Aminergic Transmitter Systems

P. Falkai

INTRODUCTION

The biogenic amines include the catecholamines dopamine, noradrenaline and adrenaline, and the indoleamine serotonin. All of these monoamines have a claim to be regarded as central neurotransmitters, and dopamine and serotonin seem to play a crucial role in the pathophysiology of schizophrenia. This chapter attempts to summarize the most important findings related to these two transmitters and schizophrenia. Before doing so, it should be pointed out that these monoamines are interconnected closely in their biosynthesis. Their biosynthesis takes place as the stepwise conversion of amino acids in the presence of specific enzymes. The catecholamines are derived from the L-amino acid tyrosine, which is converted into L-dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase. A second enzyme, aromatic amino acid decarboxylase (AADC), converts DOPA into dopamine, which may be converted consecutively into noradrenaline and adrenaline, reactions that are catalysed by the enzymes dopamine β-hydroxylase (DBH) and phenylethanolamine-*N*-methyltransferase (PNMT), respectively.

The sequence of reactions by which serotonin is formed involves two steps: the amino acid tryptophan is first converted into 5-hydroxytryptophan by the enzyme tryptophan hydroxylase. Then AADC converts this intermediary amino acid into serotonin (for an overview, see Niewenhuys 1985).

DOPAMINE

The dopamine hypothesis of schizophrenia, which postulates that schizophrenia is related to increased dopamine function, has been a predominant theory on schizophrenia for a long time (for review, see Carlsson *et al.*, 2001), although many attempts have been made to devaluate the central role of dopamine. Besides the compelling evidence that blockade of dopamine D2 receptors generates an antipsychotic response (e.g. Kapur and Seeman, 2001), there are several other lines of evidence supporting the notion that dopamine plays an important role in the pathophysiology of schizophrenia. Some of this evidence is outlined below, stressing newer approaches and pointing out new frontiers, such as dopamine-stabilizing agents, and the role of dopamine within the complex circuitry of the human brain.

Evidence for Dopamine Dysfunction

Indirect Pharmacological Evidence

Concentrations of dopamine and its metabolite homovanillic acid (HVA) in post-mortem brains of schizophrenic patients have consistently yielded patient–control differences, although the areas where the abnormalities are found are not consistent (e.g. Davis *et al.*, 1991).

Receptor studies have also been fairly consistent, with D2 but not D1 receptors increased in the striatum of schizophrenics. Interestingly, when D2 receptors were examined in patients who were not schizophrenic (e.g. Alzheimer's disease and Huntington's disease) but who had previously been treated with neuroleptics, striatal dopamine receptors were found to be increased by only 25% in contrast to the more than 100% increases found in schizophrenics (Seeman *et al.*, 1987).

A large number of studies measuring HVA found an increase in schizophrenia (for overview, see Widerlov, 1988). However, cerebrospinal fluid (CSF) HVA has been found to be decreased in subgroups of schizophrenic patients compared with control groups, such as patients who respond poorly to neuroleptics.

HVA measured in plasma (pHVA) seems be associated with activity of central, striatal dopamine neurons in human subjects (Kahn and Davidson, 1993). When neuroleptic treatment is discontinued in schizophrenic patients, pHVA increases in those patients experiencing a symptomatic worsening (Davidson *et al.*, 1991b). In contrast, neuroleptic treatment decreases pHVA concentrations, particularly in patients who benefit from that treatment (Davidson *et al.*, 1991a).

Direct Evidence for Dopaminergic Dysfunction from Imaging Studies

Imaging of Dopamine Receptors

In vivo examination of D2 receptor density using positron emission tomography (PET) has provided conflicting results (Table XVII-2.1). Using the ligands raclopride and bromospiperone (Farde *et al.*, 1990; Martinot *et al.*, 1989), no difference was detected between schizophrenics and control subjects, while using methylspiperone a difference in D2 receptor density was detectable (Wong *et al.*, 1986). Meanwhile, meta-analyses have proven that a substantial proportion of newer treated patients with schizophrenia have increased numbers of striatal dopamine receptors (Laruelle, 1998; Zakzanis and Hansen, 1998). Initially, there were difficulties in examining extrastriatal dopamine receptors, as there is only a small number in cortical regions, such as the functionally important limbic nuclei. Since 1997, several interesting papers have been published along these lines: one described decreased D2 receptor binding in the anterior cingulated cortex in schizophrenia (Suhara *et al.*, 2002); another described a marked upregulation induced by classical as well as atypical neuroleptics in the temporal cortex (Xiberas *et al.*, 2001b); a further paper described a differential effect of haloperidol (upregulation) and clozapine (downregulation) in striatal and extrastriatal regions (Talvik *et al.*, 2001); and finally, another study demonstrated a differential effect of amisulpride in low and high dosages (Xiberas *et al.*, 2001a). Low plasma

Table XVII-2.1 The dopaminergic system in schizophrenia: imaging studies (1)

Receptor subtype	Distribution	Selected literature	Detailed findings in schizophrenia	Change in schizophrenia overall
D1	Cortical and striatal	Okubo *et al.* (1997)	Cortical: increased Striatal: decreased	Cortical: increase Striatal: no change
D2/3	Striatal	Laruelle (1998), Zakzanis and Hansen (1998)	Increased in a substantial proportion of patients	Increase
	Extrastriatal (cortical and limbic areas)	Goldsmith *et al.* (1997), Suhara *et al.* (2002)	No clear pattern of receptor density; change in laminar distribution?	No change
D4	Striatal	Seeman *et al.* (1993), Soares and Innis (1999)	6 × increase; no replication	No change

Table XVII-2.2 The dopaminergic system in schizophrenia: imaging studies (2)

Parameter	Distribution/ localization	Selected literature	Detailed findings in schizophrenia	Change in schizophrenia overall
Dopamine release	Synaptic cleft	Breier *et al.* (1997), Abi-Dargham *et al.* (1998)	Enhanced amphetamine-induced displacement of postsynaptic D2 binding via dopamine outflow Presynaptic (vesicle) and postsynaptic (membrane transporter) are involved	Increase
Dopamine synthesis	Terminals of nigrostriatal fibres	Hietala *et al.* (1999), Lindström *et al.* (1998)	Increased striatal uptake of [^{18}F] FDOPA	Increase
Dopamine basal levels	Synaptic cleft	Laruelle *et al.* (1998)	Increased in schizophrenia	Increase

concentrations induced marked extrastriatal binding and low striatal binding, whereas higher plasma concentrations induced marked binding in both extrastriatal and striatal regions. This suggest that there might be a distinct effect of dopamine on striatal and extrastriatal regions, and that currently the right tools are in development to investigate these questions in more detail.

Finally, PET studies examining different antipsychotics found that the threshold for clinical response and extrapyramidal side effects could be separated in terms of different D2 occupancy (Farde *et al.*, 1992; Nordstrom *et al.*, 1993; Kapur *et al.*, 2000a). This has helped us to understand that neuroleptics act via the dopaminergic system.

Imaging of Further Aspects of the Dopaminergic System: Release, Uptake and Basal Levels

In recent years, modern imaging technology has progressed to measuring the release of dopamine precursors and dopamine itself in schizophrenia (Table XVII-2.2). It has been shown that the synthesis of labelled dopamine or fluorodopamine in the brain, determined by means of PET following administration of radiolabelled L-DOPA or fluoro-L-DOPA, is increased in drug-naive schizophrenic patients compared with age-matched controls (Hietala *et al.*, 1994; Dao-Costella *et al.*, 1997). Single photon emission computed tomography (SPECT) and PET studies, using a sophisticated technique to measure the release of dopamine in the basal ganglia *in vivo*, have shown that following an amphetamine challenge, this release is elevated in drug-naive schizophrenic patients compared with age-matched controls, and that this elevation correlates to the induction of positive psychotic symptoms (Laruelle *et al.*, 1996; Breier *et al.*, 1997; Abi-Dargham *et al.*, 1998). In an additional series of experiments, Laruelle (2000), using the SPECT technique with alpha-methyltyrosine as a tool, obtained evidence that the unchallenged release of dopamine is elevated in schizophrenic patients compared with controls. As well as release of dopamine, its uptake and the basal levels are additional interesting markers to investigate the function of the dopaminergic system in schizophrenia (see Table XVII-2.1 for further details).

Taking several shortcomings of these methods into account (for detailed discussion, see Carlsson *et al.*, 2001), generally these data support the notion that a dysfunction of the dopaminergic system is involved in the pathophysiology of schizophrenia, which supports treatment strategies involving this transmitter system. Recent efforts have focused on the D4 and, partly, D3 and D1 receptor subtypes. In general, although antipsychotic effectively is transmitted via D2 receptor blockade, it this no longer an attractive target for improved antipsychotic therapy. This is partly because classical D2 receptor blockade is associated with concomitant hypodopaminergia, supporting the development of negative symptoms and cognitive deficits.

Further Post-Mortem Evidence for Dysfunction of the Dopaminergic System in Schizophrenia

Using post-mortem histological analyses of human brain tissue, investigators have begun to identify subtle structural abnormalities in the prefrontal cortex of schizophrenia subjects; many of these abnormalities may contribute to the cognitive deficits observed in this illness. Relevant to this chapter are reported abnormalities in the structure of mesoprefrontal dopaminergic neurons in schizophrenia subjects. An early morphometric study provided the first suggestion that the structural integrity of mesoprefrontal dopaminergic neurons may be abnormal in schizophrenia subjects (Bogerts *et al.*, 1983). Investigators observed decreased size and number of neuromelanin-containing cell bodies in the ventral tegmental area of schizophrenia subjects. However, additional studies are required to determine to what extent this effect is due to a specific decrease in the size and number of cortically projecting dopamine-containing neurons. Recent studies of dopaminergic neuron structure have focused on the integrity of dopaminergic nerve terminals within the prefrontal cortex. Immunocytochemical analyses of post-mortem tissue have revealed a decreased density of fibres immunoreactive for tyrosine hydroxylase and dopamine transporter protein in the prefrontal cortex of schizophrenia subjects (Akil *et al.*, 1999). In contrast, the density of fibres immunoreactive for the serotonin transporter is unaffected, suggesting that the loss of proteins associated with

dopaminergic terminals may be a specific correlate of the disorder (Gurevich and Joyce, 1997; Akil *et al.*, 1999).

It is not clear whether the reduction in tyrosine hydroxylase and dopamine transporter levels in the prefrontal cortex of schizophrenia subjects is due to altered protein levels in dopaminergic nerve terminals, or altered protein levels in dopaminergic nerve terminals, or altered number/length of dopaminergic terminals. However, the hypothesis that dopaminergic nerve terminal density may actually be decreased is consistent with emerging data that structural abnormalities in the prefrontal cortex of schizophrenia subjects involve a reduction in neuropil volume (Lewis *et al.*, 1999; Selemon and Goldman-Rakic, 1999; Lewis and Gonzalez-Burgos, 2000). Specifically, recent studies indicate that there is an increase in neuronal density in the prefrontal cortex of schizophrenia subjects with no change in the total number of neurons (Pakkenberg, 1993; Akbarian *et al.*, 1995; Daviss and Lewis, 1995; Rajkowska, 1997; Rajkowska *et al.*, 1998, Selemon *et al.*, 1998). One interpretation of the latter findings is that the increased neuronal density is a consequence of loss of surrounding neuropil.

Structural abnormalities other than those involving dopaminergic nerve terminals are also thought to contribute to reduced neuropil and impaired functional capacity of the prefrontal cortex in schizophrenia subjects. For example, results of post-mortem studies indicate that pyramidal cells in the prefrontal cortex of schizophrenia patients exhibit a decreased somal size and a decreased density of dendritic spines (Garey *et al.*, 1998; Rajkowska *et al.*, 1998; Glanz and Lewis, 2000; Pierri *et al.*, 2001). Several markers of γ-aminobutyric acid (GABA)-containing interneurons are also affected in schizophrenia in the absence of detectable changes in cell number (Akbarian *et al.*, 1995; Woo *et al.*, 1998; Pierri *et al.*, 1999; Volk *et al.*, 2000). The decrease in density of GABA membrane transporter immunoreactive axon cartridges on the axon initial segment of pyramidal cells in the prefrontal cortex of schizophrenia subjects (Woo *et al.*, 1998) suggests that alterations in the structure of interneurons also contribute to a reduction in the neuropil.

Beyond D2 Blockade: Dopaminergic Stabilizers in the Treatment of Schizophrenia

A series of compounds capable of stabilizing the dopaminergic system without inducing hypodopaminergia have been developed and are being tested in clinical trials. Some of these new drugs are partial dopamine receptor agonists, e.g. (−)-3-(3-hydroxyphenyl)-*N*-n-propylpiperidine ((−)-3PPP), acting on the D2 family of receptors (Lahti *et al.*, 1998). Others are pure antagonists, again acting on the D2 family of receptors, and can thus readjust elevated dopamine functions. In contrast to the currently used antipsychotic agents, these antagonists do not cause hypodopaminergia; on the contrary, they antagonize subnormal dopamine function. The reason for this aberrant pharmacological profile seems to be that their action on different subpopulations of dopamine receptors differs from that of the currently used drugs. Thus, whereas they exert a strong action on dopaminergic autoreceptors, they have a weaker effect postsynaptically and seem unable to reach a subpopulation of postsynaptic dopamine receptors (Svensson *et al.*, 1986; Sonesson *et al.*, 1994; Hansson *et al.*, 1995).

Connecting Phenotype and Genotype: Catechol-O-Methyltransferase and Schizophrenia

About half of the risk for developing schizophrenia can be attributed to genetic factors; the remaining half is attributed to nongenetic, environmental influences. The search for a genetic basis of schizophrenia has led to a number of informative chromosomal regions where the successibility genes are situated. It seems likely that each gene will explain only a very limited percentage of the attributed risk. Therefore, future research will try to connect these successibility genes with the neurobiological mechanism contributing to the pathophysiology of schizophrenia. An elegant set of data has been published (Egan *et al.*, 2001) supporting the notion of the dysfunction of the dopaminergic system in schizophrenia. The relationship of a common functional polymorphism (Val (108/158) Met) in the catechol-O-methyltransferase (COMT) gene was examined, which accounts for a four-fold variation in enzyme activity and dopamine catabolism, with both prefrontally mediate cognition and cortical physiology. In 175 patients with schizophrenia, 219 unaffected siblings, and 55 controls, COMT genotype was related in allele dosage fashion to performance on the Wisconsin card sorting test of executive cognition and explained 4% of variance ($P = 0.001$) in frequency of perseverative errors. Consistent with other evidence that dopamine enhances prefrontal neuronal function, the load of the low-activity Met allele predicted enhanced cognitive performance. Then the effect of COMT genotype on prefrontal physiology was examined during a working memory task in three separate subgroups assayed with functional magnetic resonance imaging (fMRI). Met allele load consistently predicted a more efficient physiological response in the prefrontal cortex. Finally, in a family-based association analysis of 104 trios, a significant increase in transmission of the Val allele to the schizophrenic offspring was found. These data suggest that the COMT Val allele, because it increases prefrontal dopamine catabolism, impairs prefrontal cognition and physiology, and by this mechanisms slightly increases the risk for schizophrenia.

This is a fine example of connecting the phenotype of dopamine dysfunction with a functional polymorphism. Although the effect on the risk for schizophrenia is small, it shows how to examine if biological markers are relevant for the pathophysiology of schizophrenia.

Conclusions

Increased dopamine function or activity in striatal areas is suggested indirectly by post-mortem studies finding increased levels of dopamine and HVA as well as increased binding affinity to D2 receptors. Neuroleptics consistently decrease pHVA, an effect associated with treatment response. Since neuroleptic treatment is particularly effective in decreasing the positive symptoms of schizophrenia, and pHVA may mostly reflect striatal dopamine activity, increased dopamine activity in the striatum seems to be associated with the positive symptoms of schizophrenia. Furthermore, there is additional indirect evidence that negative symptoms are associated with decreased mesocortical dopamine activity. However, there is direct evidence from recent imaging studies that challenged and unchallenged dopamine release in newer treated schizophrenia. Furthermore, PET studies using receptor ligands have shown convincingly that D2 blockade is mandatory to cause an antipsychotic effect. Classical D2 blockade is, however, accompanied by undesirable hypodopaminergia, leading to negative symptoms, including cognitive dysfunction. Therefore, the development of dopamine-stabilizing agents would improve the pharmacotherapy of schizophrenia considerably.

SEROTONIN

In 1954, lysergic acid diethylamide (LSD) was observed to have hallucinogenic properties, and a comparison was made with certain psychotic symptoms of schizophrenia (e.g. van Praag, 1992). Since LSD is a serotonin (5-hydroxytryptamine, 5-HT) antagonist, these effects were considered to reflect a relative deficit of 5-HT in the central nervous system. The early 5-HT hypothesis was revised such that both a surplus and a deficit of 5-HT could account

Table XVII-2.3 The serotonergic system in schizophrenia: imaging studies

Receptor type	Localization	Selected literature	Detailed findings in schizophrenia	Change in schizophrenia overall
5-$HT_{2A/C}$ [^{18}F-setoperone]	Cortical areas	Trichard *et al.* (1998), Lewis *et al.* (1998)	No significant difference; not associated with age decrease; no correlation with length of illness or symptomatology	No change

for psychoses (van Praag *et al.*, 1992). The revival of interest in 5-HT research is due predominantly to the discovery that certain compounds inhibiting various subtypes of 5-HT receptors may have therapeutic potential in schizophrenia. Of particular interest was the discovery of atypical neuroleptics, with their inhibiting effects on 5-HT receptor subtypes. Below, we present indirect and direct evidence for the involvement of serotonin in the pathophysiology of schizophrenia.

Indirect Methods for Examining Serotonergic Function

5-HT Agonists and Schizophrenia

Considering the widespread use of selective 5-HT uptake inhibitors, the induction of psychotic symptoms is extremely rare. Few paranoid or psychotic reactions have been reported with fluoxetine (Lindenmayer *et al.*, 1990; van Praag *et al.*, 1992). It may, however, be that 5-HT uptake inhibitors do not increase 5-HT activity sufficiently or in a way that is focused enough to elicit psychotic reactions. It is unlikely that simply increasing 5-HT function would induce psychosis.

5-HT Challenge Studies with Schizophrenia

MCPP, a metabolite of trazodone, binds to all 5-HT receptor subtypes, but most potently to 5-HT_{2c} and 5-HT_1 receptors m-Chlorophenylpiperazine (MCPP) challenge studies among schizophrenics have received much attention, but results have been inconsistent. Most studies have found that MCPP caused hormone release as compared with placebo, and several investigators have found that ongoing treatment with clozapine blocked the release of adrenocorticotropic hormone (ACTH), cortisol, prolactin and growth hormone, whereas treatment with haloperidol did not, thus providing evidence that clozapine effectively blocks the hormonal response of the 5-HT system (e.g. Owen *et al.*, 1993).

Post-Mortem and Cerebrospinal Fluid Studies on 5-HT Function

Of the post-mortem studies reviewed by Bleich *et al.* (1991), some found evidence of increased 5-HT concentrations in schizophrenics compared with normals, while others found decreased 5-HT levels or no differences between groups.

Of the CSF 5-hydroxyindoleacetic acid (5-HIAA) studies reviewed by Bleich *et al.* (1991), three found indications of reduced 5-HT metabolism among schizophrenics and six found no differences between groups.

Owing to the similarity between human blood platelets and central nervous system 5-HT synaptosomes, platelets appear to offer a peripheral model of 5-HT function (Bleich *et al.*, 1991). Eight investigators have found elevated platelet or whole-blood 5-HT levels in chronic schizophrenics, one study found lower levels in schizophrenics, and only three studies found no differences between patients and normals.

Direct Methods of Examining Serotonergic Function from Imaging Studies

Although many current atypical antipsychotics show significantly greater 5-HT_{2A} than D2 occupancy, 5-HT_{2A} occupancy may not be a necessary condition for atypicality (Kapur and Seeman, 2001). PET studies using specific 5-HT ligands have helped to shed light on these questions (Table XVII-2.3). In summary, it seems that 5-HT_{2A} blockade is neither necessary (since antipsychotics achieve response without 5-HT_{2A} blockade) nor sufficient for antipsychotic response (Kapur, 1998; Kapur *et al.*, 2000a). In addition, the published imaging data on 5-$HT_{2A/C}$ occupancy revealed no differences between schizophrenics and control subjects (Trichard *et al.*, 1998; Lewis *et al.*, 1998). These observations support recent reports that fananserin (Truffinet *et al.*, 1999) and MDL-100907 (Report, 1999), both with high 5-HT_{2A} occupancy but devoid of D2 occupancy, failed to work as antipsychotics. Does the presence of 5-HT occupancy exert an attenuating effect on the D2–extrapyramidal side effects relationship? Since the mismatch in D2 occupancy alone can explain the differences in extrapyramidal side effects and prolactin effects between typical and atypical antipsychotics (Kapur *et al.*, 1999; Kapur *et al.*, 2000b), it is unclear whether the superiority of atypical antipsychotics in these domains should be accorded to their 5-HT_2 blockade or to a more appropriate dosing regarding their D2 blockade (Kapur and Seeman, 2001).

Conclusions

The indirect methods of examining serotonergic function partly support the notion that this transmitter is involved in the pathophysiology of schizophrenia. Direct evidence from PET studies does not support a substantial influence of the serotonergic system. Whether serotonin has an attenuating function on the development of extrapyramidal side effects in atypical neuroleptics is still unclear.

BEYOND DOPAMINE AND SEROTONIN

In the past decade, research has moved away from a unitary catecholaminergic hypothesis involving only dopamine, serotonin or others like glutamate and GABA. A new direction has emerged focusing on the interaction of a variety of neurotransmitters in complex neurocircuits engaged in the control of major mental functions, such as affect, emotions and cognition, and their involvement in reward-directed and other complex behaviour (Carlsson *et al.*, 2001). Rather than trying to identify a single culprit in psychotogenesis, the emphasis is now moving towards trying to understand these interactions and how imbalances in such circuitry can arise, perhaps on a multifactorial basis. This would argue for a role of not only dopamine and glutamate but also serotonin, noradrenaline and GABA. There is now convincing evidence that a primary disturbance in one neurotransmitter system will inevitably influence several other systems. To try to establish the order in which a

complex chain of events has arisen, and thus to identify the origin, would in general seem unrealistic. A more modest aim would be to try to describe aberrations in the patterns of physiological and biochemical events, and to try to correlate such aberrations to behavioural changes (Carlsson *et al.*, 2001).

As an alternative to the multireceptor hypotheses, it was recently proposed (Kapur and Seeman, 2001) that the atypical antipsychotic effect can be produced by appropriate modulation of the D2 receptor alone; the blockade of other receptors is neither necessary nor sufficient. The authors of this hypothesis propose that fast dissociation from the D2 receptor makes an antipsychotic more accommodating of physiological dopamine transmission, permitting an antipsychotic effect without motor side effects, prolactin elevation or secondary negative symptoms.

Amino Acid Transmitter Systems

U. Heresco-Levy

INTRODUCTION

Until recently, the study of amino acids systems in the context of schizophrenia has been relatively neglected, although excitatory and inhibitory amino acids are the most prevalent neurotransmitters in the human central nervous system (CNS) (see Chapter V). Currently, accumulating basic science and clinical data indicate that dysfunctions in neurotransmission modulated by the excitatory amino acids (EAA) glutamate (GLU) and its congeners may play a pivotal role in the pathophysiology of schizophrenia. These hypotheses led during the last decade to the evaluation of innovative pharmacological approaches for treatment-resistant schizophrenia patients. Moreover, a possible role of the inhibitory amino acid γ-aminobutyric acid (GABA) in this illness is presently being reassessed in the context of newly proposed interactions between GABA, EAA and other neurotransmitter systems.

EXCITATORY AMINO ACIDS

Most of the excitatory neuronal transmission in the CNS is mediated by the endogenous EAA, GLU, aspartate and homocysteine, GLU systems being the best characterized of the EAA systems. Almost all the neurones in the brain are influenced by GLU, and pre- and postsynaptic GLU receptors are found on neurones throughout the CNS. The action of GLU and its congeners is mediated at three subtypes of ionotropic receptors: amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate and *N*-methyl-D-aspartate (NMDA) and at two distinct families of metabotropic, G protein-coupled receptors (see Chapter V). Due to the involvement of glutamatergic neurotransmission in a wide array of brain functions, the study of EAA systems presently represents one of the most promising research areas in neuroscience. Within this context, a link between glutamatergic neurotransmission and schizophrenia is supported by multiple lines of evidence.

Anatomical and Physiological Considerations

Schizophrenia is a human brain disease characterized by a wide array of mental dysfunctions over a lifelong course. Traditionally viewed as comprising primarily positive and negative symptoms, it is now recognized that cognitive impairments also constitute a key symptom group in this illness. The distribution and functions of glutamatergic systems within the brain strongly suggest that deficits in EAA-mediated neurotransmission may be involved in the pathogenesis of schizophrenia symptomatology. Glutamatergic fibres give rise to the major afferent, intrinsic and efferent pathways through the cortex. Many sensory organs, including the cochlea, olfactory bulb and retina, use GLU as their principal neurotransmitter. Within the brain, thalamocortical fibres, which represent the main input to the cortex, are primarily glutamatergic in nature. Virtually all pyramidal neurones in the cerebral cortex are glutamatergic. The dense, mutually facilitatory GLU-mediated connections between pyramidal cells is a basic requirement for the extensive parallel information-processing operations of the cortex. Pyramidal neurones in the cortex project to both cortical and subcortical structures. The corticostriatal pathway, which originates from the entire neocortex and projects to the ipsilateral candate, the putamen and, to a smaller extent, the nucleus accumbens, may be specifically implicated in the pathophysiology of schizophrenia. Corticostriated fibres impinge on the same intrinsic structural neurones as the dopamergic fibres of the nigrostriatal tract. Corticostriatal and nigrostriatal fibres exert behavioural effects that are genetically antagonistic. In experimental animals, corticostriated ablation produces transient stereotypes similar to those induced by amphetamine, facilitates amphetamine-induced stereotypies and circling, and markedly inhibits haloperidol-induced catalepsy. The effects of corticostriatal ablation are not accompanied by increases in dopamine (DA) metabolite levels or by alterations in DA receptor density. The functional dysregulation of dopaminergic neurotransmission induced by corticostriated ablation may serve as a model for behavioural disorganization in schizophrenia. A similar system, the corticothalamic system, regulates information flow into the cortex. Abnormalities of corticothalamic neurotransmission may contribute to the sensory-gating abnormalities associated with schizophrenia.

A specific model for an involvement of GLU in psychosis and schizophrenia has been suggested, based on extensive animal studies, by Carlsson and Carlsson (1990a, 1990b). According to this hypothesis, GLU acting at the NMDA receptor and DA activity at the D_2 receptor together produce a balanced intracellular signal at postsynaptic neurones in the striatum in order to provide an optimal feedback from basal ganglia and thalamus to cortex. A relative increase in dopaminergic activity and/or a relative decrease in glutamatergic transmission could precipitate psychosis. This formulation, although derived solely from preclinical studies, is highly consistent with the known pharmacology of schizophrenia. Furthermore, it suggests that overactivity of the dopaminergic system observed in schizophrenia may be due to a primary abnormality in glutamatergic neurotransmission or that the hyperdopaminergic state of schizophrenia could be responsible for a disturbance of EAA systems.

Glutamatergic fibres also give rise to the major afferent, intrinsic and efferent pathways of the hippocampal formation, and disruption of the glutamatergic pathways within the hippocampus is associated with severe disturbances in memory formation. The cortex, hippocampus and parahippocampal gyrus are all characterized by a high level of EAA receptors (for review see Ulas and Cotman, 1993). The NMDA subtype of GLU receptors appears to be concentrated primarily in the limbic system, being therefore very important to function in the limbic cortex, anterior cingulate, hippocampus and ultimately other areas of the human brain. NMDA but also

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

non-NMDA glutamatergic receptors play an important role in a variety of cardinal normal CNS functions, including memory and learning, synaptic and developmental plasticity, sensory information and coordinated movement patterns (for review see Cotman *et al.*, 1988; Reid and Morris, 1991). Thus, while the involvement of glutamatergic transmission in these complex processes continues to be defined, it is increasingly evident that altered EAA receptor function may be of significance in the pathophysiology of schizophrenia.

Excitotoxicity and Neurodegeneration

In addition to its broad role in human brain functions, glutamatergic neurotransmission may be involved in excitotoxic and chronic neurodegenerative brain disorders (Olney, 1989; Whetsell and Shapira, 1993). Excitotoxicity refers to a paradoxical phenomenon whereby the neuroexcitatory action of GLU and related compounds, an action necessary for normal CNS functioning, becomes transformed into a neuropathological process that can rapidly kill CNS neurones. While stimulation of either NMDA or non-NMDA receptors can lead to excitotoxicity, the final common pathway for cell death appears to be the uncontrolled influx of CA^{2+} through opened unblocked NMDA receptor channels (Rothman and Olney, 1987; Choi *et al.*, 1988).

Either hyper- or hypofunction of EAA transmitter systems may be postulated as a basis for neuropsychiatric disorders. According to the hyperfunction concept, excessive activation of postsynaptic receptors can cause brain damage. However, when endogenous EAA transmitters, due to a hyperfunctional state, induce brain damage, this is essentially an autoexcitotoxic process in which the EAA neural network damages itself; i.e. the cells bearing EAA receptors and EAA receptors themselves are destroyed, rendering the EAA neural system hypofunctional. One mechanism by which GLU hypofunction might occur could be by an autoexcitotoxic process in which subtle brain damage induced by an excitotoxic mechanism in early life would destroy postsynaptic cells that house the GLU receptor system, thereby rendering the GLU neural network functionally deficient. In this context Olney and Farber (1995) have recently described a neurotoxic mechanism model that may be involved in schizophrenia. This pathogenic mechanism, ultimately leading to necrosis, begins with inhibition of NMDA receptors, and results in the final disinhibition of cortical excitatory cholinergic neurones, by way of reduced stimulation of inhibitory GABAergic interneurones secondary to glutamatergic blockade. This complex chain of events could explain how a pathological reduction in glutamatergic stimulation may ultimately result in cell loss. In support of this hypothesis are pharmacological data generated in animal studies using high doses of non-competitive NMDA receptor antagonists. Bridging those data with human pathology will be necessary to verify this plausible hypothesis.

An additional model of EAA-related cell death that may be operant in schizophrenia has been proposed by Coyle and Puttfarcken (1993). According to this model glutamatergic transmission, over a chronic time period, potentiates pathological intracellular primary oxidative processes and hence promotes oxidative cell death. In this formulation, GLU-mediated neurotransmission, especially if mildly elevated, could promote intracellular oxidation and diminish intracellular antioxidative protection. This process could potentiate other primary CNS pathology to result in overt brain illness. These processes should be characterized by cell loss but not by remarkable gliosis. Based on evidence of reduced neuronal density in schizophrenia, this model hypothetically associates oxidative stress mechanisms with the aetiology of schizophrenia.

Neurochemical Abnormalities

Further support for a role of EAA systems in schizophrenia derives from assessments of EAA levels and post-mortem brain neurochemical abnormalities in this illness. Although the first report of reduced GLU concentration in CSF of schizophrenia patients (Kim *et al.*, 1980) was not supported by later studies (Perry, 1982; Gattaz *et al.*, 1985), subsequent reports have indicated a significant reduction in the release of GLU induced by veratridine (Sherman *et al.*, 1991a), kainate and NMDA (Sherman *et al.*, 1991b) in synaptosomal fractions prepared from post-mortem brains of schizophrenics. Moreover, studies documenting altered density of GLU receptors in various regions of post-mortem brain of schizophrenia patients in comparison to normals were reported. The findings include increased [^{3}H]kainate binding in the prefrontal cortex (Nishikawa *et al.*, 1983; Deakin *et al.*, 1989), increased [^{3}H]MK-801 binding in the putamen (Kornhuber *et al.*, 1989) and in the temporal cortex, whereas [^{3}H]AMPA binding changed only minimally in the entire cerebral cortices (Kurumaji *et al.*, 1992). The negative correlation observed between GLU concentration in subcortical areas and receptor binding in terminal cortical areas from post-mortem studies (Toru *et al.*, 1988) and the increase in the number of postsynaptic GLU receptors reported in response to deafferentiation in rat hippocampus (Ulas *et al.*, 1990a, 1990b) support the hypothesis of glutamatergic hypofunction including compensatory upregulation of GLU receptors in some regions of frontal and temporal cortex in schizophrenia.

Recent findings bring further support to this hypothesis. Tsai *et al.* (1995) have reported reduced levels of GLU and aspartate in the hippocampus and frontal cortex in schizophrenia, in comparison to normal tissue. They also have found increased *N*-acetylaspartylglutamate (NAAG) — putative GLU precursor — and reduced activity of *N*-acetyl-α-linked acidic dipeptidase (NAALDase) — the enzyme that converts NAAG to *N*-acetylaspartate (NAA) and GLU in the same tissue. Reduced activity of an important GLU-synthesizing enzyme such as NAALDase could account for regional reduction in GLU-mediated neurotransmission and a secondary upregulation of GLU receptors in the cortex. Furthermore, Ishimaru *et al.* (1994) found that strychnine-insensitive glycine (GLY) binding sites coupled with the NMDA receptor–ionophore complex (see Chapter V) are increased in the cerebral cortex of chronic schizophrenics, not in terms of affinity but in the maximum number of binding sites. Since agonist action at the strychnine-insensitive GLY binding sites is an absolute requirement for the opening of the ion channel at the NMDA receptor–ionophore complex, these findings suggest that the increases in NMDA receptor-associated GLY binding sites, possibly ascribed to the postsynaptic compensation for impaired glutamatergic neurotransmission, might be implicated in the pathophysiology of schizophrenia.

EAA Receptor Regulation by Antipsychotics

Preliminary data indicate that presently available antipsychotics may, directly or indirectly, interact with glutamatergic brain systems. Gattaz *et al.* (1985) demonstrated a lack of change in GLU levels in CSF of neuroleptic-free, paranoid schizophrenia patients, in contrast to significantly elevated (33%) levels of GLU in patients on conventional neuroleptics. Alfredsson and Wiesel (1990) reported that during sulpiride treatment serum GLU levels increased in responders while they decreased in non-responders. Recently, Goff *et al.* (1996) found that patients treated with clozapine had significantly higher serum GLU concentrations than did patients treated with conventional neuroleptics. Moreover, it was shown that switching from conventional neuroleptics to clozapine was associated with increased serum GLU and aspartate concentrations (Evins *et al.*, 1997). In animal studies, acute administration of clozapine, but not haloperidol, increased medial prefrontal cortical GLU and aspartate concentrations (Daly and Moghaddam, 1993; Yamamoto and Cooperman, 1994), suggesting that clozapine may have selective actions on cortical EAA systems.

Several studies suggest that neuroleptics interact with the NMDA receptor–ion channel complex. It has been shown that in rat brain chronic haloperidol treatment upregulates binding of [^{3}H]TCP (an analogue of phencyclidine (PCP) and non-competitive NMDA receptor antagonist) to the PCP receptor located within the NMDA receptor–ion channel (Byrd *et al.*, 1987). The increase in [^{3}H]TCP binding levels appeared to be due to a striking (50%) increase in the maximal density of PCP receptors. This elevated density of PCP receptors after chronic haloperidol treatment contrasts with the observation of Kornhuber *et al.* (1989), suggesting that haloperidol does not interact directly with [^{3}H]MK-801 binding to NMDA receptor-ion channel PCP sites in post-mortem human brain.

Growing evidence suggests that clozapine and possibly other atypical antipsychotics may act in part by increasing activity at the NMDA receptor. Clozapine has been reported to be the most potent of the antipsychotic agents tested in blocking NMDA receptor antagonist-induced neurotoxicity (Farber *et al.*, 1993; Olney and Farber, 1994), stereotypy (Tiedtke *et al.*, 1990), social isolation (Corbett *et al.*, 1995) and deficits in sensorimotor gating of the startle response (Bakshi *et al.*, 1994; Lang *et al.*, 1992). Furthermore, in humans clozapine blunts psychotropic effects induced by the PCP derivative ketamine (Malhotra *et al.*, 1997a). Blocking of NMDA receptor antagonist-induced neurotoxicity (Farber *et al.*, 1996), isolative behaviour (Corbett *et al.*, 1995) and information gating dysfunction (Bakshi and Geyer, 1995) was also produced by olanzapine, suggesting that other atypical agents may share glutamatergic properties in common with clozapine. Taken together, these findings raise the important question as to whether different clinical profiles of conventional and atypical antipsychotics may reflect different mutual interactions of these drugs with both glutamatergic and dopaminergic systems.

Psychotomimetic Effects of NMDA Receptor Antagonists

The most compelling evidence linking glutamatergic receptor function with schizophrenia is provided by the psychotomimetic effects induced by PCP and related agents (e.g. ketamine). These agents were initially developed for use as general anaesthetics. However, in early clinical trials PCP was found to induce psychotomimetic effects in approximately 20% of exposed subjects (Corssen and Domino, 1966). In clinical trials performed four decades ago, the psychotic symptoms induced by PCP closely resembled those of schizophrenia, leading to the hypothesis that PCP-induced psychosis might serve as an effective clinical model for this illness (Luby *et al.*, 1962). During the last decade, ketamine administration has also been found to induce transient positive and negative schizophrenia-like symptoms and cognitive deficits in normal volunteers (Krystal *et al.*, 1994; Malhotra *et al.*, 1996) and exacerbation of psychosis in drug-free (Malhotra *et al.*, 1997b) or remitted (Lahti *et al.*, 1995a) schizophrenia patients. Lahti *et al.* (1995b, 1995c) found that ketamine increases regional cerebral blood flow (rCBF) in anterior cingulate and decreases flow in hippocampus, lingual gyrus and cerebellum of schizophrenia patients and normals. Furthermore, a correlation between BPRS ratings and rCBF in the medial and anterior aspects of the temporal lobe and in the ventral striatum was found. It was suggested (Tamminga, 1998) that schizophrenia patients may show a greater and longer response of anterior cingulate cortex to a fixed ketamine dose, without gross change in receptor number, suggesting the possibility of increased endogenous sensitivity to excitatory signals in this region. PET scans with [^{18}F]deoxyglucose following ketamine administration to normal volunteers identified a large area of activation in the prefrontal cortex, sparing most of the remaining brain (Breier *et al.*, 1998). In addition, conceptual disorganization was related to the degree of activation. These data suggest that the prefrontal cortex, an important region for many cognitive functions that have been shown to be abnormal in schizophrenia, may mediate the behavioural effects of NMDA receptor antagonists. Moreover, using positron emission tomography (PET) raclopride scanning, Breier *et al.* (1998) found that raclopride binding to D_2 receptors is decreased following ketamine administration, suggesting that ketamine induces DA release in the striatum. These findings bring further support to the hypothesis of GLU/DA interaction in the pathogenesis of behavioural syndromes induced by NMDA receptor antagonists.

PCP and ketamine induce their behavioural effects by binding to the PCP site located within the ion channel associated with the NMDA receptor (Javitt and Zukin, 1991). Their binding to this site leads to non-competitive blockade of NMDA receptor-mediated neurotransmission, indicating that endogenous NMDA dysfunction may play a critical role in the pathophysiology of schizophrenia. Moreover, in rodents, systemic injection of PCP and other non-competitive NMDA antagonists induces a characteristic behavioural syndrome, including hyperactivity and stereotypies. This syndrome is sensitive to administration of GLY-site agonists of the NMDA receptor, including GLY, D-serine and D-alanine (Toth and Lajtha, 1986; Contreras, 1990; Tanii *et al.*, 1994; Javitt *et al.*, 1997), but not to the administration of similar doses of a variety of other amino acids (Toth and Lajtha, 1986), further supporting a primary NMDA receptor involvement.

In recent years, it has been shown that non-competitive as well as competitive NMDA receptor antagonists may induce neurodegenerative changes in corticolimbic regions of the rat brain (Olney *et al.*, 1989, 1991; Hargreaves *et al.*, 1993). Furthermore, competitive NMDA antagonists (e.g. CPP, CGS-19755) that block NMDA receptors by acting at the NMDA, rather than PCP, recognition site have been developed. Although the behavioural effects of these agents are less well characterized than those of ketamine and PCP, they also appear to induce PCP-like behavioural effects in humans (Muir and Lees, 1995; Kristensen *et al.*, 1992; Grotta, 1994). These findings are in agreement with the concept of NMDA receptor hypofunction in schizophrenia and led to the hypothesis that this phenomenon may not be PCP receptor specific, but could result from a dysfunctional blockade of the NMDA receptor–ionophore complex (Olney and Farber, 1995).

NMDA RECEPTOR-BASED TREATMENT APPROACHES

At present there is an intense search for pharmacological strategies aimed at modulating glutamatergic neurotransmission in schizophrenia. Within this framework, research has recently focused on assessing the therapeutic potential of enhancing NMDA receptor function. Due to its structural complexity and relative abundance of modulation sites (see Chapter V), the NMDA receptor represents an inherently rich target for the development of innovative pharmacological interventions and corresponding new drugs. Since direct-acting NMDA agonists are potentially excitotoxic, the main NMDA receptor-based treatment approach for schizophrenia that has been clinically investigated during the last decade is the enhancement of NMDA receptor-mediated neurotransmission via administration of compounds having full or partial agonist activity at the strychnine-insensitive GLY recognition site of the receptor. Based on the general theoretical framework of the PCP model of schizophrenia, five compounds, milacemide, GLY, D-serine, D-cycloserine and D-alanine, have been assessed, mainly as adjuvant pharmacotherapy, in samples of treatment-resistant schizophrenia patients.

Milacemide, an amino acetamide derivative that has been extensively studied in humans as a potential antiepileptic and cognition enhancer, increases GLY levels in the CNS by dissociating into GLY-amide and then GLY, after passing through the blood–brain barrier (DeVarbeke *et al.*, 1988). In rats, after milacemide administration, whole-brain GLY levels increase by approximately 30%.

