also attenuates memory impairments induced by NMDA antagonists (e.g. MK-801) (Kawabe *et al.*, 1998). Recently, it was also shown that D-cycloserine could attenuate the cognitive impairment induced in monkeys who have developed Parkinson's disease (Schneider *et al.*, 2000). Parkinson's disease is induced experimentally in monkeys after chronic administration of 1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine (MPTP) (Gerlach *et al.*, 1991).

In humans, the effects of bioglycine, a biologically active form of the amino acid glycine, were tested on attention and memory in young and middle-aged men. It was shown that bioglycine, whilst improving retrieval from episodic memory, did not affect divided or focused attention in either group. It did, however, improve sustained attention in the middle-aged men (File *et al.*, 1999).

The numerous studies on the cognitive effects of NMDA antagonists on memory and related functions in animals contrast with the few studies on the effects of NMDA antagonists on memory function in humans. The most investigated drug has been ketamine. However, the psychotogenic effects of this compound, and of the other known NMDA antagonists that can be given in humans, limits the investigations into the role of NMDA receptor ligands on memory function.

THE ROLE OF AMINO ACID NEUROTRANSMITTERS IN DEMENTIA

The most common dementias, dementia of the Alzheimer's type and substance-induced persisting dementia, are due to a neuronal degeneration process that parallels the ageing process, except that the mechanisms underlying the initiation and progression of this degeneration process are still, for the most part, unknown. Other common dementias, such as that associated with HIV, are caused by an infection, although the mechanisms underlying the generation of these dementias are also unknown. The role of glutamate, or more generally of the excitatory amino acids, in neuronal degeneration processes is now well established. Glutamate facilitates learning and memory function, while at the same time it can induce neuronal degeneration if it is activated continuously, making the study of the role of glutamate in dementias challenging. GABA and glycine, two important neurotransmitters in the brain, interact with glutamate pathways to control glutamate release and glutamate neuronal activation, respectively, which makes the study of these two neurotransmitter systems and their relationship to dementias also of key importance.

In the previous sections, the roles of NMDA, GABA and glycine in memory and learning were highlighted under normal conditions or when applying experimental models of impaired cognitive function. In the following sections, their roles in the progression of the neuronal degeneration and, more directly, their relationship to a demented brain will be highlighted.

Alzheimer's Dementia

There is evidence that among the neurons most vulnerable to degeneration in Alzheimer's disease are those that utilize glutamate as a neurotransmitter. For instance, pronounced degeneration is observed in glutamatergic neurons of the entorhinal cortex and hippocampus (Braak and Braak, 1991; Hyman *et al.*, 1984; Pearson *et al.*, 1985). The involvement of a degenerative process with respect to glutamate is supported by a decrease in glutamic acid levels, as well as the loss of glutamate terminals in hippocampal and cortical regions in Alzheimer's disease (Cowburn *et al.*, 1990; Hyman *et al.*, 1987; Procter *et al.*, 1989). These findings suggest the importance of degeneration of glutamatergic neurons in the pathological manifestations of Alzheimer's disease (Greenamyre and Young, 1989; Myhrer, 1993; Palmer and Gershon, 1990).

The suggestion that glutamate plays a role in neuronal death due to excitotoxicity is not exclusive to Alzheimer's disease. Amino acid receptor-mediated excitotoxicity appears to contribute to neuronal death associated with several neurological disorders, including epilepsy, hypoxic ischaemic insult, and Alzheimer's disease (Choi, 1988). In a recent study (Aronica *et al.*, 1998), the distribution of NMDA receptors in the hippocampus was compared between Alzheimer's disease patients and controls; it was revealed that in the vulnerable regions, such as the CA1 region, immunolabelling of glutamate subtype receptors (GluR 1/2, GluR5/6/7 and NR1) was reduced in patients, presumably due to cell loss.

Studies have been carried out with post-mortem brains of Alzheimer's disease patients using proton (H^1) and phosphorus (P^{31}) magnetic resonance spectroscopy (MRS) as a technique to identify levels of several metabolites, among which were metabolites of excitatory and inhibitory amino acids. Most of these studies have reported elevations in L-glutamate, indicating that generally compounds related to excitatory neurotransmission increase in Alzheimer's disease (for a recent study, see Klunk *et al.*, 1996).

GABA and Alzheimer's Dementia

It is well established that GABA neurons are spared in Alzheimer's disease (Nagga *et al.*, 1999), whereas glutamate and cholinergic neurons are damaged at specific brain areas, including the hippocampus and the basal forebrain (see above). Studies that set out to examine the distribution of GABA-A receptor subunits in the hippocampus of patients with Alzheimer's dementia have revealed that the $\alpha 5$ subunit-containing GABA-A receptors is relatively spared (Howell *et al.*, 2000), whereas the $\alpha 1$ subunit-containing GABA-A receptors appear to be vulnerable as the disease progresses (Mizukami *et al.*, 1998). The roles of these variable responses of selected GABA subunits in the process of the disease is not clear. However, these data suggest that GABA released from the spared neurons in the hippocampus can still activate the intact $\alpha 5$-subunit-containing receptors. Since GABA interacts with glutamate neurons in the hippocampus (Walker *et al.*, 2001) and with cholinergic neurons in the basal forebrain (Casamenti *et al.*, 1986; Moore *et al.*, 1995) to inhibit the neuronal activation of glutamatergic and cholinergic neurons respectively, its effects upon the remaining glutamatergic or cholinergic neurons must further impair the availability of glutamate and acetylcholine in the hippocampus and cortex, respectively. An inverse agonist at the benzodiazepine site on the GABA-A receptor complex will reverse the GABA inhibition and allow more release of acetylcholine in the cortex and glutamate in the hippocampus. The pharmacology reflecting the relationships between GABA, glutamate and cholinergic neurotransmitter with memory has been demonstrated in several studies, and is summarized in a review by Izquierdo and Medina (1995). Thus, the idea of developing an inverse agonist as a treatment for Alzheimer's disease remains valid (Eid and Rose, 1999; see also discussion in the section on GABA and cognition above).

Glutamate and Alzheimer's Dementia

The role of glutamate in cognitive processes has been highlighted in several reviews, and was discussed earlier in this chapter. Although its role is complex, there are several explanations why dysfunction of glutamate neurotransmission could be an underlying mechanism of Alzheimer's disease. Histological results of neuronal

loss in Alzheimer's disease were associated with reduced glutamate activity in the neocortical pyramidal cells, which are part of the cortico-cortical connections, and also in other neurons in the cerebral cortex (Greenamyre and Maragos, 1993). Memory deficits, as discussed in a previous session, can be seen in animals and humans when glutamate antagonists are administered. Many of the impairments seen resemble the cognitive dysfunction seen in Alzheimer's disease, which further supports the idea that a reduction of NMDA may be the cause of the memory decline seen in Alzheimer's disease. This idea is supported further by the finding that the degree of loss of neocortical pyramidal cells shown to be associated with glutamatergic hypoactivity in Alzheimer's disease patients post-mortem (Greenamyre and Maragos, 1993) correlated well with the severity of cognitive deficits (Sumpter *et al.*, 1986).

In addition, glutamate exerts an excitotoxic action that leads to degeneration of the neurons. This action of glutamate has been especially highlighted in conjunction with ischaemic damage, when glutamate release dramatically increases. Recent evidence suggests that excessive release of glutamate, contributing to excitotoxic neuronal death, may be an aetiological mechanism in chronic neurodegenerative disorders, including Alzheimer's disease (Kornhuber and Weller, 1997). Two recent findings provide additional convincing evidence for a significant role of glutamate in Alzheimer's disease: first, the finding that amyloid precursor protein plays an important role in regulating glutamate levels in the synapse (Mattson *et al.*, 1999), and second that the β-amyloid protein, a key component of senile plaques, can enhance the neurotoxicity of glutamate (Blanchard *et al.*, 1997). Data from autoradiographic ligand-binding studies examining the glutamate receptor integrity in brains of Alzheimer's disease patients have shown conflicting results. Some studies report loss of glutamatergic receptors from cortical and hippocampal areas (Greenamyre *et al.*, 1985; Greenamyre *et al.*, 1987), whereas others report stable levels (Geddes *et al.*, 1986; Monaghan *et al.*, 1987). Several subunits of the NMDA receptor have been identified recently, and there are data to suggest that some subunits are more involved than others in learning and memory (Tang *et al.*, 1999). Thus, the inconsistency in the literature with regard to NMDA receptor density in Alzheimer's disease when compared with controls may reflect different vulnerabilities of the different subunit-protein-containing receptors. In a recent study, a reduction in several of the NMDA subunit protein levels was found in the hippocampus (NR1 and NR2B) and in the entorhinal cortex (NR2A and NR2B) of Alzheimer's disease patients' brains when compared with normal brains (Sze *et al.*, 2001). Importantly, the severity of the decrement correlated strongly with the magnitude of the cognitive impairments as measured by the mini mental state examination. When the NMDA subunit protein level was measured in early-stage Alzheimer's disease and compared with control brains, these differences were not found (Sze *et al.*, 2001). Based on this finding, the authors suggested that the changes in the glutamate subunit protein levels might be the result of a neuronal degeneration, part of the progress of Alzheimer's disease.

There is evidence to suggest that the neurodegeneration seen in Alzheimer's disease may be the result of a hyperactivation of the glutamate neurons. When glutamate is released under normal conditions in the synaptic cleft, where it remains for only 1–2 ms (Clements *et al.*, 1992), it induces a calcium influx into the cell and a short-term depolarization of the neuron, which serves acute physiological demands. If glutamatergic neurons are activated continuously, and glutamate remains for longer in the synaptic cleft, then an increase in calcium influx into the cell occurs. The calcium activates several catabolic enzymes, including nucleases, proteases and phospholipases, which may promote neuronal death. It is now widely accepted that increased activity of these enzymes, and accumulation of their toxic products, promotes neuronal death in hypoxia, ischaemia and trauma. Prolonged exposure to enhanced concentration of glutamate, which activates these enzymes, can therefore induce excitotoxicity *per se* (for a summary review, see Kornhuber and Weller, 1997).

The bimodal properties of NMDA antagonists with regard to cognitive functions, on the one hand to promote neuronal degeneration due to excitotoxicity and induce neuronal lesions, and on the other hand to promote neuronal plasticity, an essential mechanism underlying learning and memory, have challenged researchers when developing treatment approaches.

The role of NMDA antagonists to counteract excitotoxic insults due to either an excess of glutamate activity or other conditions has been well established (Parsons *et al.*, 1999). At the same time however, several reports in the literature have demonstrated the impairment in memory and learning induced by NMDA antagonists (see previous section).

If an impairment of cognitive functions in the first instance is the price to pay for delaying or even blocking a degenerative process that may not have led to any further impairment than the one the treatment itself induced, then an alternative approach should be followed. The non-competitive antagonists MK-801 and PCP, due to their low offset rate from the receptor and weak voltage dependency (Parsons *et al.*, 1999), tend to block the receptor for a long time and independently of its current activation. Because of this, these compounds can prevent possible excitotoxic events occurring, but at the same time reduce the responsiveness of the receptor to a physiological demand.

It has been suggested that memantine, a recently developed weak non-competitive antagonist at the NMDA site, may offer a better treatment approach to Alzheimer's dementia (Parsons *et al.*, 1999). Memantine, due to its receptor kinetics (a combination of fast offset and strong voltage dependency), dissociates rapidly from the receptor when the receptor is activated physiologically, but blocks the receptor when it is activated continually in a moderate fashion (Parsons *et al.*, 1998). Parsons *et al.*, (1999) suggest that memantine may act at the NMDA receptor like a potent Mg^{2+} ion. Thus, memantine, like Mg^{2+}, would leave the receptor channel in the presence of a depolarization event; however, memantine in contrast to Mg^{2+} will remain bound at the receptor if a moderate depolarization is prolonged, as in the case of chronic excitotoxic insults (Parsons *et al.*, 1995; Parsons *et al.*, 1999). An alternative hypothesis was put forward by Blanpied *et al.* (1997) when studying the tendency of non-competitive receptor ligands to be trapped in the NMDA channels. Using cultured rat cortical neurons, they showed that memantine blocked NMDA-activated channels by binding to a site at which it remained trapped after channel closure and agonist dissociation from the receptor. When memantine and the NMDA agonists were removed from the culture medium, a significant number (12%) of the blocked channels released the blocker, i.e. memantine exhibited partial trapping. On the basis of their findings, Blanpied *et al.*, using a simple kinetic model of blocker action, proposed that partial trapping guarantees that during synaptic communication in the presence of a blocker, some channels will release the blocker between synaptic responses. Thus, partial trapping (as in the case of memantine) will allow some receptors to be activated under physiological activation, whereas this will not be possible if the trapping is complete, as in the case of MK-801 or other types of ligands that undergo complete trapping.

There are no data from clinical studies to support the beneficial effects of memantine suggested here. Clinical evaluation of memantine with Alzheimer's disease patients is limited to two studies (Ditzler, 1991; Gortelmeyer and Erbler, 1992) that have demonstrated some functional improvement. However, several reports from preclinical studies have demonstrated the beneficial neuroprotective effects of memantine using animal models of Alzheimer's disease. In one such study, for example (Wenk *et al.*, 1995), NMDA was injected into the nucleus basalis of

Meynert, the main source of cholinergic efferents into the cortex, and the induced decrease in acetylcholinetransferase, indicating a reduction in cholinergic activity, was blocked if memantine was administered beforehand. When the behavioural sequelae of such NMDA-induced lesions were studied, the learning deficits seen in performance on a T-maze were no longer present if the animals were treated with memantine beforehand (Wenk *et al.*, 1994). Furthermore, learning deficits in a spatial learning task seen in animals with entorhinal cortex lesions (thought to be another model of Alzheimer's disease) were improved over time (performance reaching the levels of non-lesioned animals) when memantine, but not MK-801, was administered (Zajaczkowski *et al.*, 1996). In fact, MK-801 further enhanced the lesion-induced impairment of reference memory.

Thus, the ability of memantine to be neuroprotective and to slow down the degeneration of neurons, so restoring cognitive function, may not be in conflict with the known acute effects of NMDA blockers to impair neuronal plasticity (Collingridge and Singer, 1990). However, further studies in the clinical population, or alternatively better animal models of the disease, are required to confirm the hypotheses generated from the preclinical findings.

There are as yet no models of Alzheimer's disease developed in animals to allow the testing of memantine or other glutamatergic antagonists. The models referred to here are functional models dependent on discrete lesions, and do not relate closely to Alzheimer's disease. The recent development of transgenic mice, which appear to express mutations related to the human amyloid precursor protein and which show some features of the disease (Holcomb *et al.*, 1998), will allow the neuroprotective effects of glutamatergic antagonist to be tested in a more convincing manner.

Glycine and Alzheimer's Dementia

The role of the glycine B site at the NMDA receptor in Alzheimer's disease is not well investigated. A new drug, FK 960 (*N*-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate), a potential antidementia drug, has been developed. *In vitro* studies provide evidence for an interaction of FK 960 with either cholinergic or glutamatergic systems. FK 960 reversed the effect of scopolamine, which had abolished an increase in regional cerebral blood flow response to a vibrotactile stimulation in monkeys. However, FK 960 did not reverse the effect of (+)-3-amino-1-hydroxy-2-pyrrolidone (HA-966), an antagonist of the glycine modulatory site on the NMDA receptors, which had also abolished the increase in regional cerebral blood flow. These findings suggest that FK 960 may only bring about its effects by enhancing cholinergic neurotransmission (Tsukada *et al.*, 1999). There is a report on the beneficial effects of D-glycoserine, a partial agonist at the glycine B site, after short treatment. This improved the scores in the cognitive subscale of the Alzheimer's disease assessment scale for up to 3.0 points when given at a dose of 100 mg per day (Tsai *et al.*, 1998a; Tsai *et al.*, 1999). Some recent studies have also reported beneficial effects of D-glycoserine on cognition in healthy elderly people (File *et al.*, 1999).