Milacemide, which was eventually withdrawn from use due to hepatotoxicity unrelated to its CNS effects, was found to be capable of reversing discriminative stimulus effects of PCP and of enhancing cognition in various animal and human models, consistent with its ability to potentiate NMDA receptor neurotransmission via metabolism to GLY. However, when several schizophrenia patients were assessed while they were otherwise drug free and in a stable, yet psychotic state, milacemide did not appreciably affect symptomatology (Tamminga *et al.*, 1992). Similarly, Rosse *et al.* (1991) reported a negative study using low-dose milacemide as add-on therapy with neuroleptic-treated schizophrenia patients. The negative results of these studies could be due to the small number of patients studied and/or to the low potency of milacemide. Furthermore it should be taken into account that milacemide affects additional neurotransmitter systems. For example, it increases central serotonin and DA levels by inhibiting the action of monoamine oxidase type A, raising doubts regarding the role of the GLY site as the specific, primary site of action of this drug.

Glycine (GLY) is a small, neutral amino acid constituting 1–5% of dietary protein that in the spinal cord and brain stem acts as an inhibitory neurotransmitter at a strychnine-sensitive site. By contrast, in forebrain, GLY is one of the most potent agonists known to act at the strychnine-insensitive GLY site associated with the NMDA receptor. Its coagonist action at this site positively modulates NMDA receptor function by increasing the frequency of NMDA ionophore opening and by delaying NMDA receptor desensitization (see Chapter V). Permeation of GLY into brain following peripheral administration is the lowest of any naturally occurring amino acid (Oldendorph, 1971) and large peripheral doses of GLY must be administered in order to obtain modest elevations in CNS levels.

To date, the results of the first 10 open label and controlled studies investigating the therapeutic potential of various adjuvant GLY regimens in a total of approximately 140 schizophrenia patients are available (Table XVII-3.1). The earliest study with GLY (Waziri, 1988) was performed before the relationship between GLY and NMDA function was fully appreciated, based on the observation that schizophrenia subjects had lower serine hydroxymethyl transferase (SHMT) activity than controls. Since SHMT activity is the major source of GLY in the brain, it was postulated that schizophrenia may be associated with decreased CNS GLY levels, although this hypothesis has not been confirmed (Korpi *et al.*, 1987a; Perry and Hansen, 1985). In this naturalistic study, four of 11 patients were noted to show 'definite salutary response' as indicated by decreased need for neuroleptics and improved social/vocational functioning, following administration of 5–25 g per day GLY. Subsequently, as interest in NMDA receptor-mediated neurotransmission increased, additional studies were performed with GLY doses of up to ~60 g per day. The first controlled GLY trial (Potkin *et al.*, 1992), which used a GLY dose of 15 g per day, demonstrated significant global improvement following GLY treatment and a trend towards improvement on the BPRS. Using an increased adjuvant GLY dose of approximately 30 g per day, Javitt *et al.* (1994) found a significant 17% mean reduction in negative symptoms, as measured by the PANSS, in a sample of neuroleptics-treated chronic schizophrenia patients. In contrast, in two controlled studies, no therapeutic effects were registered when 30 g per day (Potkin *et al.*, 1999) and 60 g per day (Evins *et al.*, 2000) GLY were added to the drug regimen of clozapine-treated patients. Recently, Heresco-Levy *et al.* (1996, 1999) reported the results of a 6-week double-blind, placebo-controlled, crossover trial in which 0.8 g kg^{-1} per day GLY — the highest GLY dose used to date in schizophrenia — were added to the antipsychotic regimen received by inpatients fulfilling treatment-resistance criteria. A significant 30% mean reduction in total BPRS scores and a 30% mean decline in negative symptoms, as measured by the PANSS, were observed during treatment with GLY, whereas no significant change in symptoms was observed during placebo treatment. Cognitive and depression symptoms also improved significantly, by 16% and 17%, respectively, during treatment with GLY but not placebo. The treatment by time interaction remained significant for negative and cognitive symptoms even following covariation for changes in depression and extrapyramidal symptom scores. GLY treatment led to a significant 3.5-fold increase in serum GLY levels and low pretreatment GLY levels significantly predicted clinical response. These findings provide initial support for the hypotheses that (a) GLY may be effective for the treatment of primary negative symptoms of schizophrenia and (b) patients with consistently low serum GLY levels may be the population of choice for treatment with GLY-site agonists.

D-Serine (DSR) acts as an endogenous full agonist at the NMDA receptor-associated GLY site (for review, see Hashimoto and Oka, 1997). GLY overloading can increase DSR in the brain through the GLY cleavage system; conversely, DSR can be converted sequentially to *l*-serine and GLY by racemase and SHMT. DSR has the advantage of being more permeable than GLY at the blood–brain barrier, thus requiring a reduced amount per dose. To date, two studies assessing DSR as an add-on agent to other antipsychotics in schizophrenia treatment have been reported. In a 6-week placebo-controlled, parallel group trial (Tsai *et al.*, 1998) a 30 mg kg^{-1} per day DSR dose resulted in significant 21%, 17% and 12% mean reductions, respectively, in negative, positive and cognitive symptoms, as measured by the PANSS. The cognitive enhancing effect was supported by improved performance in the Wisconsin Card Sorting Test (WCST). Given the observed effect on positive symptoms registered in this study, it has been suggested (Krystal and D'Souza, 1998; Tsai *et al.*, 1998) that DSR may represent the drug of choice for a GLY-site agonist monotherapy trial in schizophrenia. Nevertheless, in a methodologically identical study (Tsai *et al.*, 1999a), similarly to results registered with GLY treatment, no significant symptom changes were registered when the same DSR dose (i.e. 30 mg kg^{-1} per day) was added to clozapine treatment.

D-Cycloserine (DCS, d-4-amino-3-isoxazolidone, seromycin) is an antituberculosis drug that, unlike GLY, readily crosses the blood–brain barrier and acts as a relatively selective partial agonist at the GLY site for a narrow range of concentrations (Thompson *et al.*, 1992; Watson *et al.*, 1990). Potentially beneficial DCS psychotropic effects were first reported four decades ago, when 500–1000 mg per day DCS was routinely used as part of multidrug antituberculosis regimens. However, administration of 500–3000 mg per day DCS in a naturalistic study to nine drug-free schizophrenia patients resulted mainly in exacerbation of psychotic symptoms, psychomotor agitation, confusion and mood alterations (Simeon *et al.*, 1970).

The discovery of DCS physiological impact at the NMDA receptor led, during the last decade, to renewed interest in DCS-induced psychotropic effects and initial trials have attempted to define the DCS dose range over which adjuvant treatment with this compound may be beneficial in schizophrenia (Table XVII-3.2). DCS regimens of $\leq$30 mg per day were ineffective (Rosse *et al.*, 1996), while dosages of $\geq$100 mg per day led to positive symptom exacerbations (Cascella *et al.*, 1994; van Berckel *et al.*, 1999). In two single-blind dose escalation trials, only a 50 mg per day DCS regimen led to significant improvements in negative symptoms when administered to typical neuroleptics (Goff *et al.*, 1995), but not to clozapine-maintained (Goff *et al.*, 1996) patients. Serum glutamate concentrations at baseline and the change in GLY concentrations significantly correlated with response of negative symptoms. Recently, Goff *et al.* (1999a, 1999b) replicated the findings of their preliminary dose-finding trials in two double-blind, placebo-controlled studies. Addition of 50 mg per day DCS to clozapine led to significant negative symptoms worsening, compared to placebo (Goff *et al.*, 1999b). In contrast, the addition of the same DCS regimen to typical neuroleptics (Goff *et al.*, 1999a)

Table XVII-3.1 Clinical trials with glycine (GLY) in the treatment of schizophrenia

Study	Sample size	Design	Study duration (weeks)	Antipsychotic treatment	Daily GLY dose (g)	Symptoms[a] measures	Outcome
Waziri (1988)	11	Open label, naturalistic	36	Varied	5–25	Not specified	35% improved; neuroleptic treatment reduced or withdrawn
Rosse *et al.* (1989)	8	Open label	≤8	Varied	10.8	BPRS, SANS, CGI	33%: improved BPRS 33%: worsened BPRS
Costa *et al.* (1990)	6	Open label	6	Varied	15	BPRS: >30% improvement	33% improved
Heh *et al.* (1992)	8	Open label	≤5	Drug-free	≤20	BPRS: >30% improvement	No therapeutic effects
Potkin *et al.* (1992)	18	Double-blind, placebo-controlled	6	Varied	15	BPRS: >30% improvement SANS, CGI	Trend towards improvement with GLY (20% improved >30% in BPRS)
Javitt *et al.* (1994)	14	Double-blind, placebo-controlled followed by open label	8 blind 8 open	Varied	30	PANSS	17% improvement in negative symptoms
Leiderman *et al.* (1996)	5	Open label	8	Varied	60	SANS, PANSS	Significant SANS improvement
Potkin *et al.* (1999)	19	Double-blind, placebo-controlled	12	Clozapine	30	BPRS, SANS	No therapeutic effects
Heresco-Levy *et al.* (1996, 1999)	22	Double-blind, placebo-controlled crossover	6	Varied	60	BPRS, PANSS	30% improvement in negative symptoms
Evins *et al.* (2000)	30	Double-blind, placebo-controlled	8	Clozapine	60	BPRS, SANS PANSS	No therapeutic effects

resulted in a significant mean 23% reduction in negative symptoms as measured by SANS total scores. The rate of reduction in total SANS scores in the DCS group remained significantly greater than for the placebo group after controlling for change in extrapyramidal, positive and depression symptoms. A 50 mg per day DCS adjuvant regimen has been recently assessed also in a sample of treatment-resistant schizophrenia patients receiving conventional neuroleptics, olanzapine and risperidone (Heresco-Levy *et al.*, 2001). In this study, DCS treatment resulted in a mean 15% reduction in negative symptoms and the negative symptoms improvement did not differ between patients treated with conventional neuroleptics versus risperidone and olanzapine. Low pretreatment GLY and serine serum levels significantly predicted clinical response.

Similarly to the conclusions of GLY studies, the results of DCS trials performed to date suggest that DCS adjuvant treatment may be effective against primary negative symptoms of schizophrenia, in particular among patients having low GLY, and possibly serine, serum levels. However, the therapeutic DCS dose range appears to be restricted around a regimen of approximately 50 mg per day. This limitation may be due to the partial agonist characteristics of DCS. As a partial agonist at the GLY site, producing 40–60% activity compared to GLY, DCS acts as an agonist in the presence of low GLY concentrations and as an antagonist in the presence of high concentrations (Emmett *et al.*, 1991). DCS effects are further determined by the relative concentrations of other endogenous ligands possessing varying degrees of agonist activity, such as serine and alanine.

D-Alanine has a lower affinity for the GLY site than GLY or DSR and, although there is evidence to suggest that it is actively transported into the CNS, its precise bioavailability and pharmacokinetics are yet to be determined. In animal models of psychosis, intraventricular administration of D-alanine inhibits methamphetamine and PCP-induced hyperactivity and blocks PCP/MK-801-induced stereotypies and ataxia. Recently the results of the first adjuvant D-alanine trial in schizophrenia have been presented (Tsai *et al.*, 1999b). In this 6-week controlled study, D-alanine treatment resulted in mean 20%, 15% and 12% reductions, respectively, in negative, positive and cognitive symptoms as measured by the PANSS.

Safety Issues and Future Directions

In the studies performed to date, the administration of GLY-site agonists of the NMDA receptor has been well tolerated by schizophrenia patients and no significant side effects or alterations in clinical laboratory parameters have been registered. Nevertheless, the main safety issue concerning the use of this type of agent is neurotoxicity. In order to examine possible GLY-induced neuronal and/or glial pathology, two controlled studies were recently performed in which rats were randomized to receive dietary supplementation with GLY. In the first study rats received 0.8 and 3.2 $g\,kg^{-1}$ per day GLY for 2 weeks (Shoham *et al.*, 1999); in a subsequent study rats received dietary supplementation with 1 and 5 $g\,kg^{-1}$ per day GLY for 1, 3 and 5 months (Shoham *et al.*, 2001). Although these dietary regimens resulted in significant, dose-dependent GLY levels increases, extensive morphological and immunohistochemical examination did not reveal any evidence of neurotoxic damage at any of the treatment intervals studied.

Overall, the results of the first generation of small clinical trials with GLY-site agonists support the NMDA receptor hypofunction hypothesis of schizophrenia and warrant further, larger-scale investigation. The aims of studies presently performed in this field include: (1) the assessment of GLY-site modulators as mono- versus add-on therapy, (2) the comparison of efficacies of full versus partial agonists of the GLY-site, and (3) the assessment of clinical effects of these agents as adjuvants to widely used atypical antipsychotics such as risperidone and olanzapine. This last issue highlights the importance of better understanding the interactions between this group of drugs and the mechanism of action of atypical antipsychotics. Presently, the lack of clinical response to GLY-site agonists in clozapine-treated patients is hypothesized to indicate that activity at the GLY modulatory site may be a possible mechanism contributing to clozapine efficacy.

A related alternate strategy for enhancing NMDA-mediated neurotransmission may be the use of GLY uptake antagonists. The degree to which presynaptically released GLU stimulates NMDA receptor-mediated activity depends upon the tonic GLY levels in the immediate surrounding region. The recent molecular and biochemical characterization of a class of GLY transporter proteins in brain (Liu *et al.*, 1993; Smith *et al.*, 1992) suggests that GLY concentration in micro domains may be regulated by these transporters. Of these, the GLY transporter type 1 (GLYT1) is expressed primarily in glia and neurones of the neocortex and archicortex in association with regions of high NMDA expression (Zafra *et al.*, 1995). GLYT1 may serve to maintain low intrasynaptic GLY level specifically in the local region around NMDA receptors. Inhibition of GLYT1 transporters may thus lead to GLY level elevations in the immediate vicinity of NMDA receptors and augmentation of NMDA receptor-mediated neurotransmission without requiring administration of exogenous GLY. GLY transport antagonists suitable for clinical trials are not yet available. Nevertheless, the GLY derivative glycyldodecylamide (GDA) was found to be approximately 80-fold more potent than GLY in reversing PCP-induced hyperactivity (Toth *et al.*, 1986). Recently, Javitt and Frusciante (1997) have demonstrated that GDA acts as a selective GLY uptake antagonist at concentrations similar to those that would be obtained after peripheral administration. Furthermore, in animal behavioural studies, the potency of several novel GDA-related compounds for inhibiting PCP-induced hyperactivity *in vivo* correlated significantly with their potency in antagonizing GLY transport *in vitro* (Javitt *et al.*, 1999). These findings suggest that GLY transport antagonists may induce effects similar to GLY and may therefore represent an appropriate alternative for targetted drug development.

ADDITIONAL GLUTAMATERGIC DYSFUNCTION MECHANISMS AND TREATMENT APPROACHES

The pharmacological manipulation of neurotransmission mediated at non-NMDA glutamatergic receptors may also represent a potentially beneficial treatment approach for psychotic states and schizophrenia.

Svensson and colleagues revealed that the major mechanism which drives burst firing in ventral tegmental area (VTA) dopaminergic neurones is activation of NMDA receptors, mediating the influence on DA cells from glutamatergic afferents, e.g. from the prefrontal cortex. Accordingly, schizophrenomimetic NMDA receptor antagonists, such as PCP, were found to cause dramatic distortions of central DA neuronal signalling even at very low doses. DA neurones projecting to subcortical areas deployed a monotonous, high-frequency firing, whereas DA neurones from the VTA that provide the DA innervation of the prefrontal cortex showed literal abolition of burst firing, thus rendering this dopaminergic projection incapable of effective phasic signalling (for review, see Svensson, 2000). Significantly, the firing pattern of dopaminergic neurones activated by systemic administration of the potent and selective NMDA receptor antagonist MK-801 was quite similar to the high-frequency, non-bursting firing pattern previously observed after local application of quisqualate or kainate, i.e. AMPA and kainate receptor agonists (for review see Svensson *et al.*, 1997), indicating the possibility that NMDA receptor antagonists might release GLU onto VTA dopaminergic neurones. Accordingly, it was recently reported that effects of NMDA antagonists may also be mediated

through excess activity at AMPA/kainate receptors. It has been shown that the local administration of CNQX, an AMPA/kainate antagonist, blocks the hyperlocomotion and increase in DA release seen in the VTA after systemic administration of MK-801, suggesting that excess stimulation at non-NMDA receptors may mediate these effects (Mathé *et al.*, 1998). Since most antipsychotics and particularly clozapine have been observed to antagonize the behaviourally stimulant action of PCP-like drugs, the effect of two chemically different AMPA receptor antagonists, GYKI 52466 and LY 326325, were investigated in the classical conditioned avoidance response (CAR) paradigm in the rat. Systemic administration of both compounds resulted in significant suppression of CAR without any effect on escape behaviour. Importantly, no catalepsy was observed (Mathé *et al.*, 1999). Taken together, these accumulating data indicate an antipsychotic effect of AMPA receptor antagonists with a low liability for extrapyramidal side effects, suggesting, in principle, an atypical antipsychotic profile. This possibility is further strengthened by additional findings indicating the ability of AMPA receptor antagonists to ameliorate cognitive deficits induced in rat by ketamine (Moghaddam *et al.*, 1997).

Moghaddam (2000) used a novel approach to normalize the glutamatergic hyperactivity produced by PCP by targetting the group II metabotropic GLU receptors (mGLURs). This group of receptors (mGLU2, mGLU3) has been located in forebrain regions, in particular the striatum and frontal cortex, and are thought to regulate GLU release by presynaptic mechanisms. Stimulation of these receptors in rodents, at an agonist dose that had no effect on spontaneous activity, attenuated PCP-induced working memory deficits, hyperlocomotion and stereotypy (Moghaddam and Adams, 1998). This behavioural reversal was accompanied by reduced activation of GLU efflux by PCP, but not by reduced presynaptic dopaminergic hyperactivity in cortical and subcortical regions. These data suggest that targetting the group II mGLURs may represent an additional therapeutic strategy for normalizing glutamatergic dysfunction in psychotic disorders, including schizophrenia.

Additional evidence in favour of a potential role for this group of compounds in psychosis treatment was hypothesized to derive also from the emerging role of GLU mechanisms in generating the psychotropic effects induced by psychedelic hallucinogens such as LSD. These hallucinogens have been found to enhance glutamatergic neurotransmission via their action at $5HT_{2A}$ receptors. In the prefrontal cortex, $5HT_{2A}$ receptor stimulation increases GLU release, as indicated by a marked increase in the frequency of postsynaptic potentials/currents in the apical dendritic region of layer V pyramidal cells. These effects were found to be suppressed by group II/III mGLURs agonists (for review see Aghajanian and Marek, 2000).

Ampakines are a newly developed class of low-molecular-weight drugs that freely cross the blood–brain barrier, increase AMPA receptor gated ionic currents and thereby enhance post-excitatory synaptic transmission in the cortical telencephalon (Staubli *et al.*, 1994a; Rogers *et al.*, 1997). These compounds facilitate long-term potentiation (Staubli *et al.*, 1994a) and enhance learning and memory in rodents (Staubli *et al.*, 1994b) and humans (Ingvar *et al.*, 1997), suggesting that they may improve cognitive dysfunction in patients. Moreover, ampakines substantially reduce methamphetamine-induced behavioural abnormalities in animals and interact positively with typical and atypical antipsychotics in blocking methamphetamine effects (Johnson *et al.*, 1999). These findings have been interpreted as raising the possibility that this family of drugs could be useful in the treatment of schizophrenia (Lynch, 1999).

Lamotrigine (3,5-diamino-6-[2,3-dichlorphenyl]-1,2,4-triazine) is a new anticonvulsant that stabilizes neuronal membranes and attenuates cortical GLU release. This compound is efficacious in the treatment of affective disorders and preliminary reports indicate that it may also be useful for schizoaffective patients (Erfurth *et al.*, 1998). Moreover, Anand *et al.* (2000) recently demonstrated attenuation of neuropsychiatric effects of ketamine with lamotrigine in healthy volunteers. The efficacy of lamotrigine in the treatment of schizophrenia is presently investigated in controlled clinical trials.

INHIBITORY AMINO ACIDS: γ-AMINOBUTYRIC ACID

γ-Aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain, is prevalent throughout the CNS, but at comparatively low concentrations in brain stem and spinal cord. In the cortex, GABA is localized primarily to intrinsic interneurones that participate in local feedback loops and exert a tonic inhibition on cortical pyramidal neurones to prevent uncontrolled excitatory activity. Physiologically, the most common function of inhibitory GABAergic neurons appears to be to focus and refine the firing pattern (nerve impulse generation) of the projection neurones that transfer neural information from one functional unit to another (see Chapter V). Traditionally, a role for GABA in the pathophysiology of schizophrenia has been assessed, leading to some experimental and clinical evidence, in the context of complex interactions between GABAergic and other brain neurotransmitter systems.

GABA Levels and Brain Structural Measures

Attempts to uncover a GABA disturbance in schizophrenia by direct measurements of GABA levels have had mixed results. CSF GABA has been reported not to differ significantly in schizophrenia patients and normal controls in a majority of studies, although some patients may have lower levels (Lichtshtein *et al.*, 1978; van Kammen *et al.*, 1982). Plasma GABA was also found to be similar in male schizophrenia patients and control subjects (Petty and Sherman, 1984). While several post-mortem studies of schizophrenia patients have revealed decreased GABA in some regions of the brain (Perry *et al.*, 1979; Korpi *et al.*, 1987b; Toru *et al.*, 1988), not all studies have observed such decreases. In a recent study, plasma levels of GABA were associated with prefrontal sulcal widening and ventricle–brain ratios, but not global sulcal widening in 62 drug-free schizophrenia patients. CSF GABA measurements were not associated with brain structural measures, but were associated with age and age of illness onset (van Kammen *et al.*, 1998). It was hypothesized that GABA synthesis and transmission may be impaired only in specific pathways, cortex layers or brain regions in schizophrenia subjects and compensated for in others.

GABA/Dopamine Interactions

A GABA disturbance in schizophrenia was first suggested by Roberts (1972), who hypothesized that low levels of GABA in the brain may lead to a state of disinhibition which, in turn, could produce the symptoms seen in schizophrenia. Subsequently, Roberts (1976) revised this concept into a GABA/DA imbalance hypothesis which postulates inadequate GABA inhibition of DA neurotransmission in this illness. The highest GABA levels in mammalian brain are located in the DA-rich basal ganglia. GABA-containing neurones there are intrinsic to the striatum, form a long feedback-loop path from the striatum to the substantia nigra pars reticulata and globus pallidus (i.e. from postsynaptic to presynaptic neurones), and constitute a major efferent pathway from the substantia nigra to the thalamus, superior colliculus and reticular system. These tracts modify dopaminergic function in these and other sites by decreasing presynaptic DA release. In rats, GABA-mimetic drugs attenuate acute neuroleptic-induced activation of nigrostriatal and mesolimbic DA neurones and retard DA neurone postsynaptic responses to chronic neuroleptic blockage

(Lloyd and Morselli, 1987). Evidence reviewed by Garbutt and van Kammen (1983) suggests that GABA inhibits the firing of DA neurones in the substantia nigra and VTA — the origin of the mesolimbic and mesocortical tracts. The evidence includes spiking in the nucleus accumbens when GABA antagonists were injected into the VTA in an animal model. Additional recent research has shown that GABA mediates the inhibition of cortical DA activity in rat brain (Wassef *et al.*, 1999). When this tonic inhibition exerted by the thalamic mediodorsal nucleus is disrupted, DA activity increases in certain target regions of the cortex (Jones *et al.*, 1988). Moreover, GABA has been observed to produce a dose-dependent decrease in the release of striatal DA. Reid *et al.* (1988) found that the striatal level of homovanillic acid and dihydroxyphenylacetic acid rose in the presence of GABA. It has also been reported that GABA antagonists stimulate DA release that is preloaded into the inner retinal cells of fish in a Ca^{2+}-dependent fashion and not via direct membrane action; the release was shown to be inhibited by excess GABA (Ishita *et al.*, 1988). In one study, valproic acid (a GABAergic compound), when applied to cultured rat cells in concentrations equivalent to therapeutic levels, was observed to limit the repetitive firing of the cells without altering the postsynaptic GABA response (MacDonald and McLean, 1987). The drug enhanced the inhibitory postsynaptic potential in the hippocampal cells of guinea-pigs (CA3 pyramidal cells and granule cells) and suppressed the spontaneous spiking and repetitive discharges evoked by GABA antagonists. The close association of GABA and DA in the lateral septum and nucleus accumbens in rats supports the anatomic plausibility of GABA/DA systems interaction (Onteniente *et al.*, 1987).

The available evidence is nevertheless contradictory regarding the uniform DA downregulation by GABA. DA was found to have a mild stimulatory effect on both the pyramidal cortical neurones and the GABAergic interneurones impinging on them (Penit-Soria *et al.*, 1987). Monteleone *et al.* (1985, 1986) found that sodium valproate failed to enhance basal secretion of growth hormone and did not reduce plasma prolactin secretion in patients with chronic schizophrenia — evidence that seems to contradict the hypothesis of DA downregulation by GABA. Moreover, DA neurones in substantia nigra and VTA may be activated by GABA. Systemic muscimol (a GABA receptor agonist) administration in the rat (Waszczak and Walters, 1979) produced increased DA neurones firing in pars compacta of the substantia nigra. Non-DA neurones in the adjacent pars reticulata were inhibited by systemic muscimol and were found to be more sensitive to iontophoretic GABA inhibition than the pars compacta DA neurones. Similar findings were reported by Grace *et al.* (1980). These studies have suggested the presence of a GABA-sensitive intermediate connection. Depressing the firing of this inhibitory pathway with systemic GABA leads to increased DA cell firing. It appears, therefore, that GABA may actually activate DA neurones in certain areas. In agreement with this concept, GABA has been shown both to increase and decrease DA turnover, depending upon the brain region assayed, the duration of stimulation and whether DA antagonists are administered (Cheramy *et al.*, 1978; Fuxe *et al.*, 1979). Overall, these findings suggest that GABA acts at a number of sites to influence DA neuronal activity. The final outcome may thus represent an integration of several actions and is not limited to monosynaptic inhibition (Garbutt and van Kammen, 1983).

GABA/Glutamate Interactions

GABA and GLU are known to modulate each other's release in rat brain cortex and hippocampus (Bonnano *et al.*, 1993). Recently, Olney and Farber (1995), on the basis of extensive animal investigations, have proposed a model of schizophrenia, implying that GABA and GLU systems may be abnormally integrated in this illness within the cingulate gyrus and possibly other regions such as the hippocampus and amygdala. According to this model, hypofunctional NMDA-sensitive GLU receptors on GABAergic interneurones could be responsible for loss or impairment of inhibitory modulation in schizophrenia. It was emphasized that the NMDA receptor hypofunction might be induced during development by any mechanism that impairs the functional status of NMDA receptors or that impairs or destroys specific GABA neurones through which the function of these receptors is expressed. Accordingly, loss of specific GABAergic neurones would represent an NMDA receptor hypofunction-equivalent condition.

Consistent with this hypothesis, reduction in the density of interneurones (Benes *et al.*, 1991) and upregulation of $GABA_A$ receptor binding activity (Benes *et al.*, 1992) have been demonstrated in the upper cortical laminae of the cingulate region in schizophrenia patients. Furthermore, an additional pathogenesis model, developed from post-mortem studies of the anterior cingulate region of schizophrenia subjects (for review, see Benes, 1993, 1995), shows some striking similarities with the hypothesis of Olney and Farber. According to this model, loss or impairment of GABA cells in layer II may be triggered, at least in part, by excessive glutamatergic inputs that pass through this layer. Moreover, DA projections to the cortex have been found to form direct appositions with GABAergic cells, and a relative increase in the number of such contacts could arise if there is a loss and/or a decrease in the activity of these GABAergic interneurones.

GABA and Synaptic Connectivity

Prefrontal cortex dysfunction in schizophrenia may be related to abnormalities in the synaptic connectivity of this region. Post-mortem studies suggest that such alterations in connectivity may involve GABA neurones. Both the uptake (Simpson *et al.*, 1989; Reynolds *et al.*, 1990) and release (Sherman *et al.*, 1991) of GABA have been reported to be reduced in cortical synaptosomes prepared from schizophrenia subjects. In the prefrontal cortex, the activity of glutamic acid decarboxylase, the synthetic enzyme for GABA, is reduced in subjects with schizophrenia (Bird *et al.*, 1979; Sherman *et al.*, 1991a, 1991b), as is the expression of the mRNA for this enzyme. In addition, ligand binding studies have revealed abnormalities in prefrontal cortex $GABA_A$ receptor in schizophrenia (Benes *et al.*, 1996). Although the expression levels of $GABA_A$ receptor subunit mRNAs are not altered significantly, preliminary studies suggest that expression of the short isoform of the $\gamma 2$ subunit of this receptor may be markedly reduced in the prefrontal cortex in schizophrenia (Huntsman *et al.*, 1998).

The chandelier cells are the GABAergic interneurone subclass hypothesized to be preferentially involved in connectivity dysfunctions in schizophrenia since they (1) receive direct synaptic input from DA axons, (2) exert powerful inhibitory control over the excitatory output of layer III pyramidal neurones, and (3) undergo substantial developmental changes during late adolescence, the typical age of onset of schizophrenia (for review, see Lewis *et al.*, 1999). Consistent with this hypothesis, recent studies have reported that the axon terminals of chandelier neurones, as revealed by immunoreactivity for the GABA membrane transporter, are reduced substantially in the middle layers of the prefrontal cortex of schizophrenia patients. This alteration appears to be selective for the chandelier class of GABA neurones and for the disease process of schizophrenia (Lewis *et al.*, 1999; Woo *et al.*, 1988).

TREATMENT APPROACHES

The available evidence indicates the possibility of a GABAergic deficit in schizophrenia, thus suggesting that activation of GABA receptors may be therapeutically beneficial. Agents that promote

$GABA_A$ neurotransmission prevent NMDA receptor hypofunction-induced neurotoxicity in the rat cerebral cortex (Olney *et al.*, 1991) and attenuate the psychotomimetic effects associated with ketamine use in anaesthesia (Reich and Silway, 1989). However, while more research is clearly needed, the main drawback with GABA hypotheses of schizophrenia is that presently used drugs working directly on GABA systems are not impressive therapeutically in patients suffering from this illness.

Benzodiazepines (BZ) binding to CNS BZ receptors, which are structurally and functionally linked to $GABA_A$ receptors and to chloride ionophores, facilitates GABA neurotransmission and results in decreased neuronal excitability (see Chapter V). Both BZ and GABA receptors are heterogeneous. BZ effects on neuronal excitability apparently mediate their anxiolitic, hypnotic and anti-convulsant action. As treatment for schizophrenia, BZ have been studied extensively, either alone or as adjuvants to antipsychotic drugs. The findings of these studies are overall in agreement with clinical experience and suggest that: (1) response is highly variable and about one-third to one-half of patients improve, (2) actual antipsychotic effects are seen in a small number of patients and only in conjunction with antipsychotic use, and (3) BZ are potentially most useful as adjuvants to neuroleptics in the acute management of psychotic agitation (for review see Wolkowitz and Pickar, 1991; Hollister *et al.*, 1993; Wassef *et al.*, 1999). There is also evidence that supplementing antipsychotic treatment with a benzodiazepine during periods of florid psychosis reduces agitation and that diazepam may be beneficial in treating early-warning signs of symptom exacerbation in schizophrenia (Carpenter *et al.*, 1999). However, efforts to substitute BZ for antipsychotic drugs in treating full psychotic episodes have not proven effective and lower-dose BZ, as adjuncts to antipsychotic medication, have not proven very effective at enhancing therapeutic outcome in partially responsive patients (Wolkowitz *et al.*, 1992).

Regarding the limited efficacy of BZ and other GABA agonists in schizophrenia, Olney and Farber (1995) stressed that since the initial pathological event that may render GABAergic neurones defective in this illness is proposed to occur in prenatal life, the administration of GABA agonist drugs ~20 years later in order to correct this imbalance is not likely to be successful because GABA receptors with which the drug must interact will have been deleted from the brain or will have been reconnected in some aberrant manner.

GABA agonists, including those with preferential affinity for $GABA_A$ receptors (e.g. tetrahydroisoxazolopyridol) or with $GABA_{A+B}$ activity (e.g. SL 76002), have been, overall, disappointing in clinical trials in schizophrenia (for review see Lloyd and Morselli, 1987), as were the studies examining the therapeutic potential of GABA transaminase inhibitors (Casey *et al.*, 1980; Thaker *et al.*, 1983).

Valproic acid enhances central GABAergic tone and its use as adjuvant to antipsychotic drugs has resulted, in a number of studies, in positive treatment outcome (for review, see Wassef *et al.*, 1999). Following a careful risk–benefit assessment, valproate-augmented pharmacotherapy may represent, on a case-by-case basis, a viable treatment option for schizophrenia patients who are resistant to treatment with conventional neuroleptics.

FUTURE TREATMENT DIRECTIONS

The allosteric modulation characteristics of compounds acting at BZ receptors may influence their clinical efficacy. Full allosteric modulators of GABA-gated Cl^- channels have a high incidence of tolerance and dependence liability. Imidazenil is a partial allosteric modulator of $GABA_A$ receptors which binds to BZ recognition sites with high affinity but exerts a moderate allosteric modulation of GABA-gated Cl^- current intensity. Its testing in the treatment of schizophrenia has been proposed since this compound is virtually devoid of tolerance and dependence liability in rodents and non-human primates and its activity is not changed in rats that are tolerant to BZ acting as full allosteric modulators of GABA-gated Cl^- currents (Costa and Guidotti, 2000).

Alternative GABA-based treatment approaches are presently conceptualized. New agents, such as tiagabine, that selectively inhibit uptake of GABA by the neuronal GABA membrane transporter GAT-1 (Borden *et al.*, 1994) may be potentially therapeutic. Moreover, the identification of selective alterations in the chandelier subclass of GABA neurones and related circuitry may also reveal options for novel forms of therapeutic intervention in schizophrenia and other psychotic disorders.

Peptidergic Transmitter Systems in Schizophrenia

S. Iritani

PEPTIDES AS NEUROTRANSMITTERS

Mental and neuronal functions of mammals depend on the activities of neurones in the central nervous system. These neurones act and transmit information primarily by chemical means. Since the concept of the neurotransmitter was advanced in the 1950s, various substances intrinsically present in the central nervous system were found to be involved in neurotransmission. The concept of a neuromodifier, which does not directly participate in neurotransmission but modifies this function, was also proposed. Neurotransmitter (Panton, 1958) and neuromodifier (Barchas *et al.*, 1978) criteria were precisely defined. However, as research has advanced, it has become difficult to confirm that these criteria are sufficiently fulfilled in many neurotransmitter or neuromodifier candidates, or to clearly distinguish neurotransmitters and neuromodifiers. For these reasons, the idea that all substances involved in chemical transmission should be referred to collectively as neuroregulators has been presented.

Neuroregulator candidates include acetylcholine, amines, amino acids, purine bodies and peptides.

Peptides are macromolecular compounds with a molecular weight of about 10 000 or less in which some amino acids are linked by peptide bonds, consisting of an amino group and an α-carboxyl group. After the discovery of angiotensin in 1945, many peptides intrinsically present in the central nervous system were discovered in the 1970s and 1980s. In 1998 a peptide called orexin was found to be present in the brain, and more than 100 peptides have been discovered to date. These peptides with neurophysiological activities can be called neuropeptides or neuroactive peptides, because they do not strictly fulfil the criteria of neurotransmitters.

Of the neuroregulators, acetylcholine, monoamines and neuroamino acids are called classic transmitters to distinguish them from neuropeptides. Research to data has revealed the coexistence of classic neurotransmitters, classic neurotransmitters and peptides, and peptides in the central nervous system. The presence of both histamine and GABA in the posterior hypothalamus, and of dopamine and GABA in the olfactory bulb (Kosaka *et al.*, 1985), are examples of coexistence of classic neurotransmitters; the presence of acetylcholine and substance P in the tegmental nuclei in the dorsolateral part of the pons (Vincent, 1983b), catecholamine and neuropeptide Y (Everitt *et al.*, 1984), and dopamine and neurotensin in the hypothalamus (Ibata *et al.*, 1983), are examples of coexistence of classic neurotransmitters and peptides. Many other cases of coexistence of peptides have also been noted.

A hypothesis that neuropeptides and classic transmitters always cooperate with each other in neurotransmission has not been established, because not all classic neurotransmitters coexist with neuropeptides. However, as neuropeptides have been shown to be released in large quantities compared with classic neurotransmitters when neurones discharge frequently (Hökelt, 1997), peptide transmitters are considered to be closely related to modification of transmission or the plasticity of synapses, as mentioned later, rather than neurotransmission itself. At any rate, neuropeptides are considered to coexist and compete with so-called classic transmitters or other peptides to enhance the function of neurotransmission. In this sense, the peptidergic neuronal system is not present independently but constitutes part of neurotransmission in the brain.

However, when mental activities and functions of individual neuropeptides in the central nervous system were examined more closely, each of them was found to have characteristic actions. Neuropeptides were first shown to be involved in higher mental activities by De Wied (1964). They demonstrated that learning of aversion was impaired in animals that had undergone resection of the anterior lobe of the pituitary gland, and that this impairment was alleviated by the administration of adrenocorticotrophic hormone (ACTH). Furthermore, they showed that aversion behaviour was impaired in rats that had undergone resection of the posterior lobe of the pituitary gland but that learning of aversion was improved by the administration of vasopressin (De Wied, 1965). From these reports, vasopressin came to be considered to enhance memory. Later, this action of vasopressin was confirmed in the brain as learning of aversion was shown to be promoted by direct infusion of vasopressin into the hippocampus in animal experiments (Kovacs *et al.*, 1986). In addition, anatomical and, primarily, immunohistochemical investigations have revealed the rich presence of peptides in the hippocampus and frontal lobe of the cerebral cortex, leading to speculation of an involvement of peptides in higher mental functions. For example, comparison of the anatomical distribution of substance P between rodents and primates showed that neural networks were much richer in the primates, and that substance P is related to higher mental and neuronal functions (Iritani *et al.*, 1989). From these findings, neuropeptides are considered to play important roles, which are not supplementary to the roles of classic neurotransmitters, in the central nervous system.

NEURONAL DEVELOPMENT AND NEUROPEPTIDES

What are the reasons that neurones select neuropeptides as media for neurotransmission? Although neuropeptides coexist with classic neurotransmitters, this is not always the case, and no pattern has been discovered for their coexistence.

In the process of their development, neurones are considered not only to differentiate according to the genetic programme but also to be affected by various environmental factors. Neurones select a few from a large number of neurotransmitters during the period of development, increase their synthesis as they grow, and begin to accurately transmit neural activities to target cells (Patterson and Nawa, 1993). Recently, functions of neurotrophic factors have come to be studied widely and intensively in connection with neuronal development and differentiation. BDNF (brain-derived neurotrophic factor) and NT-5 (neurotrophin-5) are examples of such

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

neurotrophic factors; they act on suppressive GABA neurones of the cerebral cortex and striatum when administered into the cerebral ventricle, and begin to synthesize suppressive neuropeptide Y and somatostatin (Nawa, 1993, Nawa *et al.*, 1994). In fact, the coexistence of GABA neurones and peptides, such as substance P and neuropeptide Y, has been confirmed anatomically. These factors regulate the functional differentiation of neurones, and the production and secretion of transmitters, more dynamically than used to be considered in the process of nerve growth. Neuropeptides are considered to play important roles also in the dynamism of the process of neuronal network formation. Neuropeptides such as somatostatin (Hayashi *et al.*, 1990), substance P (Yamashita *et al.*, 1990) and cholecystokinin (Yamashita, 1992) are known to be expressed in large quantities in the central nervous system during embryonic development and in the period after birth. Recently, the role of neurotrophin in the expression of neuropeptides has been studied extensively (Carnahan and Nawa, 1995). In the process of neuronal network formation, TrkB, which is a specific receptor of BDNF, is expressed in large quantities during the first 4 months after birth, when synapse formation progresses markedly (Hayashi *et al.*, 1999). On the other hand, neuropeptides themselves are thought to have a neurotrophic function in neuronal development (Schwaltz, 1992).

Recently, the hypothesis that schizophrenia is caused by disturbance of neural development has come to be understood widely in relation to functional insufficiency of neurotrophic factors such as BDNF, but knowledge concerning the functions of neurotrophic factors remains incomplete. The hypothesis of neurodevelopmental disorder as a cause of schizophrenia was formed after a large number of reports of morphological abnormalities of the brain of schizophrenic patients appeared from the 1980s as a result of improvements in image analysis; these abnormalities were considered to be due to impaired development of the central nervous system. Recently, Takahashi *et al.* (2000) reported abnormal expression of BDNF in the brain of patients with schizophrenia.

Although morphological abnormalities have been reported in nearly all areas of the brain of schizophrenic patients, the interest of recent morphological studies has been directed primarily to two areas: the medial side of the temporal lobe and limbic system, including the hippocampus (Bogerts *et al.*, 1990), and the frontal lobe (Benes *et al.*, 1991). The features of morphological abnormalities are quantitative changes with statistical significance, and abnormalities of the arrangement or position of cells, which are clarified only by statistical analyses, rather than qualitative abnormalities such as degeneration, and they are explained by disturbance of brain development. Since neurotrophic factors are directly related to neuronal differentiation and the development of the central nervous system (Maisonpierre *et al.*, 1990; Thoenen, 1991), the morphological and anatomical abnormalities of the brain of schizophrenic patients reported to date can be explained by this hypothesis. In addition, biochemical abnormalities as well as morphological abnormalities may be explained in connection with neurotrophic factors. These factors are known to exert marked effects on the expression of neurotransmitters (Wagner and Kostyk, 1990), and a balance is considered to be maintained between neurotransmitters and neurotrophic factors (Kornhuber and Weller, 1994). In fact, BDNF, which is a neurotrophic factor, plays a very important role in the development and differentiation of the dopaminergic neuronal system in the embryonic period (Hyman *et al.*, 1991). This indicates that neurotrophic factors have a role in neuronal construction including biochemical neuronal transmission. Naturally, neurotrophic factors have been shown to affect induction and differentiation of various peptides as well as classic neurotransmitters in the central nervous system (Loudes *et al.*, 2000; Kerekes *et al.*, 2000). Moreover, some studies have demonstrated that these factors act protectively on neurones and are involved in the repair of injured neurones (Hagg and Varon, 1993; Gash *et al.*, 1996), and that they maintain and develop the plasticity of synapses (Lo, 1995). The continuous progression of so-called negative symptoms such as reduced stress tolerance, and impaired learning ability and mental function, can be explained by viewing the functional insufficiency of these factors with the pathological features of schizophrenia. At any rate, findings concerning neurotrophic factors obtained to date have allowed explanation of various phenomena and symptoms of schizophrenia in connection with functional insufficiency of neurotrophic factors. However, clarification of the mechanisms of individual symptoms of schizophrenia, e.g. hallucination and delusion and thought process disorder, along with elucidation of the functional insufficiency of neurotransmitters, is needed.

Here we have shown that neurotrophic factors play important roles in the biological aetiology of schizophrenia and that functions of these factors are closely related to neurotransmitters, which directly mediate mental and neural functions. We will next evaluate pathological changes in neuropeptides, which are a group of neurotransmitters, in schizophrenia.

NEUROPEPTIDES IN SCHIZOPHRENIA

As research on neurotransmitters progressed, it became clear that schizophrenia is caused not by an abnormality of a single neurotransmitter but by a disturbance of balance among several neurotransmitters that interact with each other (Weinberger and Lipska, 1995; Bachus and Kleinman, 1996). Studies of nerve function regulators, including neurotransmitters, in schizophrenia can be generally divided into those of the post-mortem brain, those of cerebrospinal fluid and those of pharmacological effects. In studies of the post-mortem brain, the neuropeptide content and that their receptors is measured, and histological evaluations are made. In studies of cerebrospinal fluid, the neuropeptide content of the cerebrospinal fluid collected from patients is examined. Concerning pharmacological function, the effects of administration of neuropeptides in animal models has been studied.

There are slight differences in the classification of neuropeptides among investigators, but they can be roughly classified as follows:

I. Brain–gut peptides (neurotensin, cholecystokinin, substance P, neuropeptide Y, peptide YY, somatostatin, VIP, etc.)
II. Opioid peptides (endorphins, enkephalins)
III. Hormones released from the hypothalamus (TRH, somatostatin, GRH, CRH, etc.)
IV. Pituitary hormone (vasopressin, oxytocin, etc.)
V. Others (orexin, nociceptin, etc.)

New peptides are continually being discovered in the body; therefore, the conventional classification of neuropeptides has limitations.

The greatest number of reports concerning neuropeptides in schizophrenic patients published during the past 10 years were about brain–gut peptides.

Brain–Gut Peptides

Neurotensin (NT)

Sharma *et al.* (1997) measured the content of NT in cerebrospinal fluid from 29 patients with schizophrenia and 13 patients with schizoaffective disorder. Their psychiatric symptoms were also evaluated by the BPRS (Brief Psychiatric Rating Scale). NT was measured, and symptomatic assessment was made, after a mean drug-free period of 15 or more days. Then, after 4 weeks of neuroleptic medication, NT was measured and symptomatic assessment was made again. In the drug-free state, psychiatric

symptoms were stronger in patients with a lower NT level in cerebrospinal fluid. Also, after 4 weeks' medication, improvements in psychiatric symptoms according to the BPRS, particularly improvements in negative symptoms, were positively correlated with the NT concentration in cerebrospinal fluid. There are already a few reports on the relationship between negative symptoms of schizophrenia and NT in cerebrospinal fluid.

Widerlov *et al.* (1982) measured the NT concentration in cerebrospinal fluid in 21 patients with schizophrenia and 12 normal controls once during a period of no neuroleptic treatment and once during a period of neuroleptic treatment. The NT concentration was markedly lower in nine of the 21 schizophrenic patients during the no-neuroleptic treatment period. No difference was observed in the other schizophrenic patients compared with the normal controls. In the nine schizophrenic patients, NT concentration during the neuroleptic treatment period was increased nearly to the normal control level. All three patients with catatonic schizophrenia and six of the seven patients with disorganized schizophrenia belonged to this group of nine patients. A negative correlation was observed between the symptom of 'slowness of movement' (Comprehensive Psychopathological Rating Scale) and NT concentration.

Similarly, Breslin *et al.* (1994) studied NT concentration in cerebrospinal fluid in 15 patients with schizophrenia and 10 normal controls during a period when neuroleptic medication was off and during a period when it was on. Although no difference was observed in NT concentration between the patients and normal controls, it increased during the neuroleptic-on period in seven patients in whom NT concentration was relatively low during the neuroleptic-off period. The NT concentration in cerebrospinal fluid was related to deficit symptoms.

Nemeroff *et al.* (1989) measured NT concentration in cerebrospinal fluid in patients with schizophrenia, depression, eating disorders and premenstrual syndrome. It was found to be increased in some of the patients with schizophrenia. None of these patients had paranoid-type schizophrenia.

Garver *et al.* (1991) studied the NT concentration in cerebrospinal fluid and its responses to antipsychotic medication in patients who exhibited psychiatric symptoms. They noted that the NT concentration was relatively low, and its response to antipsychotic medication was poor, in a group of female patients. Thinking disorder, hallucination/delusion, behavioural disorganization and impaired functioning were more notable in these patients than in those with a relatively high NT concentration.

From these studies, the presence of a subgroup of schizophrenic patients in whom the NT concentration in cerebrospinal fluid is originally low, is not poorly responsive to treatment, and is closely related to negative symptoms was suggested.

Concerning studies of the post-mortem brain, Wolf *et al.* (1995) quantitatively analysed NT receptors in the entorhinal cortex using autoradiography. Receptors were concentrated specifically in layer II, and they were reduced by 40% in the brains of schizophrenic patients compared with the normal control brain. These sites were in agreement with the sites of cytoarchitectural abnormalities in the brain of schizophrenic patients reported by Arnold *et al.* (1991).

Binder *et al.* (2001) showed that an NT receptor agonist produces similar effects to antipsychotic drugs in an animal model of schizophrenia. Studies to date have accumulated evidence suggesting that NT and the dopaminergic neuronal system influence each other anatomically, neurochemically, electrophysiologically, behaviourally and pharmacologically (Lambert *et al.*, 1995).

Cholecystokinin (CCK)

Mauri *et al.* (1998) measured the CCK concentration in peripheral blood in 30 drug-free schizophrenic patients and 22 normal controls. Simultaneously, the mental state of the patients was evaluated using the BPRS, SAPS (Scale for Assessment of Positive Symptoms) and SANS (Scale for Assessment of Negative Symptoms). The CCK concentration in peripheral blood was measured again in nine patients after 4 weeks' antipsychotic treatment. As a result, a negative correlation was observed between the CCK concentration and SANS score, and the CCK concentration tended to be lower in patients who responded poorly to antipsychotic treatment. However, these are data of the CCK concentration in peripheral blood; how closely they reflect the kinetics of the neurotransmitter in the brain must be evaluated carefully.

Garver *et al.* (1990) measured the CCK concentration in cerebrospinal fluid in 11 drug-free patients with schizophrenia and six normal controls. The CCK concentration was significantly lower in the patients than in normal controls, and in male patients than in female patients. When the responses to antipsychotic medication were examined later, the CCK concentration was significantly lower in the poor-response group than in the good-response group.

Bachus *et al.* (1997) studied the expression of CCK mRNA by *in situ* hybridization histochemistry using the post-mortem brains of seven schizophrenic patients and seven normal controls. The expression of CCK mRNA was reduced in layers III and IV of the entorhinal cortex and subiculum of the schizophrenic patients compared with normal controls. This decrease was considered to be a pathological feature of schizophrenia rather than a result of medication, as judged from the status of medication and the findings from neuroleptic medication in animal experiments.

Virgo *et al.* (1995) studied the expression of CCK mRNA *in situ* using the post-mortem brains of eight schizophrenic patients and eight normal controls. The expression of CCK mRNA was markedly reduced, i.e. by 83% in the frontal lobe and 63% in the temporal lobe, compared with the normal controls. No association was observed between the reduction in mRNA and medication or the duration of illness.

Kerwin *et al.* (1992) studied CCK receptors in the hippocampus of the post-mortem brains of 11 schizophrenic patients and 11 normal controls by autoradiography. Receptors were significantly reduced in the CA1 region of the hippocampus in the schizophrenic patients. Zachrisson *et al.* (1999) found that the expression of mRNA of CCK(B) receptors in the frontal lobe was reduced in patients with schizophrenia. Also, CCK(A) receptors are related to auditory hallucination of schizophrenia (Wei and Hemmings, 1999), and their gene polymorphism has been reported (Tachikawa *et al.*, 2000).

Anatomically, coexistence of dopamine neurones and CCK in the central nervous system has been known, and the findings that the activities of dopaminergic neurones are suppressed by a CCK antagonist (Rasmussen *et al.*, 1991; Rasmussen, 1994), that a CCK antagonist administered to an animal model of schizophrenia produced similar effects to neuroleptics (Feifel and Swerdlow, 1997), and that D_2 receptors and CCK or CCK receptors markedly influence each other (Fuxe *et al.*, 1995), suggest that changes in CCK in schizophrenia are closely related to the dopamine hypothesis.

Substance P (SP)

Rimon *et al.* (1984) measured the concentration of SP in cerebrospinal fluid in 12 patients with schizophrenia, 12 patients with depression and 15 normal subjects. They found that SP concentration was significantly increased in the depression group compared with the normal control and schizophrenia groups. There was no significant finding in the schizophrenia group.

Kaiya *et al.* (1981) measured the immunoreactivity of SP in peripheral blood in a schizophrenia group, non-schizophrenic psychiatric disease group, and normal control group. The immunoreactivity of SP was significantly enhanced in the schizophrenic group

with a 1 year or longer history of medication. When the immunoreactivity was measured again in eight drug-free schizophrenic patients after five months of medication, it was reduced in five but was increased in three, and the results were inconsistent. While the immunoreactivity 120 min after chlorpromazine injection was not changed, it was increased 90 min after electroconvulsive therapy in male patients. Since this study was conducted under the influence of drug therapy, whether the changes in the SP activity are pathological features of schizophrenia or not should be evaluated cautiously.

Toru *et al.* (1988) measured the immunoreactivity of SP at 34 sites in the brain using post-mortem brains of 14 schizophrenic patients and 10 normal controls. The activity was high at 12 sites including the frontal lobe cortex and substantia nigra.

However, some authors reported no significant changes in the SP concentration in cerebrospinal fluid or the post-mortem brain of schizophrenic patients (Heikkila *et al.*, 1990; Iadarola *et al.*, 1991), and no consensus has been reached.

Shirayama *et al.* (2000) administered PCP (an NMDA antagonist, dopamine uptake inhibitor, schizophrenomimetic drug), methamphetamine (MAP) (a dopamine agonist), and MK-810 (an NMDA antagonist) to rats and studied changes in the SP content of the prefrontal cortex and midbrain substantia nigra. As a result, SP in the prefrontal cortex decreased after the administration of PCP and MK-801, and SP in the substantia nigra decreased after the administration of PCP and MAP. Also, when PCP was administered to rats pretreated with haloperidol (a dopamine D_2 receptor antagonist, representative neuroleptic), the SP content in the substantia nigra was not reduced. This indicates that the SP level in the substantia nigra is dopamine dependent. This observation suggests that the SP level in the substantia nigra is closely related to functions of the dopaminergic neuronal system and that the SP level in the prefrontal cortex is closely related to functions of the glutaminergic neuronal system.

As observed above, there have not been consistent findings concerning changes in the SP level in schizophrenic patients, but it is estimated to change in association with the levels of classic neurotransmitters.

Neuropeptide Y (NPY) and Peptide YY (PYY)

NPY and PYY are coded by a common gene and are called the pancreatic peptide family. Widerlov *et al.* (1988) measured the immunoreactivity of NPY and PYY in cerebrospinal fluid of patients with depression, patients with schizophrenia and normal controls. The NPY activity in cerebrospinal fluid was significantly reduced in depressed patients compared with schizophrenic patients or normal controls, and the PYY activity was significantly lower in drug-free schizophrenic patients. These differences suggest that the processes of synthesis, metabolism and degradation of these peptides vary among diseases and that they serve as disease markers.

Peters *et al.* (1990) studied the immunoreactivity of NPY in cerebrospinal fluid in 35 drug-free patients with chronic schizophrenia. The immunoreactivity of NPY was significantly higher in the patients than in normal controls, and it was reduced as the patient grew older and as the duration of illness increased. The authors measured the NPY activity in cerebrospinal fluid before and after suspension of haloperidol administration in 31 patients and demonstrated that the NPY activity was significantly increased by suspension of haloperidol administration. There was no difference in NPY activity between the group in which psychiatric symptoms were exacerbated by suspension of medication and the group in which no exacerbation was observed.

Thus, the results of measurements of NPY and PYY in cerebrospinal fluid were not consistent. Berrettini *et al.* (1987) even reported that diseases cannot be detected from data of the NPY level in cerebrospinal fluid.

Frederiksen *et al.* (1991) measured the NPY and PYY contents in the grey matter of the temporal lobe in post-mortem brains of 14 schizophrenic patients and 21 normal controls and showed that they were significantly reduced in the patients compared to controls.

Sakai *et al.* (1995) chronically administered haloperidol to rats and studied changes in the NPY level in the brain. The NPY concentration was increased in the cerebral cortex but was reduced in the striate body.

Iritani *et al.* (2000) examined NYP-positive fibres in the hippocampus in the post-mortem brains of six schizophrenic patients and three normal controls. They reported morphological abnormalities of NYP-positive fibres in the field of the dentate gyrus not observed in the normal controls, and they linked these findings with the developmental disturbance hypothesis of schizophrenia.

Somatostatin (SOM)

SOM is a hypothalamic hormone and was discovered in 1972. This neuropeptide was subsequently found to be distributed also in the stomach, intestines, and head of the pancreas and is classified as a brain–gut peptide. Its receptors are also distributed widely in the brain, pituitary gland, digestive tract, pancreas and thyroid gland.

Reinikainen *et al.* (1990) measured the immunoreactivity of SOM in cerebrospinal fluid of 11 patients with chronic schizophrenia having cognitive disorders and in eight normal controls. The immunoreactivity was significantly reduced in the schizophrenia group. This decrease was not related to cognitive decline measured by the MMSE (Minimal-Mental Examination), the BPRS, or the dose of neuroleptics. However, an association between cognitive disorders and SOM concentration in cerebrospinal fluid was suggested.

Doran *et al.* (1986) measured the SOM level in cerebrospinal fluid in 44 patients with schizophrenia and 19 patients with depression in connection with the results of the dexamethasone inhibition test. The SOM level in cerebrospinal fluid was lower in the depression group than in the schizophrenia group and in the group that did not respond to the dexamethasone inhibition test regardless of the diagnosis. These results suggest a relationship between the functions of the hypothalamic–pituitary–adrenal axis and the SOM level in cerebrospinal fluid.

Bissette *et al.* (1986) measured the immunoreactivity of SOM in cerebrospinal fluid in 11 patients with schizophrenia, 17 patients with depression, 29 patients with dementia and 10 normal controls. The SOM level in cerebrospinal fluid was lower in all disease groups than in the normal control group. Therefore, impairment of cognitive function was suggested to be related to the SOM level in cerebrospinal fluid. Contrary to these reports, Gerner *et al.* (1985) reported that the SOM level in cerebrospinal fluid was high in some schizophrenic patients. Although reports on the SOM level in cerebrospinal fluid are contradicted and further evaluation is needed, these discrepancies may be due to differences in the selection of patients, selection of normal controls and medication.

Sharma *et al.* (1994) studied changes in the immunoreactivity of SOM in cerebrospinal fluid associated with antipsychotic medication in 14 patients with schizophrenia. It increased significantly in 13 of the 14 patients after medication, with a significant positive correlation between the immunoreactivities of SOM in cerebrospinal fluid during and after treatment. In animal experiments also, the SOM content of the brain was confirmed to be increased by administration of a neuroleptic (haloperidol) (Sakai *et al.*, 1995). However, Beal and Martin (1984) experimentally showed decreases in the immunoreactivity of SOM in the striate body amygdaloid body, and nucleus accumbens after the administration of neuroleptics (pimozide, chlorpromazine, fulphenazine).

Also, Doran *et al.* (1989) studied changes in the SOM and homovanillic acid (HVA) levels in cerebrospinal fluid of 14 patients with schizophrenia associated with fluphenazine treatment. SOM concentration in cerebrospinal fluid decreased significantly after treatment, but HVA increased as SOM decreased. In addition, a positive correlation was observed between SOM and HVA concentrations in cerebrospinal fluid in 46 drug-free patients with schizophrenia. These findings suggest a close relationship between SOM and dopamine, but the mechanism of this relationship remains unknown. The reports by Sharma and Doran disagree concerning changes in the SOM level in cerebrospinal fluid associated with antipsychotic medication. This discrepancy may be due to differences in the drug type, dose, administration period, time of measurement and subjects. At any rate, it appears certain that dopaminergic nerve blockers induce changes in SOM concentration.

Nemeroff *et al.* (1983) reported low SOM levels in the frontal lobe (Brodmann area 12) in the post-mortem brains of schizophrenic patients. Iritani and Satoh (1991) reported that SOM-containing cells and SOM-containing fibres, which are rich and densely distributed in the monkey cerebral neocortex, form a network and suggested that SOM is involved in higher mental functions.

From these reports, SOM is considered to be closely related to the dopaminergic neuronal system and to be an aetiological factor of schizophrenia. Histologically, the frontal lobe cortex is considered to be an area of interest.

Other Brain–Gut Peptides

Rafaelsen and Gjerris (1985) measured the concentration of vasoactive intestinal polypeptide (VIP) in cerebrospinal fluid of patients with schizophrenia, depression and mania. A significant decrease was observed only in the depressed patients.

Roberts *et al.* (1983) measured the VIP level at 10 sites of the brain using the post-mortem brains of 14 schizophrenic patients and 12 normal controls. VIP was increased in the amygdaloid body of patients with schizophrenia (type II). In a similar study of post-mortem brains, a decrease in VIP in the cerebral cortex of schizophrenic patients has been reported (Gabriel *et al.*, 1996), and evaluation at various sites of the brain from functional viewpoints is considered to be needed.

Changes in the calcitonin gene-related peptide (CGRP) level have been evaluated in cerebrospinal fluid of patients with psychiatric disorders. An increase was noted in depression, but no significant change was observed in schizophrenia (Mathe *et al.*, 1994).

Concerning these neuropeptides, their relationships with classic neurotransmitters and their individual physiological activities remain largely unknown, and further accumulation of knowledge is needed before their involvement in the aetiology of schizophrenia can be discussed.

Opioid Peptides (Endorphins, Enkephalins)

Wiegant *et al.* (1988) measured α-, β- and γ-endorphin levels in the hypothalamus of the post-mortem brains of schizophrenic patients and normal controls. The α- and γ-endorphin levels were significantly increased in the schizophrenic patients compared with the normal controls.

Lindström *et al.* (1978, 1986) measured the concentration of fraction I (opioid receptor-active fraction) of endorphin in cerebrospinal fluid of schizophrenic patients. The fraction I level was higher in the schizophrenic patients than in the normal controls, and it was negatively correlated with symptoms such as hallucination and 'indecision' (CPRS: Comprehensive Psychopathological Rating Scale). Among the patients, a high fraction I level was observed significantly more frequently in those with disorganized schizophrenia. In drug-free patients, the increase in fraction I was related to low HVA (a metabolic product of dopamine) level.

Naber *et al.* (1981) measured β-endorphin level in cerebrospinal fluid in patients with psychiatric disorders including schizophrenia, but no significant observation was made in schizophrenia.

Wen *et al.* (1983) measured the met-enkephalin (ME) concentration in cerebrospinal fluid in 18 patients with schizophrenia and 18 patients with neurological disorders such as headache. The ME concentration was significantly lower in the schizophrenic patients.

Opioid peptide levels were studied primarily in serum and cerebrospinal fluid from the late 1970s to the 1980s, but no results that linked them with the aetiology of schizophrenia were obtained. Following the lack of consistent results the involvement of opioids in the treatment of schizophrenia has not been pursued further.

Weatherspoon *et al.* (1996) showed that β-endorphin inhibits the release of dopamine mediated by NMDA receptors in the nucleus accumbens and caudate putamen in guinea-pigs. It seems more reasonable to consider that opioid peptide levels change in association with classic neurotransmitters rather than that they are directly related to the pathology of schizophrenia.

McDaniel *et al.* (1990) reported dose-dependent impairment of spatial memory in rats after infusion of dynorphin into the bilateral dorsal parts of the hippocampus. This impairment was blocked by the administration of naloxone (an opioid antagonist). This suggests that dynorphin specifically impairs spatial learning and memory in the dorsal part of the hippocampus and that this effect is mediated by opioid receptors. Aigner and Mishkin (1988) evaluated the effect of naloxone administration on visual recognition in monkeys and observed that visual recognition was dose-dependently promoted by naloxone administration. Martinez and Graaf (1985) showed that learning was promoted in mice by naloxone administration.

Thus, opioid peptide inhibits learning, but how this is related to the symptoms of schizophrenia is still unclear. However, it seems likely to be related to symptoms of schizophrenia such as cognition impairment and learning impairment.

Hormones Released from the Hypothalamus

Thyrotrophin-Releasing Hormone (TRH)

TRH is a small peptide consisting of three amino acids which was isolated from the porcine hypothalamus in 1966. TRH is present in the central nervous system and peripheral nervous system and is considered to be a neuropeptide involved in neurosecretion, i.e. promotion of thyroid-stimulating hormone (TSH) and prolactin secretion, and neurotransmission. In the central nervous system, it is distributed in the hypothalamus and medulla oblongata, and its receptors are also observed in many areas including the amygdaloid body, hippocampus and pyriform cortex. Pharmacological actions of TRH are diverse. In the psychiatric and neurological fields, they are evaluated in relation to learning and memory (Mellow *et al.*, 1989) and depression (Prange *et al.*, 1972).

Miyamoto *et al.* (1979) administered TRH to rats intraperitoneally or into the nucleus accumbens and observed a significant enhancement of their activity. Sharp *et al.* (1982) incubated sections of rat brain tissues (hypothalamus, nucleus accumbens) with a TRH analogue and demonstrated dose-dependent increases in dopamine release. This hyperactivity is considered to be due to an enhancement of dopamine release from the septal nucleus accumbens not mediated by direct stimulation of dopamine receptors.

Beasley *et al.* (1988) studied responses of TSH to TRH in 19 patients with acute psychiatric disorders, including seven patients with schizophrenia. They considered that a decrease in the responsiveness of TSH was related to the diagnosis of emotional disorders and that good responses to antipsychotic medications are expected. Siris *et al.* (1991) studied similar responsiveness in 25 schizophrenic patients with postpsychotic depressive state

and 34 age- and sex-matched patients with depression. No difference was observed in the responsiveness between the two groups; this conflicts with the results of Beasley *et al.* that responses to antipsychotic medication can be expected in schizophrenic patients showing reduced responses of TSH. In schizophrenia, TRH is evaluated in relation to the dopamine hypothesis as it enhances the dopamine release aside from its responses to TSH.

Corticotrophin-Releasing Factor (CRF)

CRF is a hypothalamic hormone consisting of 41 amino acids. In the central nervous system, CRF neurones are distributed in the cerebral cortex (particularly layers II and III), limbic system and brain stem as well as in the hypothalamus. Concerning mental and neural functions, CRF administered in the central nervous system promotes discharges of noradrenergic neurones in the ceruleus nucleus and thus induces the release of noradrenaline at sites that the ceruleus nucleus projects to, causing an elevation of the level of consciousness (Owens and Nemeroff, 1991). Matsuzaki *et al.* (1989) administered CRF into the cerebral ventricle of rats and observed an enhancement of dopamine metabolism in the frontal lobe, hippocampus and amygdaloid body, and behavioural changes considered to be associated with them. They are evaluated in connection with stress-induced behavioural changes.

Banki *et al.* (1987) measured the immunoreactivity of CRF in cerebrospinal fluid in 23 patients with schizophrenia, 54 patients with depression and 138 normal controls. CRF concentration was markedly increased in the depressed patients compared with the normal controls and patients with other psychiatric disorders. Also, it was slightly but significantly increased in the schizophrenic patients compared with the normal controls.

Forman *et al.* (1994) evaluated CRF concentration in cerebrospinal fluid in 21 males with chronic schizophrenia. When the concentration was measured after haloperidol was replaced by placebo, it increased in 18 of the 21 patients. The concentration was unrelated to the severity of the disease or symptoms such as depression and anxiety.

In 1995, urocortin was discovered as a member of the CRF family. This peptide is widely distributed in the brain and digestive tract and has extremely high affinity to CRF receptors. Although its physiological actions remain largely unknown, it may be related to schizophrenia (Rubinstein, 2000).

Luteinizing Hormone-Releasing Hormone (LHRH), Gonadotrophin-Releasing Hormone (GnRH) and Growth Hormone-Releasing Hormone (GHRH)

Gil-Ad *et al.* (1981) studied the responses of growth hormone (GH) to LHRH and TRH in 10 adolescent males with schizophrenia with a mean age of 15 years and nine age-matched normal controls. Before antipsychotic treatment, a marked increase in GH due to LHRH was observed in eight of the 10 patients and a marked increase in GH due to TRH was observed in four of the six patients. No change was observed in the normal control group. Three months after antipsychotic treatment, no increase in GH was observed in five of the six patients treated with LHRH, but GH increased in three of the four patients treated with TRH.

Brambilla *et al.* (1976) measured the responsiveness of gonadotrophin to GnRH in 15 males with chronic schizophrenia (dissociated hebephrenia) and 15 controls with mental retardation matched for age and duration of hospitalization. In the schizophrenia group, both follicite-stimulating hormone (FSH) and LH increased compared with the control group. Chlorpromazine therapy had no effect.

Nerozzi *et al.* (1990) studied the responses of GH to GHRH in 18 males with schizophrenia (DSM-III) (13 in the acute period, five in the chronic period) and nine normal controls but observed no significant difference. Peabody *et al.* (1990), on the other hand, studied responses of GH to GHRH in seven patients with schizophrenia (RDC; Research Diagnostic Criteria for a selected group of function disorder), three schizoaffective patients, seven patients with depression and nine normal controls. Responses of GH were significantly smaller in the schizophrenic patients than in the normal controls.

Effects of many neuropeptides released from the hypothalamus on neurotransmission remain unclear. Research to date in psychiatric disorders has focused primarily on neuroendocrine responses.

Pituitary Hormones (Vasopressin, Oxytocin)

Glovinsky *et al.* (1994) compared the oxytocin concentration in cerebrospinal fluid between schizophrenic patients and normal controls but observed no difference between the two groups or change due to neuroleptic treatment.

Legross *et al.* (1992) administered apomorphine (a direct dopamine agonist) to nine males with schizophrenia (drug-free for 2 weeks or longer) and nine healthy male controls and measured the serum oxytocin–neurophysin (Oxt-np) and vasopressin–neurophysin (Vas-np) concentrations. In the normal control group, both Oxt-np and Vas-np increased, with a peak 20 min after administration. In the schizophrenia group, the release of Vas-np was reduced, but the release of Oxt-np was increased, compared with the normal control group. An increase in the activities of dopaminergic nerves was suggested to enhance the functions of oxytocin-mediated nerves more notably in schizophrenia.

Feifel and Reza (1999) evaluated the function of oxytocin in rats using prepulse inhibition (PPI) as a research paradigm. Deficit of PPI is considered to be related to the pathology of schizophrenia. Although the administration of discipline (a non-competitive NMDA antagonist) and amphetamine (an indirect dopamine agonist) reduced PPI, this reduction was dose-dependently prevented by subcutaneous administration of oxytocin. These results suggest that oxytocin prevents inhibition of PPI via the dopaminergic or glutaminergic nervous system and that it may have an antipsychotic activity.

Thus, neuropeptides known as pituitary hormones have been studied primarily with regard to pharmacological aspects. However, details of the mechanisms of their relationships with classic neurotransmitters are still unknown.

Some patients with schizophrenia are known to exhibit symptoms of water intoxication, but the causes of these symptoms remain unknown. There have been a few studies on secretion and actions of vasopressin as an antidiuretic hormone in patients exhibiting such symptoms.

Goldman *et al.* (1997) measured the secretion of arginine-vasopressin (AVP) in six schizophrenic patients showing polydipsia and hyponatraemia and eight patients not showing these symptoms. In the hyponatraemic group, AVP secretion was increased with exacerbation of mental symptoms. Delva *et al.* (1990) showed that responses of AVP in the kidney were poor in patients with chronic schizophrenia who develop water intoxication. However, how these observations are related to the essential pathology of schizophrenia is uncertain, and whether there are abnormalities of this peptide related to neurotransmission or not is unknown.

Others (Orexin, Nociceptin)

As a result of the marked advances in molecular biology, information concerning many genes has become available, while their functions remain unknown. In the course of genome research, many genes considered to code for receptors of physiologically active substances have been discovered. Two peptides, i.e. orexin-A and -B, were identified in studies of such orphan receptors (Sakurai

et al., 1998). Orexin is distributed over the entire mammalian cerebrum and has been shown to be involved in diverse mental and neural functions: mice administered orexin in the frontal lobe and limbic system exhibit an enhancement of eating behaviour and spontaneous activities, and promotion of stereotyped behaviour, involuntary actions, drinking behaviour and awakening (Sakurai *et al.*, 1999; Hagan *et al.*, 1999). Also, orexin is closely related to sleeping and awakening, and functional insufficiency of the orexin-mediated nerves was found to be involved in the pathology of narcolepsy (Peyron *et al.*, 2000). No relationship between this peptide with the pathology of schizophrenia has yet been reported. However, as it is distributed richly in the regions that have been concerned principally with the pathogenesis of schizophrenia, and as its diverse actions are related to a wide range of mental and neural functions, it will be a major subject of future research.

Similarly, nociceptin, a neuropeptide, was discovered in research of ligands of orphan receptors (Meunier *et al.*, 1995). Although this nociceptin receptor structurally resembles the opioid receptor, it has no effect on known opioids. Nociceptin and its receptors are present densely in the central nervous system including the hippocampus, and this peptide was suggested by studies using mice defective in nociceptin receptor gene to control plastic changes in the nervous system (Manabe *et al.*, 1998). How this peptide is related to the pathology of schizophrenia must still be clarified, and it must be studied in connection with the nerve development disturbance hypothesis from the viewpoint of the regulatory mechanism of synaptic transmission.

As observed above, new peptides are being discovered and identified one after another as a result of improvements in molecular biological techniques, but their mental and neurological functions remain largely unknown, and their relationships with the pathology of psychiatric disorders must as yet be evaluated.

STUDIES OF NEUROPEPTIDES FROM PHARMACOLOGICAL VIEWPOINTS

Some neuropeptides and their antagonists may serve as antipsychotic drugs, and studies concerning their use as possible drugs have accumulated. NT is the most widely studied among such neuropeptides.

More than 20 years ago, Nemeroff (1980) presented the hypothesis that NT is an endogenous neuroleptic. Since then, many studies concerning the actions of NT as an antipsychotic have been carried out. These studies have been conducted on the basis of the thought that functional insufficiency of the NT-mediated nervous system is an aetiological factor of schizophrenia and that NT receptors interact with dopamine D_2 receptors (Fuxe *et al.*, 1995). Von Euler *et al.* (1991) showed that NT reduces the affinity of dopamine D_2 receptors to dopamine agonists through direct receptor–receptor interaction. Many studies have demonstrated that NT acts as an antipsychotic in the limbic system and, particularly, that it produces effects similar to those of a non-typical antipsychotic such as clozapine (Jolicoeur *et al.*, 1981, 1993; Kasckow and Nemeroff, 1991; Radke *et al.*, 1998).

Several clinical studies have been performed on the basis of the hypothesis that disturbance of endorphin metabolism is an aetiological factor of schizophrenia. This hypothesis assumes that α-endorphins with amphetamine-like activities are produced in excess and that the production of γ-endorphins is reduced. Verhoeven *et al.* (1978) reported the first of these clinical studies. Moderate improvements were observed in drug-free schizophrenic patients by the administration of Des-Tyr^1-γ-endorphins (DTγE). A few authors then reported the clinical efficacy of DTγE (van Ree *et al.*, 1978; Metz *et al.*, 1981) while others reported opposite results (Tamminga *et al.*, 1981; Meltzer *et al.*, 1982). Nowadays, the efficacy of DTγE for the treatment of schizophrenia is thought to be doubtful (Montgomery *et al.*, 1992).

Naloxone (an opiate receptor blocker) therapy was attempted in schizophrenic patients on the basis of the concept that schizophrenia is related to hyperactivity of the opioid-mediated fibres in the central nervous system (McNicholas and Martin (1984). Gunne *et al.* (1977) first administered naloxone clinically to schizophrenic patients and noted alleviation or disappearance of auditory hallucination after treatment. After this report, the effectiveness of naloxone as an antipsychotic was evaluated, but there have been reports that supported (Cohen *et al.*, 1985) and those that refuted (Pickar *et al.*, 1989) its effectiveness.

Ceruletide, a CCK-related peptide, was administered to schizophrenic patients on the basis of the results of animal experiments suggesting that CCK acts on the dopaminergic neuronal system and produces behavioural pharmacological effects similar to those of antipsychotics (Cohen *et al.*, 1982; van Ree *et al.*, 1983; Feifel *et al.*, 1999). Moroji *et al.* (1982) showed that ceruletide has therapeutic effects on both positive and negative symptoms of schizophrenia and that these effects are of long duration. However, there have been reports that denied its effectiveness (Mattes *et al.*, 1985; Tamminga *et al.*, 1986).

From the results of animal experiments using a CCK antagonist (Zetler, 1985), a CCK receptor antagonist was estimated to produce its antipsychotic effect by reducing the enhancement of dopamine metabolism, and proglumide (an unselective CCK antagonist) was used tentatively in schizophrenic patients. However, its effectiveness was not established (Innis *et al.*, 1986; Hicks *et al.*, 1989).

As observed above, the possibility of neuropeptides or their antagonists as treatments for schizophrenia has been evaluated. However, there remain a number of unknown aspects including the essential functions of the peptides, their relationships with classic transmitters and their pharmacological behaviour, and further research is needed concerning their action mechanisms, which provide the basis for this hypothesis. However, as dopamine antagonists are the mainstay of antipsychotic medication today, neuropeptides are closely related to the aetiology and pathology of schizophrenia, and drugs that act via the peptidergic neuronal system are still attractive as possible treatments for the disease.

THE FUTURE OF NEUROPEPTIDES IN PSYCHIATRY

During the past decades, a number of neuropeptides have been discovered in the body and their functions have been studied. These research activities are still continuing. As a result, neuropeptides are known to be involved in diverse brain functions including memory and learning, emotion, senses, appetite, sexual drive and sleep. In addition, new peptides are being discovered as a result of technical improvements in molecular neuroscience. For example, many receptors, ligands of which have not been found, have been cloned recently, and orexin and nociception have been identified in the course of the search for their ligands. It is considered that new neuropeptides will continue to be identified. Detailed functions of neuropeptides have also been clarified as a result of the advent of new technology such as the preparation of knockout mice.

The relationship between the aetiology of schizophrenia and neuropeptides has been discussed in connection with classic neurotransmitters. Classic neurotransmitters such as dopamine and noradrenaline are known to coexist with neuropeptides in the same neurones, and they act under a strong mutual influence. However, despite accumulation of research, the relationship of neuropeptides with the aetiology of schizophrenia remains unknown. Further evaluation by various approaches, such as anatomical, physiological, pharmacological and molecular neurological, is needed. On the

basis of these results, the role of neuropeptides in the pathogenesis of schizophrenia is still unclear.

Most of the anatomical changes in neuropeptides reported to date have been observed in areas such as the medial part of the temporal lobe and frontal lobe. These areas have attracted attention in morphological research of schizophrenia. Akbarian *et al.* (1993a, 1993b) examined the development hypothesis of this disease on the basis of examination of the distribution of cells containing NADPH-d (nicotinamide adenine dinucleotide phosphate) in the brain of schizophrenic patients. Many NADPH-d-containing cells coexist with neuropeptides such as SOM and NPY (Vincent *et al.*, 1983a; Unger and Lange, 1992). Although their interactions must still be clarified, evaluation of neuropeptides from the viewpoint of the development disturbance hypothesis of schizophrenia is necessary.

Recently, the concept that homeostasis of the body is maintained by a network that tightly links the neural, endocrine and immune systems was presented (Blalock, 1994). This is a concept that allows comprehensive understanding of the pathophysiology and aetiology of various diseases including neurological disorders, responses to stress and protective mechanisms of the body. Neuropeptides play important roles as mediators of information transmission in such a biological system. For example, some neuropeptides have been shown to exert marked effects on the immune system, and specific parts of the brain have been found to be closely related to immune functions. Thus, neuropeptides perform as yet unknown functions in the body, and the quest for their roles in the aetiology of mental and neurological disorders should lead to clarification of their pathology.

Neuroimmunology of Schizophrenia

N. Müller

INTRODUCTION

Immunological alterations in schizophrenia have been described in the international literature since the beginning of the last century (Bruce and Peebles, 1903; Dameshek, 1930; Lehmann-Facius, 1939). However, for several reasons the focus of interest has changed from the immune system since the 1960s. One reason was the introduction of antipsychotics into the therapy of schizophrenia, leading to the dopamine hypothesis as the focus of research activities. Another reason was that the components and functions of the immune system have not been understood very well during those times, while during the last decade major advances in immunological research could be observed.

With regard to clinical symptomatology, acuity of the symptoms, course, treatment response and probably also aetiology, schizophrenia is a heterogeneous disorder. Besides methodological pitfalls, this heterogeneity might contribute to the heterogeneity of the results of biological investigations, which can be found in nearly all fields of biological research in schizophrenia. A widespread heterogeneity can also be observed in the results of immunological studies in schizophrenia (overview: Müller and Ackenheil, 1998).

The objectives of psychoneuroimmunology are to elucidate the reciprocal influences of the nervous system and the immune system and their effects on behaviour and health. This field covers *in vitro* studies of tissue and lymphocytes, investigations of the influence of stress, stress-coping and personality traits on the function of the immune system, also the role of psychological factors during pathogenesis, and the course of tumour disorders and their psychotherapeutic treatment. Additionally, human behaviour studies and animal experiments, e.g. conditioning studies (Ader and Cohen, 1975) or investigations into the dependency of coupling behaviour from the HLA system (Eggert *et al.*, 1990), belong to the broad spectrum of psychoneuroimmunology.

Cytokines mediate the information between cells of the peripheral immune system and the central nervous system (CNS). In part, they are actively transported through the blood–brain barrier, but they are also released from (activated) astrocytes and microglial cells. Interleukin- (IL-)1, IL-2, IL-4, IL-6, IL-10 and tumour necrosis factor α (TNF-α) are the most relevant activating cytokines known to act on the CNS. Cytokines behave like a network since they can activate cells to produce other cytokines. Recent findings show that cytokines are relevant in psychiatric disorders, possibly mainly due to their influence on neurotransmission. From a clinical point of view endogenous psychoses show several parallels to autoimmune disorders. These include onset during early adulthood in many cases, genetic vulnerability, waxing and waning course and, as in depression, the sex ratio.

During the 1950s, several investigations tested the hypothesis that schizophrenia may be an autoimmune disorder. Serum components which showed features of anti-self antibodies directed against brain tissue have been described in schizophrenic patients (Fessel, 1963; Heath and Krupp, 1967; Pandey *et al.*, 1981). With the increasing dominance of the dopamine hypothesis of schizophrenia created by the 2000 Nobel prize winner A. Carlsson (Carlsson and Lindquist, 1963), immunological investigations in psychiatry were disregarded by the scientific community for several years. Later Knight tried to integrate the autoimmune and dopamine hypotheses of schizophrenia by postulating that schizophrenia may be due to dopamine receptor-stimulating auto-antibodies (Knight, 1982). During recent years, several inadequacies of the dopamine hypothesis as to the cause of schizophrenia became evident, e.g. the schizophrenic negative symptomatology or the resistance to antipsychotic therapy with dopamine receptor-blocking substances in about 20–30% of patients. Therefore, other biological models of explanation became of increasing interest. In parallel, the noradrenaline (Schildkraut, 1965; Matussek, 1966) and serotonin hypotheses (Coppen and Swade, 1988) of depression were not sufficient to explain depressive disorders. Nevertheless, there is no doubt about the major role of the catecholaminergic neurotransmission in affective and schizophrenic disorders, and one focus of psychoimmunological research in this field is the influence of immunological processes on catecholaminergic neurotransmission.

The increasing role of psychoneuroimmunology is also due to the rapid development of immunological methods. Thanks to the recent immunological and molecular biological investigation techniques, our knowledge of the function, mechanisms of regulation and interaction of the immune system is growing, as shown in Figure XVII-5.1. A much more accurate description of the interaction and function of the highly differentiated and variable immune system is possible owing to the recent methodological advances.

That immune processes can mediate psychotic phenomena is shown by psychiatric disturbances which occur during different

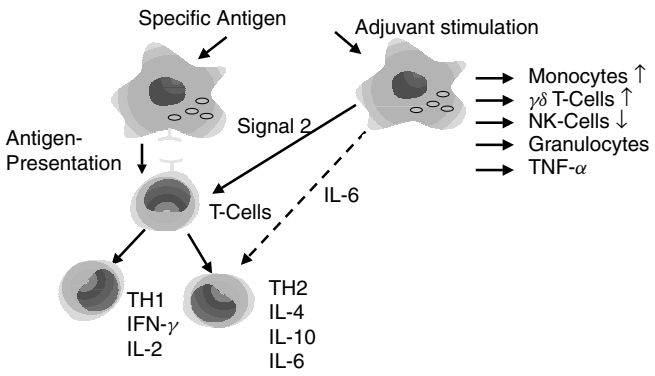

Figure XVII-5.1 Model of immune activation in schizophrenia: predominance of the unspecific immune system and the TH2 answer

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

autoimmune disorders, such as lupus erythematosus (Krüger, 1984), scleroderma (Müller *et al.*, 1992), Sjögren's syndrome (Raps *et al.*, 1986), and anti-phospholipid syndrome (Kurtz and Müller, 1994).