Oestrogen and Alzheimer's Dementia

One interesting example of a substance with a complex profile with regard to its interaction with the amino acid neurotransmitters that also has a potent neuroprotective action is oestradiol. Oestrogen replacement therapy for postmenopausal women has proven beneficial in protecting against cognitive deterioration, and has also been shown to decrease the incidence of Alzheimer's disease (Costa *et al.*, 1999; Yaffe *et al.*, 2000a; Yaffe *et al.*, 2000b). Basic neuroscience findings provide an explanation for the mechanisms by which oestrogen may affect cognition. There is evidence that oestradiol increases dendritic spine density in hippocampal neuronal cell cultures (a function related to neuronal plasticity, by reducing GABA neurotransmission in hippocampus) (Murphy *et al.*, 1998). Oestrogen was also shown to enhance basal forebrain, hippocampus and cortex cholinergic activity by influencing the synthetic enzyme for acetylcholine (Gibbs and Aggarwal, 1998) and by increasing the number of cholinergic neurons (Miller and Franklin, 1999; Miller *et al.*, 1999). It has also been reported that oestradiol enhances compensatory synaptic sprouting in the outer molecular layer of the dentate gyrus in response to an entorhinal cortex lesion (Stone *et al.*, 1998). *In vitro* studies examining the protective effects of oestrogen against excitotoxic insults causing neuronal injury or death, such as hypoxia, ischaemia or excitatory amino acids, have also shown that oestradiol prevents neuronal injury and degeneration including cellular death (Weaver *et al.*, 1997; Harms *et al.*, 2001). There is some evidence that this neuroprotective effect may be due to a negative modulation of NMDA receptors (Weaver *et al.*, 1997).

On the basis of such findings, researchers have suggested that replacement of oestrogen in elderly females would reinstate, at least in part, cognitive abilities and may prevent the incidence of Alzheimer's disease. This proposal has received a measure of empirical support in the clinical setting. Kimura (1995) demonstrated that women receiving oestrogen replacement therapy outperform women not receiving such therapy on verbal fluency, perceptual speed, spatial awareness, motor control and articulation. Several studies since have confirmed the protection of hormone replacement therapy (HRT) against cognitive deterioration and incidence of Alzheimer's disease (Birge, 1996; Birge, 1997; Birge *et al.*, 2001; Costa *et al.*, 1999; Yaffe *et al.*, 2000b; but see Binder *et al.*, 2001). These reports on the effects of HRT on cognitive deterioration and/or incidence of Alzheimer's disease derive from studies with women who needed or wished to have the oestrogen replacement, and who had started the treatment mostly in the perimenopausal age band. We have published a study (Duka *et al.*, 2000) that was designed to investigate further the effects of oestrogen on memory in a group of healthy elderly females aged 55–65 years who had never previously taken HRT. We were able to demonstrate that even a 3-week treatment regime with oestrogens can improve aspects of learning and memory.

Although there are several empirical reports on the reduced incidence of Alzheimer's disease among women who were given HRT, there is only one prospective study testing the effects of oestradiol on the progression of Alzheimer's disease (Mulnard *et al.*, 2000). In this study, the progression of the disease over 1 year (at 2, 6, 12 and 15 months of follow-up) was compared between placebo and oestradiol treatment and evaluated on the basis of change on the clinical global impression scale, as well as on global measures of mood, memory, attention, language and motor function. There was no difference in the progression of the disease between the two groups. Thus, the findings from this prospective study did not support the role of oestrogen for the treatment of this disease; it did not, however, reject a protective role of HRT treatment for the development of Alzheimer's disease. In a previous small study with Alzheimer's disease patients in which cognitive tasks like the Stroop and Buschke verbal memory were used as primary measures, there were positive effects found on cognition following transdermal application of oestradiol (Asthana *et al.*, 1999). From the evidence presented here, it can be concluded that oestradiol effects on cognition and neuroprotection may be related, at least in part, to mechanisms involving the excitatory and inhibitory amino acids. For instance, the protective effect of oestradiol against neuronal death is thought to be due, among other factors, to an inhibition of NMDA receptors (Weaver *et al.*, 1997). The increase of dendritic spine density in the pyramidal cells of

the CA1 area of the hippocampus induced by oestradiol is thought to be related to an increase in NMDA binding and an increase in the sensitivity of the pyramidal cells to NMDA synaptic input, suggesting that the new spines and synapses induced by oestradiol are enriched in NMDA receptors. This effect of oestradiol to induce an increase in dendritic spine density is suggested to be due to the reduction of GABA inhibition by oestradiol in this hippocampal area (Murphy *et al.*, 1998).

Alcohol-Induced Dementia

It is well established that chronic alcohol abuse induces morphological, physiological and biochemical changes in the brain that are associated with cognitive impairment. The cognitive deficits can be attributed mostly to associated frontal pathology (Joyce and Robbins, 1991; Joyce and Robbins, 1993; Oscar-Berman, 1980; Tarter *et al.*, 1985; Stephens *et al.*, 1992; Fein *et al.*, 1990). The amnestic effects of alcohol, however, appear to be related more to hippocampal dysfunction (Melia *et al.*, 1996; Ryabinin, 1998). In chronic alcoholics, Korsakoff's syndrome or alcohol dementia may be present. Korsakoff's syndrome is characterized by severe anterograde memory impairment, whereas other cognitive abilities remain intact. Alcohol dementia, however, presents with additional cognitive deficits. Wernicke's encephalopathy is an acute neurological condition characterized by mental confusion, abnormal gaze, ataxia, and loss of recent memory (Langlais, 1995; Fadda and Rossetti, 1998). It is assumed that a basic mechanism, an alcohol-induced neuronal degeneration process, must be involved in the sequelae of chronic alcoholism.

Ethanol possesses a complex pharmacology (Littleton and Little, 1994), which includes facilitation of GABAergic transmission through an action at the GABA–benzodiazepine-chloride-channel complex (Suzdak *et al.*, 1986; Mehta and Ticku, 1988), antagonism of glutamatergic transmission through an action at NMDA glutamatergic receptors (Hoffman *et al.*, 1989; Lovinger *et al.*, 1989), and an action at 5-hydroxytryptamine (5-HT) 5-HT_3 (Lovinger and White, 1991) and $5HT_1$ receptors (Grant and Colombo, 1993). Alcohol also interacts with neuronal voltage-gated calcium channels (Twombly *et al.*, 1990; Littleton and Little, 1994). It is now well established that the neurophysiological and brain-damaging effects of alcohol are mediated mainly via the glutamatergic system. Alcohol acutely disrupts the glutamatergic neurotransmission by inhibiting the response of NMDA receptors. In a study with recently detoxified alcoholics, administration of ketamine hydrochloride, an NMDA receptor antagonist, induced ethanol-like subjective effects (Krystal *et al.*, 1998b). In addition, the chronic effects of ethanol appear to be the result of a promotion of neuronal toxicity through upregulation or changes in the functional state of NMDA receptors. For example, superfusion with ethanol of hippocampal slice preparations or primary cell cultures reduces excitatory synaptic transmission (Lovinger *et al.*, 1989; Lovinger *et al.*, 1990; Wirkner *et al.*, 1999) on to NMDA receptors, as measured by NMDA-activated membrane current. It is generally agreed that chronic ethanol treatment will increase the sensitivity of neurons to NMDA agonists (Blevins *et al.*, 1995). However, the findings with regard to an upregulation of NMDA receptors are less consistent.

Whereas several studies have reported an increase of NMDA receptor binding (Hoffman *et al.*, 1992; Hoffman *et al.*, 1995) or an upregulation of certain NMDA receptor subunits (e.g. Hu *et al.*, 1996; Follesa and Ticku, 1996), others report no change in NMDA receptor density or subunit levels (Chandler *et al.*, 1997; Blevins *et al.*, 1997). In another study in which the brains of alcoholic patients were compared with those of matching normal controls for their maximal binding and affinities of NMDA receptors, using as ligands competitive and non-competitive antagonists, no differences were found (Freund and Anderson, 1999). In a recent study, Nagy *et al.* (2001) investigated the chronic effects of ethanol in an *in vitro* preparation in which chronic but intermittent ethanol treatment was applied on primary cultures of cortical neurons. This kind of ethanol treatment is thought to provide a good model for the study of the mechanisms underlying the kindling-like phenomenon of withdrawal observed in humans (Ballenger and Post, 1978; Brown *et al.*, 1988). In the Nagy *et al.* study, the damage of neuronal cells when alcohol was withdrawn from the medium was measured in the absence and in the presence of an NMDA non-competitive antagonist MK-801, using as a marker lactate dehydrogenase (LDH) released into the culture media. The increase in LDH during withdrawal was reduced by either introduction of alcohol again or by addition of MK-801 into the culture media. Interestingly, the presence of a GABA-A receptor antagonist muscimol in the culture media did not show any effect, further supporting the view that NMDA mechanisms are involved in the excitotoxic effects of withdrawal from alcohol (Stephens, 1995; Nagy *et al.*, 2001). However, when cerebrospinal fluid (CSF) levels of excitatory amino acid neurotransmitters (aspartate, glycine and *N*-acetylaspartylglutamate) and of GABA, together with markers of oxidative stress, were measured in alcoholics 1 week and 1 month after alcohol withdrawal, the excitatory amino acid levels were found to be increased, while those of GABA were decreased. In addition, a relationship was found between the excitatory amino acid levels and the levels of oxidative stress markers. Thus, an increase in the activity of the glutamatergic system at withdrawal and subsequent brain damage may be caused partly by an inhibition of GABAergic inhibitory systems (Tsai *et al.*, 1998b).

It is well established that patients undergoing alcohol withdrawal are more likely to experience seizures if they have undergone previous episodes of detoxification (Booth and Blow, 1993; Brown *et al.*, 1988; Lechtenberg and Worner, 1991). Analogous findings have also been reported from animal experiments, which showed that the severity of the withdrawal intensity increased following several withdrawal episodes (Becker, 1994; Becker and Hale, 1993; Baker and Cannon, 1979; Kokka *et al.*, 1993). While the development of sensitization to repeated ethanol withdrawal is illustrated clearly by the increase in seizure sensitivity in both patients and animal models, it is less clear whether cognitive deterioration seen in alcoholism also undergoes a similar process of sensitization. Nagy *et al.* (2001), for example, have suggested that the processes seen during withdrawal may be relevant for increased excitability, but they may also initiate an excitotoxicity and loss of neurons.

Korsakoff's syndrome is always accompanied by nutritional deficiencies, in particular vitamin B1 (thiamine) deficiency. Administration of thiamine will reduce the acute symptomatology of Korsakoff's syndrome and will protect the patient from further impairment due to the condition (Cook, 2000). In addition, thiamine was found recently to improve amnestic symptomatology seen in alcoholics who otherwise did not show any of signs of Korsakoff's syndrome (Ambrose *et al.*, 2001). However, incidents of Korsakoff's syndrome following thiamine deficiency alone are rare (for an example, see Parkin *et al.*, 1991), and most cases with pure thiamine deficiency unaccompanied by chronic and excessive consumption of alcohol do not progress to Korsakoff's syndrome (Homewood and Bond, 1999).

Neuropathological studies have shown a significant decrease in volume and weight of the brain, whilst imaging techniques have revealed significant functional alterations of the frontal lobe (Hunter *et al.*, 1989; Hunter, 1990), followed by the thalamus, hypothalamus (Shear *et al.*, 1996; Sullivan *et al.*, 1999; Kril *et al.*, 1997; Harding *et al.*, 2000), basal nucleus of Meynert (Arendt *et al.*, 1983; Lotfi and Meyer, 1989; Butters, 1985), and the medial temporal lobe structures in Korsakoff's syndrome or alcohol dementia sufferers (Fadda and Rossetti, 1998). However, little is known

about the underlying mechanisms involved in alcohol-induced brain damage. As discussed above, there is accumulated evidence that withdrawal excitability may share a molecular mechanism of neurotoxicity linked to an increase in the NMDA neurotransmission. Recent research into the relationship between alcoholism and dementia has focused on the role of the nutritional deficiencies present in chronic alcoholism. Pyrithiamine, which induces thiamine deficiency, produces a range of neuropathological and behavioural abnormalities in rodents and has been used as a model of Wernicke–Korsakoff syndrome.

Studies on thiamine-deficiency-induced brain damage have again provided some evidence of an NMDA involvement in the development of Korsakoff's syndrome in chronic alcoholism. Pyrithiamine-treated animals showed a higher sensitivity to the amnestic effects of NMDA antagonists (Savage *et al.*, 1999). Neuronal degeneration seen in the thalamus of animals treated with pyrithiamine was found to be similar to the cytopathological changes induced by glutamate (Ikonomidou *et al.*, 1989). In addition, the neuronal degeneration was blocked with pretreatment with the NMDA antagonist dizolcipine. In another study, a neuroprotective effect of MK-801, a non-competitive NMDA antagonist, against pyrithiamine-induced neuronal damage in the thalamus has been reported. However, in this report the effect of the NMDA antagonist was attributed mostly to its anticonvulsant activity (Todd and Butterworth, 1998).

Recent reports in the literature have highlighted a relationship between homocysteine levels and alcoholism. Homocysteine is a sulphur-amino acid putative neurotransmitter at the NMDA receptors. Its role in vascular diseases has been known for some years. Its importance in relationship to alcoholism has been discussed only recently, however. In one study, homocysteine levels were found to be high in 29 chronic alcoholics compared with controls who underwent withdrawal from alcohol (Bleich *et al.*, 2000b). In another study, Bleich *et al.* (2000a) found higher levels of homocysteine in plasma samples of patients who suffered withdrawal seizures during withdrawal compared with alcoholics who did not. The authors also reported that the same patients had more alcohol in their blood at admission; however, homocysteine levels were the best predictor for the occurrence and intensity of seizures at withdrawal. High levels of homocysteine were also found in social drinkers who consume high amounts of alcohol (Koehler *et al.*, 2001). As discussed above, the development of seizures at withdrawal may be the result of a neuronal kindling mechanism associated with increased sensitivity of the NMDA receptor. It may therefore be reasonable to suggest that increased homocysteine (an agonist at the NMDA receptor) may be an additional factor involved in this phenomenon. A direct relationship between homocysteine and alcohol dementia has not yet been found; therefore, homocysteine may be involved in the damage of brain areas that are not part of learning and memory function.

HIV Dementia

Dementia due to HIV is the most common cause of dementia in children, young adults and middle-aged people, according to a recent review (Nath and Geiger, 1998). The dementia is characterized by cognitive decline, motor dysfunction and behavioural abnormalities associated with pronounced cortical atrophy (Atwood *et al.*, 1993; Power and Johnson, 1995). The toxic effects of the HIV-1 envelope glycoprotein gp120 was thought to be responsible at least in part for the dementia seen in HIV (Doble, 1999; Lipton, 1992c; Pugh *et al.*, 2000). *In vitro* studies showing that the toxic effects due to this protein coat were modulated by activation or blocking of glutamate receptors led to the hypothesis of an involvement of glutamate in these toxic effects (Lipton, 1992a; Lipton, 1992b). Further studies have demonstrated that the presence of macrophages generated during the infection process is essential for the toxic effects of gp120 to be manifested. Previous studies have shown that monocytes infected by HIV release small molecules that activate the NMDA receptors (Giulian *et al.*, 1990; Giulian *et al.*, 1993), confirming a relationship between excitatory amino acid activation and the dementia seen in HIV. The authors of these latter studies have proposed that this molecule may be quinolinic acid, a potent NMDA receptor agonist.

In the early 1980s, quinolinic acid was thought to be a non-physiological active metabolite of tryptophan. It is now suggested that quinolinic acid is a selective activator of the glutamate receptors sensitive to NMDA, which leads to an excitation of neurons seen as an increase in firing rate (Stone, 1993). Although the neurons themselves are not infected by the HIV-1 virus, at least part of the neuronal injury observed in the brain is thought to be mediated by NMDA receptor activation (Lipton, 1994).

Quinolinic acid is the only known endogenous compound that activates the glutamate receptors selectively for NMDA. Recent reports suggest strongly that quinolinic acid may be an important factor in the development of AIDS dementia. In patients with the AIDS–dementia complex, the levels of quinolinic acid in the CSF are increased up to 20-fold (Heyes *et al.*, 1989; Heyes *et al.*, 1991), and levels in the brain are reported to be 300-fold higher than in the CSF.

Children with HIV-1 infection also showed increased quinolinic acid in the CSF compared with controls. In post-mortem brains of AIDS patients, the levels of quinolinic acid were found to be approximately 20 times higher than in controls (23 pmol 10 mg *v*. 1 pmol 10 mg (Achim *et al.*, 1993). Changes in the quinolinic acid in the CSF might be the consequence of general brain deterioration. However, there are no reports of an increase of quinolinic acid in the CSF or the post-mortem brains of Alzheimer's disease patients. One study has reported high levels of kynurenic acid in all areas of the Alzheimer's diseased brain (especially in the striatum, which was found to contain double the normal levels) (Baran *et al.*, 1999). Kynurenic acid is another endogenous compound that blocks glutamate receptors. The authors suggested that the levels of kynurenic acid might have been enough to block the NMDA receptors to induce a decrease of memory.

These findings have led to the introduction of clinical studies to test the potential of NMDA antagonists in treating HIV dementia. At present, the psychogenic effects seen in HIV sufferers are treated by drugs such as neuroleptics or selective serotonin reuptake inhibitors (SSRIs), depending on whether psychosis or depression is the prominent clinical syndrome. Other mechanisms, e.g. an excess of concentration of chemokines (Rausch and Stover, 2001), as possible mechanisms underlying the excitotoxicity seen in HIV have also been discussed and supported by recent studies, but it is beyond the scope of this chapter to present mechanisms unrelated to amino acids.

Vascular Dementia

Vascular dementia results from brain damage at certain areas of the brain where blood supply has been limited due to the damage of arteries. The process is the result of neuronal necrosis following limited blood supply, i.e. hypoxia. Hypoxia results in excitotoxic events that must involve glutamate receptor activation. However, when the clinical picture of vascular or multi-infarct dementia is manifested, the processes that lead to the cell or brain area damage are no longer present. It may be that this could be the reason why there is very little information in the literature about the biological mechanisms underlying multi-infarct dementia.

Brain Injury

Traumatic brain injury is one of the leading causes of death and disability. Cognitive disorders and amnesia are some of the disabilities seen in traumatic brain injury. Like many of the cognitive disorders discussed in this chapter, in traumatic brain injury many excitotoxic processes take place that could be associated with NMDA release. One important difference in the case of traumatic brain injury is that a surprisingly good outcome can be seen in young patients, which is the result of compensation for lost function rather than recovery of the injured area.

The young brain that still retains plasticity is able to compensate, whereas an elderly brain has less plasticity and is more likely to suffer from degeneration. Thus, the management of cognitive disorders aims not only to stop the degeneration process but also to allow healthy tissue to compensate functionally. It should be commonly accepted that recovery is not possible.

SUMMARY

This chapter has looked at the role of amino acid transmitter systems in cognitive disorders. The main inhibitory amino acid neurotransmitter, GABA, and the main excitatory amino acid neurotransmitter, glutamate, in the brain are both implicated in the dementias, firstly by their direct participation in learning and memory processes, and secondly by their involvement in neuronal degeneration.

The first part of this chapter examined the function of GABA and glutamate in cognition. Most information on the role of GABAergic activity on cognition is derived from reports of the effects of benzodiazepine ligands on memory. Whereas benzodiazepines have an amnestic effect, partial inverse agonists at the benzodiazepine receptors enhance memory. However, the weakness of the effect and the psychotogenic side effects mean that these ligands are of little use in the treatment of Alzheimer's disease. The $\alpha 5$ GABA receptor subunit is now suggested to be the site that mediates the amnestic effects of benzodiazepines, therefore new benzodiazepine inverse agonist ligands specific for the $\alpha 5$ GABA receptor subunit may be the future candidates for treating Alzheimer's dementia. It is well established that NMDA plays a crucial role in learning and memory. NMDA antagonists have been shown to impair memory in animal studies, but as yet there are no useful compounds that interact with NMDA receptors that can be used in human studies as tools to understand the role of glutamate on memory.

The second part of this chapter explored the role of amino acids in dementia in Alzheimer's disease, alcoholic dementia and HIV. It is now well established that glutamate, or more generally the excitatory amino acids, play a part in neuronal degeneration processes. Glutamate facilitates learning and memory function, while at the same time it can induce neuronal degeneration if it is activated continuously. Dysfunction of glutamate neurotransmission could be an underlying mechanism of Alzheimer's dementia. A substance with a complex profile with regard to its interaction with the amino acid neurotransmitters is oestradiol. Oestrogen replacement therapy for postmenopausal women has proven beneficial in protecting against cognitive deterioration, and it has also been shown to decrease the incidence of Alzheimer's disease. There is some evidence that this neuroprotective effect may be due to a negative modulation of NMDA receptors.

It is now well established that the neurophysiological and brain-damaging effects of alcohol are mediated mainly via the glutamatergic system. Alcohol acutely disrupts glutamatergic neurotransmission by inhibiting the response of NMDA receptors. In addition, the chronic effects of ethanol appear to be the result of a promotion of neuronal toxicity through changes in the functional state of NMDA receptors. Studies on thiamine-deficiency-induced brain damage have again provided some evidence of an NMDA involvement in the development of Korsakoff's syndrome in chronic alcoholism, and recent reports have highlighted a relationship between levels of homocysteine, a neurotransmitter at the NMDA receptors, and alcoholism, although no direct relationship has yet been found between homocysteine and alcoholic dementia.

There is a confirmed relationship between excitatory amino acid activation and the dementia seen in HIV. Studies have shown that monocytes infected by HIV release small molecules that activate the NMDA receptors. The molecules may be quinolinic acid, which is suggested to be a potent and selective activator of the glutamate receptors sensitive to NMDA. These findings have led to the introduction of clinical studies to test the potential of NMDA antagonists in treating HIV dementia.

Thus, the proposal that amino acid transmitter systems, particularly GABA and glutamate, play a role in cognitive disorders has been backed by considerable evidence from both human and animal studies. Several promising compounds may in future provide relief from the neurodegenerative effects of dementia.

ACKNOWLEDGEMENT

I would like to thank Dr. Julia Townshend for her valuable comments on an earlier draft of this chapter.

Neuropeptides and Cognitive Disorders

Garth Bissette

INTRODUCTION

Evidence for the role of neuropeptides in cognitive disorders includes several possible avenues: (1) the concentration of the neuropeptide may be found to be altered in brain regions or cerebrospinal fluid (CSF) of subjects with a cognitive disorder; (2) the neuropeptide may be associated with a metabolic or pathologic event that produces cognitive dysfunction; or (3) the administration of a neuropeptide receptor agonist or antagonist for therapeutic purposes may increase or decrease cognitive abilities. For the purposes of this review, we will not focus on neuropeptides located outside the central nervous system (CNS), and we will not attempt to incorporate the extensive literature on peripheral endocrine contributions to the cognitive state. We will review the existing data on cognitive alterations associated with CNS neuropeptides as found in both the human and laboratory animal literature.

Cognitive disorders are described in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 2000) as encompassing delirium, dementia and amnesia. Human cognition involves memory, visuospatial skills, reading, writing, mathematics, executive abilities and abstractive function. For most laboratory animals, only memory functions are directly assessable in determining cognitive abilities, although primates and some species of monkey may exhibit some executive and abstractive cognitive behaviours that can be quantitated reproducibly. Amnesia is characterized by a memory disorder in the absence of other cognitive impairments, while delirium is characterized by a disturbance in consciousness and cognition that develops over a short period of time. Dementia is characterized by a memory disturbance and one or more other cognitive deficits. Because delirium is a relatively rapid and usually transient phenomena, there is not as much research literature investigating the potential role of neuropeptides in this disorder. In contrast, the literature for both amnesia and dementia is more extensive — in the latter case, quite voluminous. This review will, necessarily, limit the coverage of these research domains to approximately the last decade, although seminal findings from earlier research publications will be mentioned.

NEUROPEPTIDE NEUROBIOLOGY

For a more comprehensive review than space allows here, see Owens *et al.* (2000) or Hokfelt *et al.* (1995). Neuropeptides are defined by convention as encompassing approximately 90 or fewer amino acids, with a combined molecular weight of less than 10 000 daltons. They are phylogenetically ancient molecules that have often been conserved across phyla to a remarkable degree. In fact, a yeast peptide mating factor shares a similar sequence of amino acids as the mammalian gonadotropin-releasing hormone (GnRH) neuropeptide. Neuropeptides are produced by transcription of DNA and translation of RNA into a protein product. This precursor protein or prohormone contains one or more copies of the active neuropeptide, which is cleaved from the precursor protein by specific processing enzymes during transport from the ribosome–Golgi complex to storage sites in vesicles. The active neuropeptide is then released into the synaptic gap, where it competes for access to the postsynaptic receptor. After binding to the receptor, the neuropeptide or its active fragment either is incorporated into the postsynaptic cell or dissociates from the receptor binding site.

Neuropeptide signalling is halted by degradation of the neuropeptide sequence into smaller fragments or individual amino acids, which are then incorporated into the general metabolic amino acid pool. Several specific peptidase enzymes that recognize particular sequences of amino acids cleave the active peptide into fragments and eventually single amino acids. No evidence for reuptake of intact neuropeptides by the presynaptic neuron has been described as occurs for the biogenic amine neurotransmitters.

Because only a few amino acids within the complete peptide sequence are required for binding to the neuropeptide receptor, it is possible for neuropeptide metabolic fragments to have activity at the receptor or for specific receptors to exist for the fragment. Furthermore, many neuropeptide families are composed of peptides with homologous sequences of amino acids but with separate messenger RNA and genes. If a peptide receptor recognizes the sequences held in common by the neuropeptide family, then it is possible to have several ligands competing for the binding site, usually with slightly different affinities. All neuropeptide receptors characterized to date use G-protein-coupled second messengers to transduce the signal at the postsynaptic membrane. Some neuropeptides, such as neurotensin or thyrotropin-releasing hormone (TRH), complex with a receptor that is then translocated from the neuronal membrane to the cell nucleus, where specific regulatory effects on gene expression ensue.

The physiological effects of neuropeptides continue for minutes to hours after binding to their receptors, compared with the seconds or minutes for many of the classical chemical and amino acid neurotransmitters. These characteristics are all the more remarkable because the concentrations of neuropeptides range from the picomolar to femtomolar, relative to the nanomolar to micromolar concentrations of the classical chemical neurotransmitters or the millimolar concentrations of certain amino acid neurotransmitters, such as glutamic acid.

Thus, neuropeptides possess unique ability to mediate chronic physiological effects, such as psychiatric symptoms. Neuropeptides themselves, however, have major limitations as direct therapeutic agents. Usually, they cannot be delivered orally, as gut peptidases are designed to destroy them. Unless designed for a physiological role via the circulatory system, most neuropeptides have quite short half-lives in blood and few are capable of penetrating the

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

blood–brain barrier. Thus, much hope for direct manipulation of neuropeptide receptors rests in chemicals that have similar three-dimensional structures with the active amino acid sequence (epitope) of the neuropeptide of interest. Because the amino acids that compose the epitope recognized by the receptor are often not contiguous in the amino acid sequence, this task requires an understanding of tertiary protein structure in solution, which is a notoriously difficult problem. However, several pharmaceutical companies have developed chemical agonists or antagonists for proteins that bind to neuropeptides, and a few of these are currently in clinical trials.

Most neuropeptides can be measured directly only by immunoassay, which uses the unique ability of the immune system to recognize subtle differences in amino acid sequences of proteins. Radioimmunoassay (RIA) and enzyme-linked immunosorbent assays (ELISA) are used principally to measure quantitatively relative concentrations, while immunohistochemistry reveals precise cellular anatomic location. The information gained from such assays has both strengths and weaknesses. Strengths of quantitative assays include an assessment of relative concentration that approximates the contributions of extracellular synaptic availability and vesicular content of the target neuropeptide. Weaknesses of immunoassays are the possible recognition of similar epitopes in fragments of the active peptide or related peptides with homologous sequences, and the inability to determine functional meaning from concentration measures.

If the relative concentration of a neuropeptide differs across experimental groups, there are several mechanisms that could contribute to such changes. An increase in expression of the precursor protein product of the neuropeptide messenger RNA that is processed to the active neuropeptide in rates that exceed degradation by peptidases is one possibility. Other possibilities are decreased degradation relative to active peptide production, decreased release of the active peptide from vesicular stores with continued synthesis of new product, and a combination of these. The reverse can be said for decreased concentrations. Without evidence of releasability and evaluation of peptidase activity and mRNA expression, the turnover of a neuropeptide cannot be approximated. Having stated this, it must be said that one can come much closer to an understanding of synaptic availability with concentration evidence alone than one can with either mRNA content or peptidase activity alone. Knowledge of mRNA concentration alone is particularly limited as the expression level, mRNA degradation and synthesis rates, and precursor processing rate all affect active neuropeptide concentrations. Neuropeptide receptor populations are subject to similar constraints, although an increase or decrease in receptor numbers can give evidence for chronically decreased or increased release of their endogenous neuropeptide ligands, respectively.

Over 100 distinct, biologically active neuropeptides have been discovered that occur in the CNS of animals. Estimates are that there may be several hundred in total. A majority of these have specific receptors, but only a few have well-defined physiological roles. Those that have been implicated in cognitive disorders number between ten and 20, but only a few of these have been associated reproducibly with specific cognitive deficits.

ADRENOCORTICOTROPIC HORMONE

This 39-amino acid pituitary hormone (see Table XV-4.1) is derived from a larger 265-amino acid precursor, proopiomelanocortin (POMC), which contains sequences that give rise to beta and gamma lipotropin, beta-endorphin, and alpha, beta and gamma melanocyte-stimulating hormones. A sequence of seven amino acids in positions 4–10 of adrenocorticotropin hormone (ACTH) are also contained in the melanocyte-stimulating hormones. DeWied and colleagues were among the first to demonstrate that ACTH 4–10 could influence cognitive behaviours. Using electric foot shock to induce laboratory rats to climb a pole to escape, it was demonstrated that peripheral administration of ACTH 4–10 in physiologically large doses would increase the latency for extinction of this learned response. An analogue of ACTH 4–10 with the substitution of a dextrarotary phenylalanine residue in position 7 exhibited the reverse effect on extinction of an active avoidance response (van Nispen and Greven, 1982) and a [Met $(O_2)^4$, D-Lys^8, Phe^9-ACTH 4–9] analogue known as Organon 2766 with oral activity was developed for clinical use.

VASOPRESSIN

Release of ACTH is regulated physiologically by several hypothalamic neuropeptides, including corticotropin-releasing factor (CRF), urocortin and vasopressin (Table XV-4.1). Two types of peripheral vasopressin receptors (VP1 and VP2) have been identified (see Rinaman *et al.*, 1995 for review). It is not surprising that vasopressin has also been shown to be active in facilitating laboratory rat performance in a memory task (see Van Ree *et al.*, 1985 for review). Le Moal (1992) demonstrated that peripheral vasopressin may produce these effects by a generally aversive, systemic effect on peripheral vasopressin receptors rather than at CNS sites. Later work,

Table XV-4.1 Structures of neuropeptides implicated in cognitive disorders

ACTH	Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Ser-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH

Cholecystokinin	Asp-Tyr(SO_3H)-Met-Gly-Trp-Met-Asp-Phe-OH

however, demonstrated that direct injection of vasopressin into rat brains could facilitate memory consolidation, and that this effect could be blocked by antagonists of the VP1 receptor. Using a vasopressin antagonist applied directly into the lateral septum, social recognition was reported to be impaired in male rats while spatial memory was unaffected (Everts and Koolhaas, 1999). Further evidence of vasopressin's role in social memory in males subjected to a vasopressin antagonist was demonstrated in rats receiving prenatal doses of an androgen antagonist, flutamide. Rats so treated were able to recognize familiar juveniles in spite of treatment with the vasopressin receptor antagonist (Axelson *et al.*, 1999), indicating that an intact androgen supply during development is crucial to the social recognition effects of vasopressin.