Modern immunological methods at first led to the investigation of lymphocyte sub-populations by monoclonal antibodies. Different cell surface markers point to different functions of the lymphocytes. During the 1980s, several researchers studied the cellular immune system in different psychiatric disorders (McAllister *et al.*, 1989; Villemain *et al.*, 1989; Müller *et al.*, 1991, 1993a, 1993b; Sperner-Unterweger *et al.*, 1992; Maes *et al.*, 1995). The findings in the cellular immune system, in particular in schizophrenic and affective psychoses, indicated that there was an immune activation in these disorders, which, in turn, raised the question as to the function of cytokines, a key factor in the activation of the immune system.

THE CYTOKINE NETWORK IN THE CNS

The signalling, differentiation and function of the (peripheral) cellular immune system is mediated and characterized by cytokines. Cytokines activate CNS cells in different ways. First, several cytokines such as IL-1 (Banks and Kastin, 1992), IL-2 (Banks *et al.*, 1993) and TNF-α (Gutierrez *et al.*, 1993) can be transported from the blood into the CNS by active transport mechanisms, as *in vitro* studies have pointed out. Second, glia cells secrete cytokines after activation by an antigenic challenge. Finally, Norris and Benveniste (1993) recently reported that cytokine secretion in the CNS can be stimulated by neurotransmitters. They showed that noradrenaline stimulates the release of IL-6 from astrocytes *in vitro* in a dose-dependent manner, an effect that can be antagonized by blocking the adrenergic receptors. Since IL-6 is closely linked with the function of other cytokines e.g. IL-1, IL-2 and TNF-α, this finding indicates that neurotransmitters can activate the cascade of cytokines (Ransohoff and Benveniste, 1996). This may represent an important psychoneuroimmunological regulative mechanism affecting (auto-)immune disorders, susceptibility to infections and psychiatric disorders. The noradrenaline released during stress (Engel *et al.*, 1980) may act as a cytokine-activating stimulus, which thus activates immune phenomena mediated by the cytokine cascade.

GLIAL CELL DYSFUNCTION IN SCHIZOPHRENIA

Astrocytes form the largest cell population in the CNS, exceeding neurones by more than 10-fold (Benveniste, 1992). Astrocytes are located immediately beside neurones, often enfolding them. This localization underlines the close relationship between astrocytes and neuronal function. About 10% of the glia cells are microglia cells (Benveniste, 1992). Both microglia cells and astrocytes can produce and release cytokines after activation, as shown schematically in Figure XVII-5.2.

Some authors postulate that microglial dysfunction initiated by early CNS viral exposure results in the abnormal neural development and neurotransmitter dysfunction seen in schizophrenia (Munn, 2000). This theory is confirmed by findings of abnormally high microglial activation in a subgroup of schizophrenic patients (Bayer *et al.*, 1999). An increase of the numerical density of HLA-DR-positive microglial cells (HLA-DR is the marker of HLA class II activation in the peripheral blood and of microglial activation in the CNS) especially in the temporal and frontal cortex of chronic schizophrenics, not related to ageing, has been described recently (Radewicz *et al.*, 2000).

THE CONCEPT OF INNATE AND ADAPTIVE IMMUNITY IN HUMANS

The immune system has developed during evolution over millions of years. In order to guarantee successful defence against numerous varying invading, life-threatening micro-organisms like bacteria or viruses, a highly differentiated system consisting of different lines of defence was established. A widespread heterogeneity was the consequence: two functionally different immune systems both representing different types of barriers and each consisting of

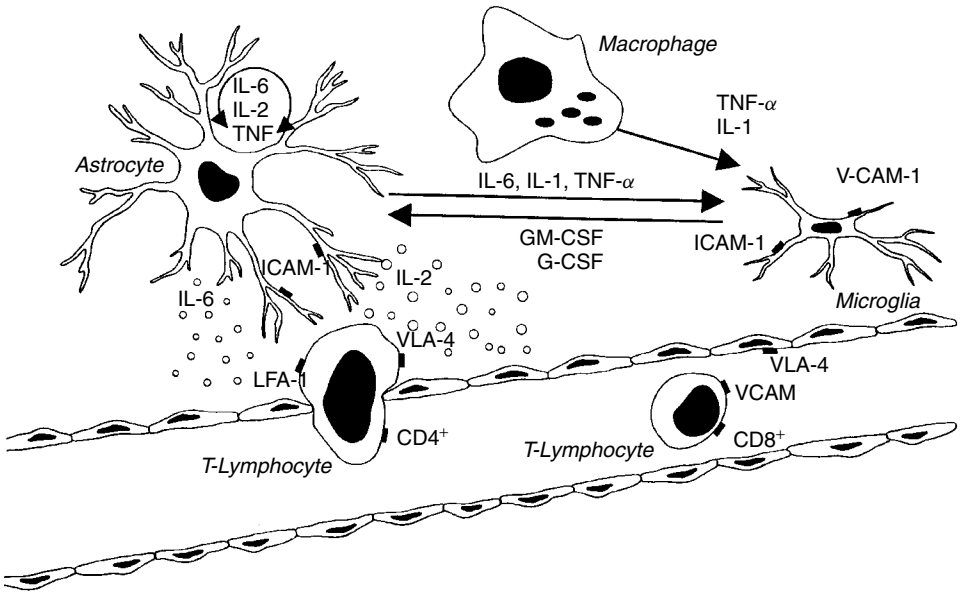

Figure XVII-5.2 Schematic overview on the network of blood lymphocytes, adhesion, glial cells, cytokine production after activation, and the blood-brain-barrier

Table XVII-5.1 Components of the unspecific 'innate' and the more specific cellular 'adaptive' immune systems in humans

Components	Innate	Adaptive
Cellular	Monocytes Macrophages Granulocytes NK cells γ/δ cells	T and B cells
Humoral	Complement, APP, mannose-binding lectin (MBL)	Antibodies

cellular and humoral immune components. The 'innate' immune system is the phylogenetically older, 'primitive' one. Its cellular arm is represented by monocytes/macrophages, granulocytes and natural killer (NK) cells. The humoral arm consists of acute-phase proteins and the complement system. This 'unspecific' immune system represents the first line of defence.

The specific part of the immune system of higher organisms including humans is the 'adaptive' immune system, consisting of the cellular arm of the T and B cells and the humoral arm of specific antibodies. This system includes higher functions like memory and can be conditioned. In case of a re-exposition to a specific antigen, this system can recognize the enemy and initiate a specific immune response (Table XVII-5.1).

The 'innate' and 'adaptive' immune systems are functionally balanced. Within the 'adaptive' immune system is another balance regarding the activation of the cellular and the humoral immune system. The cellular arm of the adaptive immune system is mainly activated by the T-helper-1 (TH-1) system: helper cells, which produce the activating 'immunotransmitters' IL-2, IL-12, IFN-γ and TNF-α. The humoral arm of the adaptive immune system is mainly activated via the TH-2 system: helper cells, which produce mainly IL-4, IL-10 and IL-6.

RELATIONSHIP BETWEEN CLINICAL CHARACTERISTICS AND IMMUNE ALTERATIONS

Signs of an inflammatory disease process in schizophrenia have been observed in a subgroup of schizophrenic patients (Körschenhausen *et al.*, 1996). Clinical features of this subgroup showing signs of an immunological or inflammatory disease have been studied by several groups of researchers. It was observed, however, that the symptomatology, e.g. paranoid symptoms or negative symptoms (Cazullo *et al.*, 1998; Müller and Ackenheil, 1995), acuity (Korte *et al.*, 1998; Sperner-Unterweger *et al.*, 1992; Wilke *et al.*, 1996) and drug treatment (Özek *et al.*, 1971; Saunders and Muchmore, 1964; Maes *et al.*, 1995; Masserini *et al.*, 1990; Müller *et al.*, 1991, 1997b, 1997c, 1999; Pollmächer *et al.*, 1996) influence the immunological parameters. Also the clinical response to treatment with neuroleptics seems to be related to immune parameters (Müller *et al.*, 1993a). The present author's own data show that the IgG content of CSF is especially high in patients with pronounced schizophrenic negative symptoms, which are associated with an unfavourable course of the disorder and often with treatment resistance (Müller and Ackenheil, 1995). Those findings fit with the suggestion that the inflammatory response system is activated in patients which are treatment resistant to antipsychotic medication (Maes *et al.*, 2000).

However, a clear-cut differentiation between immunological subgroups in schizophrenia is not yet established. The discussion of this relationship between clinical characteristics of schizophrenia and parameters of the immune system may help to define subgroups which are characterized by disturbances of the immune system.

GENETICS AND SCHIZOPHRENIA

There is no doubt that environmental and genetic factors play a role in schizophrenia. Studies in monozygotic twins showed that the risk of a healthy monozygotic twin of a schizophrenic twin is about 50% to develop a schizophrenic disorder as well, i.e. about 50% of the risk is attributed to genetic factors and 50% to environmental factors. One of the strongest findings of genetic linkage studies in schizophrenia points to the chromosomal region 6p22–23. Several genes are located very near to this region which are associated with immune function. The HLA region (6p23.1) is crucially involved in immune function, e.g. during (viral) infection (Lindholm *et al.*, 1999; Schwab *et al.*, 1995).

A common genetic vulnerability locus has been suggested on the HLA class II allele DQB1*0602 for schizophrenia, multiple sclerosis and narcolepsy, although confirmation studies are still lacking (Großkopf *et al.*, 1998). For African-American schizophrenics, a negative association could be found in two studies (Nimgaronkar *et al.*, 1992; Nimgaronkar *et al.*, 1997) and in one study for Chinese schizophrenics (Nimgaronkar *et al.*, 1995). Those interesting but divergent results underline that further investigations of HLA class II in schizophrenia should be carried out.

This finding is of special interest because there is one more link to the immune function and schizophrenia on chromosome 6: Retroviral control elements have been identified on chromosome 6 near the HLA region in patients with insulin-dependent diabetes mellitus (IDDM: Badenhoop *et al.*, 1996), whereas a marked vulnerability for IDDM has been found in first-degree relatives of schizophrenic patients (Wright *et al.*, 1996). IDDM, however, is inversely associated with schizophrenia (Finney, 1989). Another candidate for HLA investigations is the DRB1*04 gene because it is positively associated with rheumatoid arthritis, an autoimmune disease that is inversely associated with schizophrenia (Eaton *et al.*, 1992). A negative genetic association of DRB1*04 with schizophrenia has been found (Wright *et al.*, 1996) and there is evidence that this might be a robust result (Wright *et al.*, 2001), e.g. the preferential non-transmission of DRB1*04 alleles from heterozygous parents to schizophrenic offspring (Wright *et al.*, 1997).

Another methodological approach is the investigation of characteristics in the immune function of the schizophrenic disorder and HLA genes. An example for such an approach is the association between HLA genes and the maternal immune response of mothers from schizophrenic offspring (Wright *et al.*, 1993).

Our own study showed a strong relationship between cytotoxic gamma/delta T cells in unmedicated schizophrenic patients, the blood–brain barrier and the HLA allele DPA 02011 (Müller *et al.*, 1998).

The introduction of HLA genotyping has effectively eliminated the inaccuracies associated with HLA serotyping and has revealed the genetic polymorphism within the HLA system as a complexity previously unimagined.

Many HLA investigations were performed before the era of HLA genotyping, and different associations especially between the HLA class I system and schizophrenia have been reported without conclusive results (overview: Wright *et al.*, 2001).

However, studies of the association between specific characteristics of the schizophrenic disorder and the HLA class I system showed some interesting results. Several studies focused on the association of HLA class I and response to antipsychotic treatment or increased risk for adverse effects of neuroleptics.

These studies found an association between HLA-Bw44 and the titres of auto-antibodies to chlorpromazine in chronic schizophrenics (Canoso *et al.*, 1982). A significant difference in the treatment

response to γ-endorphin in schizophrenia with respect to HLA-B15 has also been described (DeJongh *et al.*, 1982). Moreover, there have been reports showing HLA-B44 to be associated with an increased risk of developing tardive dyskinesia (Canoso *et al.*, 1986) and drug-induced Parkinsonism (Metzer *et al.*, 1989). In a preliminary study a positive association between HLA-A1 and an increased risk for neuroleptic-induced akathisia was observed (Brown and White, 1991). A cluster-analytic study (Müller *et al.*, 1993) showed that the altered immune function in schizophrenia, especially the enhanced $CD3^+$ and $CD4^+$ cells and the reduced inhibition of the activated immune system ('suppressor cell function'; see above), was significantly related to the HLA class I system and to the family history of psychiatric diseases. This statistical method, which analyses in a combined manner immune-functional, immune-genetic and clinical data, showed two independent factors: the HLA system and the family history of psychiatric diseases contributing to the altered immune function in schizophrenia.

Genetic determinants of infection include genes which modulate the immune response, the expression of viral receptors and the susceptibility of cells to soluble factors generated during the course of viral infection (Yolken *et al.*, 1999).

VIRUS HYPOTHESIS OF SCHIZOPHRENIA

Different case reports of patients presenting with psychiatric symptoms during viral infections with herpes simplex encephalitis, varicella zoster encephalitis, or subacute sclerosing panencephalitis led to the suggestion that viral infections might play a role in the pathogenesis of schizophrenia. Epidemiological data of an increased number of manifestations of schizophrenia in winter-born people (Torrey *et al.*, 1977), of geographic variations (Torrey, 1987), and of an increased incidence of schizophrenia in children of mothers infected by an epidemic influenza during pregnancy in England in 1957 (O'Callaghan *et al.*, 1991) point to a virus pathogenesis as well (Yolken and Torrey, 1995). Numerous studies have detected raised titres of antibodies against certain viruses (herpes simplex, measles, cytomegalovirus, varicella, Borna virus) in schizophrenic patients as compared to controls and/or increased cerebrospinal fluid (CSF)/serum ratios of viral antibodies, indicating a local synthesis of antibodies in the brain or CSF (Hoechtlen and Müller, 1992; Torrey *et al.*, 1977; Albrecht *et al.*, 1980; Bechter *et al.*, 1999; Gottlieb-Stematsky *et al.*, 1981), but the significance of these findings is debated. Viruses or a virus genome were not detectable in the CSF or brain tissue of schizophrenic patients by most authors (Stevens *et al.*, 1984; Taylor and Crow, 1986; Alexander *et al.*, 1992).

It may be assumed that viruses may be detectable only during certain states of virus-induced diseases ('hit and quit'). Thus, the fact that viruses or a virus genome could not be isolated does not exclude the involvement of viruses in the pathogenesis of the disease. On the other hand, comparable findings were described in multiple sclerosis (MS), a disease with a probable autoimmune pathogenesis. In MS, raised virus antibody titres are discussed as representing a polyspecific local synthesis of antibodies against neurotropic viruses, particularly measles, rubella and varicella zoster virus (MRZ reaction) (Stevens, 1988). The polyspecific antiviral response seems to indicate an immune dysregulation in accordance with an unspecific activation of antibody-producing B cells, although an involvement of viruses in the aetiology of MS has not been excluded until now. MS and schizophrenia show some further parallels, like waxing and waning course, genetic factor and early onset in a number of cases (Felgenhauer 1990). Moreover, MS cases sometimes appear as schizophrenia-like psychosis (Pisiur-Strehlow *et al.*, 1988), too.

The virus and the autoimmune hypotheses of schizophrenia may be connected with regard to the role of viruses in molecular mimicry: viruses induce cells to change their identity, probably via expressing surface antigens; thus they are not recognized as 'self', but as 'non-self' and therefore are attacked by their own immune cells. From that point of view, our findings of an immune activation in schizophrenia are compatible with both the virus and the autoimmune hypotheses of schizophrenia.

Recent studies indicate that schizophrenia is associated with the upregulation of a number of different RNA species (Yolken *et al.*, 1999). These RNAs are supposed to represent genomic or messenger RNA derived from novel viral agents. In this regard it is of interest that several of the (predicted) proteins are homologous to viruses of non-human origin. The authors discuss the possibility that certain unidentified human retroviruses may contribute to schizophrenia together with genetic determinants — viral infection of neuronal cells can, in combination with genetic determinants of susceptibility, result in the profound alteration of brain function typical of schizophrenia (Yolken *et al.*, 1999). Interestingly, a case of subclinical Borna disease viral encephalitis presenting as schizophrenia has been described recently. While schizophrenic positive symptoms improved during antipsychotic pharmacological treatment, negative symptoms did not. Therefore, the authors decided to use the CSF filtration method, an experimental therapeutic method for treatment of therapy-resistant patients suffering from Guillain–Barré syndrome. The schizophrenic negative symptoms rapidly improved, as did neurological soft signs and cognitive function. The authors suggest that toxic factors are removed by the filtration (Bechter *et al.*, 1999). From a scientific point of view, those therapeutic approaches are interesting but of course need further evaluation.

NEURODEVELOPMENTAL HYPOTHESIS

The excess of late winter/early spring births in patients with schizophrenia has been attributed to infectious, nutritional or other environmental factors (Torrey *et al.*, 1997; Mortensen *et al.*, 1999). The hypothesis that an infection of pregnant mothers is related to an increased risk for schizophrenia in the offspring implicates sequelae for the development of the unborn offspring. The pathological mechanisms underlying prenatal and perinatal risk factors for schizophrenia, including infection, remain largely unstudied. Infection during pregnancy is one of various factors defined as obstretical complication. Cytokines are known to regulate normal brain development and have been implicated in abnormal brain development (Merill, 1992; Mehler *et al.*, 1995; Mehler and Kessler, 1997). It has been hypothesized that pro-inflammatory cytokines generated by the immune system are important mediators of the association between maternal infection, abnormal brain development and increased risk for schizophrenia and other neurodevelopmental disorders (Leviton, 1993; Jarskog *et al.*, 1997). There is no doubt about the significant association between obstretical complications and the ultimate development of schizophrenia (Geddes and Lawrie, 1995; Jones *et al.*, 1998; Dalman *et al.*, 1999; Hultman *et al.*, 1999).

Not only are influenza and other viral infections during pregnancy known to be associated with an increased incidence of schizophrenia in an offspring, but it is likely that the association between *in utero* or early post-natal exposure to obstretical complications and schizophrenia is a more general phenomenon not limited to a single aetiological viral agent such as influenza. Infectious processes in general but also other pathological factors such as hypoxia are known to lead to an altered cytokine production in the brain.

Pro-inflammatory cytokines are neurotoxic to a variety of developing neurones *in vitro*. For example, IL-1β, IL-6 and TNF-α decrease survival of foetal dopaminergic and serotonergic neurones *in vitro* (Jarskog *et al.*, 1997). Moreover, IL-1β decreases neurone

survival in primary cultures of embryonic rat hippocampus (Arajujo and Cotman, 1995) and TNF-α potentiates glutamate excitotoxicity in cultures of foetal cortical neurones (Chao and Hu, 1994). In an animal model of prenatal exposure to infection with pregnant rats it could be shown that *Escherichia coli* lipopolysaccharides (LPS) in different doses lead to alterations of cytokine levels. Low-dose LPS was associated with significant increase of IL-1β, IL-6 and TNF-α in the placenta and IL-6 in the amniotic fluid. High-dose LPS was associated with a significant elevation of IL-6 and TNF-α in the placenta, and of TNF-α in the amniotic fluid, but with a significant decrease of TNF-α in the foetal brain. These observations show that maternal exposure to infection alters pro-inflammatory cytokine levels in the foetal environment, which may have a significant impact on the developing brain (Urakubo *et al.*, 2001).

BLOOD–BRAIN BARRIER IMPAIRMENT

Abnormalities of the CSF are regularly reported in about 20–30% of psychiatric patients (Kirch *et al.*, 1985; Naber *et al.*, 1986). Investigations of schizophrenic patients have shown increased total protein content (>45 mg%) or a blood–brain barrier (BBB) impairment in about one-third, and an intrathecal IgG production in 15% of patients (Müller and Ackenheil, 1995). The increased immunoglobulins and the BBB disturbance are likely to be part of an immune process whose pathophysiological relevance is not yet clear. Nevertheless, a correlation of schizophrenic psychopathology with IgG content suggests a close relationship between the immune process and the schizophrenia in those patients who show negative symptoms (Müller and Ackenheil, 1995).

The physiological function of a CNS immune activation is, however, the defence against invading antigens. For example, it could be shown that an infection with herpes virus which cannot activate glia cells takes a more disadvantageous course than an infection with herpes virus involving activated glial cells (astrocytes) in the immune response (Lewandowski *et al.*, 1994). Infection with measles virus *in vitro* shows that the levels of cytokine release in glia cells depend on the duration of infection (Schneider-Schaulies *et al.*, 1993).

On the other hand, a local CNS immune activation may be controlled insufficiently due to a lack of communication between the peripheral immune system and the CNS. T cells invading from the peripheral blood into the CNS are able to control an immune activating process in the CNS. There are hints that a T cell penetration through the BBB is necessary for control of several inflammatory processes (Reich *et al.*, 1992; Shankar *et al.*, 1992).

A BBB disturbance is accompanied by an involvement of astrocytes, because the capillary endothelial cells, which are connected by tight junctions, are surrounded almost completely by astrocytes that modulate the BBB in the small vessels (Benveniste, 1992; Cancilla and DeBault, 1983). The present author's investigations have shown that antipsychotic treatment and psychopathological improvement are associated with a significant increase in the adhesion molecule expressing T-helper cells VLA-4$^+$/CD4$^+$ and the VLA-4$^+$/CD8$^+$ lymphocytes in the blood; moreover, a strong relationship between VLA-4$^+$/CD4$^+$ and LFA-1$^+$/CD4$^+$ lymphocytes and both BBB disturbance and CSF parameters (total protein, albumin, IgG) was observed (Müller *et al.*, 1997c). VLA-4 and LFA-1 are surface markers which are expressed on lymphocytes in order to mediate adhesion of lymphocytes to endothelial cells and a penetration into the tissue (Fabry *et al.*, 1992, 1994; Oppenheimer-Marks *et al.*, 1991). One speculative explanation of these findings is that VLA-4/CD4$^+$ and LFA-1/CD4$^+$ lymphocytes are involved in an immunoregulatory mechanism taking place between astrocytes and/or microglial cells and lymphocytes from the blood that is supported by the action of neuroleptics (Müller *et al.*, 1997c, 1999).

IL-2 and IL-6 play a pivotal role in the disturbance of the BBB. The peripheral application of IL-2 can cause an alteration of the BBB (Rosenstein *et al.*, 1986; Ellison *et al.*, 1987, 1990; Saris *et al.*, 1988) and a disturbance of the BBB seems to be involved in the CNS effects of peripherally applied IL-2. The alteration of the BBB by intrathecal application of IL-2 (Watts *et al.*, 1989) suggests that an increased intracerebral IL-2 production may contribute to the opening of the BBB.

As mentioned above, in many cases of schizophrenic patients obstretical complications such as pre-, peri- or post-natal CNS damage are suggested to contribute to the pathogenesis (Murray and O'Callaghan, 1991). Moreover, in those cases, a BBB disturbance may contribute to the pathological process, because birth complications are often connected with a disturbed BBB (Ebbesen and Knudsen, 1992), which promotes the invasion of immune activating components, such as infectious agents, into the CNS.

IL-6 also alleviates the invasion of lymphocytes into the CNS and promotes impairment of the BBB (Muraguchi *et al.*, 1988).

Due to an increased permeability of the BBB, a primarily local CNS process may spread into the periphery and activate the peripheral immune system. An increased communication between CNS immune system and peripheral immune system may include both a regulatory process leading to elimination of activating antigens (Reich *et al.*, 1992; Shankar *et al.*, 1992) and damage to CNS structures by invading auto-aggressive cells, as was suggested in MS (Ransohoff and Bö, 1996).

ACTIVATION OF THE INNATE 'UNSPECIFIC' IMMUNE SYSTEM IN SCHIZOPHRENIA

Although systematic investigations of the innate immune system are lacking in schizophrenia there are several hints that this part of the immune system may be more activated in schizophrenic patients than in controls. There is a report that monocytes are increased in schizophrenic patients compared to controls (Wilke *et al.*, 1996) and our own investigations of unmedicated schizophrenic patients also showed increased amounts of monocytes in schizophrenia compared to controls (unpublished results). An increase of cells of the 'first immune barrier' was also found in $\gamma\delta^+$CD8$^+$ cells in unmedicated schizophrenics (Müller *et al.*, 1998).

One of the key cytokines which initiates the immune response and in particular activates the B cell system is IL-6. Activated monocytes and macrophages are the major sources of the production and release of IL-6. Vice versa, increased levels of IL-6, as mentioned in the next paragraph, might be the result of the activation of the monocyte/macrophage system, leading to an overproduction of IL-6 by the innate immune system.

Since a significantly higher proportion of mononuclear phagocytes/macrophages in the CSF of schizophrenics has been reported compared to neurological controls, which was followed by a normalization of the cytological picture at a follow-up investigation in a small subgroup of patients during antipsychotic treatment, it seems that similar immunological processes take place in the peripheral and the CNS immune systems (Nikkilä *et al.*, 1999).

IL-6 IN THE CNS

IL-6 is a pleiotropic cytokine which is released from different cell types in the blood (macrophages, monocytes, T and B cells). One function of IL-6 is to activate B cells to synthesize antibodies (Plata-Salaman, 1991). However, like several other cytokines, IL-6 is not only synthesized and released in immune cells of the peripheral blood, but is also produced by activated astrocytes and microglia cells in the CNS. Several findings suggest that IL-6 may

mediate the exacerbation of autoimmune disorders in the CNS (Dunn, 1992); e.g. IL-6 supports the differentiation of B cells, the local IgG synthesis in the CNS and a BBB disturbance (Frei *et al.*, 1989; Muraguchi *et al.*, 1988). In the hypothalamus, IL-6 can induce the release of growth hormone-releasing hormone and thyroid-stimulating hormone, and it stimulates *in vitro* the secretion of prolactin and growth hormone from pituitary cells (Spangelo *et al.*, 1989).

A strong relationship between IL-6 and neurotransmitter production has been reported by different studies. IL-6 can stimulate neurones *in vitro* to secrete dopamine and probably other catecholamines as well (Hama *et al.*, 1991). The peripheral application of IL-6 in animal experiments enhanced the dopaminergic and serotonergic turnover in the hippocampus and frontal cortex, without affecting noradrenaline (Zalcman *et al.*, 1994). Conversely, noradrenaline can stimulate astrocytes to release IL-6 (Dunn, 1992). Both observations point to a direct influence of activating cytokines, especially IL-6, to the catecholaminergic neurotransmitter system.

IL-6 AND SCHIZOPHRENIA

Several reports showed increased serum IL-6 levels in schizophrenia (Ganguli *et al.*, 1994; Maes *et al.*, 1995; Frommberger *et al.*, 1997; Lin *et al.*, 1998). Two of the report's authors described a relationship between increased IL-6 levels and clinical features of schizophrenia: high serum- IL-6 levels were related to the duration of the disorder (Ganguli *et al.*, 1994) and to treatment resistance (Lin *et al.*, 1998). These findings suggest that IL-6 serum levels might be especially high in patients with an unfavourable course of the disease. On the other hand, methodological concerns have to be considered: IL-6 is a cytokine which is released mainly paracrinely and the function of serum levels is not yet fully established. Moreover, the cytokine IL-6, like IL-2, IL-1 and other cytokines, is not stable and many methodological pitfalls have to be considered.

The soluble IL-6 receptor (sIL-6R) is a more stable marker of the IL-6 system, both in the blood and in the CSF. Investigations of the sIL-6R levels in the CSF, however, showed that high levels of sIL-6R can be found especially in schizophrenic patients with a more marked paranoid–hallucinatory syndrome (Müller *et al.*, 1997b). These investigations also point to a more altered IL-6 system in patients with an unfavourable course of the disease: longer duration of illness, treatment resistance or more marked paranoid–hallucinatory symptomatology.

Another study found reduced levels of sgp130 in the CSF of schizophrenic patients compared to depressed patients and psychiatric healthy controls (Schwarz *et al.*, 2001). This result supports the view of a disturbance in the IL-6 system in schizophrenia, because gp130 is part of the IL-6 system. The soluble protein spg130 is acting as an antagonist to the gp130 receptor and mediates the inhibition of the IL-6 system (Narazaki *et al.*, 1993). Functionally, decreased sgp130 levels in the CSF point to a decrease in the inhibition of the IL-6 system and a functional increase in the activation.

ANTIPSYCHOTIC THERAPY AND THE IL-6 SYSTEM

There are several observations indicating that antipsychotic therapy with neuroleptics is accompanied by a functional decrease of the IL-6 system. A significant decrease of IL-6 during therapy with neuroleptics was described by Maes and co-workers (1995). Two studies found a significant decrease of sIL-6R levels during antipsychotic therapy with neuroleptics (Maes *et al.*, 1995; Müller *et al.*, 1997a). Studies from human CNS cell cultures also showed an inhibitory effect of different neuroleptics to the production of IL-6 after stimulation with lipopolysaccharides, which was more marked in phenothiazines compared to butyrophenones (unpublished results). Similar observations have been described by other authors (Lin *et al.*, 1998).

There are indications for a time-dependent effect of antipsychotic treatment to IL-6: one study reported that short-term treatment with clozapine (median 12 days) induced an increase in IL-6 levels (Maes *et al.*, 1997) and another group found an increase of IL-6 after 2 weeks of clozapine treatment but a decrease after a further 4 weeks of treatment (Pollmächer *et al.*, 1996).

T-HELPER-2 CELL ACTIVATION IN SCHIZOPHRENIA

IL-6 is not only a product of macrophage/monocyte activation, but also of the activation of the TH-2 system. Therefore it cannot be differentiated whether a functional increase of the IL-6 system is a product of TH-2 activation or of the monocyte/macrophage line. However, other results point to an activation of the TH-2 system in schizophrenia.

IL-10 is a cytokine that is produced by TH-2 cells. An increase of IL-10 in schizophrenic patients compared to healthy controls was reported (Cazzullo *et al.*, 1998). Another study observed a strong relationship between IL-10 levels and schizophrenic negative symptoms in the CSF of 62 unmedicated schizophrenics (van Kammen *et al.*, 1997). In medicated schizophrenics treated with haloperidol, a significant relationship between CSF IL-10 levels and the severity of schizophrenic psychosis, as measured by the Bunney–Hamburg psychosis rating scale, was found (van Kammen *et al.*, 1997). These findings indicate that IL-10 levels in the CSF are related to the severity of the psychosis, especially to the negative symptoms.

Another characteristic cytokine that is produced by TH-2 cells is IL-4. An increase of IL-4 levels in the CSF of juvenile schizophrenic patients has recently been reported (Mittleman *et al.*, 1997). The production of IgE is also an indicator for the activation of the TH-2 immune response. Increased levels of IgE in schizophrenic patients compared to controls have been observed (Ramchand *et al.*, 1994). The latter findings indicate that the probable increase of the TH-2 system in schizophrenia is not only a phenomenon of the peripheral immune system, but that it also seems to play a role in the CNS immune system.

Earlier descriptions of elevated $CD3^+$ and $CD4^+$ cells in unmedicated schizophrenics are consistent with the hypothesis of a shift to the TH-2 system, with a diminished TH-1 immune response in schizophrenia (Müller *et al.*, 1991; Sperner-Unterweger *et al.*, 1999).

As shown in Figure XVII-5.3 there is a functional balance between the TH-1 and TH-2 system. It would be expected that an

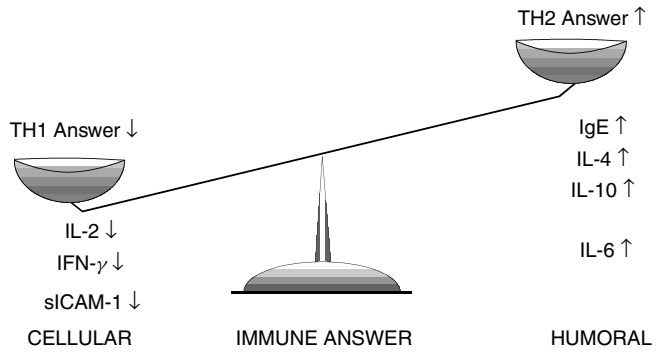

Figure XVII-5.3 Dysbalance of the immune system in schizophrenia. Insufficient activation of the TH-1 answer and relative overactivation of the TH-2 system

overactivation of the TH-2 system is associated with an underactivation of the TH-1 system. Many different findings over decades point to a decreased activation of the TH-1 system in schizophrenia.

T-HELPER-1 SYSTEM AND SCHIZOPHRENIA

The key characteristics of the TH-1 system are the production of IFN-γ and IL-2. One of the often replicated findings in schizophrenia is the decreased *in vitro* production of IL-2 (Villemain *et al.*, 1989; Ganguli *et al.*, 1995; Hornberg *et al.*, 1995; Bessler *et al.*, 1995; Cazzullo *et al.*, 1998). This phenomenon has often been interpreted as the consequence of an exhaustion of the lymphocytes after overproduction of IL-2; however, it might also reflect the reduced capacity of lymphocytes to produce IL-2. The observation of a decreased production of IL-2 fits well with another finding: the decreased production of IFN-γ (Wilke *et al.*, 1996; Rothermund *et al.*, 1996). Both findings point to a blunted production of TH-1-related cytokines and to an underactivation of the TH-1 system in schizophrenia. A lack of activation of the TH-1-related cellular immune system has also be postulated by other researchers (Sperner-Unterweger *et al.*, 1999). Our own findings of the decreased production of lymphocytes after stimulation with different specific antigens also might reflect the reduced capacity for a TH-1-mediated immune answer in schizophrenia. Especially after stimulation with tuberculin, which provokes a TH-1-mediated immune answer, the reaction was blunted (Müller *et al.*, 1991).

DECREASED LEVELS OF sICAM-1 IN UNMEDICATED SCHIZOPHRENICS

Recently, decreased levels of the soluble intercellular adhesion molecule 1 (sICAM-1) in the serum of schizophrenic patients have been described (Wieselmann, personal communication; Schwarz *et al.*, 2000). ICAM-1 is a molecule that mediates the adhesion of lymphocytes to other lymphocytes, to endothelial cells and to parenchymatic cells, but it also mediates the signal for the activation of the cellular immune system. ICAM-1 is part of the TH-1 immune response (van Seventer *et al.*, 1990; Kuhlmann *et al.*, 1991). Therefore, decreased levels of the soluble form of ICAM-1, which is shedded from lymphocytes, seem to represent the state of activation of the TH-1 system. However, reduced sICAM-1 levels have been found not only in the serum but also recently in the CSF of schizophrenic patients (Schwarz *et al.*, in preparation). The latter finding indicates that the blunted activation of the TH-1 system may not be restricted to the peripheral immune system, because CSF parameters reflect more directly the immune pathology of the CNS.

One of the 'classical' epidemiological findings in schizophrenia research is the negative association between schizophrenia and rheumatoid arthritis (Vinogradov *et al.*, 1991). This negative association can be interpreted as two sides of the TH-1/TH-2 balance coin, represented by increased sICAM-1 levels in rheumatoid arthritis and decreased sICAM-1 levels in schizophrenia. SICAM-1 is also a key molecule that mediates the inflammatory reaction in rheumatoid arthritis: increased sICAM-1 levels are regularly found in rheumatoid arthritis (Neidhart *et al.*, 1995). Rheumatoid arthritis is a disorder that is primarily mediated by the cellular TH-1-related immune system.

BLUNTED REACTION OF THE CUTANEOUS CELLULAR IMMUNE RESPONSE IN SCHIZOPHRENIA

The blunted cutaneous reaction to antigens of the Multitest Mérieux which can be observed in schizophrenic patients (Müller *et al.*, in preparation) also points to a blunted response of cell-mediated immunity in schizophrenia. A very early description of this phenomenon, long before the era of neuroleptics, concerned the hyposensitivity to guinea-pig serum, injected intracutaneously in schizophrenic patients, compared to a control group (Molholm, 1942). Such a blunted reaction of a cell-mediated (TH-1) immune response was not only observed in the cutaneous reaction to antigens, but also a decreased antibody production after vaccination with salmonella was found in unmedicated schizophrenic patients (Özek *et al.*, 1971). The descriptions of immune reactions before the era of neuroleptics exclude the possibility that the observed phenomena may be artefacts of the effects of neuroleptics.

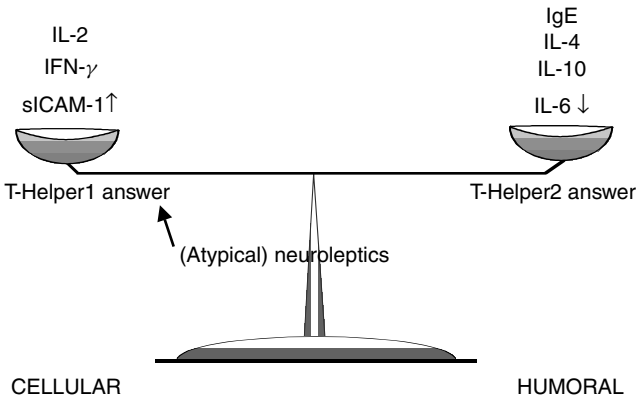

Figure XVII-5.4 Different markers of the immune system point to an immune activation of the TH-1 response during therapy with (atypical) antipsychotics

Antipsychotic therapy, however, is associated with different effects on the immune system. Nevertheless, these effects may counter-regulate the immune effects of the disease. Neuroleptics mainly activate the TH-1 system.

TH-1 SYSTEM AND ANTIPSYCHOTIC THERAPY

Recent findings indicate that neuroleptics may have TH-1-stimulating effects. *In vitro* studies show that the blunted IFN-γ production becomes normalized after therapy with neuroleptics (Wilke *et al.*, 1996). The increase of soluble IL-2 receptors has been described by several groups (Maes *et al.*, 1994; Pollmächer *et al.*, 1995; Müller *et al.*, 1997a). Since sIL-2R are shedded from activated T cells, the increase might reflect an increase of activated, IL-2-bearing T cells.

An increase in $CD4^+CD45RO^+$ cells during therapy with neuroleptics was observed by different groups (Cazzullo *et al.*, 1998; Müller *et al.*, 1997c). $CD4^+CD45RO^+$ cells ('memory cells') are one of the main sources of interferon-γ production. The increase of this sub-population during therapy may contribute to an increase in IFN-γ production. Reduced sICAM-1 levels in the serum of schizophrenics do not normalize during short-term antipsychotic therapy, but a statistically non-significant tendency to increased sICAM-1 could be observed (Schwarz *et al.*, 2000). On the other hand, the leucocyte function antigen 1 (LFA-1) molecule on $CD4^+$ cells shows increased expression during antipsychotic therapy (Müller *et al.*, 1999). LFA-1 is the counter-molecule to ICAM-1. Moreover, the blunted reaction to vaccination with salmonella was not observed in patients who were treated with neuroleptics (Özek *et al.*, 1971). These studies indicate that the TH-1-mediated immune response increases during antipsychotic therapy. Recently,

an elevation of IL-18 serum levels has been described in medicated schizophrenics (Tanaka *et al.*, 2000). Since IL-18 plays a pivotal role in the TH-1 response, this finding fits with other descriptions of a TH-1 activation during antipsychotic treatment.

Interestingly, there is a recent report describing a correlation between the dose of short-term antipsychotic treatment and the mononuclear cell count in the CSF, the CSF macrophage count, as well as the total lymphocyte count (Wahlbeck *et al.*, 2000). The correlation was found especially in patients treated with chlorpromazine-like antipsychotics. This is the first report that describes a relationship between antipsychotic treatment and cellular immunity in the CSF; further investigations have to elucidate whether lymphocytes and macrophages are activated — an activation of the cellular immune system also within the CNS could reflect an activation of the peripheral immune system. Moreover, it would be interesting to know whether a special subgroup of schizophrenics shows an increase of immune cells in the CSF — the total cell count was within the normal range.

B CELLS AND ANTIPSYCHOTIC TREATMENT

Activated B cells are antibody-producing cells. Several observations in the literature indicate that B cells are activated during antipsychotic treatment and antibody production might increase. As early as the 1970s, *in vitro* studies showed an increase of antibody production after stimulation with phenothiazines (Gallien *et al.*, 1977; Zarrabi *et al.*, 1979).

Many studies have described increased antibody production in schizophrenic patients, those observations leading to the discussion of an autoimmune origin of schizophrenia (Ganguli *et al.*, 1987). Nevertheless, the role of antipsychotic treatment has not been considered in several of these studies. Although findings have repeatedly reported that about 20–35% of schizophrenic patients show features of an autoimmune process (Müller and Ackenheil, 1998), the role of actual or former therapy with neuroleptics may not have been taken sufficiently into consideration.

An increase of IgG — antibodies are mainly IgG antibodies — in the CSF has been described, especially in patients with predominant negative symptoms (Müller and Ackenheil, 1995). Increased antibodies against heat shock protein 60 is one of the recent interesting findings in schizophrenia, because it may reflect a mechanism of loss of neuronal protection (Schwarz *et al.*, 1998b, 1999; Kilidireas *et al.*, 1992). However, antibodies against heat shock protein 60 are found especially in patients during antipsychotic therapy.

An increased number of patients with activated B cells ($CD5^+CD19^+$ cells) compared to healthy controls have been described in schizophrenia treated with antipsychotics. Our own study shows an increase of activated B cells during antipsychotic therapy (Müller *et al.*, 1997c). It seems that not only the TH-1 cell system is activated during antipsychotic therapy, but also antibody production by activated B cells.

During antipsychotic therapy, both arms of the specific 'adaptive' immune system seem to become activated: the specific cellular immunity of the TH-1 system, and also the B cell system with its humoral arm, antibody production. An activation of the unspecific 'innate' immune system can be found mainly in unmedicated schizophrenic patients, the latter indicating that this may reflect the disease process and not the result of antipsychotic treatment.

OUTLOOK

Different immunological methods and different clinical features of schizophrenic patients regarding the acuity or chronicity, subtype, course or state of medication have to be taken into account in the discussion of heterogeneous results of immunological studies. Moreover, it has to be realized that schizophrenia is not a disease entity but a syndrome. Therefore, results have to be interpreted cautiously.

However, alterations of the immune system in schizophrenia have been observed for a long time. In the context of both modern sophisticated immunological methods and the current knowledge of the different and multiple functions of immune cells, cytokines, soluble factors etc., more precise suggestions and explanations regarding the interrelationship of the immune functions are possible. The functional differentiation between the innate and adaptive immune system and the T-helper-1 and T-helper-2 conceptualization, especially, allow functional deficits in schizophrenia to be defined. This leads to a more consistent theory of the immune disturbances in schizophrenia, the role of antipsychotic therapy and implications for an immune therapy in schizophrenia.