Initial double-blind, crossover clinical trials of an intranasally administered vasopressin analogue, desglycinamide-9-arginine-8-vasopressin, (Organon 5667), for memory improvement in patients with amnestic disorders such as Korsakoff's syndrome, Alzheimer's disease and head injury was not successful (Jennekins-Schinkel *et al.*, 1985). However, basal plasma vasopressin secretion in Korsakoff's syndrome subjects is elevated relative to non-alcoholic controls, and stimulation of vasopressin secretion with hypertonic saline produced fluctuations in vasopressin in Korsakoff's syndrome subjects that were seen to a lesser degree in non-amnestic alcoholics, indicating dysregulation of vasopressin in these disorders (Emsley *et al.*, 1995). Subjects with memory impairment due to electroconvulsive therapy (ECT) (Mattes *et al.*, 1990) and severe impairments due to Korsakoff's syndrome did not benefit from intranasal vasopressin or vasopressin analogues, but those with mild cognitive deficits due to diabetes or alcoholism did show improvement (Laczi *et al.*, 1987). While an early report of Organon 5667's potential effectiveness in improving memory of a list of low imagery words in Alzheimer's disease subjects has been reported (Peabody *et al.*, 1985), neither the Jennekins-Schinkel study (1985) nor a later, multicentre, double-blind, placebo-controlled trial of Organon 5667 in 115 Alzheimer's disease subjects over 84 days (Wolters *et al.*, 1990) showed promise as a treatment for dementia.

There have been two independent reports of altered secretion of vasopressin in alcoholics undergoing severe withdrawal symptoms. The first study found increased plasma vasopressin in withdrawn alcoholics relative to normal controls (Emsley *et al.*, 1987), while the second study reported increased vasopressin in the withdrawn alcoholic patients with delirium tremens, but decreased vasopressin secretion in the alcoholics after 10 days of withdrawal (Trabert *et al.*, 1992).

Vasopressin involvement in dementing disorders has not been researched extensively, but at least one report has claimed an increase in vasopressin levels in the temporal cortex of post-mortem Alzheimer's diseased brain (Labudova *et al.*, 1998). Most reports concerning vasopressin changes in Alzheimer's disease have not found any differences. No differences in control and Alzheimer's disease levels of vasopressin in the locus coeruleus have been observed, despite degeneration of noradrenergic cells in this region in late-stage Alzheimer's disease (van Zwieten *et al.*, 1994). The number of CRF neurons in the paraventricular nucleus of the hypothalamus that also colocalize vasopressin are increased similarly in Alzheimer's disease and controls with age (Raadsheer *et al.*, 1994), although vasopressin mRNA levels in the paraventricular nucleus of the hypothalamus and supraoptic nucleus remain unchanged in Alzheimer's disease and normal subjects (Lucassen *et al.*, 1997). There is some disagreement about the status of plasma vasopressin in Alzheimer's disease, with reports of no change in plasma or CSF relative to controls (Peskind *et al.*, 1995a) and reports of an increase in plasma but not CSF levels of vasopressin (Nadal *et al.*, 1994). Reports of increased numbers of vasopressin receptors in the choroid plexus have been published (Korting *et al.*, 1996), but vasopressin secretion after overnight water deprivation (Albert *et al.*, 1994) or due to hyperosmotic challenge (Peskind *et al.*, 1995b) does not reveal differences between Alzheimer's disease subjects and controls. These data indicate that vasopressin remains relatively unaltered in Alzheimer's disease, and argue against a vasopressin deficit underlying the memory disturbance seen in Alzheimer's disease. However, recent data indicate that vasopressin and bradykinin stimulate secretion of the amyloid precursor protein (APP) by activating alpha-secretase (Nitsch *et al.*, 1998). As alpha-secretase processing of APP yields less of the potentially toxic beta-amyloid 1–40, vasopressin receptor agonists may have a therapeutic role in Alzheimer's disease.

SUBSTANCE P

Substance P (Table XV-4.1) is an 11-amino acid member of the neurokinin peptide family that has been implicated in learning and memory functions in normal and lesioned laboratory animals (see Huston and Hasenohrl, 1995 for review). The memory-enhancing and -reinforcing effects of full-length substance P and C-terminal fragments of substance P are seen after nanomolar peripheral doses of substance P, and are accompanied by increased dopamine turnover in the nucleus accumbens but not the striatum. Others have reported that the long-lasting (21 days), memory-enhancing effects of post-training, peripherally administered substance P in rats reside in the N-terminus (substance P 1–7), with C-terminal fragments (substance P 7–11) being inactive (Tomaz and Nogueira, 1997). The substance P 1–7 N-terminal fragment has been shown to increase the *N*-methyl-D-aspartate (NMDA) receptor subunit NR2A in the hippocampus, periaqueductal grey and ventral tegmental areas and subunits NR2B and NR1 in the hippocampus and nucleus accumbens within a few hours of intracerebroventricular injection (Zhou *et al.*, 2000), indicating a glutaminergic mechanism for memory enhancement by substance P. This beneficial effect of exogenous substance P on memory is not limited to mammals, as goldfish also improve performance in an appetitive-motivated memory task after peripheral substance P injection (Mattioli *et al.*, 1997). Depending on where in the brain exogenous substance P is injected after training, either facilitation of memory (lateral hypothalamus; Staubli and Huston, 1979) or induction of amnesia (substantia nigra and amygdala; Huston and Staubli, 1978) have been reported. Inhibition of prolyl endopeptidase degradation of substance P is also associated with improvements in spatial memory in rats performing a water-maze task, although the possible contribution of other peptides, such as TRH and vasopressin, that are also metabolized by this peptidase cannot be ruled out (Toide *et al.*, 1997). In animal models of amyloid-induced deficits, where exogenous beta-amyloid was administered to rats (Nag *et al.*, 1999) or where endogenous beta-amyloid was overexpressed in transgenic mice (Tomidokoro *et al.*, 2000), substance P levels were decreased in brain regions containing senile plaques or in cortex, respectively. In another study using 18- and 26-month-old transgenic mice with the V717F mutation in APP, a decrease in substance P in nerve fibres around the granule cells of the hippocampus was observed (Diez *et al.*, 2000). The reversal of the amnestic effects of a variety of drugs or ECT by substance P has also been demonstrated in laboratory animals. Post-training peripheral administration of substance P reversed the amnestic effect of cyclohexamide or electroconvulsive shock (ECS) in mice and facilitated retention of foot-shock-enhanced passive avoidance (Schlesinger *et al.*, 1983). Similarly, post-training administration of substance P or its N-terminal fragment reversed diazepam-induced amnesia in rats performing an avoidance task (Costa and Tomaz, 1998).

Evidence for substance P involvement in human dementia symptoms can be found in studies using CSF and post-mortem brain. In a study comparing Alzheimer's disease subjects, patients with

multi-infarct dementia, and normal controls, significantly lower concentrations of substance P were found in Alzheimer's disease subjects relative to normal controls (Martinez, 1993). In a comparison of lumbar CSF from living patients with probable Alzheimer's disease and ventricular CSF from post-mortem, autopsy-confirmed Alzheimer's disease subjects, no differences were found in lumbar CSF levels of substance P between probable Alzheimer's disease patients and non-Alzheimer's disease controls, but higher substance P levels were found in late-onset versus early-onset Alzheimer's disease cases (Rosler *et al.*, 2001). The ventricular CSF levels of substance P were lower than post-mortem lumbar CSF levels, but no differences were seen between Alzheimer's disease patients and controls. In an elegant post-mortem immunohistochemical study using Alzheimer's disease subjects and non-demented controls with and without high levels of senile plaques, amygdala concentrations of substance P were found to be reduced in Alzheimer's disease subjects relative to the normal controls, although senile plaques contained dystrophic neurites staining for substance P in all cases (Benzing *et al.*, 1993).

In another immunohistochemical study, substance P neurons in the remaining developmental cortical subplate beneath the striate cortex of Alzheimer's disease subjects were found to be decreased relative to age-matched non-Alzheimer's disease controls (Ang and Shul, 1995). However, in a recent immunohistochemical investigation using post-mortem Alzheimer's disease tissue and age-matched non-Alzheimer's disease control tissue, no real differences in substance P staining intensity were seen in the hippocampus, frontal cortex or occipital cortex (Yew *et al.*, 1995). Substance P receptors are decreased in the striatum of Alzheimer's disease subjects relative to Parkinson's disease patients, but not controls (Rioux and Joyce, 1993), while the activity of the metalloendopeptidases that degrade substance P were found to be decreased in Alzheimer's diseased temporal cortex but not hippocampus or caudate nucleus post-mortem tissue, relative to non-Alzheimer's disease controls (Waters and Davis, 1995).

ENDOGENOUS OPIOIDS

The endogenous opioids comprise a family of neuropeptides that interact with one or more types of opioid receptors (for review, see Wagner and Chavkin, 1995). One of the possible cleavage products of the POMC precursor protein is beta-endorphin (Table XV-4.1), which is released from the anterior pituitary by the actions of CRF, vasopressin or urocortin on POMC cells. The enkephalins Met-enkephalin (MEK) (Table XV-4.1) and Leu-enkephalin (LEK) (Table XV-4.1) are derived by differential processing of the pro-enkephalin precursor protein. Four different bioactive products can be obtained from the pro-dynorphin precursor protein: dynorphins A and B (Table XV-4.1), and alpha- and beta-neoendorphin. The opioid receptors comprise three major subtypes: mu, delta and kappa opioid receptors. Unlike most neuropeptides, a chemical antagonist for opioid receptors, naloxone, has been known for some time. This panoply of possible agonists and multiple receptors provides a rich substrate for behavioural and physiological responses to painful stimuli.

Most of the evidence for a role for endogenous opioids in cognitive disorders is found for beta-endorphin, which can be measured and, more importantly, alterations interpreted, from blood samples. In delirium, beta-endorphin is decreased in spinal fluid relative to non-delirious age-matched controls, and this decrease correlates with performance on the mini-mental status exam (Koponen *et al.*, 1989b). A follow-up 1 year later saw continued deficits in beta-endorphin in CSF from delirious patients (Koponen and Riekkinen, 1990). However, beta-endorphin in blood was elevated in post-operative delirium (McIntosh *et al.*, 1985) and was not changed in alcoholics undergoing acute withdrawal (Brambilla *et al.*, 1988)

Much of the evidence for endogenous opioid actions in amnesia comes from animal studies. Peripheral administration of beta-endorphin produces retrograde amnesia in rats (Izquierdo *et al.*, 1980), and intracerebroventricular beta-endorphin or MEK produces a similar effect (Lucion *et al.*, 1982). In contrast to these findings, pentylenetetrazol seizure-induced amnesia is reversed by beta-endorphin administered peripherally (Baratti *et al.*, 1990). In a series of papers, researchers demonstrated the ability of dynorphin A to reverse passive-avoidance-task amnesia in mice produced by galanin (Kameyama *et al.*, 1994) or scopolamine (Ukai *et al.*, 1995), or carbon-monoxide-delayed amnesia for a Y-maze task in mice (Hiramtsu *et al.*, 1997). Others found that dynorphin would enhance avoidance performance in mice, while mu and delta receptor antagonists also had this effect (Ilyutchenok and Dubrovina, 1995). In a surprising report in light of the above data, these researchers reported that dynorphin agonists for delta 1 and delta 2 receptors could actually produce amnesia in mice in a variety of learning tasks (Ukai *et al.*, 1997). The latest contribution from this laboratory used beta-amyloid to induce amnesia in mice and found that dynorphin A (full-length, or with the first amino acid deleted) could improve performance in both passive-avoidance and Y-maze performance (Hiramatsu *et al.*, 2000).

Human evidence for endogenous opioid involvement in amnestic disorders includes a post-mortem brain study of Wernicke–Korsakoff's syndrome patients where, relative to controls, these subjects and alcoholics had increased beta-endorphin levels in the mammillary bodies, the site of neurodegeneration in this syndrome (Summers *et al.*, 1991). In another study implicating endogenous opioids in the production of amnestic symptoms, the opioid receptor antagonist naloxone was shown to reduce the adverse cognitive effects of ECT, including amnesia (Prudic *et al.*, 1999).

There is a large literature on the effects of endogenous opioids in dementing disorders, principally Alzheimer's disease. Beta-endorphin has been found to be increased in blood from clinically diagnosed 'probable' Alzheimer's disease subjects relative to cognitively normal, age-matched controls (Franceschi *et al.*, 1988), and others have seen a similar increase in beta-endorphin blood levels of demented Parkinson's disease patients (Rabey *et al.*, 1990). This elevation in plasma beta-endorphin levels was shown to be increased in Alzheimer's disease relative to normal controls, normal elderly controls, or multi-infarct dementia subjects (Rolandi *et al.*, 1992). The concentration of beta-endorphin in CSF from Alzheimer's disease subjects has been shown to be normal relative to controls and does not change with severity of dementia in Alzheimer's disease. However, Binswanger's disease subjects had increased levels of beta-endorphin in CSF (Lee *et al.*, 1990). Others have confirmed the finding of normal levels of beta-endorphin in CSF from Alzheimer's disease subjects (Martinez *et al.*, 1993). Dynorphin A (1–8) levels in CSF from Alzheimer's disease subjects have been reported to be reduced to around 60% of those for age-matched non-demented controls (Sunderland *et al.*, 1991).

Using post-mortem tissue, the amount of MEK immunohistochemical staining in striasomes in the striatum and globus pallidus of Alzheimer's disease subjects was similar to that seen in age-matched normal controls (Matsumoto *et al.*, 1990). This finding of normal MEK in striatal patches was later confirmed (Gearing *et al.*, 1997) and shown to have no association with beta-amyloid-containing senile plaques. Receptors for MEK and LEK (mainly delta opioid receptors) were reported to be decreased in the temporal cortex, amygdala and hippocampus of Alzheimer's disease subjects compared with age-matched controls, while the external globus pallidus was unchanged (Rinne *et al.*, 1993). In another report that assessed opioid receptor populations in Alzheimer's disease, the number (B_{max}) and binding affinity (K_d) of mu receptors were normal in the frontal cortex, amygdala and putamen, while the

number of kappa receptors was increased in the amygdala and the numbers of both kappa and delta opioid receptors were decreased in the putamen relative to age-matched controls (Barg *et al.*, 1993). In both Alzheimer's disease and Down's syndrome post-mortem tissue, the frontal cortex concentrations of LEK and dynorphin have been reported to be decreased relative to normal controls (Risser *et al.*, 1996).

GALANIN

Galanin (Table XV-4.1) was originally purified from the colon and pituitary. It is a 30-amino acid neuropeptide that generally inhibits the firing of neurons with which it communicates (see Bartfei, 1995 for review). Recently, a third galanin receptor, GAL3, was cloned in rats and humans (Smith *et al.*, 1998). The major evidence for galanin involvement in cognitive disorders is in Alzheimer's disease. Galanin is one of the only neuropeptides shown to increase in concentration in Alzheimer's disease, rather than decrease or show no change. Found in neurons of the nucleus basalis of Meynert, where acetylcholine-producing neurons degenerate in Alzheimer's disease, galanin has been shown to increase in concentration and inhibit cholinergic cell activity (see Crawley, 1996 for review). The concentration of galanin is increased significantly in post-mortem Alzheimer's disease tissue in several frontal, temporal and parietal cortical regions (Gabriel *et al.*, 1994), and temporal, but not occipital, cortical receptors for galanin are decreased (Ikeda *et al.*, 1995), which may indicate downregulation in response to increased galanin release. Others have reported galanin receptors to be increased in the hippocampus, decreased in the caudate nucleus, and unchanged in the frontal and entorhinal cortex of Alzheimer's disease compared with age-matched controls (Rodriguez-Puertas *et al.*, 1997). In contrast to these findings, confocal microscopic examination of nucleus basalis neurons in Alzheimer's disease demonstrated galanin hyperinnervation of basalis cholinergic neurons (Bowser *et al.*, 1997), and autoradiography indicated increased numbers of galanin receptors in the nucleus basalis in late-stage but not early-stage Alzheimer's disease tissue (Mufson *et al.*, 2000). Noradrenergic neurons of the locus coeruleus that express galanin mRNA are preserved in Alzheimer's disease tissue, indicating the specificity of the changes observed in the nucleus basalis (Miller *et al.*, 1999).

Animal evidence for galanin association with cognitive function includes administration of exogenous galanin to rats with or without 192IgG-saporin lesions of nucleus basalis cholinergic neurons. Exogenous galanin reduced accuracy in a delayed non-matching to position memory task in both lesioned and normal rats, and this effect on memory of the cholinergic lesion was not attenuated by administration of a galanin antagonist, M40 (McDonald *et al.*, 1997). A later paper from this group used the galanin antagonist in addition to a muscarinic M1 cholinergic receptor agonist and reported improvement of performance in this delayed non-matching to position memory task (McDonald *et al.*, 1998). Using transgenic mice with overexpression of a mutated human APP gene, galanin immunoreactivity was increased in several hippocampal neuronal fields and in the ventral cortex, while diffuse galanin staining in noradrenergic fibres of the hippocampus were no longer visible at 26 months of age in these transgenic mice (Diez *et al.*, 2000). Non-peptide galanin antagonists have also been developed and shown to reverse the inhibitory effects of galanin on acetylcholine release in rat hippocampal brain slices (Scott *et al.*, 2000).

THYROTROPIN-RELEASING HORMONE

There is little direct evidence for alteration of TRH (Table XV-4.1) in cognitive disorders, and TRH remains undisturbed in Alzheimer's diseased brain (Nemeroff *et al.*, 1989), yet a body of evidence does exist that supports a role for TRH or TRH analogues in the treatment of cognitive disorders (see Bennett *et al.*, 1997 for review). This tripeptide regulates the release of thyrotropin and prolactin from the anterior pituitary and is implicated in physiological regulation of body temperature (see Mason *et al.*, 1995 for review). Pharmacologically, TRH reverses the effects of drugs that produce depression of CNS activity, such as alcohol and barbiturates, and assists in neuronal recovery from damage through trophic effects. This arousal-like effect of TRH may be responsible for its beneficial effects in cognitive disorders, and TRH may be particularly useful in this regard as it produces CNS effects after peripheral administration. Using synthetic TRH to induce release of thyrotropin from the pituitary, a lack of dose response to TRH stimulation was observed in Alzheimer's disease subjects (Lampe *et al.*, 1988), indicating possibly reduced sensitivity of pituitary TRH receptors. However, other attempts to replicate this effect of TRH on thyroid-stimulating hormone (TSH) (Molchan *et al.*, 1991; Tsuboyama *et al.*, 1991; Albert *et al.*, 1993) or prolactin (Bille *et al.*, 1991) did not observe differences between Alzheimer's disease subjects and age-matched normal controls. Researchers at National Institutes of Health (NIH) used intravenous doses of TRH in Alzheimer's disease subjects and reported increased arousal and improvement in mood, as well as a modest increase in semantic memory (Mellow *et al.*, 1989). This ability to improve cognition was demonstrated later in normal subjects with transient scopolamine-induced memory impairment (Molchan *et al.*, 1990). A TRH analogue, posatirelin, has been used in the treatment of Alzheimer's disease, and after 3 months of daily intramuscular injections, in a variety of measures involving intellectual function, orientation and memory, the TRH-treated group were improved over groups receiving placebo or a reference drug, citicoline (Parnetti *et al.*, 1995). This same group of researchers assessed the effect of this analogue on vascular dementia subjects compared with placebo-treated controls; after 3 months of daily intramuscular injection, they found similar improvements as before in the posatirelin group (Parnetti *et al.*, 1996).

Animal studies have largely confirmed the clinical reports of beneficial effects of TRH analogues on memory task performance. Using a slowly released formulation of TRH administered subcutaneously, TRH blood levels were increased for up to 4 weeks, increased time was spent in the open arms of an elevated plus maze, and improved spatial memory performance was seen in a water-maze task of a strain of senescence-accelerated mice compared with a normally ageing strain (Miyamoto *et al.*, 1994). Effects were not seen immediately after injection, but were first present 10/days after initial injection of TRH. In a study using aged rats, inhibition of a peptidase that metabolizes TRH by the compound JTP-4819 improved spatial memory impairments in water-maze performance that were present in the aged rats relative to non-aged controls (Toide *et al.*, 1997). A TRH analogue with N-terminal substitutions that improves cognitive and motor recovery after a fluid percussion brain injury in rats has been developed that is devoid of analeptic or endocrine effects (Faden *et al.*, 1999). Others have demonstrated the ability of nicotinic receptor antagonists to abolish the neuroprotective effects of TRH in restoring consciousness to mice with concussive head injury (Lestage *et al.*, 1998).

CHOLECYSTOKININ

Cholecystokinin (CCK) is a 33-amino acid neuropeptide (Table XV-4.1) that shares sequence similarity with the gut hormone gastrin (see review by Beinfeld, 1995). There are two CCK receptors, CCKA and CCKB; the C-terminal 8-amino-acid sulphated fragment of CCK has activity at both receptor subtypes. Although normal levels of CCK are found in Alzheimer's diseased brain, there are several reports of cognitive effects of analogues interacting

with both CCK receptor subtypes. Intravenous administration of the CCK analogue ceruletide improved event-related potentials as measured by electroencephalography (EEG) in the brains of young, but not aged, subjects (Dodt *et al.*, 1996). Intravenous administration of the CCK-4 fragment has produced panic attacks in humans, and it has been suggested that this effect is due to CCK altering information processing (Aluoja *et al.*, 1997), while others have found that CCK-4 administration decreases short-term memory performance (Shlik *et al.*, 1998).

Animal evidence for CCK effects on cognitive processes indicates the possibility of more than one CCKB receptor subtype (see Dauge and Lena, 1998 and Fink *et al.*, 1998 for reviews). While the general consensus from animal studies supports the concept that CCKA agonists and CCKB antagonists improve memory function, exceptions have been noted. Using a two trial memory task with periods of 2 and 6 hours after initial training, the CCKB agonist BC 264 improved memory at the 6-hour timepoint after post-training intraperitoneal injection, while the CCKB agonist BC 197 disrupted memory at the 2-hour timepoint (Lena *et al.*, 1999). These results have been interpreted as indicating the possible existence of subtypes of CCKB receptors, as selective CCKB antagonists abolished these effects while selective CCKA antagonists were without effect. These effects of BC 264 were later extended to aged rats, and demonstrated that injection before training was not effective while post-training injection was effective (Taghzouti *et al.*, 1999). Using an olfactory recognition test of memory, the memory-enhancing effects of a CCKB antagonist were abolished by perforant path lesions, while this lesion did not alter CCKA agonist effects but a subdiaphragmatic vagotomy did (Lemaire *et al.*, 1994).

SOMATOSTATIN

Somatostatin (somatotropin-release inhibiting factor, SRIF; Table XV-4.1) is a neuropeptide that was originally isolated from the hypothalamus of sheep and pigs as a factor controlling the release of pituitary hormones (see Epelbaum *et al.*, 1994 and Rubinow *et al.*, 1995 for reviews). Somatostatin was shown to physiologically regulate the release of growth hormone and many other pituitary hormones by providing the inhibitory component of the dual regulation experienced by most of the anterior pituitary hormones. Upon further investigation, it was quickly realized that the distribution of SRIF outside of the hypothalamus was more indicative of a neurotransmitter role in addition to that as a hypothalamic releasing factor, and application of SRIF to neurons consistently inhibited their firing rate. It was subsequently found to often be colocalized within neurons containing the inhibitory transmitter, γ-aminobutyric acid (GABA) in the cortex. Two active forms have been identified that are cleaved from a larger precursor molecule and contain either 14 or 28 amino acids. Five molecular subtypes of SRIF receptors have now been cloned, and the specific peptidases contributing to the degradation of active SRIF have also been identified.

Somatostatin and Delirium

In a series of papers, researchers have demonstrated decreased SRIF concentrations in the CSF of patients with delirium. In the first paper (Koponen *et al.*, 1989a), elderly patients with delirium were shown to have significantly less SRIF in the CSF than elderly controls, and SRIF deficits were correlated with increasing cognitive dysfunction. In the next paper (Koponen *et al.*, 1990), SRIF concentrations in the CSF of delirious subjects were assessed acutely and 1 year after initial examination. Compared with age-matched non-delirious controls, SRIF was decreased in the delirious subjects' CSF and continued to decrease over time as cognitive deficits increased. These researchers then published a report of follow-up in elderly delirious subjects that encompassed 4 years from initial examination (Koponen *et al.*, 1994). As before, the SRIF concentrations in the CSF of delirious subjects continued to decline and was correlated with decreased scores on the mini-mental state exam. Schizophrenics with cognitive deficits have also been reported to have less SRIF in the CSF than normal controls, but the SRIF deficits in these subjects did not correlate with cognitive impairment (Reinikainen *et al.*, 1990).

Evidence for involvement of SRIF in amnesia is mostly found in animal studies. Using ECS to induce amnesia in rats trained in an active avoidance task motivated by foot shock, intracerebroventricular (ICV) administration of SRIF at doses of 4 μg/4 μl significantly increased the avoidance latency when administered immediately or up to 23 hours after ECS (Vecsei *et al.*, 1983); this effect was found to require the entire SRIF molecule, as both SRIF 3–6 and SRIF 7–10 were inactive (Vecsai *et al.*, 1984). Analogues of SRIF with dextrarotary amino acid substitutions (D-TRP8, D-Cys14) were later found to be effective in reversing ECS-induced amnesia (Vecsai *et al.*, 1986), although other analogues with deletions of N-terminal amino acid residues were not effective. Using cysteamine to temporarily deplete SRIF, Haroutunian *et al.* (1987) observed increased locomotor activity and deficits in retention of training performance in a passive-avoidance task. Up to 50% depletion of cortical SRIF was observed and preceded increased SRIF concentrations in the CSF. Thiamine deficiency (25 days) was used to produce impairment of an avoidance response, and this amnestic effect was correlated with decreased concentrations of SRIF in several brain regions, including the cerebral cortex, amygdala, thalamus, hippocampus and hypothalamus (Nakagawasai *et al.*, 2000). A single thiamine treatment after 14 days was sufficient to prevent both behavioural and SRIF neurochemical deficits.

Somatostatin in Alzheimer's Disease

Somatostatin concentration deficits in the cortex of Alzheimer's diseased brain post-mortem were the second neurotransmitter system to be implicated in Alzheimer's disease pathology after the discovery of the cholinergic deficits (see Bissette and Myers, 1992 and Vecsai and Klivenyi, 1995 for reviews). Among the peptides colocalized with GABA in cortical neurons, SRIF is the second most abundant after substance P and is more pervasive than either vasoactive intestinal peptide (VIP) or CCK, which do not appear to be principal targets of Alzheimer's disease pathology (Gabriel *et al.*, 1995; Mazurek and Beal, 1991). The major population of SRIF neurons affected in Alzheimer's disease are cortical interneurons that do not contain other peptides such as neuropeptide Y (Davies *et al.*, 1990; Gabriel *et al.*, 1993), with most subcortical regions, such as the nucleus basalis and hypothalamus, largely unaffected, although a recent report indicates that SRIF deficits in subcortical white matter do exist (Ang and Shul, 1995) in Alzheimer's disease. Another report (Gaspar *et al.*, 1989) has implicated SRIF 28 as the species of SRIF most involved in Alzheimer's disease pathology, and *in situ* hybridization surveys of messenger RNA for the pre-pro-SRIF precursor molecule have shown that residual synthetic capacity for SRIF exists in many regions where absolute SRIF concentrations are decreased (Dournaud *et al.*, 1994). This would indicate that the presynaptic neuronal machinery necessary to produce SRIF is capable of continued synthesis and could be a potential target for therapeutic intervention. A recent paper reported that blocking GABA-B presynaptic receptors that mediate SRIF release produced cognitive enhancing effects (Bonanno *et al.*, 1999). Further support for a dysregulation of SRIF metabolism is found in reports that claim that the amount of SRIF precursor is increased relative to the active form of the peptide in the CSF from Alzheimer's disease patients (Gomez *et al.*, 1986), and that SRIF 28

is the species reduced in the CSF from Alzheimer's disease patients (Yasuda *et al.*, 1995). However, the presumably postsynaptic SRIF receptors are not upregulated in an attempt to compensate for the reduced synaptic availability of SRIF; in fact, the opposite is the case. Several research groups (Beal *et al.*, 1985; Krantic *et al.*, 1992; Bergström *et al.*, 1991) have now reported SRIF receptor populations in post-mortem cortex to be decreased in number, but unchanged for ligand affinity, in Alzheimer's disease. In addition to the decreases in endogenous ligand concentration and receptor dysregulation, the peptidases that degrade the active forms of SRIF are also altered inappropriately (Weber *et al.*, 1992), degrading SRIF more efficiently in post-mortem Alzheimer's diseased cortex than peptidases from non-Alzheimer's diseased brain.

Attempts to address the SRIF deficit with long-acting SRIF analogues have been unsuccessful in reversing Alzheimer's disease dementia (Mouradian *et al.*, 1991), partly because of the decreased numbers of receptors and increased activity of peptidases, and uncertainty over SRIF access to the CNS after peripheral administration. The SRIF concentration deficit has been observed widely in CSF (see Bissette and Myers, 1992) as well as post-mortem brain tissue from Alzheimer's disease patients, and several papers have now described treatment-induced amelioration of these CSF deficits in SRIF concentrations that may correlate with cognitive improvement (Karlsson *et al.*, 1985; Widerlöv *et al.*, 1989; Alhainen *et al.*, 1991). Unfortunately, any disease that produces significant cognitive impairment seems to reduce SRIF concentrations in the CSF, as indicated by the temporary and reversible deficits in CSF SRIF during bouts of delirium (Koponen *et al.*, 1990). The amount of SRIF in the CSF correlates significantly with dementia severity in Alzheimer's disease (Tamminga *et al.*, 1987), and with cognitive decline in multiple sclerosis (Roca *et al.*, 1999), and it could be a useful measure of treatment response. While this lack of specificity prevents SRIF in the CSF from being useful as a diagnostic indicator for the presence of Alzheimer's disease, these data indicate that the concentration of SRIF in the CSF may be a useful biological marker for treatments that successfully improve cognitive state.

CORTICOTROPIN-RELEASING FACTOR

This 41-amino acid neuropeptide (Table XV-4.1) was isolated and characterized in the early 1980s by Vale. A binding protein sequesters CRF for quick release and provides a mechanism by which CRF signalling can be amplified quickly upon demand (for review, see De Souza and Grigoriadis, 1995). Outside of the hypothalamus, CRF is located in limbic system regions and within a population of cortical interneurons. A plethora of behavioural studies have implicated CRF systems as major mediators of behavioural responses to stimuli producing fear and anxiety, and CRF hypersecretion is suspected to be a mediator of some of the endocrine changes and behavioural symptoms of major depressive disorder in humans (Nemeroff *et al.*, 1984). Two major subtypes of CRF receptors, CRFR1 and CRFR2, are now known to exist (Chalmers *et al.*, 1995; Lovenberg *et al.*, 1995), and a portion of the bioavailable CRF is sequestered from receptors and peptidase degradation by the action of an endogenous CRF binding protein.

Corticotropin-Releasing Factor in Delirium

Comparing AD subjects with delirium with multi-infarct patients, researchers reported decreased plasma CRF in the evening and increased CRF and ACTH in the morning in the Alzheimer's disease subjects relative to the vascular dementia subjects (Suemaru *et al.*, 1991b). In a study of acute alcohol withdrawal patients, CRF in the CSF was correlated significantly and positively with CSF noradrenaline during early phases of withdrawal, and both these measures correlated with diastolic blood pressure (Hawley *et al.*, 1994).