Psychophysiology Studies of Schizophrenia

J.G. Csernansky

INTRODUCTION

The last twenty years of schizophrenia research have brought us significant advances in our understanding of the neurobiology of schizophrenia. Psychophysiological studies of subjects with schizophrenia have played an important part in this effort, especially by offering the opportunity to explore relationships between clinical symptoms, cognitive deficits, structural and functional brain abnormalities in subjects with schizophrenia. This chapter has been organized into sections. First, consideration will be given to the various types of psychophysiological abnormalities that have been found in subjects with schizophrenia. Then, studies employing psychophysiological measures to better understand the neuroanatomy and aetiology of schizophrenia will be reviewed. Finally, the use of psychophysiological measures as markers of psychotropic drug action will be considered. The emphasis of this chapter will be on recent studies, which should serve as an efficient entry into earlier literature.

WHAT IS A PSYCHOPHYSIOLOGICAL VARIABLE?

Before beginning a review of the literature on psychophysiology and schizophrenia, it might be helpful to define what is and what is not a psychophysiological variable. A psychophysiological variable may be defined as any quantitative measurement of the activity of one of the body's physiological systems. Such variables may be peripheral, such as measurements of skin conductance or heart rate, or more closely related to the central nervous system (CNS), such as the electroencephalogram (EEG). Prior to the advent of modern techniques for structural and functional neuroimaging, psychophysiological variables were widely used to investigate the neurobiology of schizophrenia. Over years of such investigation, investigators gradually came to use psychophysiological variables that reflected as much as possible the CNS (e.g., quantitative EEG) in favour of variables that were peripheral in nature. For this reason, less attention will be given in this chapter to psychophysiological markers of peripheral types. Further, the assessment of CNS psychophysiological variables in the context of specific, induced cognitive events (e.g., the event-related potential (ERP)) became a preferred strategy to link the study of hypothesized neurobiological substrates with cognitive or clinical phenomena known to be characteristic of subjects with schizophrenia.

The development of psychophysiological variables related to the CNS has been guided largely by the desire to identify abnormalities of neural circuits that can inform us about the pathophysiology of schizophrenia, including the explanation of its behavioural abnormalities. However, schizophrenia has long been thought to be an aetiologically heterogeneous disorder, and these same variables have been used in attempts to discover aetiological factors to differentiate one form of schizophrenia from another. Finally, psychophysiological variables have been employed to monitor the effects of drug treatments.

PSYCHOPHYSIOLOGICAL ABNORMALITIES IN SUBJECTS WITH SCHIZOPHRENIA

A variety of psychophysiological abnormalities have been demonstrated in subjects with schizophrenia using four predominant approaches: (1) measurement of electrodermal responses to experimental stimuli, (2) quantitative eye movements, (3) the resting EEG, and (4) time-averaged EEG responses to experimentally induced cognitive events (i.e., the ERP). Because the first two approaches employ variables that are peripheral in nature, they will be reviewed in less detail here. However, excellent recent reviews of electrodermal measures (Nuechterlein and Dawson, 1995) and eye movements (Levy *et al.*, 1993; Broerse *et al.*, 2001) are available elsewhere.

Electrodermal Measures

Abnormal electrodermal measures of two types have been found in subjects with schizophrenia: abnormalities of resting skin conductance levels and abnormalities of changes in skin conductance elicited by an experimental stimulus. Studies in this area suggest that schizophrenia subjects can be divided into two groups: responders and non-responders (Ohman, 1981). Responders are those subjects who respond normally to orienting stimuli (e.g., an unexpected noise) and have ordinary levels of baseline skin conductance. Non-responders fail to respond normally to orienting stimuli and have exaggerated or unusually variable levels of baseline skin conductance. More recent studies of schizophrenia subjects in different clinical states (i.e., psychotic and non-psychotic) suggest that while the baseline level of skin conductance may be state-dependent (i.e., higher levels are associated with psychotic states), failure to respond normally to orienting stimuli may be a trait phenomenon (Dawson *et al.*, 1992).

Quantitative Eye Movements

Abnormal eye movements during the tracking of a smoothly moving object have been observed for many years. Approximately half of individuals with schizophrenia demonstrate the intrusion of unusual saccadic movements while attempting to follow such a target across their visual field (Holzman, 1987). This abnormality does not appear to improve with treatment and is not found as commonly in individuals with other psychiatric disorders, such as bipolar disorder. Moreover, the same abnormality has been found in the

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

relatives of individuals with schizophrenia (Iacono and Clementz, 1993). Thus, abnormal visual tracking appears to be a trait of schizophrenia, and possibly related to the genetic risk of acquiring the disease.

EEG

The EEG has been widely used to provide a physiological assessment of the activity of the CNS in subjects with schizophrenia. Compared to other approaches, such as positron emission tomography (PET) or single photon emission computed tomography (SPECT), it is non-invasive and it can be repeated as often as needed. Moreover, the EEG has been shown to be sensitive to changes in states of consciousness and cognitive events. While the recent development of functional magnetic resonance imaging has begun to overshadow the EEG as a tool for investigating the neuroanatomical basis of cognition, it has continued to offer unique psychophysiological information about CNS function in subjects with schizophrenia.

Abnormalities of the resting EEG have been reported in subjects with schizophrenia for many years. A common finding has been the presence of excessive slow wave activity, especially across EEG leads that reflect the frontal cortex (Morihisa *et al.*, 1983). When schizophrenia subjects who are psychotic and in remission from psychosis are compared, excessive slow wave activity appears to be related only to the psychotic state (Koukkou and Manske, 1986). Other studies have shown that the resting EEG is overly reactive to simple changes in physiological state, such as opening the eyes (Shagass, 1991). This latter observation has led experts to hypothesize that EEG abnormalities in schizophrenia may be more related to the dysregulation of neural circuits rather than the steady presence of either hyper- or hypo-arousal (Shagass, 1991).

As mentioned above, EEG responses to an experimentally induced cognitive event (i.e., the ERP) have been widely used to search for further evidence of neural circuit dysregulation in schizophrenia. The ERP has two major advantages over the resting EEG. First, time-averaging of the EEG signal reduces unwanted, random noise, and second, the electrophysiological responses of a preselected brain region to specific perceptual or cognitive events can be studied. By selecting a perceptual or cognitive stimulus known to discriminate schizophrenia subjects from healthy controls or from subjects with another neuropsychiatric disorder, psychophysiological information specific to schizophrenia can be collected.

After an experimental stimulus, several waveforms are usually observed in the ERP. These waveforms are named according to their electrical direction (i.e., positive (P) or negative (N)) and their latency (in milliseconds) with respect to the stimulus. In some cases, progress has been made in identifying the neuroanatomical sources of these waveforms. Two of these waveforms have attracted the special interest of schizophrenia researchers over the years: the P50 and the P300.

One of the earliest ERPs following an experimental stimulus is the P50, which appears to reflect an orienting response of the CNS to a new perceptual event. Some investigators have suggested that the neuroanatomical sources of the P50 can be traced to the temporal lobe (Reite *et al.*, 1988; Goff *et al.*, 1980). Because of clinical observations that schizophrenia subjects cannot properly filter out non-salient perceptions, several groups have been interested in using the P50 to assess sensory gating mechanisms in schizophrenia. The typical experimental paradigm involves assessing the magnitude of reductions in the amplitude of the P50 during paired presentations of an auditory stimulus. Because the amplitude of the P50 is less than the amplitude of the background EEG signal, several pairings are averaged to extract the signal. This phenomenon is akin to other forms of behavioural desensitization or habituation, and has also been termed pre-pulse inhibition. In healthy subjects, intact sensory gating mechanisms are reflected by substantial reductions in P50 amplitude (Roth and Kopell, 1969). In subjects with schizophrenia, such reductions have been observed to be substantially blunted (Judd *et al.*, 1992; Freedman *et al.*, 1996).

The presence of an abnormal P50 ERP in schizophrenia subjects appears to have the characteristics of both a trait and a state. P50 abnormalities have been observed in outpatients with schizophrenia who were in relative remission from their psychosis (Dawson *et al.*, 1993). Also, P50 ERP abnormalities have been found among the relatives of subjects with schizophrenia, which suggests that such abnormalities may be a trait linked to the genetic risks of acquiring the disease (see below and Coon *et al.*, 1993). However, in contrast to these findings, P50 ERP abnormalities have been observed to be reversible in subjects with schizophrenia in some studies. For example, cigarette smoking and the administration of nicotine appear to mitigate P50 gating deficits in some subjects with schizophrenia (Adler *et al.*, 1993). This observation has been especially intriguing because of other evidence linking dysfunction of α-7 acetylcholine receptors stimulated by nicotine located on interneurones within the hippocampus to the pathophysiology of schizophrenia (Freedman *et al.*, 1995).

P300 is a later ERP, which appears to be a cognitive response to an unexpected stimulus. Because of the experimental characteristics of this ERP, it has been suggested to be related to working memory (Donchin and Coles, 1988). Both auditory and visual stimuli are capable of producing P300 ERPs, and the amplitude of the P300 can be modulated by a variety of experimental protocol parameters, such as adjusting the rarity of the unexpected stimulus (Pfefferbaum *et al.*, 1989). Unfortunately, it has been difficult to localize the neuroanatomical source or sources of the P300; many experts believe that it may be generated by a multitude of sources across the cerebral cortex. Nonetheless, the widespread nature of the P300 ERP allows one to investigate and compare its topography in neuropsychiatric disorders (Salisbury *et al.*, 1999).

P300 in subjects with schizophrenia compared to healthy controls has been observed to have both a reduced amplitude and a longer latency (Ford *et al.*, 1992). Again, this psychophysiological abnormality has the features of both a trait and state marker. In favour of the hypothesis that P300 abnormalities reflect a long-standing trait in subjects with schizophrenia, P300 amplitude reductions have been noted in schizophrenia subjects who are in remission from their psychosis (Mathalon *et al.*, 2000a). Moreover, as with the P50, P300 abnormalities have been found among the relatives of subjects with schizophrenia (Frangou *et al.*, 1997). The effects of antipsychotic drug treatment on P300 is less clear, however. In some studies, no changes in P300 have been noted during treatment with antipsychotic drugs (Ford *et al.*, 1994; Turetsky *et al.*, 1998a). However, in other studies, correlations between schizophrenia symptoms and the degree of P300 amplitude reduction have been reported (Pfefferbaum *et al.*, 1989; Turetsky *et al.*, 1998a; Mathalon *et al.*, 2000a).

Recent studies have focused on the neurobiological implications of a prolonged P300 latency in subjects with schizophrenia. In two cross-sectional studies, correlations have been noted between longer P300 latencies and longer durations of illness (O'Donnell *et al.*, 1995; Mathalon *et al.*, 2000b). Combined with evidence from *in vivo* neuroimaging studies that suggest the presence of progressive cortical grey matter losses in some subjects with schizophrenia (Gur *et al.*, 1998), these findings support recent proposals that schizophrenia is a progressive disease process in at least some individuals. Moreover, these studies provide support for the notion that P300 latency may be a useful method of detecting the phenomenon.

Other ERPs and EEG-based psychophysiological measures continue to be developed to investigate the neurobiology of schizophrenia. A negative ERP with a long latency, the N400, has been

shown to have a diminished amplitude and prolonged latency in schizophrenia subjects compared to healthy controls (Koyama *et al.*, 1991; Olichney *et al.*, 1993). Because this ERP is sensitive to components of language processing, in particular semantic congruity (Kutas and Hillyard, 1984), N400 abnormalities in schizophrenia have been interpreted as evidence of a fundamental defect in language processing that may underlie disorganized thinking. In addition to ERPs, new techniques for recording specific EEG resonances in response to repeated auditory and visual stimulation are being used to study schizophrenia. Abnormal synchronization in the alpha (Jin *et al.*, 2000) and gamma (Kwon *et al.*, 1999) ranges of EEG frequencies have been recently reported in subjects with schizophrenia. These EEG variables offer a complementary approach to ERPs for testing hypotheses related to the presence and characteristics of abnormal cortical circuitry in subjects with schizophrenia.

PSYCHOPHYSIOLOGICAL VARIABLES AS MARKERS OF NEURAL CIRCUIT DYSFUNCTION

Abnormalities of brain structure have been shown to be a key biological characteristic of schizophrenia. Moreover, these abnormalities appear to involve a group of functionally related structures in the temporal and frontal lobes. *In vivo* magnetic resonance (MR) imaging has uncovered evidence of volume reductions within the temporal lobe (Suddath *et al.*, 1989) and specifically involving the hippocampus (see Nelson *et al.*, 1998 for a meta-analysis of results) of schizophrenia subjects. Moreover, the computerized analysis of hippocampal shape has revealed that these volume losses are localized to the head of the hippocampus (Csernansky *et al.*, 1998) where projections from the hippocampus to the frontal cortex are plentiful. Volume reductions have also been reported in the parahippocampal gyrus, which forms the major input to the hippocampus (Shenton *et al.*, 1992) and in the superior temporal gyrus (McCarley *et al.*, 1993).

In vivo MR studies have also provided evidence for reductions in the total volume of the frontal lobe (Andreasen, 1986), the grey matter volume of the frontal lobe (Zipursky *et al.*, 1992) and the white matter volume of the frontal lobe (Breier *et al.*, 1992). While there have not yet been *in vivo* MR studies of the cingulate gyrus, post-mortem studies of that brain structure also suggest the presence of anatomical irregularities. Specifically, Benes and co-workers demonstrated decreased numbers and somal size of GABA interneurones, as well as compensatory increases in GABA receptors on pyramidal cells (Benes *et al.*, 1991, 1992) of the cingulate gyrus.

Moreover, abnormalities of brain structure listed have been observed early in the course of illness in subjects with schizophrenia and appear to show little progression with age in most subjects (Weinberger, 1986; Csernansky and Bardgett, 1998). This lack of progression has led many to suggest that brain structure abnormalities in schizophrenia may occur, at least in part, through defects in a neurodevelopmental process (Csernansky and Bardgett, 1998; Pearlson and Marsh, 1999). The development of cortical–cortical and subcortical–cortical connections is a critical step in successful brain organization (Goldman-Rakic, 1987). When neurones do not achieve their proper location within a brain structure due to neurodevelopmental aberrations they may not be supplied with their required growth factors and die. Thus, disturbances of neuronal division and migration are plausible explanations for the observed changes in neuronal density and grey matter volume (Bloom, 1993).

Evidence from psychophysiological studies has provided complementary evidence for functional abnormalities within this network of frontal and temporal lobe structures in schizophrenia. As reviewed above, the sources for the P50 appear to include structures within the temporal lobe, while sources for the P300 may exist within the frontal cortex. With the development of multi-electrode arrays, the topography of ERPs has begun to be investigated in subjects with schizophrenia. Using a 64-channel array, Potts *et al.* (1998) showed that P300 amplitude reductions were asymmetric; i.e., P300 amplitudes in left temporal lobe leads were more reduced than in right temporal lobe leads. Moreover, this same group has shown that this topography of P300 amplitude reductions may be relatively specific to schizophrenia, as a different topography of P300 reductions was found in subjects with manic psychosis (Salisbury *et al.*, 1999).

Other research groups have also provided evidence of a specific topography for P300 abnormalities in schizophrenia subjects. Bruder *et al.* (1999) found asymmetric reductions (left > right) of this late positive ERP in subjects with schizophrenia. Turetsky *et al.* (1998b) applied principal components analysis to data collected from a 16-electrode array and extracted three subcomponent to the P300 ERP. Specific abnormalities were then found for individual P300 subcomponents related to gender and clinical presentation (i.e., deficit versus non-deficit symptoms).

Combining evidence from high-resolution structural brain imaging and multi-array ERP studies, a picture of structural and functional abnormalities within a circuit of connected structures in the temporal and frontal lobes is beginning to emerge to explain the pathophysiology of schizophrenia. As additional information is gained from studies of functional MR imaging, this picture should come into greater focus. However, it should be kept in mind that structures within the temporal and frontal lobes are connected indirectly by pathways passing through the basal ganglia, and that the basal ganglia, especially the ventral striatum, have been hypothesized to be an important site of action for antipsychotic drugs (Csernansky and Bardgett, 1998). Thus, additional experimental approaches may be needed that include examinations of these deeper brain structures to add to our understanding of the neurobiology of schizophrenia.

PSYCHOPHYSIOLOGICAL STUDIES AND AETIOLOGICAL FACTORS

Two types of factors have been brought forward to explain the aetiology of schizophrenia: (1) genetic factors, and (2) environmental trauma to the CNS early in life. One experimental approach that has provided evidence of the genetic basis of schizophrenia has been the search for neurobiological abnormalities among the relatives of schizophrenia subjects. However, evidence to support environmental trauma as the aetiological basis of schizophrenia has been more difficult to collect, partly because detailed information about pregnancy and labour difficulties is often not available for analysis.

Several research studies have suggested that the relatives of subjects with schizophrenia may have brain structure abnormalities that are similar, but of lesser magnitude, to those observed in subjects with the disease. In a study of twins discordant for schizophrenia, Suddath *et al.* (1990) found a reduction in the volume of the left temporal lobe and hippocampus in affected twins compared to the unaffected co-twins. Interestingly, however, the 'unaffected' co-twins demonstrated brain structure volumes that were intermediate between those demonstrated by the ill co-twins and healthy controls without schizophrenia or a family history of schizophrenia. Also, Seidman and colleagues found that the non-psychotic siblings of schizophrenia patients had small decreases in the volume of the hippocampus–amygdala complex (Seidman *et al.*, 1997, 1999) and the thalamus (Seidman *et al.*, 1999) as compared to healthy controls without a family history of psychiatric disorders. Such studies provide preliminary but powerful evidence that genetic factors may be involved in the development of brain structure abnormalities in schizophrenia.

Psychophysiological studies of the relatives of subjects with schizophrenia suggest that individuals at genetic risk for developing schizophrenia have functional abnormalities related to the same group of brain structures. For example, abnormalities of P50 suppression have been reported among the relatives of schizophrenia subjects and in individuals with disorders thought to be genetically related to schizophrenia. Freedman *et al.* (1997) reported that the failure to suppress P50 after an auditory stimulus was present in relatives of schizophrenia probands. Moreover, this group discovered evidence of a linkage between this psychophysiological abnormality and a genetic locus on chromosome 15. In support of this exciting finding, Clementz *et al.* (1998) reported that similar P50 suppression abnormalities could be demonstrated in both schizophrenia subjects and their first-degree relatives. Finally, failure to suppress the P50 ERP after an auditory stimulus has been found recently in individuals with schizotypal personality disorder, a disorder found more commonly among the relatives of schizophrenia subjects than in the general population (Cadenhead *et al.*, 2000).

In keeping with the hypothesis that ERP abnormalities are present in individuals at risk for schizophrenia, Frangou *et al.* (1997) reported that both schizophrenia subjects and their first-degree relatives have prolonged P300 latencies compared to healthy controls without a family history of schizophrenia. Also, P300 amplitudes among these relatives were intermediate between schizophrenia subjects and healthy controls. Similar results have been found recently by Karoumi *et al.* (2000), who reported prolonged P300 latencies among the well siblings of subjects with schizophrenia. However, in contrast, Weisbrod *et al.* (1999) have recently reported reduced P300 amplitudes, but not prolonged P300 latencies, among the discordant monozygotic twins of subjects with schizophrenia. Discrepancies between these various results may be due to small sample sizes and the likelihood that there is some neurobiological heterogeneity among subjects with schizophrenia. In keeping with this hypothesis, Frangou *et al.* (1997) also reported that there was a bimodal distribution of P300 latencies among the first-degree relatives of schizophrenia subjects, with only 35% of such subjects demonstrating prolonged P300 latencies.

Somewhat different results were found in a study of the children of subjects with schizophrenia studied as part of the New York High-Risk Project (Friedman *et al.*, 1995). In this ground-breaking study, the children of subjects with schizophrenia and affective disorders were studied and compared to the children of subjects with mood disorders and controls longitudinally for several years. ERP testing was carried out when these children were adolescents (ages 11–19) and correlated with clinical testing as young adults (ages 20–28). Unfortunately, no differences were observed in P300 amplitudes among the three groups of adolescents, and no relationship was found between reduced P300 amplitudes in the adolescent children of the schizophrenia subjects and the occurrence of a later diagnosis of psychosis.

Despite some contradictory results, most studies suggest that individuals at risk for developing schizophrenia have ERP abnormalities that at least resemble the abnormalities found in individuals with the disease. Especially exciting have been suggestions that ERP abnormalities, such as sensory gating deficits, may be used as quantitative traits in future genetic studies of schizophrenia. However, because of the likelihood of genetic heterogeneity among individuals with schizophrenia, ERP abnormalities may not be found in all individuals with schizophrenia nor in all individuals at risk for developing schizophrenia.

PSYCHOPHYSIOLOGICAL VARIABLES TO MONITOR THE EFFECTS OF TREATMENT

Psychophysiological variables have also been employed to monitor the effects of treatments in subjects with schizophrenia. Of course, experiments where changes in psychophysiological measures are sought as an index of successful treatment must be based on observations that such measures are state-dependent. In addition, EEG markers have sometimes been used to document the activity of an experimental drug in subjects with schizophrenia, independent of any hypothesis that such subjects are characterized by abnormalities of such EEG measures.

Early studies comparing subjects with schizophrenia that were 'drug-free' or treated with conventional antipsychotic drugs suggested that conventional antipsychotic drugs were not capable of ameliorating P50 abnormalities (Freedman *et al.*, 1983). However, somewhat at odds with this apparent irreversibility of P50 abnormalities, administration of the indirect dopamine agonist, amphetamine, to normal subjects was found to disrupt the suppression of P50 after an auditory stimulus (Light *et al.*, 1999). This latter observation suggests that a reversible schizophrenia-like psychophysiological state can be produced. Perhaps helpful in resolving the uncertainty as to whether failure to suppress P50 after an auditory stimulus is reversible or irreversible, Light *et al.* (2000) have recently reported that while conventional antipsychotic drugs were not able to normalize P50 suppression in schizophrenia subjects, treatment with three second-generation antipsychotic drugs (i.e., risperidone, olanzapine and clozapine) did so. These findings suggest that while dopaminergic excesses may disrupt normal P50 suppression mechanisms, blockade of dopamine receptors (by conventional antipsychotic drugs) is not necessarily adequate to restore such disruptions when they are found in individuals with schizophrenia. The actions of second-generation antipsychotic drugs at neuroreceptors other than dopamine, such as serotonin or noradrenaline (norepinephrine), appear to be necessary to accomplish this task.

The question of whether P300 abnormalities in schizophrenia subjects can be normalized by antipsychotic medications also remains controversial. In a placebo-controlled study of schizophrenia subjects treated with the selective dopamine receptor antagonist, raclopride, treatment was not found to normalize P300 amplitudes (Ford *et al.*, 1994). However, in a more recent study of schizophrenia subjects treated with two other dopamine receptor antagonists, remoxipride or haloperidol, abnormalities in both P300 amplitude and latency were reversed (Coburn *et al.*, 1998). Unfortunately, the effects of other second-generation antipsychotic drugs on P300 abnormalities in schizophrenia subjects have not yet been well investigated. However, given the results obtained to date in reversing P50 abnormalities using second-generation antipsychotic drugs (see above), such treatments may have more promising effects with respect to normalizing P300 and other psychophysiological abnormalities.

CONCLUSIONS

A variety of psychophysiological abnormalities have been found in subjects with schizophrenia (see Table XVII-6.1 for a summary). These abnormalities often have the characteristics of both state- and trait-dependent factors. In keeping with psychophysiological abnormalities as neurobiological traits, similar abnormalities have been found in individuals at genetic risk for developing schizophrenia. In addition, studies combining these psychophysiological measures with cognitive assessments or *in vivo* structural neuroimaging suggest that schizophrenia may be related to dysfunction of a circuit of frontal and temporal lobe brain structures. Research has yet to determine whether psychophysiological abnormalities can be reversed by treatment in subjects with schizophrenia. While treatment with conventional antipsychotic drugs has been disappointing in this regard, treatment with second-generation antipsychotic drugs has offered more promising results.

Table XVII-6.1 Summary of the characteristics of psychophysiological variables in subjects with schizophrenia

Variables	Source	Reversible	Present in at-risk subjects
Skin conductance responses	Peripheral	No	Unknown
Eye tracking movements	Frontal lobe	No	Yes
Resting EEG	Cerebral cortex	Unknown	Unknown
P50 ERP	Temporal lobe	Variable[a]	Yes
P300 ERP	Frontal lobe	No	Yes

[a] Reversible by second-generation antipsychotic drugs, but not by conventional antipsychotic drugs.

Psychophysiological variables will continue to be important variables in studies of the neurobiology of schizophrenia. Because of our ability to relate these variables to both cognitive elements and neuroanatomical structures, they provide essential information for forming a comprehensive understanding of the neurobiology of schizophrenia. Because of the rapid rise of methods for functional MR imaging, future research is likely to involve the combination of such methods with psychophysiological measures. Further, techniques for psychophysiology research will continue to develop through improvements in EEG technology and more specific cognitive stimuli.

The Neuropsychology of Schizophrenia

L. Krabbendam and J. Jolles

INTRODUCTION

Schizophrenia is a major psychiatric disorder characterized by a disruption in affective, cognitive and social domains, which results in compromised ability to adapt to a changing environment and to function adequately in the community. The point prevalence, expressed as the number of cases per 1000 persons at risk, is estimated at between 1.4 and 1.6, and the lifetime prevalence ranges from 0.5% to 1.0% of the population (Jablensky, 1995). The disorder usually manifests itself between the ages of 18 and 25, but according to current neurodevelopmental models of schizophrenia may already begin during prenatal development. More specifically, it is hypothesized that a failure occurs during the period of cell migration, leading to non-optimal connections between brain areas (e.g., Weinberger, 1987). The onset of psychotic symptoms is so much later, when the affected part of the brain matures and is called 'on line' (Weinberger, 1987).

With respect to the neuropsychology of schizophrenia, the notion of deterioration in cognitive and behavioural functions was implicit in the initial conceptualization of the disorder. Kraepelin (1919) labelled the disorder 'dementia praecox', defining it as an irreversible deteriorative condition. In past decades, numerous studies have yielded evidence for cognitive deficits in patients with schizophrenia. In the 1960s, investigations into disrupted attentional functions started with systematic experimental investigations of reaction time parameters in the differentiation of schizophrenics from non-psychiatric individuals. Clinical research in the same period had shown that schizophrenic patients performed abnormally on measures of general intellectual functioning (e.g., Heaton and Crowley, 1981). Indeed, it turned out that when a group of patients with schizophrenia are compared to healthy controls on a neuropsychological test battery, performance of the patient group was worse on almost all of the tests and comparable to the performance of patients with known neurological damage. However, a description of the symptoms, cognition and behaviour of schizophrenics in terms of the dichotomy 'organic' versus 'functional' has not proved very fruitful. Nowadays, schizophrenia is considered as a psychiatric disorder with neuropsychological correlates. This more accurately characterizes the illness and enables the investigation of specific brain–behaviour relationships which underlie the variability of symptoms and neurobehavioural systems which may be affected.

In this chapter we present the neuropsychological aspects of schizophrenia, with an emphasis upon the major cognitive and behavioural functions that are affected. We do not attempt to give an elaborate overview of clinical neuropsychological research which has shown, generally, deficits in performance of schizophrenic subjects. Rather, we focus on neurocognitive processes involved in the expression of the disease and elaborate on possibly relevant modulatory factors, and on current models which attempt to understand the behavioural expression of the disease. Attentional functions, executive functioning and memory — notably working memory — are described in relation to the various experimental techniques used to measure neurocognitive processes. Important notions are evaluated such as those regarding the processing of context, theory of mind and monitoring. We will also consider vulnerability factors such as genetic and environmental factors and the relation with factors such as medication, cognitive therapy and the course of deficits. Closing paragraphs are devoted to a description of the functional significance of the neurocognitive and behavioural changes to allow better understanding of the symptoms and neurobehavioural profile of schizophrenics. The chapter does not contain material concerning neurological or 'brain localizational' aspects of schizophrenia, because Chapter XVII-8 in this book is dedicated to that subject.

THE NATURE OF THE NEUROCOGNITIVE DEFICITS IN SCHIZOPHRENIA

The range of deficits in schizophrenia is extremely broad. Roughly, when a battery of neuropsychological tests is administered to a group of patients with chronic schizophrenia, mean performance of the group will be significantly below normal performance on at least half of the tests. Reviewing all findings would be nearly impossible, and would probably obscure the central issues in this review. Therefore, this section summarizes research on three cognitive domains: attention, memory and executive function. These were chosen because impairments on these domains have been consistently implicated in schizophrenia research, and sophisticated paradigms have been developed to elucidate the nature of dysfunction in these domains.

Attentional Functions

Both clinical descriptions and subjective accounts of schizophrenia emphasize attentional deficits. Attention is a multifactorial construct, including the ability to maintain an alert state, to orient to novel stimuli, to filter relevant information and to rapidly discriminate stimuli for some duration of time. Two aspects of attention that have received particular attention in schizophrenia research are sustained and selective attention. Sustained attention refers to the capacity to maintain a state of readiness to respond to small changes in the environment. Selective attention is the capacity to focus while ignoring irrelevant information.

Sustained Attention

A widely used test to assess sustained attention is the Continuous Performance Test (CPT). In this test, stimuli, usually letters or

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

digits, are presented briefly one at a time in a random order. The subject has to respond when a certain target stimulus appears — in some variants of the task only when preceded by a certain cue. Patients with schizophrenia usually display reduced sensitivity on the CPT (Addington and Addington, 1997; Nuechterlein *et al.*, 1994; Van den Bosch *et al.*, 1996). This deficit is particularly pronounced on versions with high processing loads; for example, tasks with rapid stimulus presentation, stimulus degradation or when the previous stimulus must be remembered to make the current decision (Nelson *et al.*, 1998; Nuechterlein *et al.*, 1994). Although impaired CPT performance is a robust finding, there is as yet no consensus concerning the precise mechanism of the impaired performance. Cohen and Servan-Schreiber (1993) have constructed a computer simulation model of the CPT and other tasks to test their hypothesis that the core cognitive deficit in schizophrenia is 'an impairment in maintaining contextual information over time and in using that information to inhibit inappropriate responses'. They showed that a single disturbance to the module responsible for representing and maintaining context yielded performance impairments similar to those seen in schizophrenia. In a subsequent study, a variant of the CPT designed to elicit deficits in the processing of contextual information was administered to patients with first-episode schizophrenia and patients later in the course of their illness (Servan-Schreiber *et al.*, 1996). Specifically, the frequency of cue–target sequences (e.g., A–X) was increased, to introduce a strong tendency to respond to the letter X. Thus, in the non-cue followed by target condition (e.g., B–X), subjects had to rely on the previous letter as a context to inhibit the response to X. Two delay intervals between cue and target were used, namely 750 ms and 5 s. The prediction was that patients with schizophrenia would perform worse in the long delay condition, particularly with regard to the number of non-cue–target errors, because of a reduced capacity to maintain context. Indeed, the performance of unmedicated patients followed the pattern predicted by the context hypothesis. The deficit was worse in unmedicated patients with a longer course of the illness. The authors interpreted the results as support for the view that a single deficit in the processing of context may underlie the cognitive impairments in schizophrenia.

However, a recent study has called this explanation into question and instead suggested that a problem in encoding is at the core of deficits on this type of tasks. This study used variations of the CPT to investigate possible mechanisms of impairment, including stimulus–response mapping, use of context and working memory (Elvevåg *et al.*, 2000). The amount of stimulus–response mapping that was required was varied by using two kinds of cue–target pairs, namely with and without inherent instructions (e.g., 'ready' followed by 'press' versus 'one' followed by "nine"). As in the study by Servan-Schreiber and colleagues (1996), the sensitivity to context problems was manipulated by varying the frequency of the target stimuli; to investigate the involvement of working memory, two delay intervals between the cue and the target were used (namely, 1000 ms and 3000 ms). These tasks were administered to 20 inpatients with schizophrenia and 30 healthy volunteers. As expected, the patients performed significantly worse on all tasks than did the comparison subjects. Contrary to expectations, however, there was no differential impact of any of the task manipulations on the speed of performance of the patients. The only effect of the task manipulations was that patients made more errors at short delay intervals. This pattern of results suggests difficulties in the rapid encoding of information, leading to a differentially impaired performance in short delay intervals between stimuli, where the second stimulus interferes with constructing a representation of the first. In sum, impairment on the CPT is a robust finding in schizophrenia, but there might be more than one pathway to poor performance. One explanation suggests a deficit in the processing of context, but it has also been proposed that a dysfunction of rapid encoding is at the core of impaired CPT performance.

Selective Attention

Selective attention is often assessed using the Stroop Colour–Word Test (SCWT; Stroop, 1935). The SCWT has an interference component that requires the subject to inhibit an automated response (word reading) in favour of a less salient aspect (colour naming). A typical Stroop task consists of three conditions: (1) word reading; (2) colour naming; and (3) interference (colour names printed in conflicting colours). Several studies have demonstrated impaired performance on the SCWT, particularly in the interference condition (Barch and Carter, 1998; Krabbendam *et al.*, 2000; Liddle and Morris, 1991). Recently, investigators have begun to use single-trial versions of the Stroop task, instead of lists of stimuli printed on cards, and included a congruent condition in which the word and the print colour are the same. Typically, reaction times are shorter in congruent compared to neutral conditions, when there is no relation between colour and semantic meaning (e.g., the word chair printed in blue). This phenomenon is known as Stroop facilitation. Studies using a single-trial Stroop task have yielded evidence for an increased facilitation effect in schizophrenia (Carter *et al.*, 1992; Cohen *et al.*, 1999). This effect was further examined by Barch and colleagues (1999). Forty patients with schizophrenia and 20 healthy controls were administered blocks of congruent, incongruent and neutral trials. In each trial, a stimulus was presented in one of four colours: red, blue, green or purple. The task was to name the colour in which the stimulus was printed as quickly as possible. The congruent trials consisted of colour names presented in its own colour. The incongruent condition consisted of colour names presented in one of the three remaining colours. The neutral trials consisted of either words or squares, printed in one of the four colours. Patients with schizophrenia showed increased facilitation compared to normal controls in both word and non-word neutral conditions. In the non-word condition, the stimulus does not interfere with the (verbal) colour-naming response. Thus, an increased facilitation effect in this condition means that part of this effect can be attributed to a greater influence of the word in the congruent condition. Apparently, patients are less able than controls to ignore the word dimension in this condition, possibly due to selective attention deficits.

Memory

Verbal Memory and Intentional Learning

Memory impairment in patients with schizophrenia has been reported in several studies (Landrø, 1994; McKenna *et al.*, 1990; Saykin *et al.*, 1991). Yet, poor memory may be the consequence of a number of factors, including medication or psychopathology. To the extent that this is true, these factors cannot completely account for the memory deficit in schizophrenia. A recent meta-analysis of 70 studies documented a significant and wide-ranging deficit, which was not due to potential confounding factors such as medication status, age or severity of psychopathology (Aleman *et al.*, 1999). Verbal memory, including story recall and word list learning, seems to be more severely affected than non-verbal memory (Saykin *et al.*, 1991), although this difference was not significant in the meta-analysis by Aleman and colleagues (1999). Free recall is particularly affected (Beatty *et al.*, 1993; Paulsen *et al.*, 1995), indicating a deficit of retrieval of information. However, impaired recognition is sometimes observed, at least in the more severely disturbed patients (Clare *et al.*, 1993; Landrø, 1994), which suggests that consolidation of information may also be impaired. It has been suggested that the memory deficit in schizophrenia is in some respects analogous to the classical amnesic syndrome with intact implicit memory, relative sparing of short-term recall, an accelerated forgetting and poor long-term recall (McKenna *et al.*,

1990). This view is not supported by the meta-analysis by Aleman and colleagues, which yielded evidence for an impaired short-term memory and a normal rate of forgetting (Aleman *et al.*, 1999). Nevertheless, a relative sparing of implicit learning and memory has been reported in several studies (Clare *et al.*, 1993; Kern *et al.*, 1997).

Working Memory

An aspect of memory that has received particular attention in schizophrenia research is working memory. Working memory is the type of memory that is active and relevant only for a short period of time and is defined in content and duration by the action it subserves (Baddeley and Hitch, 1974; Fuster, 1989). Working memory accounts for the ability to guide behaviour by cognitive representations in the face of varying degrees of distraction and thus to base behaviour on thoughts and intentions rather than on direct stimulation. The term is related to the notion of context introduced in the previous section. According to Baddeley and Hitch, working memory consists of a superordinate central executive system and two slave systems for the transient storage of visuospatial and verbal information (the visuospatial sketchpad and phonological loop). Unfortunately, the term working memory is used in different ways (Baddeley and Hitch, 1994; Perry *et al.*, 2001). A major source of confusion is that sometimes only involvement of the slave systems is required to perform the working memory tasks, and sometimes the central executive system as well. Perry *et al.* (2001) propose to distinguish between transient 'online' storage, when only storage and retrieval of information are required, and executive-functioning working memory, when in addition to storage and retrieval manipulation of the information is required. The distinction between forward and backward digit spans may correspond roughly to the distinction between transient storage and executive function working memory. Another example of transient online storage is the delayed response paradigm employed by Goldman-Rakic and colleagues to investigate working memory in non-human primates (Funahashi *et al.*, 1989; Goldman and Rosvold, 1970). There are numerous tasks that tap into executive-functioning working memory, such as the Tower of London (Shallice, 1982) and the Wisconsin Card Sorting Test (WCST; Berg, 1948; Heaton, 1981). Although these tasks may not be designed specifically to assess working memory, they do require to keep in mind instructions, goals and concepts (Goldman-Rakic, 1994). Does the working memory impairment in schizophrenia involve both transient 'online' storage and executive functioning, or is the first aspect relatively intact? In general, the findings point to an impairment of both functions, although the picture is not entirely consistent. Several studies have demonstrated impaired performance on transient storage tasks in schizophrenia (e.g., Fleming *et al.*, 1997; Park and Holzman, 1992; Spitzer, 1993; Pantelis *et al.*, 1997). For example, Pantelis *et al.* (1997), using tests from the Cambridge Neuropsychological Test Automated battery (CANTAB), found evidence for impaired performance on a task that required the subject to remember a sequence of squares presented on a screen. Park and Holzman (1992) also found evidence for impaired transient storage on a spatial working memory task. However, in the same sample auditory working memory assessed with digit span forward was intact. Also, in a comparison of monozygotic twins discordant for schizophrenia the affected twin performed worse than the healthy twin in the backward but not in the forward condition (Goldberg *et al.*, 1990). However, most studies point to significant impairments in both digit span tasks. This is also apparent from the meta-analysis by Aleman *et al.* (1999). Data from 18 studies on forward span and seven studies on backward span yielded no significant difference in effect size between the two spans.

Semantic Memory

The term semantic memory refers to stored information that is impersonal, and includes knowledge of words and their meanings, knowledge about objects and their categorizations, and general information about the world. The term was introduced by Tulving to distinguish this form of memory from episodic memory, the memory for personally experienced events (Tulving, 1983). Both forms of memory are considered to be closely related and in continuous interaction with each other. The notion of impaired semantic knowledge in schizophrenia dates from several decades ago. Cameron has suggested that the core feature of thought disorders in schizophrenia was overinclusive thinking, a vagueness of boundaries between concepts making them overextensive and able to accommodate logical contradictions (Cameron, 1939). Subsequent studies have provided support for this notion (Chen *et al.*, 1994; Cutting *et al.*, 1987; Payne, 1973). The study by Chen and colleagues used a task that required subjects to verify words as members or non-members of a conceptual category. The words differed in their degree of semantic relationship to the category. Control subjects had the longest reaction time for items at the borderline of the category (e.g., penguin in the category of birds). In contrast, patients with schizophrenia took longest to respond to items that were outside the category, but semantically related to it (e.g., airplane in the category of birds). According to the authors, this pattern of results suggests an outward shift of semantic category boundaries in schizophrenia. Overinclusive thinking may be explained in terms of an activated semantic network, in which activation spreads faster than normal to other related concepts and thereby crosses over the usual boundaries of concepts (Spitzer, 1993). Such heightened activation has been experimentally demonstrated using semantic priming paradigms. Patients with schizophrenia show more semantic priming (Kwapil *et al.*, 1990; Maher *et al.*, 1996), most notably when the prime and the target are indirectly semantically related (e.g., lemon — sweet) (Spitzer *et al.*, 1993). Thus, semantic memory in schizophrenia may be qualitatively different from semantic memory in healthy controls.

Executive Functions

The Wisconsin Card Sorting Test

The executive functions comprise capacities for volitional activity, forward planning and self-regulation (Lezak, 1995). The most widely used test of executive functions is the Wisconsin Card Sorting Test (WCST). The WCST is a complex test involving concept formation, working memory and cognitive flexibility. A large amount of literature suggests impaired performance in schizophrenia in terms of increased numbers of perseverative errors and fewer categories achieved, when compared to healthy controls (Goldberg *et al.*, 1994; Haut *et al.*, 1996; Morice, 1990; Sullivan *et al.*, 1993). However, performance on the WCST seems to be heterogeneous (Braff *et al.*, 1991) with poor performance restricted to a subgroup of patients characterized by the presence of other cognitive deficits (Bellini *et al.*, 1991; Goldstein *et al.*, 1996), as well as negative symptoms and more hospitalizations (Butler *et al.*, 1992). Other authors have directed attention to the unusual and strong relationship between performance on the WCST and general intellectual ability, ageing and education, which suggests that non-specific factors account for a substantial proportion of WCST performance in schizophrenia (Heinrichs, 1990; Stratta *et al.*, 1993; Heinrichs and Zakzanis, 1998). Given the complexity of the WCST, several studies have attempted to identify specific processes that underlie test performance. Gold *et al.* (1997) have suggested that working memory, assessed by a novel measure called 'letter–number span', is a critical determinant

of WCST performance in schizophrenia. Yet, even this simpler task involves functions other than working memory, for example, aspects of executive functions. This measure involved the auditory presentation of a mixed series of alternating numbers and letters, the task being to respond by first saying the numbers in order from the smallest to the largest, followed by saying the letters in alphabetical order. In another study, a significant correlation between WCST perseverative errors and time spent on the interference test of the SCWT was observed and the authors concluded that these tests have the involvement of mental control and cognitive flexibility in common (Rossi *et al.*, 1997a). In sum, the WCST is a widely used measure of executive functions, but due to its complexity it is unclear which cognitive processes underlie poor performance, while several studies have indicated that part of the variance in WCST performance is shared with general factors, such as intellectual ability, ageing and number of hospitalizations.