Corticotropin-Releasing Factor in Alzheimer's Disease

CRF was first reported to be decreased in concentration in the frontal and temporal cortex of Alzheimer's disease post-mortem brain compared with non-Alzheimer's disease control tissues in 1985 (Bissette *et al.*, 1985). The concentration of CRF in the Alzheimer's disease group was not significantly different from the controls in subcortical regions such as the nucleus basalis or hypothalamus, although in this patient population the caudate nucleus had significantly diminished concentrations of CRF in the Alzheimer's disease group. The deficits in cortical CRF concentrations in Alzheimer's disease were quickly confirmed (De Souza *et al.*, 1986). These workers extended this finding to occipital and parietal cortical regions, and observed that the postsynaptic neurons containing CRF receptors were demonstrating an inversely proportional, regionally specific increase in CRF receptor number relative to the decrease in the concentration of the CRF endogenous ligand in an apparent attempt to compensate for the reduced synaptic availability of CRF. Based on the regional distribution of the upregulated CRF receptor population found in Alzheimer's disease, it is likely that subtype involved is the CRF_1 receptor (D. Chalmers, personal communication); previous work has shown that the increase in CRF binding in Alzheimer's diseased tissue is due to functional CRF receptors (Grigoriadis *et al.*, 1989). Immunohistochemical staining confirmed that the cortical CRF concentration decreases in Alzheimer's disease were due to degeneration of the interneurons of the cortex containing CRF (Powers *et al.*, 1987). Other areas of the brain, such as the hippocampus, hypothalamus and cerebellum, have been shown to retain substantial levels of CRF-immunoreactive fibres and cells in Alzheimer's disease (Kelley and Kowall, 1989). Most of the CRF-related changes reported in Alzheimer's disease have involved the cortical interneuron CRF circuits, and few groups have reported CRF concentration changes outside of the cortex or within the hypothalamus (for review, see Bissette, 1997). However, evidence of hypothalamic dysregulation in Alzheimer's disease has been reported for the response of the hypothalamic-pituitary-adrenal (HPA) axis to challenge with exogenous synthetic CRF (Hartzinger *et al.*, 1995). Others have reported elevations in the level of CRF mRNA in the post-mortem paraventricular nucleus of the hypothalamus in Alzheimer's diseased patients, and even greater elevations in patients with a clinical history of major depression during life (Raadsheer *et al.*, 1995). As elevations of CRF are reported in the CSF of depressed patients relative to controls (Nemeroff *et al.*, 1984), along with other indicators of increased secretion of hypothalamic CRF, it would seem possible, based upon the CRF mRNA elevations in the hypothalamus of patients with Alzheimer's disease, that CSF concentrations of CRF may also be elevated in Alzheimer's disease relative to non-Alzheimer's diseased patients if hypothalamic CRF contributes significantly to CSF concentrations. One research group has reported such an increase (Martignoni *et al.*, 1990), and demented patients with depression (Banki *et al.*, 1992) have also exhibited such increases in CSF concentrations of CRF. However, CSF concentrations of CRF in simple Alzheimer's disease have also been reported to be either unchanged (Nemeroff *et al.*, 1984; Molchan *et al.*, 1993; Pomara *et al.*, 1989; Jolkkonen *et al.*, 1990; Edvinsson *et al.*, 1993; Banki *et al.*, 1992) or decreased (Heilig *et al.*, 1995; May *et al.*, 1987; Mouradian *et al.*, 1986; Suemaru *et al.*, 1991a; Suemaru *et al.*, 1995), depending on the control and Alzheimer's disease patient populations being compared and the laboratory reporting the data. These disparities are almost certainly due to the uncertainty of the diagnosis of Alzheimer's disease in patients during life. Our group has observed some populations of Alzheimer's disease patients with a nonsignificant increase in CRF

in the post-mortem hypothalamus (Bissette *et al.*, 1985) and other Alzheimer's disease groups with relative decreases in hypothalamic CRF and SRIF that did achieve statistical significance (Bissette *et al.*, 1998). Thus, a consensus on the state of the CSF and hypothalamic CRF in Alzheimer's disease remains elusive.

Recently, a strategy (Behan *et al.*, 1995) was proposed whereby the apparently reduced synaptic availability of CRF might be restored to near-normal levels in Alzheimer's disease patients. Using shortened analogues of CRF to displace endogenous CRF from the CRF binding protein, the amount of free CRF in post-mortem Alzheimer's diseased brain was able to be increased to control levels. The amount of CRF binding protein was similar in the Alzheimer's diseased cortical tissue and in the normal control brain in the frontal, temporal, parietal and occipital cortices. The ligand that displaces native CRF from the binding protein does not produce anxiety in laboratory animals at doses that effectively improve memory and learning, as assessed with the Morris water-maze task. Once such compounds are developed that can cross the blood–brain barrier in sufficient quantities to similarly affect the CRF binding protein of living patients, it will be possible to determine which symptoms of Alzheimer's diseased are mediated by the CRF concentration deficits seen at the time of death.

In one of the most important papers on the neurochemistry of Alzheimer's disease that has been published, the Mt Sinai group (Davis *et al.*, 1999) demonstrated that CRF cortical deficits become significantly different from age-matched controls when a score of 2 (out of a possible 5) is reached on the clinical dementia rating scale. Somatostatin and acetylcholine were not decreased significantly until a score of 4 was achieved. These data can be interpreted as indicating an earlier involvement of CRF in the neurodegenerative process, and make approaches to normalizing the synaptic availability of CRF more urgent.

MISCELLANEOUS PEPTIDES

Other peptides that have been implicated in cognitive disorders but have not been assessed thoroughly include neuropeptide Y (NPY) and insulin-like growth factor 1 (IGF-1). NPY has been shown to be decreased in schizophrenia (Gabriel *et al.*, 1995) and unchanged in Alzheimer's diseased post-mortem brain (Gabriel *et al.*, 1993), but little evidence from animal studies supports a role for NPY in clinical disorders of cognition. The association of IGF-1 with growth hormone and cognitive function are reviewed by van Dam *et al.* (2000) and Dore *et al.* (2000). IGF-1 levels are unchanged in Alzheimer's diseased frontal cortex, hippocampus and cerebellum relative to controls, and IGF-1 receptor affinity and numbers are also unchanged. However, IGF-1 has been observed in neurites contained in senile plaques (Jafferali *et al.*, 2000). Others have observed plasma IGF-1 levels to be correlated positively with cognitive performance, as assessed by the mini-mental status exam in aged subjects (Rollero *et al.*, 1998); this was confirmed recently with elderly males (Aleman *et al.*, 2000).

In summary, it is obvious that much work remains to be performed in assessing the contribution of neuropeptide neurotransmitters to conditions resulting in cognitive impairment. However, the diverse physiological effects mediated by neuropeptides and the panoply of pharmacological targets provided by neuropeptide receptors ensures that this knowledge will continue to be pursued assiduously.

The Neuroendocrinology of Cognitive Disorders

Sonia J. Lupien

INTRODUCTION

For many years, endocrinologists and neuroscientists thought that hormones, which are biological products secreted by peripheral glands, did not access the brain and acted mainly at the level of the peripheral nervous system. However, in the early 1960s, the discovery of neuropeptides as substances that not only had classical endocrine effects but also affected brain and behaviour significantly extended our view of hormones and opened the door to new possibilities of hormonal actions on the brain (for a complete historical background, see De kloet, 2000). The idea of a central action of hormones was also supported by studies showing that long-term therapy with anti-inflammatory drugs (which are synthetic corticosteroids) led to significant mental and cognitive deficits known as 'steroid psychosis' (Clark *et al.*, 1952). As shown in Figure XV-5.1, the symptoms of steroid psychosis appear gradually with chronic administration of synthetic corticosteroids, and include emotional lability, anxiety, distractibility, pressured speech, sensory flooding, insomnia, depression and cognitive impairment.

Grade 1	Mild euphoria Lessened fatigue Improved concentration Elevated mood
Grade 2	Heightened euphoria Flight of ideas Impaired Judgement Insomnia Increased appetite Memory impairment
Grade 3	Anxiety Phobia Rumination Hypomania Depression
Grade 4	Psychosis

Figure XV-5.1 Chronology of psychiatric symptoms occurring after long-term exposure to high levels of synthetic corticosteroids, resulting ultimately in steroid psychosis

The presence of a mental disorder induced by exposure to high levels of a corticosteroid hormone strongly suggested that these substances could, in some way, access the brain and impact on behaviour. Such a hypothesis was appropriate, since in 1943, Harris had completed a series of landmark anatomical studies that established clearly that the central nervous system regulates the hypothalamic-pituitary-adrenal axis (HPA) (for an historical review, see Harris, 1972). Following the discovery of a significant effect of corticosteroid on brain function, a significant number of animal and human studies assessed the potential impact of this steroid hormone on learning and memory. It is clear that the neuroendocrinology of cognitive disorders encompasses the unique action of corticosteroids on memory function (for reviews, see Sherwin, 1999, McGaugh, 2000, McGaugh and Izquierdo, 2000 and Sara, 2000). However, in order to describe in detail the extent and nature of the impact of hormonal variations on animal and human cognitive function, we will use the corticosteroid model (one of the most well-described models to this day), with the idea in mind that many of the methodological factors that have to be controlled for in our study of the impact of corticosteroids on cognitive function are the same as those that are important in other studies measuring the effects of various hormones on animal and human cognitive processing.

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The HPA (Figure XV-5.2) axis along with the sympathoadrenal system governs metabolic responses to the stresses of everyday life, as well as to the demands that prevail under conditions of chronic, severe stress (Sapolsky, 1992). In response to stress, hypothalamic neurons release corticotropin-releasing factor (CRF), which will trigger subsequent secretion and release of adrenocorticotropic hormone (ACTH) from the pituitary. The corticosteroids (corticosterone in animals, cortisol in humans) will be secreted and released from the adrenal glands in response to ACTH stimulation.

The responsivity of the HPA axis to stress is, in part, determined by the ability of the corticosteroids to regulate ACTH release (i.e. corticosteroid negative feedback). Circulating corticosteroids feed back on to the pituitary and specific brain regions to inhibit the secretion of releasing factors from hypothalamic neurons and pituitary ACTH (Jacobson and Sapolsky, 1991). In addition to pituitary and hypothalamic sites, there is now considerable evidence for the importance of the limbic system (particularly the hippocampus) and cortical areas (particularly the prefrontal cortex) in the regulation of HPA activity. This regulation is possible through an inhibitory role of these regions on HPA activity (Feldman and Conforti, 1985; Murros *et al.*, 1993; Moghaddam *et al.*, 1994; Bagley and Moghaddam, 1997; Shimizu *et al.*, 1997).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

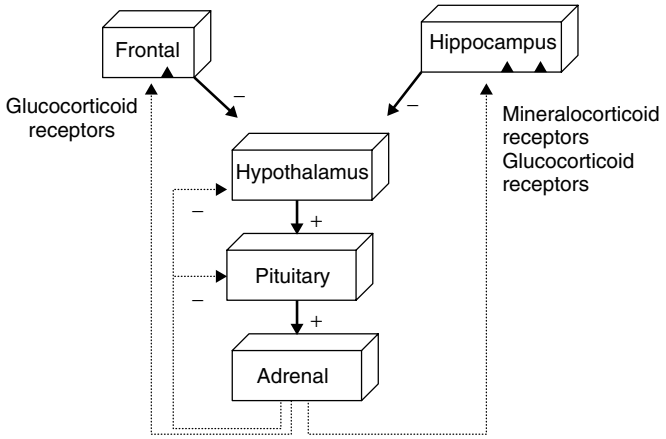

Figure XV-5.2 Schematic representation of the HPA axis. Following the perception of a stressor, the hypothalamus releases CRF, which activates the pituitary and leads to secretion of ACTH. The levels of ACTH are detected by the adrenal cortex, which then secretes corticosteroids. Corticosteroids will enter the blood circulation and act peripherally and centrally. At the level of the brain, both the frontal lobes and the hippocampus contain corticosteroid receptors, although the hippocampus contains both mineralocorticoid receptors and glucocorticoid receptors, while frontal lobes contains mostly glucocorticoid receptors. Both cortical structures inhibit the HPA axis. Along with inhibitory actions of the frontal and hippocampal region, circulating corticosteroids will act at the level of the hypothalamus to inhibit further secretion of CRF, and at the level of the pituitary to inhibit the secretion of ACTH. Circulating levels of ACTH also act at the level of the hypothalamus to inhibit secretion of CRF. The consequence of these negative feedback loops will be a significant decrease of circulating levels of corticosteroids after the end of the stressor

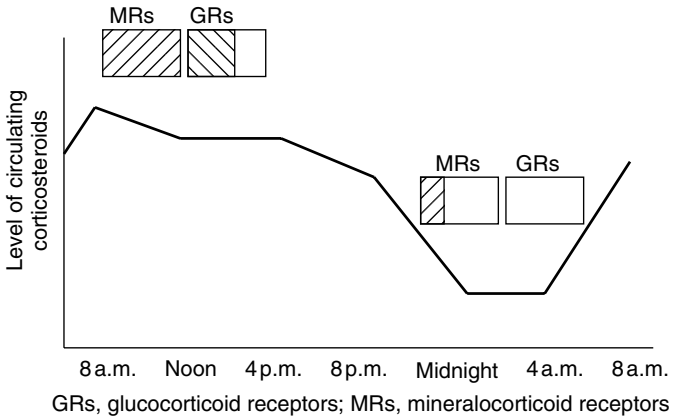

Figure XV-5.3 Circulating levels of corticosteroids at different times of the day in humans, and representation of the level of occupancy of mineralocorticoid receptors and glucocorticoid receptors at different times of day

IMPORTANT CHARACTERISTICS OF CORTICOSTEROIDS

Under basal conditions, cortisol secretion exhibits a 24-hour circadian profile in which cortisol concentrations present a morning maximum in humans (the circadian peak), with slowly declining levels during the late afternoon, evening and nocturnal period (the circadian trough), and an abrupt elevation after the first few hours of sleep. Circulating corticosteroids bind with high affinity to two corticosteroids receptor subtypes: the mineralocorticoid (type I) and glucocorticoid (type II) receptors. Although both receptor types have been implicated in mediating corticosteroid feedback effects (see Reul and De kloet, 1985), there are two major differences between mineralocorticoid and glucocorticoid receptors. First, mineralocorticoid receptors bind corticosterone with an affinity that is six to ten times higher than that of glucocorticoid receptors. As shown in Figure XV-5.3, this differential affinity results in a striking difference in occupation of the two receptor types under different conditions and time of day. Thus, during the circadian trough (the p.m. phase in humans and the a.m. phase in rats), the endogenous hormone occupies more than 90% of mineralocorticoid receptors but only 10% of glucocorticoid receptors. However, during stress and/or the circadian peak of corticosteroid secretion (the a.m. phase in humans and the p.m. phase in rats), mineralocorticoid receptors are saturated and there is occupation of approximately 67–74% of glucocorticoid receptors (Reul and De Kloet, 1985).

The second major difference between these two receptor types is related to their distribution throughout the brain. The mineralocorticoid receptor is present exclusively in the limbic system, with a preferential distribution in the hippocampus, parahippocampal gyrus, and entorhinal and insular cortices. On the contrary, the glucocorticoid receptor is present in both subcortical (paraventricular nucleus and other hypothalamic nuclei, hippocampus and parahippocampal gyrus) and cortical structures, with a preferential distribution in the prefrontal cortex (Meaney and Aitken, 1985; McEwen *et al.*, 1968; McEwen *et al.*, 1986; Diorio *et al.*, 1993). As we will see in the following section, the impact of corticosteroids on cognitive function can be best understood in terms of the differential effects of mineralocorticoid receptor and glucocorticoid receptor activation in both the hippocampus and frontal lobes, two brain structures critically involved in cognitive function (for a complete review, see De Kloet *et al.*, 1999).

ACUTE EFFECTS OF CORTICOSTEROIDS ON MEMORY

Effects on Memory Sustained by the Hippocampus

Since the seminal work performed by Scoville and Milner (1957) with amnesic patients who had undergone bilateral ablation of the hippocampus, it has been known that this structure plays a critical role in memory formation. Given the presence of corticosteroid receptors in the rodent and human hippocampus, it has been suggested that the corticosteroid modulation of hippocampal activity may underlie some aspects of the acute effects of corticosteroids observed in animal learning and memory processes. The effects of adrenal steroids on animal cognition, and the neural substrate, have been studied using, for the most part, three types of models that tap into hippocampal function. The first approach is to examine the neuroendocrine modulation of a physiological model of neuronal excitability that is relevant to memory. Hippocampal long-term potentiation (LTP) describes a long-lasting enhancement in synaptic efficacy that occurs in response to high-frequency electrical stimulation (Tyler and Discenna, 1987; Lynch *et al.*, 1988). LTP has many characteristics in common with memory, the most important being its rapid induction and long duration. The second approach is through the measure of associative learning, as defined by various aspects of conditioning behaviours. The third approach is through the study of spatial memory (Olton *et al.*, 1979; Jarrard *et al.*, 1984).

A number of rodent studies have reported that the induction of LTP in the hippocampus is blocked by the administration of corticosterone (Dubrovsky *et al.*, 1987; Filipini *et al.*, 1991). The role of corticosteroids in hippocampal LTP have been confirmed further

by studies showing that the acute administration of corticosteroids in the dentate gyrus of the hippocampus produces LTP (Filipini *et al.*, 1991; Pavlides *et al.*, 1993). In 1991, Bennett and coworkers reported the existence of a negative correlation between the magnitude of LTP in the CA1 population spike in the hippocampus and the level of circulating corticosteroids, thus suggesting a dose-dependent relationship between corticosteroids and their detrimental effects on LTP. One year later, Diamond *et al.* (1992) reported the presence of an inverted U-shaped relationship between the level of circulating corticosteroids and LTP. They described a positive correlation between corticosterone and primed burst potentiation (PBP; a low threshold form of LTP) (Bennett *et al.*, 1991) at low levels of corticosteroids, and a negative correlation between corticosterone and PBP at high levels of corticosteroids. These results provided strong support for the hypothesis that corticosteroids exert a concentration-dependent biphasic influence on LTP.

Direct effects of corticosteroids have also been observed in associative learning paradigms. For example, acute administration of either corticosterone or dexamethasone accelerates the rate of extinction of a shock-avoidance response (Bohus and Lissak, 1968; Bohus, 1970; Greidanus, 1970; Roozendaal and McGaugh, 1996). Similarly to studies performed on LTP, it has been shown that the effects of corticosteroids on animal cognition follow an inverted U-shaped relationship. In 1976, Kovacs and collaborators reported that low doses of corticosterone facilitate extinction of an avoidance response, while high doses of corticosterone delay the rate of extinction of the conditioned response. Finally, biphasic modulatory effects of corticosteroids were also reported using spatial memory paradigms (for a review, see Lupien and McEwen, 1997). Altogether, these results (obtained mainly in the rodent population) confirmed the important role of the hippocampus in explaining corticosteroid-induced cognitive impairments.

In humans, the effects of corticosteroids on learning and memory have been studied using, for the most part, measures of declarative and non-declarative memory. The logic for the inclusion of this amnesic dissociation is due to the fact that studies report that the hippocampus is essential for declarative memory but not for non-declarative memory (for a review, see Squire, 1992). Declarative memory is the conscious or voluntary recollection of previous information; non-declarative memory refers to the fact that experience changes the facility for recollection of previous information without affording conscious access to it (priming). Thus, this somewhat specialized role of the hippocampus serves as the basis for specific hypotheses regarding the relationship between increased cortisol secretion and impaired cognitive function in humans.

In general, the majority of human studies that have measured the impact of corticosteroids on cognitive function report impaired declarative memory function after acute administration of synthetic corticosteroids (for a complete review, see Lupien and McEwen, 1997). The first study performed on the acute effects of corticosteroids on human memory process was a dose–response study. In 1986, Beckwith and collaborators showed that the effects of hydrocortisone on human memory performance depend upon the dose administered. Only the highest doses of hydrocortisone (40 mg) enhanced recall when subjects were presented with lists of words. In 1993, Fehm-Wolfsdorf and collaborators reported that hydrocortisone administration in the morning (at the time of cortisol peak) impaired declarative memory function, while it had no effect on cognitive performance when administered at night. In 1996, Kirschbaum and collaborators showed that the oral administration of 10 mg hydrocortisone leads to a significant decrease in memory performance as tested 60 minutes after hydrocortisone intake. The results showed that subjects who received hydrocortisone treatment presented an impaired performance in the declarative memory task but not in the non-declarative memory task, thus suggesting that cortisol interacts with hippocampal neurons to induce cognitive deficits. More recently, De Quervain *et al.* (2000) tested the impact of an acute increase of corticosteroids as a function of the nature of memory processing. High doses of synthetic corticosteroids were administered before the acquisition of a list of words, or immediately after, or just before the retrieval of the list. The results revealed significant impairments in memory when the drug was administered just before retrieval, thus suggesting specific effects of corticosteroids on the retrieval of previously learned information.

Besides acute actions, delayed effects of corticosteroids were reported in memory studies of human subjects. In 1990, Wolkowitz and collaborators observed impaired memory performance in normal adults following 5 days' administration of high doses of prednisone (80 mg p.o. daily) but normal memory performance in another group of subjects following a more acute administration of 1 mg dexamethasone. In 1994, Newcomer and collaborators, using a 4-day administration procedure with 0.5, 1, 1 and 1 mg per day of dexamethasone in normal controls, reported impaired declarative memory performance (acquisition and recall) on the fourth day of treatment only. Similar results were obtained by the same group using hydrocortisone (Newcomer *et al.*, 1999). In both studies, no immediate or delayed effects of dexamethasone were observed on non-declarative memory or selective attention performance. Similar results were obtained by Schmidt *et al.* (1999) using a 4-day regimen of 160 mg prednisone. These results were in accordance with a hippocampal involvement in corticosteroid-related cognitive deficits and argued against a nonspecific effect of the steroid on attention and arousal.

In summary, the majority of studies performed in human populations tend to confirm the rodent literature reporting negative effects of corticosteroids on hippocampal-dependent forms of memory. Altogether, the rodent and human data have strengthened the view that stress hormones have a specific impact on the hippocampus.

Effects on Memory Sustained by the Frontal Lobes

Interestingly, there is evidence for a high density of corticosteroid receptors in the cerebral cortex of both rats (Meaney and Aitken, 1985; McEwen *et al.*, 1986) and humans (Sarrieau *et al.*, 1988). Binding studies in rats revealed a high retention of ^{3}H-CORT in the cortex, particularly in the medial prefrontal regions (McEwen *et al.*, 1968; Diorio *et al.*, 1993). Further studies in rats (Feldman and Conforti, 1985; Moghaddam *et al.*, 1994; Bagley and Moghaddam, 1997) and humans (Murros *et al.*, 1993; Shimizu *et al.*, 1997) have shown that the prefrontal cortex is a significant target for the negative feedback actions of circulating corticosteroids (Feldman and Conforti, 1985; Moghaddam *et al.*, 1994), which suggests that this area could play a significant role in the acute effects of corticosteroids on cognitive function.

Studies in nonhuman primates (Goldman-Rakic, 1987; Goldman-Rakic, 1995) and humans (Petrides and Milner, 1982; Owen *et al.*, 1990) showed that lesions of the dorsolateral prefrontal cortex (DLPFC) give rise to impairments in working memory. Working memory is the cognitive mechanism that allows us to keep a limited amount of information active for a limited period of time (see Baddeley, 1995). Thus, working memory impairments have been found in several experiments using a variety of delayed-task procedures. In these tasks, a temporal gap is introduced between a stimulus and a response, which creates the need to maintain the stimulus in a temporary memory storage. Data obtained in monkeys show that cells in the lateral prefrontal cortex become particularly active during delayed-response tasks, suggesting that these cells are actively involved in holding on to the information during the delay (Goldman-Rakic, 1990; Goldman-Rakic, 1995).

Neuropsychological evidence suggests that humans with prefrontal damage have impaired working memory (Luria, 1966;

Fuster, 1980; Damasio, 1985). These patients are also highly susceptible to proactive interference, and they perform poorly on neuropsychological tests that require response inhibition, such as the Wisconsin Card Sorting Test (WCST) (Stuss *et al.*, 1982; Shimamura, 1995). Moreover, recent neuroimaging data summarized and reviewed by Smith *et al.* (1998) (see also Dolan and Fletcher, 1997 and Ungerleider *et al.*, 1998) show a significant relationship between working memory processing and activation observed in the prefrontal cortex (Smith *et al.*, 1998; Ungerleider *et al.*, 1998).

Three studies performed in humans report that working memory is more sensitive than declarative memory to acute and short-term (10 days) increases in corticosteroids. In a study performed by Schmidt *et al.* (1999), young normal controls were administered with 160 mg prednisone for 4 days, and electroencephalogram (EEG) activity was measured on the fourth day of treatment. These authors found that participants treated with prednisone showed a significantly greater increase in self-reported negative emotion and significantly greater right frontal EEG activity compared with participants who were treated with placebo. More importantly, it was shown that the effects of prednisone on EEG activity were restricted to the frontal brain region. This finding is important in light of studies showing that the frontal cortex is implicated in the processing and regulation of emotion (Fox, 1991; Fox, 1994), and others showing that right frontal EEG activity is related to the processing of negative emotion in anxious and socially withdrawn adults (Davidson, 1993; Schmidt and Fox, 1994).

Young *et al.* (1999) administered 20 mg hydrocortisone for 10 days to young normal male volunteers and measured various cognitive functions in a randomized, placebo-controlled, crossover, within-subject design. They showed that this regimen of hydrocortisone led to deficits in cognitive function sensitive to frontal lobe dysfunction, but it did not impact on cognitive function sensitive to hippocampal damage. Similar results were obtained by our group (Lupien *et al.*, 1999a) using an acute dose–response neuroendocrine protocol. In this study, 40 young subjects were infused for 100 minutes with either hydrocortisone or placebo, and memory function was tested during the infusion period. The results revealed that performance on the working memory task decreased significantly, whereas performance on the declarative memory task remained the same following an acute elevation of corticosteroids. Curve-fit estimations revealed the existence of a significant quadratic function (U-shaped curve) between performance on the working memory task and changes in cortisol levels after hydrocortisone infusion. The results of these three studies suggest that in young people, working memory is more sensitive than declarative memory to an acute elevation of corticosteroids.

CHRONIC EFFECTS ON CORTICOSTEROIDS ON MEMORY

Due to obvious ethical reasons, most of the human studies that assess the long-term impact of hypercortisolaemia on memory function are correlational, although some have measured prospectively the impact of treatment on memory (Starkman *et al.*, 1999). In general, three types of condition associated with increases in circulating levels of corticosteroids have been studied, namely Cushing's disease (Starkman *et al.*, 1992; Starkman *et al.*, 1999), depression (Sheline *et al.*, 1996; Sheline *et al.*, 1999; Rajkowska *et al.*, 1999; Bremner *et al.*, 2000; Lucassen *et al.*, 2001) and unhealthy ageing (Davis *et al.*, 1986; Lupien *et al.*, 1998).

Clinical Disorders

Mental disturbances mimicking mild dementia, such as decrements in simple and complex attentional tasks, verbal and visual memory, encoding, storage and retrieval, have been described in depressed patients with hypercortisolism (Weingartner *et al.*, 1981; Cohen *et al.*, 1982; Rubinow *et al.*, 1984; Roy-Byrne *et al.*, 1986; Wolkowitz and Weingartner, 1988; Wolkowitz *et al.*, 1990), and in steroid psychosis following corticosteroids treatment (Hall *et al.*, 1979; Ling *et al.*, 1981; Varney *et al.*, 1984; Wolkowitz and Rapaport, 1989). Patients with Cushing's syndrome represent a powerful model in which to assess the association of hypercortisolaemia and memory impairment in humans, since these patients experience high levels of endogenous cortisol for periods of months or years. In 1992, Starkman and collaborators reported significant verbal memory impairment in patients with Cushing's disease. Using magnetic resonance imaging (MRI) of the brain, they showed that Cushing's disease patients have decreased hippocampal volume when compared with controls (Starkman *et al.*, 1992). In the same study, hippocampal volume was correlated negatively with plasma cortisol concentrations and correlated positively with scores on verbal learning and recall tasks. More recently, the same group (Starkman *et al.*, 1999) reported that therapeutic decreases in cortisol levels in Cushing's disease patients increased by 10% the hippocampal formation of treated patients, revealing some forms of reversibility of hippocampal atrophy in humans.

Similar atrophy of the hippocampus has been reported in depressed patients by Sheline *et al.* (1996) and Bremner *et al.* (2000). However, and in contrast with studies performed in Cushing's disease patients, the hippocampal atrophy reported to occur in depressed populations was observed in the absence of increased hypercortisolaemia (Sheline *et al.*, 1996; Sheline *et al.*, 1999) or the absence of cortisol measurement (Bremner *et al.*, 2000) in patient populations. In this context, it is particularly difficult to associate the observed hippocampal atrophy with the presence of hypercortisolaemia in this patient population.

Unhealthy Ageing

It is well known that the hippocampus is a brain structure that can atrophy as an organism ages (Jack *et al.*, 1998). Because prolonged exposure to corticosteroids has been reported to have detrimental effects on the hippocampus, a role of corticosteroids in the development of age-related cognitive impairments has been suggested (see Landfield *et al.*, 1978; Landfield *et al.*, 1981).

The results of studies performed on HPA activity during ageing in animals have indicated that in the rat, changes in HPA function are not an inevitable consequence of ageing, and individual differences in HPA activity are related closely to hippocampal dysfunction and cognitive impairments (Landfield *et al.*, 1978; Landfield *et al.*, 1981; Meaney *et al.*, 1988; Meaney *et al.*, 1991; Issa *et al.*, 1990; Yau *et al.*, 1995; Rowe *et al.*, 1997). In 1978, Landfield and collaborators showed that adrenal corticosteroid levels predict the magnitude of hippocampal neuron loss and cognitive impairments in the rat. These results suggested that in a normal population of laboratory rats, individual differences in HPA activity should serve as a predictor of age-related hippocampal pathology. This question was examined later by Issa *et al.* (1990), who screened a large sample of aged (22–28 months) rats using a test of spatial memory. The rationale was this: if HPA dysfunction is associated with hippocampal pathology and not merely with advanced age, then one would expect that a sample of aged, cognitively impaired (ACI) and aged, cognitively unimpaired (ACU) rats should differ considerably in HPA activity. Issa *et al.* used the Morris water maze to screen over 100 aged animals in order to select aged animals that were either cognitively impaired or unimpaired (>2 SD or <0.5 SD from the mean of 6-month-old animals; respectively). According to this criteria, about 30% of the animals were designated as ACI and a comparable percentage as ACU (underscoring the extreme variation in cognitive decline in aged rats) (see also Gage *et al.*,

1984 and Gallagher and Pellymounter, 1988). Interestingly, both groups of aged animals showed a loss of hippocampal neurons; however, the decrease in neuron density was substantially greater in the ACI rats.

The ACI animals showed increased plasma ACTH and corticosterone levels under both basal and post-stress conditions, whereas HPA activity in the ACU animals did not differ from 6-month-old controls. The increase in basal ACTH and corticosterone in the ACI rats was observed only in the p.m. phase of the cycle. Interestingly, while both aged groups showed a loss of hippocampal corticosteroid receptors (with no change in hypothalamic or pituitary receptor density), the loss was significantly greater in the ACI animals. The ACI rats also showed a significant decrease in hippocampal mineralocorticoid receptor density. These findings demonstrate the overall loss of hippocampal corticosteroid receptors in the ACI animals. Taken together with the findings of the Landfield studies, these data strongly suggest that long-term exposure to increased corticosteroid levels is selectively associated with the occurrence of hippocampal pathology and impaired cognition in later life.

Before 1991, the majority of human studies performed in order to measure whether basal cortisol levels increase with ageing in human populations were cross-sectional studies. In general, these studies revealed that basal cortisol levels generally do not change across age in healthy subjects (West *et al.*, 1961; Jensen and Blichert-Toft, 1971; Sherman *et al.*, 1985; Waltman *et al.*, 1991), although higher evening levels of plasma cortisol levels (Friedman *et al.*, 1969; Jensen and Blichert-Toft, 1971; Touitou *et al.*, 1982) and lower morning basal plasma cortisol levels (Maes *et al.*, 1994) have been reported in aged subjects, as well as a phase advance in their diurnal rhythm (Drafta *et al.*, 1982; Sherman *et al.*, 1985). This picture is consistent with animal studies indicating that in the rat, increased HPA activity is not a necessary consequence of ageing, but is significantly more prevalent in aged rats selected for spatial memory deficits than in cognitively unimpaired aged rats (Landfield *et al.*, 1978; Landfield *et al.*, 1981; Issa *et al.*, 1990).

However, interpretations of the results of earlier cross-sectional studies in healthy human subjects were somewhat compromised by the fact that HPA activity was often measured only once in young and elderly subjects in order to assess the existence of increased cortisol secretion in elderly subjects as a group. Since increased HPA activity does not seem to be a universal feature of ageing, this approach masked the individual differences that are common in aged populations and that are predictive of neuropathology in aged rats (McEwen *et al.*, 1986; Sapolsky *et al.*, 1986; Miller *et al.*, 1994). Moreover, the fact that each subject was measured only once might have obscured the age-related changes in cortisol levels in individual subjects. Indeed, animal data have shown that it is the cumulative exposure of the hippocampus to high levels of stress hormones that proves to be detrimental for an organism, rather than acutely high levels of stress hormones at one point in the individual's life (Landfield *et al.*, 1978; Landfield *et al.*, 1981).