Tower of London

Shallice (1982) introduced this test, derived from the Tower of Hanoi puzzle. The task is to move a number of coloured beads placed on three upright poles so as to reproduce a certain pattern. The subject must look ahead and divide the task into a series of subtasks, and carry these out in the right order to obtain the solution in a minimum number of moves. Pantelis *et al.* (1997) used an automated version of this task, which is part of the CANTAB. This allowed for the registration of planning and execution latencies. Performance of hospitalized patients with schizophrenia ($N = 36$) was compared to that of normal subjects and patients with neurological disorders. The patients with schizophrenia were able to complete the task, but made fewer solutions within the minimum number of moves, and required more moves for completion compared to the healthy volunteers. Also, time needed for completion was longer for the patients with schizophrenia than for the healthy volunteers. The patients with schizophrenia were not impaired in their 'initial thinking' (planning) latencies, but had significantly prolonged 'subsequent thinking' (execution) latencies. This pattern resembled that of the group with frontal lobe lesions and contrasted with the prolonged 'initial thinking' time seen in Parkinson's disease. However, in a sample of 24 outpatients with schizophrenia, performance on the Tower of London was normal, whereas on the WCST and the Behavioural Assessment of the Dysexecutive Syndrome (BADS; see next section) performance was impaired (Krabbendam *et al.*, 1999). Although this study did not record time needed for completion, the findings do suggest that the Tower of London is less sensitive to deficits of planning than the other two tests.

The Behavioural Assessment of the Dysexecutive Syndrome

It has been difficult to develop satisfactory methods for demonstrating and quantifying executive functions, because the structured nature of most neuropsychological examinations gives the patient insufficient opportunity to make use of these functions (Lezak, 1982). Moreover, the standard tests tend to focus on individual components of executive functioning. Yet, what is impaired in patients with impaired executive functions is the ability to initiate, integrate and monitor the use of these components (Shallice and Burgess, 1991). Patients with gross difficulties in daily life may therefore perform within normal limits on the standard executive tests. To overcome these shortcomings, a test battery has been developed, with the aim of being able to predict which everyday problems would arise as a result of impaired executive functioning. The Behavioural Assessment of the Dysexecutive Syndrome (BADS; Wilson *et al.*, 1996) presents the subject with a series of unstructured tasks that are designed to reflect daily life situations. For example, in the subtest Modified Six Elements the subject is told to do six tasks (dictation, simple arithmetic and picture naming, each of which has two sections) in 10 minutes. It is impossible to complete all tasks in 10 minutes, but the subject should do at least something of all six sections, without breaking certain rules. Recent findings suggested that the BADS can indeed identify executive deficits in schizophrenia (Evans *et al.*, 1997; Krabbendam *et al.*, 1999). Significant impairments on the BADS were even found in a subgroup who displayed intact general intellectual functioning (Evans *et al.*, 1997).

General Intelligence

Global intellectual decline is a common finding in schizophrenia (Braff *et al.*, 1991; Blanchard and Neale, 1994; see Aylward *et al.*, 1984, for a review of earlier studies), even in first-episode patients (e.g., Bilder *et al.*, 2000; Mohamed *et al.*, 1999). However, a decline in intelligence quotient (IQ) may not be universal. A cluster analysis of neurocognitive data of 104 patients with chronic schizophrenia yielded a five-cluster solution, two being characterized by average IQ and a normal cognitive profile, except for motor impairments and slightly higher than normal recall intrusion rates, respectively (Heinrichs and Awad, 1993; Heinrichs *et al.*, 1997). Only one cluster (24% of the patients) suggested generalized impairment, the other two clusters comprising patients with low-average IQ and a selective executive or executive-motor dysfunction. In a sample of 117 consecutively admitted patients with chronic schizophrenia, Weickert and colleagues (2000) found a general intellectual decline of 10 points or more from premorbid levels, estimated by means of reading scores, in 60 patients (51%). The remaining patients showed no significant decline relative to estimated premorbid IQ. Half of these patients (i.e., 25% of the total sample) had impaired premorbid IQs and half displayed average estimated premorbid intellectual levels. This latter group showed cognitive profiles similar to normal, except for the presence of executive function deficits and, possibly, attention and encoding. This pattern of compromised executive functions in the presence of normal intelligence has been described previously (Elliot *et al.*, 1995; Evans *et al.*, 1997; Heinrichs and Awad, 1993; Shallice *et al.*, 1991).

The concept of intelligence encompasses a range of cognitive functions and abilities. Therefore, intelligence tests are not well suited to examine specific patterns of deficits, unless the findings are considered in the context of detailed cognitive assessments. Nonetheless, one advantage is associated with the use of intelligence tests. That is, because intelligence tests are widely used in schools, conscript cohorts and hospitals, large data sets are available. This allows for the possibility to investigate the course of the intellectual impairment from premorbid to postmorbid state. Findings based on these data will be discussed below in the sections on course of the deficits and on cognitive vulnerability indicators.

Integrative Approaches

Generalized Deficit

An issue that continues to raise considerable debate is whether the cognitive deficit in schizophrenia can best be characterized in terms of a generalized or a specific impairment. Given the broad range of cognitive deficits, the most parsimonious explanation would be that patients with schizophrenia have a generalized deficit and perform poorly on all tests (Blanchard and Neale, 1994; Mohamed *et al.*, 1999). However, not all deficits fit such an explanation. Some abnormalities of attention and information processing can be demonstrated on tasks that require minimal effort, for example defective sensory gating. Other deficits result in superior rather than

deficient performance, for example on latent inhibition paradigms (Braff, 1993; see also below). Moreover, within the context of this generalized deficit, the question becomes whether patients perform disproportionately worse on some tests (Green, 1998).

Several candidates for such a differential deficit have been proposed, notably attention (Weickert *et al.*, 2000), verbal learning and memory (Bilder *et al.*, 2000; McKenna *et al.*, 1990; Saykin *et al.*, 1991) and executive functions (Evans *et al.*, 1997; Riley *et al.*, 2000; Weickert *et al.*, 2000). However, the findings of a differential deficit should be interpreted in the context of the psychometric limitations of the neuropsychological tests. As Chapman and Chapman (1978) have pointed out, a differential deficit in performance does not necessarily indicate a differential deficit in ability. To measure differential deficit in ability, tests must be matched on psychometric characteristics of test reliability and test difficulty. In addition, differential discriminating power of the various tasks may obscure any differential deficits in ability. The study by Saykin and co-workers (1991) used standardized residual scores (Chapman and Chapman, 1989) as an alternative strategy for the elaborate procedures for matching tasks on their psychometric properties. However, Blanchard and Neale (1994) have argued that this method does not allow for inferences regarding differential abilities, when used in the context of a generalized performance deficit. Thus, given the psychometric limitations of currently available cognitive tests, findings of generalized and differential deficits must be interpreted with caution.

Processing of Context

In normal information processing, perception is dependent on an interaction between the external stimuli and memories of regularities in previous input. When appropriate material from memory is activated, this results in expectancies and response biases, so that temporal and spatial redundancy is used to reduce information-processing demands. Hemsley (1994, 1987) has proposed that the rapid and automatic assessment of the significance of the sensory input on the basis of past regularities is impaired in schizophrenia. According to this model, it should be possible to develop tasks at which patients with schizophrenia perform better than normal controls, namely when the latter group forms expectancies which are inappropriate to the stimulus presented. The latent inhibition paradigm, derived from animal studies, is an example of a task at which patients display superior performance (Hemsley, 1993; Lubow and Gewirtz, 1995). In the first stage of the paradigm, a stimulus is repeatedly presented to the subjects; in the second stage, this pre-exposed stimulus is paired with reinforcement in a classical or instrumental learning procedure. Pre-exposed subjects learn this association much more slowly than subjects who did not receive the first stage of pre-exposure. This effect is interpreted as a reduction in the deployment of attention to a stimulus that is redundant, since it has no consequences according to the learned regularity. Patients with acute schizophrenia perform better than normals in the pre-exposure condition, apparently due to their continuing to attend to the redundant stimulus (Baruch *et al.*, 1988; Gray *et al.*, 1992). Patients with chronic schizophrenia and patients who have been treated with antipsychotic medication for several weeks show no differences in performance on latent inhibition tasks compared to healthy individuals. The link between abnormal latent inhibition and psychotic symptoms may be that, following a loosening of the perceptual context, attention may be captured by incidental details of the environment. These details would normally not reach awareness, but the conscious registration initiates a search for the reasons for its occurrence (Hemsley, 1994). According to the model, symptoms such as poverty of speech, social withdrawal and retardation are learned over time to cope with the high levels of information overloads. However, this model cannot easily account for the finding that negative symptoms may be present at a very early stage of the illness (Arndt *et al.*, 1995).

Computational Models

Based on computer simulation models that specify mechanisms of normal information processing underlying task performance, Cohen and Servan-Schreiber (1992; see also above) have also emphasized the role of context information. According to their model, a single mechanism that is responsible for the representation and maintenance of context information may account for the pervasive cognitive impairment in schizophrenia. Given the similarities between definitions of context and working memory, this view is in line with the proposal by other authors that a reduction of working memory capacity is the core dysfunction in schizophrenia (Fleming *et al.*, 1994; Goldman-Rakic, 1994). Processing of context information may be relevant to almost all cognitive tasks, although it is particularly important in tasks that require to maintain information over time and to inhibit habitual responses. Cohen and Servan-Schreiber have constructed computer simulation models of three tasks: the SCWT, the Continuous Performance Test and a lexical disambiguation task (Cohen *et al.*, 1999; Cohen and Servan-Schreiber, 1992). Each model consisted of an input module for representing externally presented stimuli, an output module for producing a response, an associative module for relating stimuli to appropriate responses, and a context module that can regulate the flow of information through the associative module. Reciprocal connections between the associative module and the context module allowed stimuli presented to the network to help establish the context, which in turn can influence the processing of subsequent stimuli. The context module carried out both the maintenance of information and the inhibition of irrelevant information, indicating that both memory and inhibition reflect the operation of a single mechanism. When this context module was disturbed, the model predicted changes in performance similar to the actual performance deficits of patients with schizophrenia. This was the case for each of the three computer models.

Course of the Deficits

Two contrasting hypotheses have been postulated concerning the natural course of the cognitive deficits in schizophrenia. According to the first, the cognitive deficits follow a course analogous to progressive dementia, consistent with the view that schizophrenia involves a neurodegenerative process. In the second view, the cognitive deficits are considered relatively stable, in accordance with a neurodevelopmental model of schizophrenia. During recent decades, both longitudinal and cross-sectional studies of cognitive deficits have mainly supported the neurodevelopmental hypothesis (Goldberg *et al.*, 1993b; Rund, 1998). Mild cognitive deficits may be present premorbidly, as indicated by studies following large samples of children of parents with schizophrenia from childhood into the age of risk, like the Israeli High-Risk Study (Mirsky *et al.*, 1995b) and the New York High-Risk Project (Cornblatt *et al.*, 1999). Prospective studies of large birth cohorts have supported the association between cognitive deficits in childhood and adult psychosis (Cannon *et al.*, 1999; Jones *et al.*, 1994a, 1994b; Kremen *et al.*, 1998). Also, there is evidence that subgroups of patients with schizophrenia show lower estimates of premorbid IQ than controls on the basis of reading scores (Crawford *et al.*, 1992; Gilvarry *et al.*, 2000).

Following the onset of the first psychotic episode, most patients experience a substantial decline in cognitive functions compared to their premorbid level (Goldberg *et al.*, 1993b; Weickert *et al.*, 2000). That onset of the psychotic symptoms and the cognitive

decline do not occur in childhood but so much later may be because only then does the affected part of the brain mature and is called 'on line' (Weinberger, 1987). Most cognitive deficits persist during clinical remission (Cantor Graae *et al.*, 1995; Goldberg *et al.*, 1993b; Nopoulos *et al.*, 1994; Nuechterlein *et al.*, 1994). Once established early in the course of the disorder, the deficits seem to be relatively stable over the years (Goldberg *et al.*, 1993b; Rund, 1998). Thus, cross-sectional studies of first-episode patients have shown patterns of deficits similar to patients later in the course of their illness (Bilder *et al.*, 2000; Heaton *et al.*, 1994; Mohamed *et al.*, 1999; Saykin *et al.*, 1994). Furthermore, cross-sectional studies across a wide age range have suggested stable cognitive impairments (Eyler Zorrilla *et al.*, 2000). Most recent longitudinal studies also point to a stability of cognitive functioning (Censits *et al.*, 1997; Gold *et al.*, 1999), early in the course of the disorder (Hoff *et al.*, 1999; Nopoulos *et al.*, 1994) but also in older patients (Harvey *et al.*, 1995). Yet, the time between baseline and follow-up was 1 or 2 years in most studies, except for the study by Gold *et al.* (5 years) and Hoff *et al.* (5 years), indicating the need for studies of longer duration.

However, the neurodevelopmental model cannot account for all findings. A subgroup of geriatric patients with chronic schizophrenia displays severe cognitive and functional impairments that implicate decline at some time point after the onset of illness (Friedman *et al.*, 1999a; Harvey *et al.*, 1999a, 1999b). Also, it has been suggested that progressive age-related deterioration in schizophrenia occurs in specific cognitive functions, notably abstraction ability (Fucetola *et al.*, 2000) or processing resources (Granholm *et al.*, 2000). This is in line with the view recently put forward by Lieberman (1999), that it is premature to reject a role for neurodegenerative processes in the pathophysiology of schizophrenia.

SYMPTOMS OF SCHIZOPHRENIA AND COGNITIVE DEFICITS

Positive and Negative Syndromes

Attempts to link the cognitive deficits to symptoms of schizophrenia have mainly focused on the relation with positive and negative syndromes (see Strauss, 1993, for a review of earlier studies). The main approach has been to correlate the degree of cognitive deficits to the severity of symptoms of both dimensions. Negative symptoms have been found to be associated with deficits in verbal and visual memory, visual/motor processing and impaired executive functions (Berman *et al.*, 1997; Capleton, 1996; O'Leary *et al.*, 2000; Rossi *et al.*, 1997b). Positive symptoms have been found to co-occur with impaired auditory attention and verbal memory (Berman *et al.*, 1997; Green and Walker, 1986), but the evidence is more in favour of independence between positive symptoms and neuropsychological deficits (O'Leary *et al.*, 2000; Voruganti *et al.*, 1997). In accordance with this, several studies have shown that the paranoid subtype, characterized by delusions and hallucinations, is associated with better performance in memory, attention and executive functions, compared to the other subtypes (Seltzer *et al.*, 1997; see Zalewski *et al.*, 1998, for a review).

Liddle (1987) has proposed that the symptoms of disorganization can best be seen as a separate cluster within the positive dimension, which has been confirmed by subsequent factor analyses (Johnstone and Frith, 1996). The dimension of disorganization might be associated with impaired cognitive functions, notably impaired selective attention and inhibition (Liddle and Morris, 1991; Van der Does *et al.*, 1996); low verbal IQ and impaired concept attainment (O'Leary *et al.*, 2000); and impaired visual and auditory attention (Brekke *et al.*, 1995).

However, correlations between symptoms and deficits are generally quite modest. It seems that most of the variance of symptoms must be attributed to factors other than neurocognition. In fact, several studies have found that symptoms and neurocognition are independent. This is particularly the case for the positive symptom cluster (Brekke *et al.*, 1995; O'Leary *et al.*, 2000; Voruganti *et al.*, 1997), but similar results have been found for negative symptoms as well (Seaton *et al.*, 1999; Suslow *et al.*, 1998). Further, a major drawback of this correlational approach is that it is descriptive instead of explanatory, which means that it offers no insight into the reason for the association (Green, 1998). An alternative approach has been to take individual symptoms of psychosis as the starting point and examine possible cognitive mechanisms that may underlie them. In the next section, two cognitive accounts of psychotic symptoms will be discussed, namely theory of mind and self-monitoring.

Theory of Mind

Theory of mind refers to the ability to explain the behaviour of others in terms of their mental states (Premack and Woodruff, 1978). In normal children, this ability emerges in the pre-school years, manifested for example in the use of mental state expressions in their language and the understanding of the consequences of false belief, (e.g., understanding the actions of characters within stories that are a result of their false beliefs about the state of the world) (Leslie, 1987). In recent decades, most research on theory of mind, in humans has focused on children with autism. There is evidence that autistic children have a specific deficit in theory of mind that is apparent, for example, from deficits in pretend play and difficulties in the understanding of false belief (Baron-Cohen *et al.*, 1985). In schizophrenia, interest in theory of mind abilities has been less explicit, although several studies of social competence in schizophrenia did refer to the ability to infer mental states in others (e.g., Cutting and Murphy, 1990; Diamond, 1956). For example, Diamond (1956) presented evidence to support the notion that patients with schizophrenia are unable adequately to internalize the point of view of others. Frith (1992) has applied the concept of theory of mind to specific symptoms of schizophrenia, namely delusions of reference, misidentification and persecution, as well as third-person hallucinations. According to Frith, these experiences are by their very nature characterized by a misinterpretation of another person's behaviour or intentions. Whereas autistic children may never develop mentalizing ability, patients with schizophrenia may lose an ability they once had (Frith and Corcoran, 1996).

In a series of experiments, Frith and his co-workers were able to demonstrate impaired theory of mind in subgroups of patients with schizophrenia on a number of newly devised tasks (Corcoran *et al.*, 1995, 1997; Doody *et al.*, 1998; Frith and Corcoran, 1996). Patients with behavioural signs (i.e., negative symptoms and disorganization) and those with paranoid delusions had problems on a hinting task that requires the ability to infer intentions behind indirect speech, in contrast to patients with passivity experiences and patients in remission, who performed normally (Corcoran *et al.*, 1995). A similar pattern of results was found in a subsequent study using stories that involved false beliefs, so that to understand the stories subjects had to infer the mental states of the characters (Frith and Corcoran, 1996). Again, patients with behavioural signs and those with paranoid delusions were impaired on this task, while patients with passivity experiences and those in remission did not differ from normal controls. There were no differences in IQ score between the patients with paranoid delusions and those with passivity experiences or remitted patients, making it unlikely that the observed differences in theory of mind ability could be ascribed to general cognitive impairment. In contrast, the poor performance of patients with behavioural signs was mediated by

their poor general cognitive abilities. Another study indicated that impaired performance on theory of mind tasks is found in patients with schizophrenia, but not in patients with affective disorders with psychotic symptoms (Doody *et al.*, 1998). Although these studies confirmed the initial hypothesis that impaired theory of mind is associated with specific symptoms, evidence from other studies is mixed. Using a series of comic strips, Sarfati and colleagues found that only patients with thought disorganization had difficulties interpreting the behaviour of the characters (Sarfati and Hardy Bayle, 1999; Sarfati *et al.*, 1997), independent of the mode of presentation, verbal or pictorial (Sarfati *et al.*, 1999). A study by another group included three groups: patients with schizophrenia, patients with depression and deluded patients with psychotic disorders other than schizophrenia (Drury *et al.*, 1998). Patients were investigated during the acute phase and following recovery. In line with the hypothesis, patients with schizophrenia displayed impaired theory of mind abilities compared to non-schizophrenia patients, during psychosis but not following recovery. However, more subtle theory of mind tasks, like the interpretation of irony, failed to distinguish between the groups, which is difficult to reconcile with Frith's account. Furthermore, there were no differences in performance between patients with delusions of reference and persecution, and non-deluded patients, a finding not in line with the notion that impaired theory of mind is the critical mechanism underlying these delusions.

Taken together, the findings indicate that patients with schizophrenia certainly have difficulties performing theory of mind tasks. These difficulties are state rather than trait variables. The impairments seem to be particularly pronounced in patients with negative symptoms or positive behavioural signs, while the predicted association with delusions has been found in some studies. General cognitive abilities seem to mediate only part of the associations between symptoms of schizophrenia and theory of mind abilities.

Source Monitoring

Source monitoring refers to the processes involved in making attributions about the origin of memories, knowledge and beliefs (Johnson *et al.*, 1993). This decision-making process can apply to various types of distinctions, namely between memories of internally generated information and externally derived information, for example memories for imagination versus memories for perceived events ('reality monitoring'), or between different external sources ('external source monitoring') or between internally generated sources, for example memories of what one said versus memories of what one thought ('internal source monitoring') (Johnson *et al.*, 1993). The notion of reality monitoring may be particularly relevant to psychosis. The nature of several symptoms of psychosis suggests that patients with this disorder are unable to monitor the generation of their own thoughts and actions, which then results in their conclusion that these thoughts or actions came from an external source (Bentall, 1990; Frith, 1992). This may apply to hallucinations, thought insertion, made feelings and other experiences of alien control (Frith, 1992).

Action Monitoring

A number of studies have applied source-monitoring paradigms to schizophrenia. These paradigms have mainly focused on verbal monitoring (for example, (Bentall *et al.*, 1991; Brébion *et al.*, 1997; Johns *et al.*, 2001), whereas some have investigated the monitoring of actions (Franck *et al.*, 2001; Frith and Done, 1989; Mlakar *et al.*, 1994; Stirling *et al.*, 1998). Studies of action monitoring performance have mainly used tasks that require subjects to keep track of the actions they had just performed in the absence of visual feedback (Frith and Done, 1989; Mlakar *et al.*, 1994; Stirling *et al.*, 1998). The results of these three studies have supported the hypothesis that patients with experiences of alien control have difficulties monitoring their actions internally, particularly when the actions are self-generated rather than being directed by external stimuli. In the study by Franck *et al.* (2001) visual feedback was not absent but distorted. The image of a virtual hand was superimposed on a subject's real hand holding a joystick, so that the subject only saw the virtual hand. Subjects executed discrete movements, while angular biases and temporal delays were randomly introduced in some trials. The task was to decide immediately after each trial whether the movement they saw corresponded exactly to the one they made with there own hand. In the trials with angular biases patients with delusions of influence made more errors than controls and non-influenced patients with schizophrenia. This result suggests that a difficulty in keeping track of one's own actions is a critical mechanism underlying delusions of influence.

Verbal Monitoring

In the verbal monitoring paradigm developed by Johnson *et al.* (1981), subjects are required to generate answers to clues, consisting of a category and a letter, and to listen to paired associates consisting of a category and a particular. To manipulate the amount of cognitive effort involved, half of the items were easy clues or high-probability associations (e.g., 'Think of a type of dwelling beginning with H. . .', 'A type of footwear — shoe') and half were difficult clues or low-probability associations (e.g., 'Think of a fruit beginning with T. . .', 'A country — Norway'). In normals, confusion between memories of perceived and imagined events increases with decreases in the amount of cognitive effort that is associated with the self-generated event (Johnson *et al.*, 1981). After 1 week, subjects are presented a list in which their answers to the clues are mixed with the associates and with words not previously presented. Their task was to identify the source of each item on the list. Bentall *et al.* (1991) used this task to compare performance between three groups: patients with schizophrenia who were currently hallucinating, patients with delusions but no history of hallucinations, diagnosed with schizophrenia or delusional disorder, and normal controls. Both patient groups were less accurate on the source-monitoring task compared to controls. A specific bias was present in the patients with hallucinations: they more often misattributed self-generated answers to the experimenter than either the psychiatric or the healthy controls, a difference that was significant for the items that required high cognitive effort. Using a similar paradigm, another study also reported a bias toward attributing self-generated items to an external source (Brébion *et al.*, 1997). Keefe *et al.* applied multinomial modelling analysis to source-monitoring data, a method that yields separate and independent measures of recognizing information, remembering its source and response biases (Keefe *et al.*, 1999a). This analysis indicated that patients were impaired in reality monitoring, as well as internal and external monitoring. In case of ambiguity, when someone did not remember the source of the information, patients with schizophrenia showed a stronger bias than controls to report that it came from an external source.

Online Monitoring

The tasks used in the studies described so far require subjects to identify the source of events some time after they had been presented or generated. Johns *et al.* (2001) developed a paradigm that involves immediate monitoring, which might be more relevant to the mechanisms underlying the psychotic symptoms. Participants read single words aloud while they received feedback of their own voice or alien feedback (someone else's voice). In some trials, the acoustic characteristics of the speech were distorted. Immediately

after reading aloud the words, subjects had to identify the source of the speech they heard. Both patients with hallucinations and delusions and patients with delusions but no hallucinations made more errors than the control group when reading aloud with distorted feedback of their own voice. The patients with hallucinations had the strongest tendency to misattribute their distorted voice to someone else, particularly when the words presented had a negative emotional content.

Bentall (1990) has argued that the misattribution may be influenced by top-down processes, such as beliefs and expectations about the self and the world. This cognitive bias may operate in addition to deficits in discriminating between external and internal events. The bias may be reinforced by the anxiety reduction that is associated with attributing negative thoughts to an external source. The results reported by Morrison and Haddock (1997) supported the role of a cognitive bias. Subjects rated their response on a word association task in terms of how much a self-generated thought was their own. Patients with hallucinations had lower internality rating than both the psychiatric and the normal control group, particularly with emotional material. A subsequent study indicated that these internality ratings were associated with metacognitive beliefs about uncontrollability and danger (Baker and Morrison, 1998).

In sum, a number of studies have documented robust deficits of reality monitoring in schizophrenia, with a tendency to attribute events to an external source in case of ambiguity. Other forms of source monitoring, namely internal and external monitoring, may be impaired as well. The results of different studies are not entirely consistent regarding the associations with specific symptoms of psychosis. In general, if a relation between impaired source monitoring and symptoms is found, it is mainly with symptoms of alien control rather than hallucinations *per se*. However, the presence of an external attribution bias may be specifically involved in hallucinations.

COGNITIVE DEFICITS AS VULNERABILITY FACTORS

Deficits in specific functions, like source monitoring and theory of mind, are most likely state-dependent variables. However, this is certainly not the case for all cognitive deficits in schizophrenia. Strong evidence for trait-like deficits comes from studies involving non-psychotic individuals with a genetically mediated vulnerability to schizophrenia. According to the vulnerability/stress model, some individuals have a predisposition to schizophrenia that is largely determined by genetic and neurodevelopmental factors (Nuechterlein and Dawson, 1984; Zubin and Spring, 1977). Many studies have attempted to find markers of this vulnerability in first-degree adult relatives of patients with schizophrenia and in individuals with a higher risk of developing schizophrenia than the general population.

Cognitive Deficits in Non-Psychotic Relatives

Adult Relatives

Several studies have suggested that adult relatives of patients with schizophrenia have mild cognitive impairments (Faraone *et al.*, 1995, 1999; Krabbendam *et al.*, 2001; see Kremen *et al.*, 1994, for a review). The study by Krabbendam *et al.* (2001) suggested that the pattern of deficits in relatives is similar, albeit milder, to that found in patients. They found that for both patients and relatives attention, verbal memory and working memory independently discriminated from control performance, with a similar pattern in the order of the effects. A 4-year follow-up study by Faraone and colleagues indicated that the neuropsychological deficits in the non-psychotic relatives are stable over time (Faraone *et al.*, 1995, 1999). In a subsequent study, these authors demonstrated that non-psychotic individuals with two first-degree relatives with schizophrenia have lower estimated intelligence and worse performance on visual and verbal memory, compared to persons with only one first-degree relative with schizophrenia. Thus, the cognitive deficits in the relatives reflect their degree of genetic predisposition to schizophrenia.

A likely explanation for the cognitive deficits in non-psychotic adult relatives is that the deficits are transmitted within families of patients with schizophrenia, as markers of genetic risk. If this is the case, specific cognitive deficits may possibly be used as intermediate phenotypes to facilitate genetic studies of schizophrenia (Egan *et al.*, 2000; Tsuang, 1993). The advantage of this approach compared to using the schizophrenia diagnosis as the phenotype is that it may be possible to identify subgroups that are genetically more homogeneous. Further, the intermediate phenotypes may have a simpler genetic architecture. To assess whether cognitive deficits are useful as phenotypes for genetic studies, one needs to examine heritability estimates. Only few studies have done this. Chen *et al.* (1998) found very high relative risk for sustained attention in a Taiwanese cohort, which suggests that this phenotype is highly heritable. In the study by Egan and colleagues, relative risk of impaired sustained attention was in the moderate range (Egan *et al.*, 2000). Although it is too early to conclude that cognitive deficits can be used as phenotypic markers, these findings at least suggest that it would be useful to explore this possibility further.

This, however, does not mean that cognitive deficits in schizophrenia cannot be due to environmental mechanisms. Specifically, obstetric complications may be associated with schizophrenia (Dalman *et al.*, 1999) as well as with compromised intellectual development (Aylward *et al.*, 1989). In the study reported by Gilvarry and colleagues (2000, 2001), relatives of patients who have been exposed to obstetric complications performed significantly better on measures of IQ and verbal fluency than did relatives of patients not exposed to obstetric complications. This suggests that impaired IQ and verbal fluency were not transmitted in the families of the patients with a history of obstetric complications, but were a consequence of the patient's exposure to obstetric complications.

Children of Patients with Schizophrenia

The high-risk research typically involves children of a parent with schizophrenia, assessed during childhood and adolescence. A number of studies have suggested that offspring of patients with schizophrenia may display impairments in attention skills (Hans *et al.*, 1999; Mirsky *et al.*, 1995a), executive functions, memory and intellectual function (Byrne *et al.*, 1999). Unlike the adult relatives, children of patients with schizophrenia form a heterogeneous group, because some of the children will eventually develop schizophrenia themselves and others will not. Long periods of follow-up have been performed to identify the factors that are associated with later development of schizophrenia (Erlenmeyer-Kimling *et al.*, 1993; Mirsky *et al.*, 1995b). The NIMH–Israeli High-Risk Study conducted a long-term follow-up of children having a parent with schizophrenia (Mirsky *et al.*, 1995b). One hundred children were originally included, 50 of them having a parent with schizophrenia, and 50 control children. Cognitive assessments were conducted at ages 11, 17, 26 and 32. Sixty-three subjects could be included in the last assessment. The children who eventually developed schizophrenia spectrum disorders, including schizophrenia, were identifiable by attentional deficits at age 11. Results of the New York High-Risk Project have indicated that childhood deficits in attention, verbal memory and gross motor skills distinguish children who develop schizophrenia-related psychoses in adulthood from children at risk for schizophrenia who did not develop schizophrenia-related psychoses in adulthood

(Cornblatt *et al.*, 1999; Erlenmeyer-Kimling *et al.*, 2000). In this project, the offspring of patients with schizophrenia were tested neuropsychologically and behaviourally at 7–12 years of age and assessed again in mid-adulthood for psychiatric diagnoses. In sum, several cognitive abnormalities, notably attentional deficits, are present in offspring of patients with schizophrenia, particularly in those children who eventually develop schizophrenia spectrum disorders themselves.

Several population-based studies of IQ and later development of schizophrenia have been conducted (e.g., David *et al.*, 1997; Jones *et al.*, 1994a, 1994b). These studies have indicated that low IQ in childhood or young adolescence is a risk factor for subsequent development of schizophrenia. Based on a 19-year longitudinal study of a community sample, Kremen and colleagues have reported that an unexpected drop in IQ between the ages of 4 and 7 was strongly and independently associated with later psychotic symptoms (Kremen *et al.*, 1998). Two possible mechanisms may account for the relation between childhood IQ and schizophrenia. IQ could be indirectly associated with schizophrenia, with any factors causing lower IQ, such as genetic predisposition or abnormal brain development, increasing the risk for schizophrenia. Alternatively, the association could be causal, with low IQ reducing the capacity to cope with stressors or leading to false beliefs and perceptions.

Cognitive Deficits in Schizotypy

An alternative approach to identify factors associated with schizophrenia liability has been to study schizotypic subjects, either individuals diagnosed with DSM-IV schizotypal personality disorder, or individuals who display deviance on psychometric tests for schizotypy ('psychosis proneness'). This approach starts from the assumption that schizophrenia is the extreme end of a continuum that ranges from mild to severe, with schizotypy being part of this continuum (Claridge, 1994). Family studies have reported elevated rates of schizotypy in relatives of patients with schizophrenia, indicating that schizotypy shares a common genetic vulnerability to schizophrenia (Kendler *et al.*, 1993, 1994). To the extent that this is the case, schizotypal subjects may have the same pattern of cognitive deficits as individuals with schizophrenia, albeit to a lesser degree.

Based on studies involving either subjects with schizotypal personality disorder (Cadenhead *et al.*, 1999; Diforio *et al.*, 2000; Trestman *et al.*, 1995; Voglmaier *et al.*, 1997, 2000) or psychometrically identified 'psychosis-prone' subjects (Lenzenweger and Gold, 2000; Lenzenweger and Korfine, 1994; Park *et al.*, 1995), findings have indeed supported the notion of a shared cognitive liability. Cadenhead and co-workers (1999) reported widespread deficits in 20 subjects with schizotypal personality disorder, including deficits of attention, verbal working memory, abstract reasoning and general intellectual functioning. The deficits were of lesser magnitude than those observed in the patients with schizophrenia. Deficits of executive functions were found in adolescents with schizotypal personality disorder, particularly in individuals with negative symptoms (Diforio *et al.*, 2000). However, the deficits were only apparent on one test of executive function, the Modified WCST, and not on the Tower of London or verbal fluency tests, which may reflect that these tests may not be sensitive enough to detect the mild cognitive impairments in schizotypal personality disorder. In a comparison of undergraduate students who scored high and low, respectively, on the Perceptual Aberration Scale (Chapman *et al.*, 1978), high scores were associated with deficits of visuospatial working memory (Park *et al.*, 1995), but not auditory working memory (Lenzenweger and Gold, 2000). This latter finding was somewhat unexpected, given that auditory working memory is impaired in patients with schizophrenia (Aleman *et al.*, 1999; Gold *et al.*, 1997) and that the modal finding in schizotypy research is that the cognitive profile of schizotypic individuals resembles that of patients, although in attenuated form. According to the authors, one possible explanation for this result could be that the task used to assess auditory working memory (namely, letter–number span) involved discrete trials and so did not require subjects to hold online the information over a delay period, in contrast to the task used to assess visuospatial working memory.

Some studies have explored the notion of reduced cognitive inhibition in schizotypy (Beech *et al.*, 1991; Moritz and Mass, 1997; Peters *et al.*, 1994; Williams, 1995). Cognitive inhibition refers to the active suppression of irrelevant information, one of the functions of the context module in the computational model by Cohen and Servan-Schreiber described above (Cohen *et al.*, 1999; Cohen and Servan-Schreiber, 1992). These studies have used a negative priming paradigm (Tipper, 1985), which typically consists of a target word presented subsequently to a semantically related, or identical, ignored distractor word. Negative priming refers to the longer reaction times following the ignored distractor word, a phenomenon that is thought to reflect reduced inhibition. The findings converge on the point that every study reported increased negative priming, particularly in those subjects who scored high on the scales for positive schizotypal symptoms.

FUNCTIONAL CONSEQUENCES AND TREATMENT ISSUES

Impact of Cognitive Deficits on Daily Functioning

Given the scope of the cognitive impairment in schizophrenia, an important question is in what way this impairment affects daily functioning. Despite its clinical relevance, this question has been largely ignored until roughly a decade ago. Nevertheless, some trends emerge from the available empirical data.

In a review of 17 studies, Green (1996) divided the literature into three areas of functional outcome, namely community outcome, social problem solving and skill acquisition. Measures of community outcome included assessments of occupational functioning, quality of social networks and degree of independent living. Although there were large differences between studies with regard to cognitive as well as outcome measures, a replicated finding was that baseline verbal episodic memory and executive functions, assessed with the WCST, predicted community functioning at follow-up (Green, 1996; Velligan *et al.*, 2000). Social problem solving is considered to be a component of community functioning. Most studies have assessed social problem solving using laboratory measures that presents the subjects with videotaped vignettes depicting an interpersonal problem (e.g., a waitress writing down an order incorrectly; Donahoe *et al.*, 1990). The task of the subject is to describe the problem, to derive a solution and to enact this solution in a role-played simulation. Despite some variety between studies in the selection of the outcome measures, a consistent finding was that both verbal memory and vigilance, or sustained attention, were related to social problem solving, whereas executive functions were not (Green, 1996). The majority of the studies in the review were cross-sectional. Subsequent 2-year longitudinal studies of cognitive functioning and social problem solving have reported that both predictive ability of baseline cognitive functions (Addington and Addington, 2000) and the level of social functioning (Dickerson *et al.*, 1999) are stable over time.

Acquisition of psychosocial skills is another determinant of community functioning. Rehabilitation programmes involve skill acquisition, as these programmes instruct patients with regard to interpersonal skills, leisure activities and vocational skills. Studies that have investigated the relation between cognitive functions and skill acquisition have generally assessed cognition at baseline and progress of psychosocial skills during the course of a rehabilitation

programme (Green, 1996). Verbal memory was associated with skill acquisition, as it was with community functioning and social problem solving. Also, verbal working memory and vigilance were associated with skill acquisition. Executive functions did not consistently predict success of rehabilitation programmes.

This summary of findings suggests some specificity in the associations between cognitive functions and outcome. Some of the observed relations have clear face validity, for example, the finding that verbal memory predicts skill acquisition. Yet, it should be noted that the absence of relations between other cognitive functions and outcome might as well have resulted from lack of power due to small sample sizes. In fact, Velligan and colleagues (2000) found evidence for many other associations between cognitive functions and community functions. According to these authors, the multitude of associations may be due to the fact that both cognitive test performance and functional skills do not involve isolated abilities, but instead are determined by several cognitive abilities.

Eight studies that were included in the review by Green (1996) evaluated the relationship between psychotic symptoms and functional outcome. None of them reported a significant relation. However, these studies used composite measures of psychotic symptoms, and so the possibility remains that negative effects of single symptoms, for example thought disorder, were obscured. Negative symptoms showed replicated links with social problem solving, but not with skill acquisition, whereas relations with community functioning were inconsistent. According to the path model by Velligan and colleagues (1997; see also Green, 1998), the pattern of associations between symptoms, cognitive functions and functional outcome suggests that cognitive functions mediate the relation between negative symptoms and outcome. That is, when cognitive impairment is used to predict functional outcome, the contribution of negative symptoms to the prediction is very much reduced. This emphasizes the necessity of addressing cognitive impairments in pharmaceutical or psychosocial interventions.

Effect of Medication on Cognitive Functions

Conventional Antipsychotics

The therapeutic effects of conventional antipsychotic drugs are largely confined to the positive symptoms. These drugs were not designed to improve cognitive functions. Given their impact on several neurotransmitter systems that are implicated in arousal, attention as well as other cognitive functions, it is likely that they do influence cognition, either positively or negatively. Studies involving healthy volunteers have yielded evidence for negative effects, particularly for medication with sedating effects, such as thioridazine (Hindmarch and Tiplady, 1994; King, 1994). In patients, investigating the effects of antipsychotic medication on cognition is hindered by methodological and ethical concerns. For example, discontinuation or delay of drug treatment to study the course of cognitive functioning is often not advisable. Nevertheless, several reviews have concluded that the deleterious effects of antipsychotic medication on cognitive functioning in patients are only minor (Medalia *et al.*, 1988; Spohn and Strauss, 1989). For example, neuroleptically naive patients with schizophrenia had a similar pattern of cognitive deficits as did previously treated patients (Saykin *et al.*, 1994). In another study, a substantial dose reduction of conventional antipsychotic medication did not have marked effects on cognitive functioning (Seidman *et al.*, 1993). There may even be a slight beneficial effect of antipsychotic medication on cognition (Spohn and Strauss, 1989; Verdoux *et al.*, 1995).

There is one possible exception to this, namely the effect of anticholinergic medication or of the anticholinergic properties of antipsychotic drugs. Anticholinergics are known to impair memory and it seems plausible that this effect could contribute to the memory impairment seen in patients with schizophrenia (Goldberg *et al.*, 1993a; King, 1990; Spohn and Strauss, 1989) or to the failure of conventional antipsychotics to improve memory performance in schizophrenia (Mortimer, 1997).

Atypical Antipsychotics

With the development of atypical antipsychotic medication, such as clozapine, risperidone and olanzapine, the treatment of cognitive dysfunctions has become an important focus. Do these drugs really improve cognition? Keefe *et al.* (1999b) have recently performed a quantitative analysis of 15 efficacy studies, studying the effects of clozapine (10), risperidone (4), zotepine (1), ziprasidone (1) and aripiprazole (1). The authors first developed methodological standards against which studies in these area may be judged. None of the included study met all methodological requirements; for example, only three studies were double-blind whereas 12 studies were open-label studies. Despite these methodological concerns, the authors felt sufficiently confident to conclude that atypical antipsychotic drugs improve cognitive functioning in schizophrenia, when compared to conventional antipsychotics. Verbal fluency, digit–symbol substitution, fine motor function and executive functions were the strongest responders to the novel antipsychotics. Yet, even on these tests, performance of the patients with schizophrenia did not reach normal levels in any of the studies reviewed. This emphasizes the necessity to investigate the usefulness of cognition-enhancing drugs in schizophrenia, such as those that activate certain dopaminergic receptors or cholinomimetic drugs that increase cortical cholinergic activity (Friedman *et al.*, 1999b).

Cognitive Remediation

Until a few years ago, there had been little research on cognitive remediation in schizophrenia, despite the fact that it has been established for decades that cognitive deficits persist even after the psychosis subsides. However, the cognitive deficits are now viewed as having direct implications for treatment and findings in the area of neuropsychological interventions are emerging rapidly (Green and Nuechterlein, 1999).