Considering the importance of this issue, we examined a large sample of aged, healthy controls with hourly 24-hour sampling on a longitudinal basis (ranging from 3 to 6 years). Seventeen female and 34 male subjects aged 60–90 years participated in this longitudinal study. In order to have a measure of the change in cortisol levels over years for a particular subject, a simple regression analysis on plasma cortisol levels for each subject was conducted using year as the independent variable and the integrated 24-hour cortisol concentration (area under the curve) at each year as the dependent variable. The direction and amplitude of the slope of the regression line then served as the measure of the cortisol history per subject ('cortisol slope'). Indeed, the direction of the slope (positive = increasing cortisol levels with years, or negative = decreasing cortisol levels with years) gave us an indication of the changes in cortisol levels with time. The magnitude of the slope (e.g. 0.4 *v*. 0.7) gave us an indication of the rapidity of these changes over time (Lupien *et al.*, 1995).

Using this measure, we found considerable variation in plasma cortisol levels, as well as clear evidence for subgroups which show (1) a progressive year-to-year increase in cortisol levels with currently high levels (the increasing/high cortisol group), or (2) a progressive year-to-year increase in cortisol levels with currently moderate levels (the increasing/moderate cortisol group), or (3) a progressive decrease in cortisol levels with currently moderate cortisol levels (the decreasing/moderate cortisol group). We measured the endocrine and metabolic correlates of these subgroups and showed that there is no change in the circadian rhythm or corticosteroid binding globulin (CBG) levels in these three groups of subjects, nor are there any gender differences between men and women with regard to cortisol history or any other variables tested (Lupien *et al.*, 1995). We also measured the neuropsychological correlates of these subgroups and showed that the increasing/high cortisol group presents significant impairments in declarative memory when compared with the other two groups of subjects, although they do not present any impairment in non-declarative memory (Lupien *et al.*, 1994; Lupien *et al.*, 1998). This result has recently been duplicated in a larger population in which a decrease in declarative memory function was shown to be related to a significant increase of cortisol levels over a 1-year period (Seeman *et al.*, 1997). Then we measured the neuroendocrine correlates of these subgroups, particularly those concerned with levels of dehydroepiandrosterone-sulphate (DHEA-S) levels. We found that although DHEA-S levels were decreased in all subjects, this measure could not differentiate groups, nor was it related to cognitive function (Lupien *et al.*, 1999b). Next, we measured the environmental validity of our yearly laboratory cortisol measures by taking salivary samples for cortisol analysis at the subject's home four times a day over a 30-day period. Data revealed that cortisol levels clearly differentiate the subgroups over this longer period of time (Lupien *et al.*, 1998). Finally, we measured hippocampal volumes in subjects from the increasing/high cortisol and decreasing/moderate cortisol groups and reported a 14% significant decrease in the hippocampal volume of the increasing/high cortisol group when compared with the decreasing/moderate cortisol group. We also showed that hippocampal volume in this population is correlated significantly with both current salivary and dynamic (cortisol slope) plasma cortisol levels (Lupien *et al.*, 1998).

The results of our studies thus reveal that elderly human subjects showing a significant increase of cortisol levels over years with currently high cortisol levels are impaired on tests of memory known to be dependent upon hippocampal function, and present a significant 14% reduction in hippocampal volume, when compared with elderly subjects showing a decrease of cortisol levels over years with currently moderate cortisol levels. These results are in accordance with animal studies showing that cumulative exposure to high levels of corticosteroids has functional and structural consequences on the hippocampus (Landfield *et al.*, 1978; Landfield *et al.*, 1981).

MODULATORY INFLUENCES OF CORTICOSTEROIDS ON MEMORY

Although the majority of studies performed in human populations still report negative effects of corticosteroids on cognitive function (for a complete review, see Lupien and McEwen, 1997), various studies performed in rodents report a positive impact of corticosteroids on learning and memory (Micco *et al.*, 1979; Micco and McEwen, 1980; Bohus *et al.*, 1983; Veldhuis *et al.*, 1985; De Kloet *et al.*, 1988; Mitchell and Meaney, 1991).

Such a positive impact of corticosteroids on memory has been confirmed by hormone-replacement protocols. In a hormone-replacement protocol, the behaviour resulting from the absence of the hormone of interest is measured, then baseline hormonal levels are restored to normal values and the same behaviour measured again. It is postulated that if the hormone of interest has a real impact on the behaviour tested, then this behaviour should be restored to normal value after hormonal replacement (see Brown, 1998). Using this paradigm, many have reported that pretraining as well as post-training administration of corticosterone restores an impaired learned behaviour or extinction pattern induced by adrenalectomy (Micco *et al.*, 1979; Micco and McEwen, 1980; Bohus *et al.*, 1983; Veldhuis *et al.*, 1985; De Kloet *et al.*, 1988; Mitchell and Meaney, 1991). Veldhuis *et al.* (1982, 1985) have further shown that pretraining administration of corticosterone blocks the reduction in the pattern of exploratory behaviour observed after adrenalectomy. Because modulation of cortisol levels gives rise to a concomitant modulation of the learning and memory processes, direct implication of corticosteroids in memory function were postulated. The rodent studies summarized above, and hormone-replacement protocols, have shown that a physiological decrease of circulating corticosteroids is as detrimental to memory function as is a physiological increase.

The reason why hormone-replacement protocols might permit the assessment of the positive impact of corticosteroids on cognitive function relates directly to the differential involvement of mineralocorticoid and glucocorticoid receptors in cognitive function. Remember that circulating corticosteroids bind with high affinity to two corticosteroid receptor subtypes, the mineralocorticoid and glucocorticoid receptors. Although both receptor types have been implicated in mediating corticosteroid feedback effects (see Reul and De Kloet, 1985), there is a major difference between the receptors. Mineralocorticoid receptors bind corticosteroids with an affinity that is about six to ten times higher than that of glucocorticoid receptors. This differential affinity results in a striking difference in occupation of the two receptor types under different conditions and time of day.

Many studies performed in rodents have reported that the ratio of mineralocorticoid receptor/glucocorticoid receptor occupation is a major determinant of the direction of corticosteroid-induced cognitive changes (for a review, see De Kloet *et al.*, 1999). Figure XV-5.4 presents a scheme of the results obtained on LTP with variations in the levels of mineralocorticoid receptor and glucocorticoid receptor occupancy. LTP has been shown to be optimal when corticosteroid levels are elevated mildly, i.e. when the ratio of mineralocorticoid receptor/glucocorticoid receptor occupation is high (see Diamond *et al.*, 1992). In contrast, significant decreases in LTP are observed after adrenalectomy, when mineralocorticoid receptor occupancy is very low (Dubrovsky *et al.*, 1987; Filipini *et al.*, 1991), or after exogenous administration of synthetic corticosteroids (Bennett *et al.*, 1991; Pavlides *et al.*, 1993).

De Kloet *et al.* (1999) have reinterpreted the well-known inverted U-shaped function between circulating levels of corticosteroids and cognitive performance in line with the mineralocorticoid receptor/glucocorticoid receptor ratio hypothesis. In this view, cognitive function can be enhanced when most of the mineralocorticoid receptors and only some of the glucocorticoid receptors are activated (top of the inverted U-shaped function; increased mineralocorticoid receptor/glucocorticoid receptor ratio). However, when circulating levels of corticosteroid are decreased or increased significantly (extremes of the inverted U-shaped function; low mineralocorticoid receptor/glucocorticoid receptor ratio), cognitive impairments will result. The authors suggested that the negative view of corticosteroid actions on human cognitive function could be explained partly by limitations in previous human experimental designs, which did not allow differential manipulation of mineralocorticoid receptor and glucocorticoid receptor levels. In order to do this, such studies should measure cognitive function when corticosteroid occupancy is decreased (rather than increased), thus allowing functional measures of mineralocorticoid receptor/glucocorticoid receptor occupancy on learning and memory.

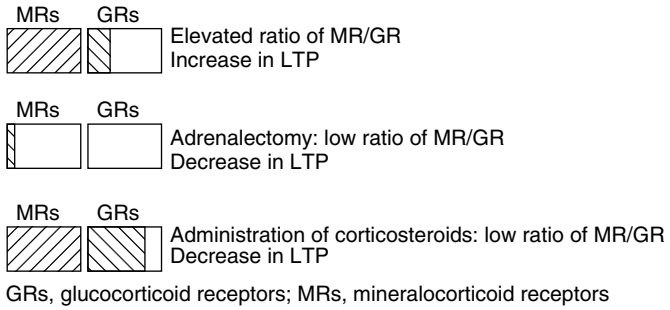

Figure XV-5.4 Level of occupancy of mineralocorticoid receptors and glucocorticoid receptors under different treatments, and its effects on LTP as a function of the ratio of mineralocorticoid receptors/glucocorticoid receptors

Acute Modulatory Effects of Corticosteroids

In order to test this suggestion, we have performed a hormone-replacement study in a population of young normal controls (Lupien *et al.*, 2002). In this protocol, we used a within-subject, double-blind experimental protocol in which we first induced a chemical lowering of corticosteroids levels by administration of metyrapone, a potent inhibitor of corticosteroids synthesis, and then restored baseline circulating corticosteroid levels with subsequent infusion of hydrocortisone. Memory performance of participants under each of these conditions was compared with that measured on a placebo day. The results showed that when compared with placebo, the pharmacological decrease of circulating levels of corticosteroids induced by metyrapone significantly impaired memory performance. Most importantly, we showed that this impairment was restored completely after hydrocortisone replacement. These results showed that corticosteroids can modulate memory function. We have suggested that this modulation can happen through a differential activation of mineralocorticoid receptors and glucocorticoid receptors. Indeed, during the metyrapone condition, mineralocorticoid receptor occupancy was low given the significant decrease of cortisol secretion induced by metyrapone. At this point, impairment in memory was observed. On the contrary, during the hydrocortisone-replacement condition, cortisol levels were restored to the levels typical of those measured in the a.m. phase, i.e. leading to a saturation of mineralocorticoid receptors, with partial occupancy of glucocorticoid receptors. This differential occupation thus led to an increased mineralocorticoid receptor/glucocorticoid receptor ratio and a restoration of baseline cognitive performance.

Chronic Modulatory Effects of Corticosteroids

As we have reported previously, results obtained from our longitudinal study of basal cortisol levels and cognitive function during human ageing show that elderly humans with an increase in cortisol levels with years and currently elevated cortisol levels at the time of testing present with both memory impairment and hippocampal atrophy (the increasing/high cortisol group) when compared with elderly people with a similar increase of cortisol levels with years but only moderate current cortisol levels at the time of testing (the increasing/moderate cortisol group). Given that the only difference between these two groups was their current cortisol levels, it was not clear whether the corticosteroid-related memory

deficits observed in the increasing/high cortisol group were related to their acutely high levels of corticosteroids at the time of testing (leading to a low mineralocorticoid receptor/glucocorticoid receptor ratio) or to a history of high corticosteroid levels (leading to hippocampal dysfunction and related memory impairments).

In order to examine this question, we measured the cognitive effects of our hormone-replacement protocol in elderly people from the increasing/high cortisol group and from the increasing/moderate cortisol group (Lupien *et al.*, submitted). We predicted that if the memory impairments of the increasing/high cortisol group were due to acute high levels of corticosteroid, then memory should benefit from an acute decrease in circulating levels of corticosteroid (which would restore the mineralocorticoid receptor/glucocorticoid receptor balance), while the memory impairment should be restored after hydrocortisone replacement. On the contrary, if the memory impairment of this group was due to their chronic exposure to high levels of corticosteroid (and thus possibly corticosteroid-induced brain dysfunction), then there should be no modulatory effects of the pharmacological manipulations on memory function. The results confirmed the chronic exposure hypothesis of memory impairments in the increasing/high cortisol group, as we showed that metyrapone treatment did not have any effect on memory performance, but hydrocortisone treatment significantly impaired memory. In contrast, we found that inhibition of cortisol production in the increasing/moderate cortisol group significantly impaired learning capacity and increased the rate of forgetting, while this pattern of cognitive impairments was reversed completely by subsequent administration of hydrocortisone.

Based on the results obtained in the increasing/high cortisol group, we suggested that the memory impairments in this group of elderly people are due to a relative loss of mineralocorticoid receptors, with normal or heightened sensitivity of glucocorticoid receptors. A loss of mineralocorticoid receptors would explain the absence of any metyrapone-induced memory effects in this population, as there are fewer mineralocorticoid receptors to bind circulating levels of corticosteroid, thus preventing any significant impact of the absence of corticosteroids on binding to mineralocorticoid receptors. Fewer mineralocorticoid receptors could also lead to a faster saturation of glucocorticoid receptors, leading to the increased sensitivity of glucocorticoid receptor activation and the induction of significant cognitive impairment after physiological increase in circulating levels of corticosteroid, as observed during the hydrocortisone-replacement condition. Our hypothesis is also supported by recent rodent (Herman and Spencer, 1998; Herman and Watson, 1995; Lopez *et al.*, 1998; Vazquez *et al.*, 1998) and human (Wetzel *et al.*,1995) studies showing that levels of mineralocorticoid receptors rather than glucocorticoid receptors are reduced markedly in response to chronic elevations in corticosteroid levels, such as those observed in elderly people with significant increases in corticosteroid levels with years.

Together, the results of these studies provide evidence that a time window for corticosteroid-induced cognitive impairments might exist and might be related to the balance in mineralocorticoid receptor/glucocorticoid receptor occupancy. Such a suggestion has important implications for studies showing that cumulative exposure to stress (Lupien *et al.*, 1998), depression (Sheline *et al.*, 1996) and/or corticosteroids (Lupien *et al.*, 1998; Starkman *et al.*, 1992) has detrimental effects on brain structures rich in corticosteroid receptors.

CONCLUSION

The data summarized in this chapter show that the best way to approach the effects of corticosteroids on animal and human cognitive function is to use a relative-impact model instead of a direct-impact model. A direct-impact model would imply that the hormone of interest has a direct and specific effect on a particular type of cognitive processing. In contrast, a relative-impact model implies that the effects of the hormone on cognitive function are relative and depend on a variety of factors that are known to be modulated by changes in the hormone of interest.

Hormones are known to be strong neuromodulators in that they tend to act on the brain by modulating an already existing connection between two cells (see Brown, 1998). In this sense, the effects of a hormone will always be relative. We have seen in this chapter that the effects of corticosteroids on animal and human cognitive function will be either positive or negative, depending on the dose and/or type of synthetic corticosteroid administered, the time of day, and the actual levels of corticosteroids achieved after administration of the synthetic compound. Given these data, one cannot view the impact of corticosteroids on cognitive function as being solely negative. Indeed, hormone-replacement protocols performed in both animal and human studies now show that corticosteroids are hormones that are necessary for adequate memory processing. Too little or too much of the hormone will have a negative impact on memory function, although these two effects are explained by very different receptor mechanisms. Given all these methodological factors to take into consideration in our study of the neuroendocrinology of cognitive disorders, we might come to the conclusion that no simple answer can be given to the impact of hormones on cognitive function. However, challenging questions still need to be studied.

ACKNOWLEDGEMENTS

SJL's research summarized in this paper was funded by a Scientist Research Award from Fonds de la recherche en santé du Québec (FRSQ), by an operating grant from the Canadian Institute of Health Research (CIHR), and by a Research Scholar Award from EJLB Foundation. The Douglas Hospital Longitudinal Study of Normal and Pathological Ageing is funded by a grant from the Canadian Alzheimer Society.

Neuroinflammation in Neurodegeneration: Lessons from Alzheimer's Disease

Tuula Pirttilä and Irina Alafuzoff

Alzheimer's disease is a neurodegenerative disorder characterized by accumulation of amyloid-β (Aβ) protein in the brain parenchyma and the walls of the leptomeningeal and parenchymal vessels. Furthermore, neurofibrillary changes and extensive neuronal loss are seen. Aβ aggregates and neurofibrillary changes are consistent features of Alzheimer's disease. Seen as neuritic plaques and tangles, they are considered to be hallmark lesions of the disease. Current post-mortem diagnosis of Alzheimer's disease is based on either semiquantitative assessment of neuritic plaques (Khachaturian, 1985; Mirra *et al.*, 1991) or regional assessment of tangles (Braak and Braak, 1991).