The interventions can take many forms, but generally involve laboratory-based exercises that are related to the cognitive process being trained. Some training programmes use cognitive rehabilitation software. For example, Medalia *et al.* used a software program entitled 'Where in the USA is Carmen Sandiego?' to remediate problem-solving skills in patients with schizophrenia (Medalia *et al.*, 2001). The purpose of this task was to solve a simulated detective case by interpreting information given to identify the suspect in order to make an arrest. Some studies focus on single tasks, for example, the WCST, to investigate whether performance can be enhanced by inducing specific task modifications, such as reinforcement or feedback (Goldberg and Weinberger, 1994; Green *et al.*, 1992; Hellman *et al.*, 1998). There are large differences between training programmes regarding the intensity and duration of the training. For example, Bell and colleagues (2001) applied neurocognitive enhancement therapy, in which every participant receives feedback about his or her cognitive functioning on a biweekly schedule, as well as cognitive exercises for up to 5 hours each week for 26 weeks and a weekly social processing group. In contrast, the computer-aided training by Medalia *et al.* (2000, 2001) consisted of 10 sessions of 25 minutes, twice weekly for 5 weeks.

Despite the growing literature, there is a paucity of controlled studies. In a recent systematic review by the Cochrane group, only three studies could be included that used a randomized design in which the impact of cognitive rehabilitation on people with schizophrenia was compared to a placebo intervention, another intervention or standard treatment (Hayes and McGrath, 2000).

This review did not include comparisons of different types of cognitive rehabilitation. Suslow and colleagues (2001) identified nine peer-reviewed studies of attention training in schizophrenia, which incorporated a control group and used external measures of outcome. Both reviews concluded that data are inconclusive and provide no evidence for or against cognitive remediation or attention training in schizophrenia. An important issue is the generalizability of the improvement. Performance on the training task can often be improved (Green *et al.*, 1992; Hellman *et al.*, 1998) but it is doubtful whether these effects generalize meaningfully (Bellack *et al.*, 1996).

Among the few methodologically adequate studies are the study by Wykes and colleagues (1999) and the one by Medalia and colleagues (2000, 2001). The study by Wykes *et al.* (1999) investigated the effects of an intensive cognitive rehabilitation programme. The intervention was targetted at deficits of executive functions, based on procedural learning and the principles of errorless learning, targetted reinforcement and massed practice. It consisted of individual daily sessions of 1 hour for up to 3 months. The control therapy was occupational therapy, matched for length of treatment and therapist contact. Seventeen patients received the cognitive treatment and 16 received occupational therapy. Some improvement in cognition followed both therapies, but the cognitive intervention was superior to the occupational therapy with regard to tests of cognitive flexibility and memory. There were no systematic changes in symptoms or social functioning in either group, with one exception: patients in the cognitive treatment showed a significant increase in self-esteem. The study by Medalia *et al.* (2000, 2001) applied computer-aided training programmes to remediate memory and problem-solving deficits. A sample of 54 patients with schizophrenia were randomly assigned to a memory-training group, a problem-solving group or a control group. Both training groups received 10 sessions of computer training. The control group participated in routine unit activities. The memory-training group improved on the training tasks during the course of the training, but they did not make greater gains on external outcome measures of memory. The subjects failed to apply the mnemonic strategies that they learned successfully within training tasks to other general measures of memory and learning. In contrast, the problem-solving group showed a significant improvement on the outcome measure that assessed problem-solving skills required for independent living, an effect that was not present in the other two groups. The authors concluded that patients with schizophrenia are responsive to problem-solving training techniques.

THE CONTRIBUTION OF CLINICAL NEUROPSYCHOLOGY

The cognitive profile in schizophrenia is characterized by a broad range of deficits. However, there is no single deficit with sufficient specificity to be useful as a diagnostic instrument. Deficits of attention, memory and executive functions may also be present in other psychiatric conditions, such as unipolar or bipolar depression, although in schizophrenia deficits are generally more severe compared to other psychiatric disorders (Martinez Aran *et al.*, 2000; Zakzanis *et al.*, 1999). Furthermore, test results of a patient with schizophrenia may be indistinguishable from those obtained in neurological disorders, such as mild traumatic brain injury (Zakzanis *et al.*, 1999). Therefore, the clinical neuropsychologist cannot rely on quantitative neuropsychological profiles to differentiate schizophrenia and a neurological condition. At the same time, no single test completely discriminates patients with schizophrenia from healthy controls. According to the quantitative review by Zakzanis *et al.* (1999), the effects of the cognitive variables are associated with a 30–40% overlap between schizophrenia and control distributions. Indeed, substantial numbers of patients with schizophrenia have normal neuropsychological profiles (Palmer *et al.*, 1997). Thus, cognitive deficit is not an inclusive feature of the illness. In sum, neuropsychological test profiles are of limited use in differential diagnosis and can only be interpreted in the context of qualitative aspects of the assessment as well as information about psychopathology, course of the deficits and premorbid functioning.

Same performance on a test does not necessarily point to the same underlying dysfunction (Keefe, 1995). Patients with schizophrenia may perform poorly for reasons that involve other cognitive and brain processes than patients with neurological disorder. Moreover, clinical neuropsychological tests were designed to be sensitive to the type of dysfunction seen with brain lesions. These tests are sensitive to a range of cognitive deficits in schizophrenia as well, but they do not tell us much about the origins of the characteristic symptoms of this disorder. Perhaps the current neuropsychological instrumentarium should be supplemented with tests that fit the psychopathology in schizophrenia, for example tests involving source monitoring or theory of mind. This may give clues to the cognitive mechanisms that may be involved in vulnerability for psychosis.

Clinical neuropsychological assessment does contribute to individual health care, but this contribution most likely concerns treatment and prognosis rather than psychiatric diagnosis. Deficits of attention, memory and executive functions predict functional outcome, possibly even more so than the psychotic symptoms do (Green, 1996; Velligan *et al.*, 2000; see 'Impact of cognitive deficits on daily functioning', above). Thus, the cognitive assessment can be used to adjust the rehabilitation programme to the strengths and weaknesses of the individual patient.

CONCLUDING REMARKS

The cognitive profile in schizophrenia is characterized by deficits across several domains, notably attention, memory and executive functions. The attentional deficits include sustained attention, the capacity to maintain a state of readiness to respond to small changes in the environment, as well as selective attention: the capacity to focus while ignoring irrelevant information. Memory functions that are particularly affected include verbal memory and learning, working memory and semantic memory. The aspects of executive functions that are compromised in schizophrenia are the capacities for volitional activity, forward planning and self-regulation. Regarding the course of the deficits, the evidence is mostly in favour of a relatively stable course, with no further deterioration once the deficits have been established during the first few years following the onset of the first psychotic episode.

An issue that continues to raise considerable debate is whether the cognitive deficit in schizophrenia can best be characterized in terms of a generalized or a specific impairment. Studies that attempt to resolve this issue have to deal with the methodological problems associated with measuring a differential deficit against a background of general impairment, that is, a deficit that is more pronounced than any other cognitive deficit. Given the psychometric limitations of the currently availably cognitive tests, findings of both generalized and specific deficits must be interpreted with caution.

A related issue is whether a single mechanism can be found that can account for the range of deficits in schizophrenia. An influential hypothesis is that a single deficit in the processing of context is sufficient to produce all cognitive deficits as well as certain symptoms of schizophrenia. Strong support for this hypothesis has come from computer models. It appeared from these models that the pervasive deficit seen in schizophrenia could be simulated by disturbance of a single context module that carried out the maintenance of information and the inhibition of irrelevant information.

The psychopathology in schizophrenia is notoriously diverse. Several classifications have been proposed, either categorical or dimensional, and numerous studies have tried to identify distinct cognitive profiles associated with these subtypings. This correlational approach has yielded some interesting results, although typically associations between symptoms and neurocognitive deficits are only modest. An alternative approach to the relation between symptoms and cognition has been to test cognitive models of individual symptoms. Two paradigms that have received substantial empirical support are theory of mind and reality monitoring, in relation to delusions and hallucinations respectively. Impairments of theory of mind seem to be particularly pronounced in patients with negative symptoms or positive behavioural signs, while the predicted association with delusions has been found in some studies. A number of studies have documented robust deficits of reality monitoring in schizophrenia, with a tendency to attribute events to an external source in case of ambiguity. Other forms of monitoring may also be impaired. In general, if a relationship between impaired reality monitoring and symptoms is found, it is mainly with symptoms of alien control rather than hallucinations *per se*. However, the presence of an external attribution bias may be specifically involved in hallucinations.

While the symptom approach tries to identify those cognitive abnormalities that may underlie specific symptoms of psychosis, the focus of the vulnerability approach is on cognitive deficits that have a trait character, independent of the symptoms. According to the vulnerability/stress model, some individuals have a predisposition to schizophrenia that is largely determined by genetic and neurodevelopmental factors. Studies have attempted to find markers of this vulnerability in first-degree adult relatives of patients with schizophrenia and in individuals with a higher risk of developing schizophrenia than the general population. It appeared from this research that cognitive deficits are robust markers of schizophrenia vulnerability, although further research should investigate whether they are useful as alternative phenotypes in genetic studies.

Although the functional relevance of the cognitive deficits in schizophrenia has not received much attention, the available data suggest that deficits of verbal episodic memory, vigilance and executive functions influence functional outcome. Deficits in these, and presumably other domains of cognitive functioning restrict the possibilities for functional recovery, possibly even more so than do the symptoms of psychosis. This indicates that successful treatment goes beyond the reduction of the symptoms of psychosis. Cognitive deficits should be a target for intervention, whether pharmaceutically or psychologically. The therapeutic effects of conventional antipsychotic medication on cognition are generally considered to be minor. There is some evidence that atypical antipsychotic drugs improve cognitive functioning in schizophrenia, when compared to conventional antipsychotics. Yet, in none of the empirical studies does performance of patients with schizophrenia reach normal levels. This emphasizes the necessity to investigate the usefulness of cognition-enhancing drugs in schizophrenia. Few studies have been conducted that examine the effects of cognitive remediation on cognitive and daily functioning in schizophrenia in a controlled design. Therefore, there is as yet no evidence for or against cognitive remediation as a treatment in schizophrenia. However, given the impact of cognitive deficits on functioning in schizophrenia, the field invites exploration.

Schizophrenia and Brain Imaging

S.-J. Blakemore

INTRODUCTION: SCHIZOPHRENIA HAS A BIOLOGICAL AETIOLOGY

It is widely accepted that schizophrenia has a biological aetiology. However, the shift towards this agreement is recent, and the aetiology of schizophrenia has been the subject of lengthy and intense debate. The debate has been split between those who propose a biological aetiology and those who postulate a psychodynamic origin to schizophrenia. In the latter camp, non-biological factors such as family interaction and stressful life events (Kuipers and Bebbington, 1988) have been proposed to play a causal role in the acquisition of schizophrenia. However, these theories have received little empirical support. In addition, in the past 50 years two main lines of evidence supporting a biological role in its aetiology have become apparent. First, there was the discovery of antipsychotic drugs in the 1950s (Delay *et al.*, 1952) and, second, the demonstration of a significant hereditary contribution to the disorder (Gottesman and Shields, 1982). These observations strongly suggest that schizophrenia has a biological basis.

However, current methodologies present challenges for research on the genetic and dopamine theories of schizophrenia. As a consequence, research has become increasingly focused on attempts to elucidate some structural or functional brain abnormality since it is widely held that schizophrenia is a disease of the brain (e.g. Ron and Harvey, 1990). The theory that some gross brain lesion characterizes schizophrenia seems unlikely. Instead, it is generally accepted that schizophrenia is characterized not by structural damage, but by functional abnormalities. This is supported by the relapsing and remitting course of the illness, fluctuations in symptoms and response to pharmacological interventions. Therefore the advent of functional neuroimaging has been important in the study of mental illness because it enables brain function and its abnormalities to be investigated. As stated by Weinberger *et al.* (1996): 'Functional neuroimaging in psychiatry has had its broadest application and greatest impact in the study of schizophrenia.'

A major problem is that images of brain function reflect the current mental state of the patient (i.e. symptoms) and these are very variable. Symptoms include disorders of inferential thinking (delusions), perception (hallucinations), goal-directed behaviour (avolition) and emotional expression. Current thinking generally distinguishes symptoms that comprise the presence of something that should be absent (positive symptoms) and the absence of something that should be present (negative symptoms; Crow, 1980). Factor-analytic studies of symptoms suggest that positive symptoms should be subdivided further into a psychotic group (comprising delusions and hallucinations) and a disorganized group (comprising disorganized speech, formal thought disorder, disorganized behaviour and inappropriate affect; Liddle, 1987). The diversity of symptoms in schizophrenia makes it unlikely that the pathophysiology can be accounted for by a single localized brain dysfunction. Instead, the strategy of attempting to localize specific symptoms to specific brain regions or connections between regions is encouraging, and this chapter will evaluate the results of such studies.

STRUCTURAL STUDIES

Computed Tomography (CT) Studies

The main finding from CT scan studies is that the lateral ventricles are enlarged in schizophrenic patients compared with normal controls. In the first study using this technique, Johnstone *et al.* (1976) found that 17 chronically hospitalized schizophrenic patients had significantly enlarged ventricles compared to normal controls. In a review of the CT literature Andreasen *et al.* (1990) noted that 36 out of 49 subsequent studies have replicated this finding to some extent. There have also been two meta-analyses of the CT scan data (Raz and Raz, 1990; Van Horn and McManus, 1992), which supported the finding of enlarged ventricles in schizophrenic patients. However, the extent of ventricular enlargement in schizophrenia is often small (e.g. Weinberger *et al.*, 1979) or even non-existent in some studies (Smith and Iacano, 1986). Positive findings might be due to the control group having smaller ventricles rather than the schizophrenic patients having larger ventricles. In support of this suggestion, Van Horn and McManus (1992) found in their meta-analysis that choice of control group was a contributing factor to the variability of control ventricle:brain ratio (VBR).

Correlation between CT findings and symptoms has been investigated. Lewis (1990) reviewed 41 CT scan studies that addressed the issue of heterogeneity of schizophrenic symptoms. Only one of 18 studies found any association between increased ventricular area and chronicity of illness. Five out of 18 found evidence of a relationship with negative symptoms. Poor treatment response was found to be associated with increased ventricular area in about half the studies. Chua and McKenna (1995) reviewed the CT literature and concluded that although the finding of increased ventricular area in schizophrenic patients is widespread and replicated, the difference between schizophrenic patients and normal controls is clearly small and depends significantly on the control group chosen.

Magnetic Resonance Imaging (MRI) Studies

MRI improves on CT owing to its better spatial resolution and ability to differentiate white and grey matter. There have been several replicated findings using structural MRI scans to investigate the structure of schizophrenics' brains. A number of studies have shown evidence for reductions in overall brain size, but most of these have used poor control groups and/or small numbers of schizophrenic patients (e.g. Andreasen *et al.*, 1986; Harvey *et al.*, 1993). In addition this finding has not been replicated by other

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

studies (DeMyer *et al.*, 1988; Andreasen *et al.*, 1990). Many MRI studies provide evidence that schizophrenic patients have larger lateral ventricles than normal controls (e.g. Coffman and Nasrallah, 1986; Kelsoe *et al.*, 1988; Suddath *et al.*, 1990; Andreasen *et al.*, 1990; Woodruff *et al.*, 1997a; Sharma *et al.*, 1998; Lieberman *et al.*, 2001). However, the results are conflicting, and there are several negative findings (e.g. Smith *et al.*, 1987; Johnstone *et al.*, 1989; Rossi *et al.*, 1994).

Temporal lobe reductions in schizophrenia have been reported, and are especially prominent in the hippocampus (Fukuzako *et al.*, 1997; Sigmundsson *et al.*, 2001), parahippocampal gyrus and the amygdala (Yurgelun-Todd *et al.*, 1996a). Suddath *et al.* (1990), using the identical twins of schizophrenic patients as controls, found evidence for reductions of the left temporal lobe, including the hippocampus. Kwon *et al.* (1999) recently replicated the finding of a reduction in volume of the left temporal lobe. Cannon *et al.* (1998) suggested that frontal and temporal structural changes might reflect genetic (or shared environmental) effects. In a study using a large group of patients and well-matched controls (the patients' non-psychotic siblings and a group of normal controls), they found that volume reductions of the frontal and temporal lobes were present in patients with schizophrenia and in some of their siblings without schizophrenia. However, temporal lobe reductions are equivocal, with some negative findings in the literature (e.g. Young *et al.*, 1991). There have been many conflicting and negative results in studies attempting to locate clinical correlates with temporal abnormalities. Many studies have found no association between chronicity and temporal lobe size (e.g. Kelsoe *et al.*, 1988; Young *et al.*, 1991), although one study found an inverse relationship between these two factors (DeLisi *et al.*, 1991). Size of the superior temporal gyrus has been associated with hallucinations (Barta *et al.*, 1990) and formal thought disorder (Shenton *et al.*, 1992). Bilateral reduction in volume of the hippocampal formation has been associated with the severity of disorganization syndrome (Fukuzako *et al.*, 1997).

Some studies have found frontal lobe reductions in schizophrenic patients (Harvey *et al.*, 1993; Cannon *et al.*, 1998; Sigmundsson *et al.*, 2001). However, the results are inconsistent, especially in relation to the precise localization of the frontal abnormalities (Raine *et al.*, 1992). Buchanan *et al.* (1998) improved on this by subdividing the prefrontal cortex (PFC) into superior, middle, inferior and orbital regions and found that patients with schizophrenia exhibited selective grey matter volume reductions in the inferior PFC bilaterally. There was no difference between the schizophrenic and control groups in any other region of the frontal lobes.

There are some MRI data that provide support for the hypothesis of disconnection between brain areas in schizophrenia. Breier *et al.* (1992) found that schizophrenic patients, compared with matched healthy controls, had reductions in the right and left amygdala, the left hippocampus and prefrontal white matter. Moreover, the right prefrontal white matter volume in schizophrenic patients was significantly related to right amygdala/hippocampal volume, suggesting there might be abnormal connections between these areas. Buchsbaum *et al.* (1997) found evidence for a decreased left hemispheric volume in frontal and temporal regions in schizophrenic patients. This result was supported by Woodruff *et al.* (1997a), who found that interregional correlations were significantly reduced in schizophrenics between prefrontal and superior temporal gyrus volumes. The authors propose that these results support the existence of a relative 'fronto-temporal dissociation' in schizophrenia.

Reversal or reduction of normal structural cerebral asymmetries may be related to the pathogenesis of schizophrenia (Crow, 1995). Lack of normal asymmetry has been especially associated with early onset of schizophrenia (Fukuzako *et al.*, 1997; DeLisi *et al.*, 1997). Maher *et al.* (1998) found that low levels of hemispheric asymmetry in the frontal and temporal areas were associated with early onset of schizophrenia, the association with frontal volume being more marked than with temporal volume. These findings are consistent with the hypothesis that failure to develop asymmetry is an important component of the pathology underlying some forms of schizophrenia.

Voxel-Based Morphometry

Voxel-based morphometry is a new approach for looking at structural brain abnormalities using MRI. It is a data-led technique in which the brain images are normalized, then differences between groups anywhere in brain are identified (Wright *et al.*, 1995). Andreasen *et al.* (1994) created normal and schizophrenic average brains, compared the latter with the former, and found decreased thalamus size in schizophrenic patients. Wolkin *et al.* (1998) used linear intersubject averaging of structural MR images to create a single averaged brain for the schizophrenic group ($n = 25$) and for the control group ($n = 25$). The signal intensity differences between these average images were consistent with cortical thinning/sulcal widening and ventricular enlargement. Recently, this technique was used in a well-controlled study to compare regional grey matter in 42 schizophrenic patients and 52 controls (Wright *et al.*, 1999). The authors found a significant reduction in paralimbic (bilateral temporal pole and insula), limbic (right amygdala) and cortical (left dorsolateral prefrontal cortex) regions in patients compared with controls.

FUNCTIONAL IMAGING

Positron-Emission Tomography (PET) Resting Studies

There are many PET metabolism studies in the literature, and this chapter is not exhaustive. The main finding from data from PET metabolism studies is that there is less metabolism in the frontal lobes of schizophrenic patients compared to normal controls. This has become known as 'hypofrontality'. The first study using isotope imaging was by Ingvar and Franzen (1974), who compared 15 normal controls with 11 patients with dementia, and two groups of schizophrenics (one group comprised nine chronic, elderly patients; the other comprised 11 younger patients). Whereas the demented patients showed a lower level of overall metabolism, both schizophrenic groups showed some evidence for reduced blood flow in anterior, relative to posterior, regions (hypofrontality; see Figure XVII-8.1).

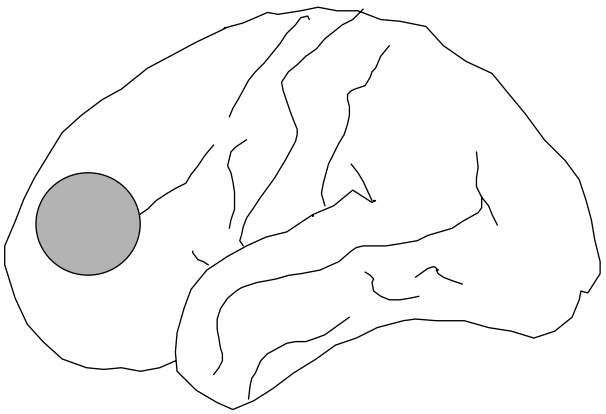

Figure XVII-8.1 Approximate average localization of hypofrontality found by Liddle *et al.* (1992), Weinberger *et al.* (1986), Daniel *et al.* (1991), Volz *et al.* (1997), Ragland *et al.* (1998), Spence *et al.* (1998), Yurgelun-Todd *et al.* (1996b) and Fletcher *et al.* (1998)

However, disagreement about the definition of hypofrontality has caused inconsistencies in the results. Studies vary on the frontal areas in which activity was measured. Some have included all anterior regions; others have looked at frontal or prefrontal subdivisions only. The earlier studies tended to use the frontal:occipital ratio as a measure of hypofrontality, whereas recently most studies have used absolute frontal flow values with or without correction for mean total brain blood flow rates. The majority of studies, using any of these definitions, have found little evidence for statistically significant hypofrontality, and in several studies hypofrontality was due to an elevated flow in posterior regions (Mathew *et al.*, 1988; Siegel *et al.*, 1993). In other studies, the differences between control and schizophrenic frontal cortex metabolism are small. It is claimed that hypofrontality is not due to the drug status of the patients at scanning (Waddington, 1990). However, recently antipsychotic medication has been found to affect brain metabolism (Miller *et al.*, 1997). Several studies have looked at clinical correlates associated with hypofrontality, but the results are inconsistent. Among those showing a positive relationship with hypofrontality are chronicity (Mathew *et al.*, 1988), negative symptoms (e.g. Ebmeier *et al.*, 1993) and neuropsychological task impairment (e.g. Paulman *et al.*, 1990).

Researchers have attempted to correlate regional cerebral blood flow (rCBF) levels with symptom severity scores for Liddle's three clinical subdivisions in 30 schizophrenic patients (Liddle *et al.*, 1992). They demonstrated that the psychomotor poverty syndrome, which has been shown to involve a diminished ability to generate words, was associated with decreased perfusion of the dorsolateral prefrontal cortex (DLPFC) at a locus that is activated in normal subjects during the internal generation of words. The disorganization syndrome, which has been shown to involve impaired suppression of inappropriate responses (e.g. in the Stroop test), was associated with increased perfusion of the right anterior cingulate gyrus at a location activated in normal subjects performing the Stroop test. The reality distortion syndrome, which might arise from disordered internal monitoring of activity, was associated with increased perfusion in the medial temporal lobe at a locus activated in normal subjects during the internal monitoring of eye movements. Therefore the abnormalities of brain metabolism underlying each of the three syndromes might be widely distributed over the brain.

Using data from the same patients, Friston *et al.* (1992) examined correlations between rCBF and a measure of psychopathology receiving equal contributions from each of Liddle's three subsystems. The degree of psychopathology correlated highly with rCBF in the left medial temporal region, and mesencephalic, thalamic and left striatal structures. The highest correlation was in the left parahippocampal region, and the authors proposed that this might be a central deficit in schizophrenia. A canonical analysis of the same data highlighted the left parahippocampal region and left striatum (globus pallidus), in which rCBF increased with increasing severity of psychopathology. Friston and colleagues suggested that disinhibition of left medial temporal lobe activity mediated by fronto-limbic connections might explain these findings.

Neuroreceptor Imaging of Antipsychotics using PET

Dopamine Receptors

Many studies have shown evidence that the density of dopamine (DA; in particular D2) receptors is increased in schizophrenic brains (Wong *et al.*, 1986; Breier *et al.*, 1997). Early PET and single photon emission computed tomography (SPECT) receptor imaging studies focused on striatal D2 receptors. However, Okubo *et al.* (1997) used PET to examine the distribution of D1 and D2 receptors in the brains of drug-naive or drug-free schizophrenic patients. Although no differences were observed in the striatum relative to control subjects, binding of the radioligand to D1 receptors was reduced in the prefrontal cortex of schizophrenics. Other studies using PET have produced contradictory results or only very weak evidence of an abnormality in DA receptor number in schizophrenia (e.g. Crawley *et al.*, 1986; Farde *et al.*, 1987; Pilowsky *et al.*, 1994).

In a meta-analysis of 15 brain-imaging studies comparing indices of dopamine function in drug-naive or drug-free patients with schizophrenia, Laruelle (1998) found that, compared to healthy controls, patients with schizophrenia present a significant but mild elevation of D2 receptor density parameters. However, other meta-analyses have shown that a significant proportion (up to a third) of schizophrenic patients cannot be discriminated from normal healthy controls in terms of D2 dopamine density (Zakzanis and Hansen, 1998; Soares and Innis, 1999). The discrepant results might in part be due to the diversity of PET methodology used in these studies.

Receptor Imaging and Antipsychotic Drug Action

PET and SPECT receptor imaging can be used to explore receptor targets for antipsychotic drug action in living patients. It is widely accepted that the 'typical' antipsychotics (such as haloperidol and perphenazine) bind mainly to the D2 receptor (Kapur, 1998). There is also broad agreement that unwanted extrapyramidal (parkinsonian) side effects of antipsychotic drugs result from high striatal D2/D3 receptor blockade by these drugs. PET receptor-binding studies have found that 60–80% D2 occupancy provides optimal antipsychotic response with little extrapyramidal side effects (Kapur, 1998).

Recent attention has been focused on the involvement of serotonin (5-HT) in the pathophysiology of schizophrenia and its role in mediating antipsychotic drug effects, especially for 'atypical' antipsychotics, such as clozapine, olanzapine, risperidone and Quetiapine. At clinically relevant doses, atypical antipsychotics tend to have a higher affinity for 5-HT receptor subtypes than for D2 receptors and are associated with few extrapyramidal side effects (Lieberman *et al.*, 1998; Silvestri *et al.*, 2001). Atypical antipsychotics differ widely in their D2 occupancy. The D2 occupancy of risperidone had been found to be within the typical range (over 60%), while that of clozapine is significantly lower (under 60%). Some atypical antipsychotics such as Quetiapine have very low (Gefvert *et al.*, 2001) and only transient D2 occupancy, which nevertheless seems to be sufficient for mediating an antipsychotic effect (Raedler *et al.*, 1999; Kapur *et al.*, 2000a).

The D2 occupancy seems to be the important mediator of response and side effects in antipsychotic treatment (Kapur *et al.*, 2000b). Freedom from motor side effects results from low D2 occupancy, not from high 5-HT2 occupancy (Kapur and Seeman, 2001). If the D2 occupancy is too high (it exceeds 80%), antipsychotics lose some of their 'atypical' properties and produce a higher incidence of extrapyramidal side effects (Kapur *et al.*, 1999; Kapur and Seeman, 2001) and negative subjective experiences such as depression (de Haan *et al.*, 2000).

Cognitive Activation Studies

Functional neuroimaging is most frequently used to evaluate the regional cerebral responses to a particular cognitive or sensorimotor process. Typically, subjects are scanned while performing an activation task, which engages the cognitive/sensorimotor process of interest, and a baseline task, which engages all components of the activation task except the cognitive/sensorimotor process of interest. Regions that show significantly more activity in the experimental state than in the baseline state are considered to be involved in the cognitive/sensorimotor process of interest. These task-specific

activity patterns can then be compared between patients and control subjects to determine how the condition affects brain function. Several types of task that have been used to evaluate brain function in schizophrenic patients are discussed in this chapter.

Task-Based Studies of Executive Function

In behavioural studies the most striking impairments are seen when schizophrenic patients perform the various complex executive tasks associated with the frontal lobes. Brain imaging makes it possible to identify the abnormal pattern of brain activity associated with this abnormal performance.

Wisconsin Card Sorting Task (WCST)

Schizophrenia is largely characterized by impairments in planning and execution and therefore tasks that involve this kind of planning and modification of behaviour have been exploited in the scanner. Several researchers have investigated brain activity in schizophrenic patients while they perform a version of the WCST. This task is known to activate the DLPFC in normal controls, and is particularly sensitive to damage to DLPFC (Berman *et al.*, 1995; Nagahama *et al.*, 1996). In the typical computerized version of the WCST subjects view a computer screen that displays a number of stimuli. These stimuli differ along three dimensions: colour, shape and number. On each of a series of trials the subjects have to match a target stimulus with one of the four standard stimuli. However, the match is not exact, but has to made in terms of either colour, shape or form. Subjects are not informed of how to make the match, but are informed after each choice whether they are right or wrong. They have to determine from trial and error which dimension is correct. After subjects have made a series of correct responses, the rule is changed and subjects must determine the new rule for matching.

Weinberger *et al.* (1986) measured rCBF using Xe^{133} inhalation SPECT in 20 medication-free patients with chronic schizophrenia and 25 normal controls during the WCST and a number-matching control task. During the WCST but not during the control task normal subjects showed increased DLPFC rCBF, whereas patients did not (patient performance was worse than that of the controls). Furthermore, in patients, DLPFC rCBF correlated positively with WCST performance. The authors suggest that this result shows that the better DLPFC was able to function, the better patients could perform the task. However, this conclusion is based on an ill-founded assumption. It is impossible to determine whether task-related underactivation *causes* or *reflects* poor task performance. This is a crucial issue in cognitive activation studies, and will be discussed in more detail throughout the chapter.

Daniel *et al.* (1991) used SPECT to study the effect of amphetamine (a DA agonist) and a placebo on rCBF in 10 chronic schizophrenic patients while they performed a version of the WCST and a matched control task. On placebo no significant activation was seen during the WCST compared with the control task. In contrast, significant activation of the left DLPFC occurred on the amphetamine trials. Daniel and colleagues point out that patients' performance improved with amphetamine relative to placebo and that with amphetamine, but not with placebo, a significant correlation was found between activation of DLPFC and performance on the WCST task. Again this is a finding that is difficult to interpret: did amphetamine facilitate task performance, which then caused an increased rCBF in the PFC? Or did amphetamine cause PFC activity to increase, which facilitated performance?

Volz *et al.* (1997) used functional magnetic resonance imaging (fMRI) to investigate activity during the WCST in 13 chronic schizophrenics on stable neuroleptic medication. They also showed evidence for lack of activation in the right PFC and a trend towards increased left temporal activity during the WCST compared to normal controls. However, again the task performance was different between the two groups and therefore the results remain ambiguous. In addition, this study was limited because a one-slice imaging technique was used, so no information about the activation pattern in adjacent brain regions was obtained.

Better WCST performance correlated with rCBF increase in prefrontal regions for controls and in the parahippocampal gyrus for patients in two recent studies (Ragland *et al.*, 1998; Riehemann *et al.*, 2001). The results suggest that schizophrenia may involve a breakdown in the integration of a fronto-temporal network that is responsive to executive and declarative memory demands in healthy individuals.

Tower of London Task

The Tower of London task involves high-level strategic planning among a number of other processes (Shallice, 1982). In this task subjects have to rearrange a set of three balls presented on a computer screen, so that their positions match a goal arrangement also presented on the screen. The complexity of the task, in terms of the number of moves necessary to complete the task, can be varied.

Andreasen *et al.* (1992) used SPECT during the Tower of London task in three different groups: 13 neuroleptic-naive schizophrenic patients; 23 non-naive schizophrenic patients who had been chronically ill but were medication free for at least 3 weeks; and 15 healthy normal volunteers. The Tower of London task activated the left mesial frontal cortex (probably including parts of the cingulate gyrus) in normal controls, but not in either patient group. Both patient groups also lacked activation of the right parietal cortex, representing the circuitry specifically activated by the Tower of London in normal controls. Importantly, decreased activation occurred only in the patients with high scores for negative symptoms. The authors therefore suggested that hypofrontality is related to negative symptoms and is not a long-term effect of neuroleptic treatment or of chronicity of illness. Again, schizophrenic patients performed poorly on the tasks involved, so whether less activation of the PFC was due to poorer performance or vice versa cannot be resolved.

The Component Processes Underlying Executive Function

One problem with studies that employ complex executive tasks is that these tasks involve many processes. For example, the WCST involves choosing a strategy, remembering the previous responses in order to learn by trial and error, attending to one dimension rather than another, and so on. In the absence of a series of carefully constructed comparison tasks it is not possible to relate the various brain regions activated with each of the component processes. In the following section studies that employed simpler tasks with far fewer component processes are reviewed.

Motor Tasks

Even tasks that require no more than the production of a simple sequence of movements can be associated with abnormal patterns of brain activity in schizophrenia. Mattay *et al.* (1997) studied seven patients with schizophrenia and seven normal subjects while they performed a finger movement task of increasing complexity. Patients showed greater ipsilateral activation in the primary sensorimotor and lateral premotor regions and had a significantly lower laterality quotient than normal subjects. These functional abnormalities increased with the complexity of the task. The authors proposed that these results demonstrate a functional disturbance in the cortical motor circuitry of schizophrenic patients. Schröder

et al. (1999) asked 12 patients and 12 healthy controls to produce sequences of movements at three different speeds during fMRI. Both groups showed increasing activity with increasing speed in sensorimotor cortex and supplementary motor area (SMA). However, the patients showed less overall activation than the controls. The differences were most marked in a subgroup of patients who were drug free at the time of testing. Both these studies raise the possibility of a fundamental but subtle problem of motor control associated with schizophrenia.

Willed Action

Willed action involves a 'higher' stage in the control of action. There is a fundamental distinction between actions elicited by external stimuli and actions elicited by internal goals (acts of will). Routine actions are specified by an external stimulus. In contrast, in willed (or self-generated) acts, the response is open-ended and involves making a deliberate choice. Willed actions are a fundamental component of executive tasks. In normal subjects, willed acts in two response modalities (speaking a word, or lifting a finger), relative to routine actions, were associated with increased blood flow in the DLPFC (Brodmann area 46; Frith *et al.*, 1991). Schizophrenic patients typically show abnormalities of willed behaviour. In chronic patients, intentions of will are no longer properly formed and so actions are rarely elicited via this route. This gives rise to behavioural negative signs (e.g. poverty of speech and action) (Frith, 1992).

In a recent PET study, subjects had to make voluntary joystick movements in the experimental condition, stereotyped (routine) movements in the baseline condition, and do nothing in a control rest condition (Spence *et al.*, 1998). The authors analysed data from 13 schizophrenic patients, comparing two occasions when symptoms were severe and when they had subsided, and included data from a normal control group to clarify the role of the left DLPFC in volition. The DLPFC was activated by normal controls for the free choice task only. However, it was not activated by schizophrenics with symptoms, but became activated when their symptoms decreased. The authors noted that the DLPFC was also activated during the stereotyped joystick movement task in schizophrenic patients in remission, in contrast to a control group. Spence and colleagues concluded that, since hypofrontality was evident in schizophrenics who can perform the experimental task, the DLPFC is not necessary for that task. In addition, hypofrontality seems to depend on current symptoms. They suggested the reason for previous equivocal hypofrontality results is that schizophrenics with a varying amount and combination of symptoms are being compared with normal controls. However, these results provoke another question. What is the functional significance of DLPFC activation in normal controls and patients without symptoms if schizophrenic patients with symptoms can perform the task without recruiting the DLPFC?

Verbal Fluency

Verbal fluency tasks involve subjects having to generate words to a given cue. For example, subjects might have to produce a word beginning with a certain letter, a different letter being presented every 5 seconds. This can be seen as a task that involves willed action since subjects have to choose for themselves precisely which word to say. Verbal fluency tasks engage a distributed brain system similar to that engaged by motor response selection tasks associated with willed action (Frith *et al.*, 1991).

Schizophrenic patients showed reduced left PFC activation and increased left temporal activation relative to control subjects during a verbal fluency task in an fMRI study (Yurgelun-Todd *et al.*, 1996b). However, the lack of frontal activation by cognitive tasks in schizophrenic patients has not consistently been located in the PFC. Dolan *et al.* (1995) and Fletcher *et al.* (1996) used a factorial design in PET to test the effect of apomorphine, a non-selective dopamine agonist, which when given in very low doses as in this experiment acts primarily on auto-receptors, thus decreasing the release of endogenous dopamine. Brain systems engaged by a paced verbal fluency task in unmedicated schizophrenic patients and normal controls were studied. Activation of the DLPFC was normal, but they found a failure of task-related activation in anterior cingulate cortex and deactivation of the left superior temporal gyrus in the schizophrenic subjects (see Figure XVII-8.2). Fletcher and colleagues therefore suggested that schizophrenia is associated with both segregated (anterior cingulate) and integrative (fronto-temporal) functional abnormalities. Cingulate activation was restored by low-dose apomorphine in schizophrenics. Additionally, the abnormal fronto-temporal pattern of activation in schizophrenic subjects was normalized by this neuropharmacological intervention. Overall, in schizophrenic subjects the effect of apomorphine was to modify the pattern of brain activity, making it more similar to that seen in control subjects. The interpretation of the apomorphine-induced reversal of the deactivation in the left temporal lobe in schizophrenic subjects is unclear. It might reflect a direct influence of apomorphine on the temporal lobe; alternatively the reversal could be due to a 'downstream' effect of the change in anterior cingulate function. The authors interpret the absence of the normal reciprocal interaction between the frontal and the superior temporal cortex in schizophrenia (the failure of task-related deactivation of the superior temporal gyrus in the schizophrenic group) as suggesting the presence of impaired functional integration. This is an important concept, especially given the relatively large amount of evidence showing a lack of temporal deactivation in the presence of a lack of frontal activation in schizophrenia.

The finding of normal prefrontal activation found in this study is in agreement with a study in which task performance was optimized by pacing the task (Frith *et al.*, 1995). Using PET, these researchers investigated rCBF of 18 chronic schizophrenic patients and six normal controls matched for age, sex and premorbid IQ, while they performed (a) paced verbal fluency, (b) paced word categorization and (c) paced word repetition. The schizophrenic patients were split into three groups according to their verbal fluency task performance level. All patient groups showed the *same* pattern of left PFC activation as control subjects, independent of their level of performance. However, in the left superior temporal cortex, all patient groups failed to show a normal deactivation when verbal fluency was compared with word repetition. Again this result was interpreted to reflect abnormal functional connectivity between frontal and temporal cortex.

Friston and Frith (1995) performed an additional analysis of their data from the same three groups of schizophrenic patients according to the level of task performance: poverty (no words), odd (wrong words) and unimpaired. They used special analytic techniques to assess cortico-cortical interactions. Normal controls showed negative fronto-temporal interactions whereas all the schizophrenic patients showed positive interactions, mostly between the left PFC and infero-temporal cortex. Friston and Frith suggested that this might represent a failure of the PFC to inhibit the temporal lobes. They postulated that the temporal lobes may be required to recognize the consequences of actions initiated by the frontal lobes in order to integrate action and perception.

Verbal Self-Monitoring

Patients with schizophrenia with auditory hallucinations and delusions show impairments on tasks that require monitoring self-generated actions. This is true for motor actions (Frith and Done, 1989; Blakemore *et al.*, 2000; Frith *et al.*, 2000) and verbal self-monitoring tasks (Johns *et al.*, 2001). In particular, when patients

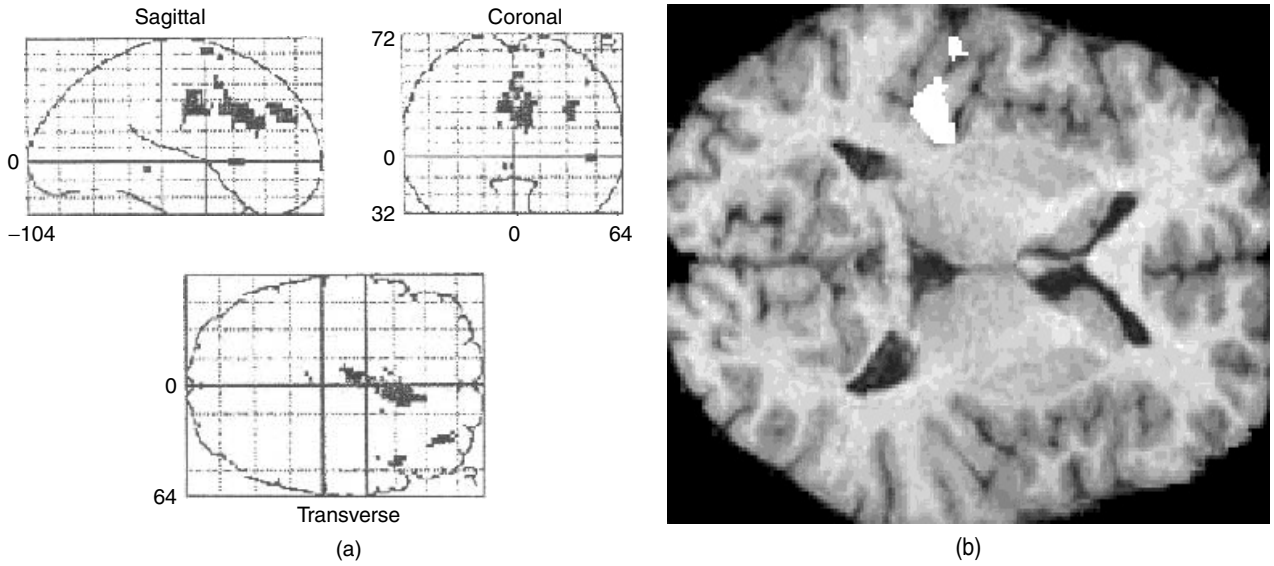

Figure XVII-8.2 (a) Statistical parametric maps (SPMs) showing brain regions where there was a significant ($p < 0.005$) difference in drug (apomorphine)–task (verbal fluency) interaction between the schizophrenic group and the control group. The area in which there was an augmenting effect of the drug on the task-related activity occurring in schizophrenics compared to controls was the anterior cingulate gyrus. In other words, the impaired cingulate activation seen during the verbal fluency task in schizophrenic patients was significantly reversed by apomorphine. (b) Transverse section showing the verbal fluency task-related deactivation of the superior temporal gyrus that was absent in schizophrenic relative to control subjects. The authors interpret the failure of task-related deactivation of the superior temporal gyrus in the schizophrenic group to suggest the presence of impaired functional temporo-frontal integration. speak aloud but hear a distorted version of their own voice, they report hearing someone else rather than themselves. Researchers have recently developed an event-related fMRI acquisition sequence to scan patients during verbal self-monitoring paradigms. Fu *et al.* (2001) compared brain activation patterns of healthy volunteers, schizophrenic patients with acute psychotic symptoms and schizophrenic patients in remission while they read adjectives aloud and heard their voice, which was either undistorted or distorted (in several ways). Words were read and heard during silent portions of the acquisition sequence to control for the problems of scanner noise. The hippocampus, cingulate and cerebellum were particularly activated when healthy controls heard their own distorted voice. Acutely psychotic patients tended to misidentify their own distorted voice as 'other' and did not engage these regions, while the pattern of activation in patients in remission was intermediate between the other two groups. This supports the notion that abnormal brain activity in schizophrenics may be associated with current symptomatology.

Memory Tasks

Memory impairments are especially enduring symptoms in schizophrenia (Green, 1996), with memory storage particularly affected (Feinstein *et al.*, 1998). The DLPFC and the hippocampal formation have been the subject of investigation in schizophrenia, as these are involved in various aspects of memory (Goldman-Rakic and Selemon, 1997; Arnold, 1997). The DLPFC is activated by semantic processing during encoding and retrieval, while hippocampal activation is associated with the detection of novelty and the creation of associations during encoding in normal individuals (Schacter *et al.*, 1996; Dolan and Fletcher, 1997).

Several functional neuroimaging studies have failed to find evidence for abnormal activation of temporal or frontal cortex in schizophrenia during memory tasks (Busatto *et al.*, 1994, using a verbal memory task with SPECT; Ragland *et al.*, 1998, using a Paired Associate Recognition Test with PET). Other studies have shown rCBF changes that overlapped in the schizophrenic and control groups, with a trend towards patients showing smaller activations than controls in frontal and superior temporal cortical regions (e.g. Ganguli *et al.*, 1997, using a verbal free-recall supraspan memory task). These differences may be due to the different type of memory tasks used by each group. Other groups have found evidence for hypofrontality during memory tasks. Carter *et al.* (1998) used PET to evaluate rCBF associated with the 'N-back' working memory (WM) task, during which subjects are presented with a sequential series of items and have to press a button when a presented item has already been presented a certain number (N) of items earlier. This task activates the PFC as a function of WM load in normal subjects. Under low WM load conditions, the accuracy of both groups in the N-back task was equal, but when the memory load increased the patients' performance deteriorated more than did that of control subjects. The rCBF response to increased WM load was significantly reduced in the patients' right DLPFC. Callicott *et al.* (1998) investigated blood oxygen level-dependent (BOLD) signal changes in 10 patients with schizophrenia and 10 controls performing a novel N-back WM task, using fMRI. After removing confounds and matching subjects for signal variance (voxel stability), decreased DLPFC activity and a tendency for overactivation of parietal cortex were seen. However, these findings are difficult to interpret in the context of abnormal task performance in patients. There may be nothing inherently abnormal about the physiology of the frontal cortex in schizophrenia, but patients may be failing to select frontally mediated cognitive strategies because of abnormal connectivity between otherwise normal regions.

Wiser *et al.* (1998) measured rCBF during a long-term recognition memory task for words in schizophrenic patients and in healthy subjects using PET. The task was designed so that performance scores were similar in the patient and control subjects. This memory retrieval task did not activate PFC, precuneus and cerebellum in patients as much as it did in the control group. This finding

suggests that there is a dysfunctional cortico-cerebellar circuit in schizophrenia.

Hypofrontality has not always been found in studies using modified tasks to optimize the performance of schizophrenic subjects. Hypofrontality was not found in a study by Heckers and colleagues (1998), in which they used PET to evaluate 13 schizophrenic patients and a group of normal control subjects during memory retrieval tasks. In this study activation of the PFC correlated with effort of retrieval, and hippocampal and parahippocampal activation occurred during successful retrieval in normal control subjects, a finding consistent with previous studies of memory in normals (Schacter *et al.*, 1996; Dolan and Fletcher, 1997). The schizophrenic patients recruited the PFC during the effort of retrieval but did not recruit the hippocampus during conscious recollection. In addition to the task-specific hippocampal underactivation, the authors observed a generally higher overall level of non-specific hippocampal activity, supporting previous metabolic studies (e.g. Liddle *et al.*, 1992). The authors suggested that high baseline hippocampal activity together with an absence of task-specific activation demonstrates abnormal cortico-hippocampal functional integration in schizophrenia. The schizophrenic patients showed a more widespread activation of prefrontal areas and parietal cortex during recollection than controls, and the authors propose that this overactivation represents an 'effort to compensate for the failed recruitment of the hippocampus'. This interpretation again moves away from the simple notion of dysfunction in isolated brain regions explaining the cognitive deficits in schizophrenia, and towards the idea that neural abnormality in schizophrenia reflects a disruption of integration between brain areas.

Fletcher *et al.* (1998) used PET to compare rCBF in memory-impaired and non-impaired schizophrenic patients with normal controls during a parametrically graded memory task. They found that DLPFC activity correlates with memory task difficulty and performance in the control group. In contrast, for both schizophrenic groups DLPFC activity levels plateaued as task difficulty increased, despite a significant difference in performance between the two schizophrenic groups. The authors therefore suggested that hypofrontality in schizophrenics correlates with *task difficulty* rather than task performance, since the memory-impaired schizophrenic group performed worse than the non-impaired, even though both groups showed no increase in PFC activity as task difficulty increased.

Unlike the control group, there was no inferior temporal/parietal deactivation in either schizophrenic group. The authors suggest that the lack of deactivation of these areas might represent a temporo-frontal disconnection in schizophrenics. Indeed they suggested that because temporal/parietal activations were not correlated with performance, they therefore might represent a core pathology of schizophrenia. This study improves on previous cognitive activation studies in which the confound of non-matched task performance occurs.

Further evidence for abnormal integration between brain areas in schizophrenia comes from a study that specifically investigated the functional integration (Fletcher *et al.*, 1999). Functional integration considers complex cognitive processes as emergent properties of interconnected brain area, building on the idea that simple cognitive processes can be localized in discrete anatomical modules (referred to as 'functional segregation'). Brain areas A and B may be functionally connected if it can be shown that an increase (or decrease) of activity in area A is associated with an increase (or decrease) in area B, which can be shown empirically by analysis of covariance. In this case, activity in A might cause activity in B, or activations in A and B might be caused by changes in another area (C), which projects to A and B. Alternatively, areas A and B may be effectively connected if their relationship can be shown to be causal. This requires a more complex approach in which the anatomical components of a cognitive system are defined. Connections between these regions are designated on the basis of empirical neuroanatomy and the connections are allocated weights or path strengths by an iterative least-squares approach in such a way that the resultant functional model of interregional influences best accounts for the observed variance–covariance structure generated by the functional neuroimaging observations (Friston *et al.*, 1993).

A simplified version of effective connectivity (Friston *et al.*, 1997) was employed by Fletcher *et al.* (1999) to evaluate effective connectivity between regions in the data from their PET study of a graded memory task in schizophrenia. They demonstrated that in control subjects, but not in the schizophrenic patients, the product of PFC and anterior cingulate gyrus (ACG) activity predicted a bilateral temporal and medial PFC deactivation. The authors interpreted these results as showing that in schizophrenia there is an abnormality in the way in which left PFC influences the left superior temporal cortex, and this abnormality is due to a failure of the ACG to modulate the prefronto-temporal relationship (see Figure XVII-8.3).

Conclusion

There is a body of evidence suggesting that schizophrenic patients show abnormal interactions and influences among brain regions (or functional integration) during cognitive tasks. There is currently little *direct* evidence in favour of this hypothesis, and several regions have been found to function abnormally, with no unequivocal evidence for any particular region being involved. However, the majority of positive findings suggest that a disruption of fronto-temporal integration is a core feature of schizophrenia. However, findings have been confounded by several factors, especially use of poor control tasks such as rest, and non-matched task performance in the schizophrenic and control groups. Future cognitive activation studies using improved methodologies should resolve issues such as whether abnormal frontal function causes or reflects poor task performance in schizophrenia. A question of clinical importance is whether different patterns of cortical interaction correlate with or predict schizophrenic symptoms or outcome.

Imaging Symptoms

Functional neuroimaging is also useful for evaluating neural activity in patients experiencing psychotic symptoms.

Hallucinations

Hallucinations, perceptions in the absence of external stimuli, are prominent among the core positive symptoms of schizophrenia. Although auditory hallucinations are more common than any other type, hallucinations in other sensory modalities occur in a proportion of patients. Hallucinations in all modalities tend to be associated with activity in the neural substrate associated with that particular sensory modality. However, there is evidence that activation of the sensory cortex particular to the false perception is not in itself sufficient for the perception. Instead, research suggests that the interaction of a distributed cortico-subcortical neural network might provide a biological basis for schizophrenic hallucinations.

Auditory Hallucinations

The most common type of hallucination in schizophrenia occurs in the auditory domain, and normally consists of spoken speech or voices (Hoffman, 1986). Functional neuroimaging studies of auditory hallucinations suggest that they involve neural systems dedicated to auditory speech perception as well as a distributed

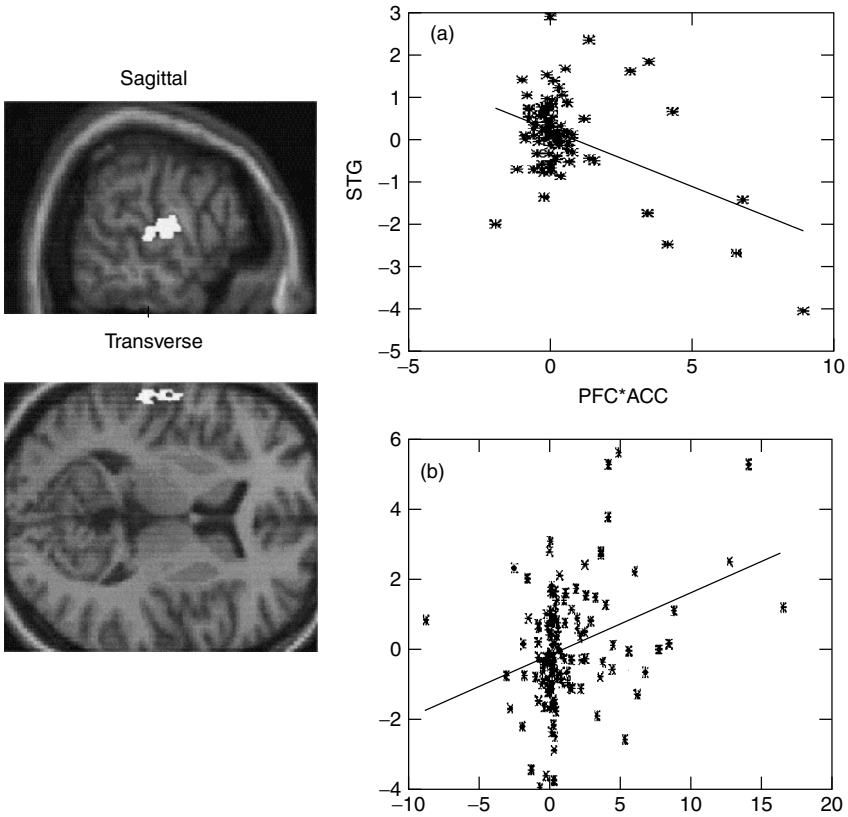

Figure XVII-8.3 Left panel: Region of left superior temporal cortex showing a significant difference between control and schizophrenic subjects ($p < 0.05$). An SPM rendered onto sagittal and transverse section of a stereotactically normalized structural MRI is shown. Right panel: Graphic representation of the relationship between activity in left superior temporal cortex (STG; *y*-axis) and the combination of cingulo-prefrontal activity (PFC × ACG; *x*-axis in (a) controls and (b) schizophrenic subjects. The linear best fit is shown for both groups. The regression coefficient of each of the two groups is considered to provide a measure of *contribution* of PFC × ACC to superior temporal cortical activity. Thus, in the controls an increase in PFC × ACC produces an inhibition of superior temporal activity. In the schizophrenic subjects the line slopes upward, indicating the opposite effect. Reprinted from Fletcher *et al.* (1999), with permission from Neuroimage

network of other cortical and subcortical areas. There are two distinct approaches to the study of the physiological basis of auditory hallucinations. The first, called the state approach, asks what changes in brain activity can be observed at the time hallucinations are occurring. The second, called the trait approach, asks whether there is a permanent abnormality of brain function present in patients who are prone to experience auditory hallucinations when they are ill. This abnormality will be observable even in the absence of current symptoms.

State Studies

Silbersweig *et al.* (1995) used PET to study brain activity associated with the occurrence of hallucinations in six schizophrenic patients. Five patients with classic auditory verbal hallucinations demonstrated activation in subcortical (thalamic and striatal) nuclei, limbic structures (especially hippocampus) and paralimbic regions (parahippocampal and cingulate gyri and orbito-frontal cortex). Temporo-parietal auditory–linguistic association cortex activation was present in each subject. One drug-naive patient had visual as well as auditory verbal hallucinations, and showed activations in visual and auditory/linguistic association cortices. The authors propose that activity in deep brain structures seen in all subjects may generate or modulate hallucinations, and the particular sensory cortical regions activated in individual patients may affect their specific perceptual content. Importantly this study pointed to the possibility that hallucinations coincide with activation of the sensory and association cortex specific to the modality of the experience, a notion that has received support from several further studies.

David *et al.* (1996) used fMRI to scan a schizophrenic patient while he was experiencing auditory hallucinations and again when hallucination free. The subject was scanned during presentation of exogenous auditory and visual stimuli, and while he was on and off antipsychotic drugs. The BOLD signal in the temporal cortex to exogenous auditory stimulation (speech) was significantly reduced when the patient was experiencing hallucinating voices, regardless of medication. Visual cortical activation to flashing lights remained the same over all four scans, whether the subject was experiencing auditory hallucinations or not.

A similar result was obtained by Woodruff *et al.* (1997b), who used fMRI to study seven schizophrenic patients while they were experiencing severe auditory verbal hallucinations and again after their hallucinations had subsided. On the former occasion, these patients had reduced responses in temporal cortex, especially the right middle temporal gyrus, to external speech, compared to when their hallucinations were mild. The authors thus proposed that auditory hallucinations are associated with reduced responsivity in temporal cortical regions that overlap with those that normally process external speech, possibly due to competition for common neurophysiological resources.

Recently, Dierks *et al.* (1999) used event-related fMRI to investigate three paranoid schizophrenics who were able to indicate the onset and offset of their hallucinations as in the study by Silbersweig *et al.* Using this design they found that primary auditory cortex, including Heschl's gyrus, was associated with the presence of auditory hallucinations. Secondary auditory cortex, temporal lobe and frontal operculum (Broca's area) were also activated during auditory hallucinations, supporting the notion that auditory hallucinations are related to inner speech. Finally hallucinations were also associated with increased activity in the hippocampus and amygdala. The authors suggested that these subcortical activations could be due to retrieval from memory of the hallucinated material and emotional reaction to the voices, respectively. A similarly elegant design was employed in a recent fMRI study (Shergill *et al.*, 2000). They found that frontal and temporal speech areas and several other cortical and subcortical regions were activated during auditory hallucinations.

Trait Studies

The finding that auditory hallucinations are associated with activation of auditory and language association areas is consistent with the proposal that auditory verbal hallucinations arise from a disorder in the experience of inner speech (Frith, 1992). This was investigated by McGuire *et al.* (1996). They used PET to evaluate the neural correlates of tasks that engaged inner speech and auditory verbal imagery in schizophrenic patients with a strong predisposition to auditory verbal hallucinations (hallucinators), schizophrenic patients with no history of hallucinations (non-hallucinators) and normal controls. There were no differences between hallucinators and controls in rCBF during thinking in sentences. However, when imagining sentences spoken in another person's voice, which entails both the generation and monitoring of inner speech, hallucinators showed reduced activation of the left middle temporal gyrus and the rostral supplementary motor area, regions activated by both normal subjects and non-hallucinators. Conversely, when non-hallucinators imagined speech, they differed from both hallucinators and controls in showing reduced activation in the right parietal operculum (see Figure XVII-8.4). McGuire and his colleagues suggest that the presence of verbal hallucinations is associated with a failure to activate areas concerned with the monitoring of inner speech.

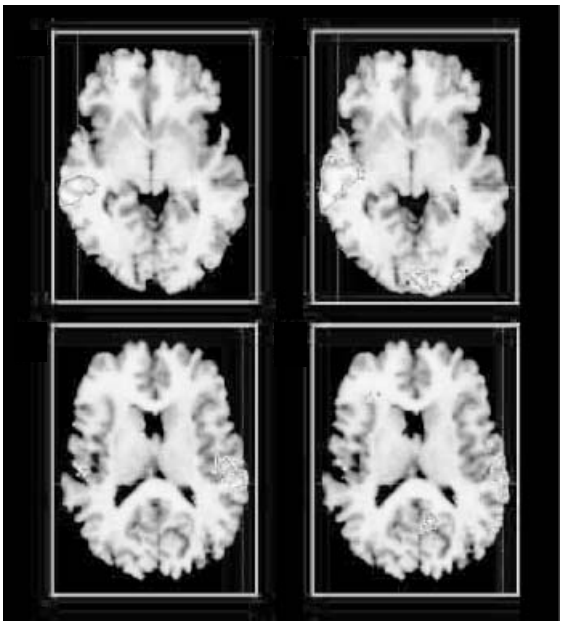

Figure XVII-8.4 Difference in rCBF between schizophrenic patients with a strong predisposition to auditory verbal hallucinations (hallucinators), schizophrenic patients with no history of hallucinations (non-hallucinators), and normal controls during tasks that engaged inner speech and auditory verbal imagery. When imagining sentences spoken in another person's voice, which entails both the generation and monitoring of inner speech, hallucinators showed reduced activation of the left middle temporal gyrus and the rostral supplementary motor area, regions activated by both normal subjects and non-hallucinators. Adapted from McGuire *et al.* (1996) (See Colour Plate XVII-8.4)

Visual Hallucinations

The neural correlates of visual hallucinations also seem to be located in the neural substrate of visual perception. At least part of the activity in the brain associated with the experience of visual hallucinations is located in the visual cortex. For example, using SPECT Hoksbergen *et al.* (1996) found that visual hallucinations were associated with hypoperfusion in the right occipito-temporal region, which showed partial normalization after the visual hallucinations had subsided. Howard *et al.* (1997) used fMRI to investigate the visual cortical response to photic stimulation during and in the absence of continuous visual hallucinations. When visual hallucinations were absent photic stimulation produced a normal bilateral activation in striate cortex. During hallucinations, very limited activation in striate cortex could be induced by exogenous visual stimulation. Similarly, ffytche *et al.* (1998) found activity in ventral extrastriate visual cortex in patients with the Charles Bonnet syndrome when they experienced visual hallucinations. Moreover, the content of the hallucinations reflected the functional specialization of the region, for example, hallucinations of colour activated V4 (the human colour centre; Zeki *et al.*, 1991).

In conclusion, functional neuroimaging studies suggest that hallucinations involve an interaction between the neural systems dedicated to the particular sensory modality in which the false perception occurs and a widely distributed cortico-subcortical system, including limbic, paralimbic and frontal areas. Intersubject variability in the specific location of the sensory activation associated with the hallucination could arise from differences between the patients in the sensory content and experience of their hallucinations.

Thought Disorder

McGuire *et al.* (1998) scanned six schizophrenic subjects with PET while they described a series of ambiguous pictures, which provoked different degrees of thought-disordered speech in each patient. The severity of thought disorder was correlated with rCBF across the 12 scans, controlling for differences in the total number of words articulated. Verbal disorganization (positive thought disorder) was inversely correlated with activity in the inferior frontal, cingulate and left superior temporal cortex, areas implicated in the regulation and monitoring of speech production. The authors propose that this reduced activity might contribute to the articulation of the linguistic anomalies that characterize positive thought disorder. Verbal disorganization was positively correlated with activity in the parahippocampal/anterior fusiform region bilaterally, which may reflect this region's role in the processing of linguistic anomalies.

Passivity Symptoms

Spence *et al.* (1997) performed a PET study in which subjects had to make voluntary joystick movements in the experimental

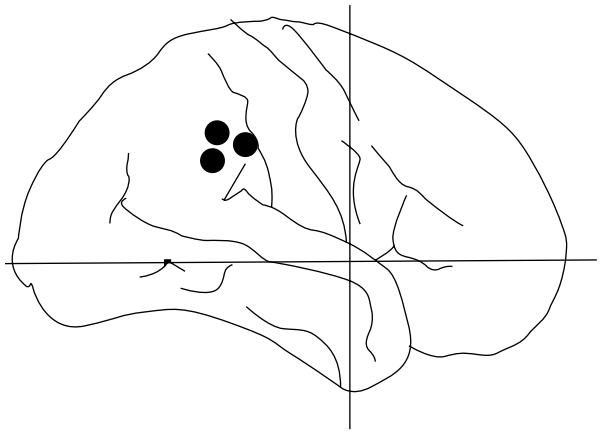

Figure XVII-8.5 Diagram of overactivity in right parietal lobe (Brodmann area 40) in patients with passivity while making voluntary joystick movements (in the study by Spence *et al.*, 1997). When patients were in remission, and no longer experienced passivity symptoms, a reversal of this hyperactivation of parietal lobe was seen. Hyperactivity in parietal cortex might reflect the patient's experiencing the movement as 'unexpected,' as if it were being caused by some external force

condition, and stereotyped (routine) movements in the baseline condition, and do nothing in the rest condition. They investigated a group of schizophrenic patients with passivity (delusions of control) and without (the same group in remission), and a group of normal controls. Schizophrenic patients with passivity showed hyperactivation of inferior parietal lobe (BA 40), the cerebellum and the cingulate cortex relative to schizophrenic patients without passivity (see Figure XVII-8.5). Similar results were found when schizophrenic patients with passivity were compared with normal controls. A comparison of all schizophrenics with normal controls revealed hypofrontality in the patients. When patients were in remission, and no longer experienced passivity symptoms, a reversal of the hyperactivation of parietal lobe and cingulate was seen. Hyperactivity in parietal cortex may reflect the 'unexpected' nature of the experienced movement in patients, as though it were being caused by an external force.

OBSTACLES TO FUNCTIONAL NEUROIMAGING AND SCHIZOPHRENIA STUDIES

Subject Matching

It is important that patients are matched to the control group on as many factors as possible, but the best way to match IQ and education level is uncertain. It is not clear whether the control group's education level should be matched to the patient's parental or premorbid education level. However, both of these are superior to matching controls to patients' current IQ level, which may be considerably impaired by illness.

Another question is whether the control group should be normal or psychiatric. Normal controls are important in order to establish a baseline model of the neural circuitry involved in an experimental task. However, there are several problems with using non-psychiatric controls. These include the fact that normal controls are not taking medication, hospitalized or affect-flattened, factors that might cause the patients to be more or less motivated, to attend or think more or less, or that might have a direct effect on rCBF. Since psychiatric patients will be more matched on these factors they may be a preferable control group. However, there are also problems with using psychiatric patients as controls. There is the question of which psychiatric population should be used. Should they be taking the same medication, or is hospitalization the more important factor? They might not be able to perform the experimental task for some reason that is different from that causing impairment in schizophrenic patients. Therefore, comparing schizophrenic with depressed patients, for example, may reveal activity specific to depression or to schizophrenia.

Experimental Tasks

As has been discussed at length throughout this chapter, there is a conceptual problem with applying the approach of cognitive activation studies to patient groups. It is difficult to interpret patterns of brain activity that differ between control and patient groups when the performance of the two groups on tasks differs in terms of degrees of efficiency and success. Any difference in brain activity between the two groups could represent a critical abnormality in schizophrenia and might cause poor task performance, or alternatively it might reflect poor performance. It is difficult to distinguish these two alternatives. Recent studies have employed tasks on which performance of the patient and control group is matched. However, there is also a problem with interpreting the results of activation studies in which the task performance of the patient and control group is matched. What do differences in brain activity mean in the context of normal task performance? If an area is activated more in the controls than in the patient group during such a task, the functional significance of that activation is difficult to understand — it is clearly not necessary for performing the task. The most obvious interpretation is that patients and controls are using different strategies to achieve similar task performance. Therefore, interpretational difficulties remain: what is the nature of the relationship between differences in brain activity and behaviour? How do these two variables relate to the schizophrenic state? These problems have not been resolved, and remain when interpreting data from studies in which task performance of patient and control groups is matched.

Symptom-Specific Groups

Schizophrenia is a heterogeneous illness, comprising a variety of different symptoms. Using groups of patients defined by diagnosis (schizophrenia) may explain the inconsistent and equivocal results of functional imaging studies, since each symptom may be associated with a different brain pattern or functional abnormality. Attempts have been made to correlate cognitive brain activity with specific symptoms or clinical signs. However, as reviewed here, the results are inconsistent.

A clear advantage of using symptom-specific schizophrenic groups is that the control group can comprise people with a diagnosis of schizophrenia, who are thus matched in terms of medication and hospitalization, but who do not have a particular symptom. Better still, the same group of schizophrenic patients can be used as their own control group if and when the symptom evaluated remits (see the study by Spence *et al.*, 1998). However, a clear shortcoming of using symptom-specific groups is that little can be discovered about schizophrenia as a syndrome.

OVERALL CONCLUSION

Although there has been no specific, replicated finding peculiar either to the syndrome of schizophrenia or to a particular symptom, there have been repeated findings of frontal and temporal abnormalities in schizophrenia, in both resting metabolism and cognitive activation studies. PET and SPECT studies have shown that the density

of DA (in particular D2) receptors is increased in schizophrenic brains, and that typical antipsychotic drugs bind mainly to D2 receptors whereas atypical antipsychotics bind mainly to 5-HT receptors. It is becoming increasingly evident from PET and fMRI studies that schizophrenic patients show abnormal interactions between brain regions during cognitive tasks. There is currently little *direct* evidence in favour of the hypothesis of functional disconnection, and several regions have been found to function abnormally, but with no unequivocal evidence for the consistent involvement of any particular region. However, the majority of positive findings suggest that a disruption of cortico-cortical (and cortico-subcortical) integration is a core feature of the schizophrenic syndrome. Future studies would do well to investigate this possibility, using methods of evaluating functional or effective connectivity to evaluate the influence of one brain region over another.

Neurogenetics of Schizophrenia

S. Zammit, M. O'Donovan and M.J. Owen

INTRODUCTION

The aetiology and pathophysiology of schizophrenia remain largely unknown although many hypotheses prevail. The one aspect of aetiology that has been strongly and repeatedly supported is the existence of an underlying genetic component. In this chapter we present an overview of the literature supporting a genetic basis for vulnerability to schizophrenia, and describe attempts to locate and identify susceptibility genes and the problems inherent with genetic studies of this disorder.

It is important to note that as there are no objective diagnostic tests for schizophrenia diagnosis is based upon patterns of clinical symptoms and signs. Within schizophrenia there is wide variation in the range of symptoms, illness course and outcome, but despite this it has not been possible to delineate aetiologically distinct subgroups. The use of structured and semi-structured interviews together with explicit operational diagnostic criteria means that it is often possible to achieve high degrees of diagnostic reliability within this disorder, and to define a syndrome with high heritability. However, the possibility remains that schizophrenia, as defined by current diagnostic criteria, includes a number of heterogeneous disease processes and that this will hinder any attempts at identifying genetic aetiological factors.

GENETIC RISK

Historical observations that schizophrenia runs in families has led to a number of family, twin and adoption studies which, despite some variation in results, overall provide strong evidence for a genetic component to this disorder with even conservative estimates suggesting a heritability of greater than 60% (McGuffin *et al.*, 1994). The methodology underlying the principles of quantitative genetics are described in detail in Chapter XII (Neurogenetics) and will therefore not be covered in this chapter.

The lifetime risk for schizophrenia in the general population worldwide is generally reported to be around 1%, with the risk increasing exponentially with the degree of relation to an affected individual. The lifetime expectancies of schizophrenia in the relatives of probands has been reviewed by Gottesman and Shields (1982), who looked at all Western European studies prior to the relatively recent introduction of operational diagnostic criteria. The risk to siblings was found to be 10%, offspring of affected probands 13%, parents of an affected proband 6% (somewhat lower than expected, probably reflecting the reproductive disadvantage conferred by schizophrenia), and risk to offspring where both parents were affected was 46%. Many of the studies in this analysis predate up-to-date methods, but in a review of seven methodologically modern studies the finding of an approximately 10-fold increase in risk of schizophrenia in first-degree relatives of schizophrenic probands remains (Kendler and Diehl, 1993).

More recent studies have shown a wider variation in lifetime expectancies for relatives, probably as a result of the use of different diagnostic criteria which vary with regard to strictness of case selection. Standardization of diagnoses is therefore an important factor in reducing bias of results. For this reason an approach used by many groups carrying out genetic studies of schizophrenia is to obtain data in a manner that allows different operational criteria to be applied to the same data set, thereby allowing direct comparisons between different studies. One example of this is the Operational Criteria Checklist (OPCRIT), which allows diagnoses according to seven different criteria to be made, including ICD-10 and DSM-III-R diagnoses (McGuffin *et al.*, 1991).

Twin and adoption literature on schizophrenia permit genetic factors to be differentiated from infective, cultural, socio-economic or other environmental factors potentially causing the familial clustering observed in family studies. Adoption studies of the three main study designs (adoptee studies, cross-fostering studies and adoptee family studies) provide evidence that there is an increased risk of schizophrenia in first-degree relatives of probands, though not in non-biologically related adopted or adoptive family members who share the same environment as probands. (Heston, 1966; Rosenthal *et al.*, 1971; Kety *et al.*, 1994; Wender *et al.*, 1974). The data of Kety *et al.* (1994) from Denmark have been reanalysed applying DSM-III criteria, with consistent results (Kendler *et al.*, 1994): 7.9% of first-degree biological relatives of proband adoptees had DSM-III schizophrenia, compared with 0.9% of first-degree relatives of control adoptees. A further Finnish study (Tienari *et al.*, 1994) found a higher prevalence of DSM-III-R schizophrenia in the adoptive offspring of mothers with schizophrenia or a related disorder, compared with control offspring (4.4% vs. 0.5%).

Twin studies compare the concordance rates between monozygotic (MZ) and dizygotic (DZ) twins, and the overwhelming evidence from these studies is that shared genes rather than shared environments underlie the increased risk of illness in relatives of probands (McGuffin *et al.*, 1994). Based upon the five most recent systematically ascertained twin studies, the proband-wise concordance rate for schizophrenia in MZ twin pairs is 41–65% compared with 0–28% for DZ twin pairs, corresponding to heritability estimates of approximately 80–85% (Cardno and Gottesman, 2000). Furthermore, a review of MZ twins reared apart (McGuffin *et al.*, 1994) found a concordance rate in this group of 58%, similar to that for MZ reared together.

It is clear therefore that although environmental factors play an important role in determining liability to schizophrenia (MZ concordance rates substantially less than 100%), the major determinant of individual variation in susceptibility seems to be genetic. Studies on the recurrence risk in various classes of relative allow us to exclude the possibility that schizophrenia is a single-gene disorder or collection of single-gene disorders even when incomplete penetrance is taken into account (O'Rourke *et al.*, 1982; McGue and Gottesman, 1989). Rather, the mode of transmission, like that

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

of other complex disorders, is complex and non-Mendelian. The commonest mode of transmission is probably oligogenic (a small number of genes of moderate effect) or polygenic (many genes of small effect) or a mixture of the two (McGuffin *et al.*, 1995). However, the number of susceptibility loci, the disease risk and attributable risk conferred by each locus, the degree of epistasis (interaction between loci) and interaction with environmental factors all remain unknown. Complex inheritance implies that not all affected individuals will carry a given susceptibility variant and, conversely, many unaffected individuals will also carry these susceptibility variants, i.e. risk alleles may be neither sufficient nor always necessary to cause schizophrenia.

The contribution of individual genes to the familiality of a disorder can be expressed in terms of λ_s, which is the relative risk to siblings compared to the general population resulting from possession of the disease allele (Risch, 1990a). By comparing expected with observed recurrence rates for a range of classes of relative, Risch (1990a) has calculated that the data for recurrence risks in the relatives of probands with schizophrenia are incompatible with the existence of a single locus of $\lambda_s > 3$ and, unless extreme epistasis exists, models with two or three loci of $\lambda_s \leq 2$ are more plausible. It should be emphasized that these calculations are based upon the assumption that the effects of genes are distributed equally across the whole population and it is quite possible that genes of larger effect are operating in a subset of patients.

Although the weight of evidence from genetic epidemiology supports the view that genes play a substantial role in aetiology, the distinction between genetic and environmental factors is not always as straightforward as at first appears. There are a number of genetic mechanisms such as somatic mutation, genomic imprinting and mitochondrial inheritance that could cause phenotypic differences, including discordance, between MZ twins and which would therefore contribute to the so-called 'environmental' effects observed in twin studies (McGuffin *et al.*, 1995; Morgan *et al.*, 1999). It is also possible that stochastic factors could play a role in mediating the effects of genotype on phenotype, particularly where a complex process such as brain development is concerned (McGuffin *et al.*, 1995), and these too would inflate the contribution of environmental effects estimated from twin and adoption studies. On the other hand, interactions between genes and environment tend to be included in the 'genetic' component of models; for example, phenylketonuria is regarded very much as a genetic disorder (eliminating all the disease genes from the population would eradicate the disease), although it could also be thought of as totally environmental (since removing all phenylalanine from the environment would also eradicate the disease).

While it is clear therefore that there is a genetic contribution to schizophrenia, it is equally clear that what is inherited is not the certainty of disease accompanying a particular genotype but rather a predisposition or liability to develop the disorder. Moreover, twin and adoption studies have also shown that schizophrenia shares familial, and probably genetic, liability with a range of other psychotic illnesses (Kendler *et al.*, 1993a) and both schizotypal and paranoid personality disorder (Kendler *et al.*, 1993b), collectively known as the schizophrenia spectrum disorders.

At its most general, the implication is that spectrum disorders probably share at least some genetic risk factors in common with schizophrenia itself, although it is also possible that all these disorders share the same risk factors under a single liability model. The hypothesis that each disorder represents a separate threshold on a liability distribution was tested on family data (Kendler *et al.*, 1995b) and the patterns of familial aggregation were found to be consistent with a spectrum model, though the order in which the disorders occurred could not be specified. There has also been support for a continuum between schizophrenia and schizotypal personality disorder (Baron and Risch, 1987), but not for one between schizophrenia and a 'spectrum' comprising a range of non-affective psychotic, neurotic, personality and other psychiatric disorders (Tsuang *et al.*, 1983). This uncertainty regarding the limits of this spectrum of disorders and its relationship with other disorders further complicates the process of genetic analysis of schizophrenia (Kendler *et al.*, 1995a, 1998; Cardno *et al.*, 2002).

GENE-MAPPING STRATEGIES

The two main groups of strategies used to identify genes in complex disorders are linkage and association. In linkage studies the aim is to identify alleles that segregate with the disease in families with two or more affected individuals. This approach can detect the presence of genes over large chromosomal distances and thus is readily applicable to genome-wide studies. It is ideally suited to detecting genes in monogenic disorders, but its power to detect genes of moderate to small effect is limited.

In association studies, on the other hand, the unit of study is a sample of unrelated people usually in the form of a case–control design. Here the aim is to detect alleles that are more (or less) common in cases than controls. Association studies have considerable power to detect the genes of small effect that are most likely to be operating in complex disorders such as schizophrenia, but depend upon the marker studied either being the pathogenic variant itself or being so close as to be in linkage disequilibrium (LD) with it. LD refers to the non-random association in a population of alleles at two closely linked loci and can occur when most cases of a disease are caused by a mutation in a common ancestor, known as a founder mutation. The disequilibrium will be eroded by recombination during meioses and therefore for LD to be maintained over many generations marker alleles need to be much closer to susceptibility loci than they do for linkage-based studies. A systematic, genome-wide search for association would thus require many thousands of markers. Other strategies employed in the search for susceptibility genes for schizophrenia that will be covered in this chapter include the investigation of cytogenetic abnormalities and quantitative trait locus (QTL) mapping. For further detail regarding the principles and techniques underlying all these strategies please refer to Chapter XII.

Linkage Studies

The first wave of molecular genetic studies of schizophrenia effectively ignored the evidence for genetic complexity by focusing on large multiply affected pedigrees under the assumption that aetiological heterogeneity exists and that such families, or at least a proportion of them, are segregating genes of major effect. This approach has been successful in other complex disorders, particularly Alzheimer's disease, where mutations in three genes, APP, PS1 and PS2, are now known to cause rare forms of the disorder where disease of unusually early onset is inherited in an autosomal dominant fashion (Goate *et al.*, 1991; Sherrington *et al.*, 1995; Levy-Lahad *et al.*, 1995). Similar studies of large families segregating schizophrenia and related phenotypes also initially produced positive findings (Sherrington *et al.*, 1989) but unfortunately these could not be replicated. The reasons for this have become clear as data from systematic genome scans have accumulated. It seems likely that highly penetrant mutations causing schizophrenia are at best extremely rare and quite possibly non-existent (McGuffin and Owen, 1996; Craddock *et al.*, 1995), with type I (false positive) errors arising largely from a combination of multiple testing and the use of statistical methodology and significance levels derived from work on single-gene disorders.

In spite of the failure to identify genes of major effect in multiply affected families, moderately significant evidence for linkage has been found in more than one data set in several

chromosomal regions. Evidence for linkage on chromosomes 22q11–12, 6p24–22, 8p22–21 and 6q have received supportive evidence from international collaborative studies (Gill *et al.*, 1996; Schizophrenia Linkage Collaborative Group, 1996; Levinson *et al.*, 2000), while a number of other promising areas of putative linkage have been supported by other individual groups, although not from larger international consortia. These include 13q14.1–q32 (Lin *et al.*, 1995; Blouin *et al.*, 1998; Brzustowicz *et al.*, 1999), 5q21–q31 (Schwab *et al.*, 1997; Straub *et al.*, 1997) and 10p15–p11 (Schwab *et al.*, 2000; Faraone *et al.*, 1998; Straub *et al.*, 1998). One other region of note is 1q21–q22 following a report of strong linkage (maximum heterogeneity LOD score of 6.5) from one study (Brzustowicz *et al.*, 2000). This finding more than meets standard criteria for claiming 'significant' linkage as proposed by Lander and Kruglyak (1995), but the need for replication from other sources remains an important issue. There have been other reports of linkage to markers on chromosome 1 (Hovatta *et al.*, 2000; Ekelund *et al.*, 2000), but these are distal to 1q21–q22 and it is not yet clear that these findings are consistent with the existence of a single susceptibility locus on 1q.

While the linkage data based upon multiplex families are not definitive, it seems likely that one or more of the above loci are true positives. However, it should be noted that in every case there are negative as well as positive findings, and in only two cases, 13q14.1–q32 and 1q21–q22, did any single study achieve 'genome-wide significance' at $p < 0.05$. Genome-wide significance refers to a linkage value that is expected by chance less than once in 20 complete genome scans and which therefore takes account of the multiple testing inherent in systematic searches for linkage.

As an alternative to linkage based upon multiplex families, some groups have advocated the use of smaller families with two or more affected in a single sibship. This is in the belief that such families may be more suited for the analysis of complex traits, and being much more common may also be more representative of disease in the general population. This approach has been successful in detecting linkage to several complex diseases, including late-onset Alzheimer's disease (Myers *et al.*, 2000). Williams *et al.* (1999) conducted the largest systematic search for linkage in affected sibling pairs (ASPs) with schizophrenia published to date. This study of 196 ASPs was designed to have power >0.95 to detect a susceptibility locus of $\lambda_s = 3$ (the maximum effect size estimated by Risch, 1990b) with genome-wide significance of 0.05. However, no regions of the genome gave linkage results approaching genome-wide significance although modest evidence (at the level expected by chance once per genome scan) was found for loci on chromosomes 4p, 18p and the centromeric region of X.

The pattern of findings from linkage studies of schizophrenia demonstrates several features that are to be expected in the search for genes involved in disorders that are predisposed to by the combined action of several genes of moderate effect (Suarez *et al.*, 1994; Lander and Schork, 1994; Lander and Kruglyak, 1995). First, no finding replicates in all data sets; secondly, levels of statistical significance and estimated effect sizes are usually modest; and thirdly, chromosomal regions of interest are typically broad (often >20–30 centimorgans). Unfortunately, it is debatable whether at present the statistical support for linkage associated with any of the regions reported above is sufficiently strong to warrant large-scale and expensive efforts aimed at cloning putative linked loci, given that some or all of these findings could be type I errors. Linkage methods can detect smaller-sized genetic effects of the magnitude likely to be operating in schizophrenia (λ_s 1.5–3) in sample sizes that are realistic (600–800 ASPs) (Hauser *et al.*, 1996; Scott *et al.*, 1997) although this would be considerably larger than sample sizes used to date. It is of great importance therefore that in the future large enough samples are used to provide sufficient power to detect linkage, though if schizophrenia does just reflect the operation of many genes of small effect then even these large-scale studies may be unsuccessful.

Association Studies

Association studies offer a powerful means of identifying genes of small effect in realistically sized samples of unrelated cases. The requirement for markers to be themselves the susceptibility locus, or at least so close as to be in linkage disequilibrium with it, means that this approach is ideally suited to the study of polymorphisms within candidate genes. The main problem with this approach is that we have such limited knowledge about the pathogenesis of schizophrenia that the potential choice of candidate genes is limited largely by the number of genes in the human genome (estimated at around 40 000).

As a result of doubts concerning the robustness of linkage findings in schizophrenia, most studies to date have focused upon functional candidate genes (i.e. those involved in a biological process thought to be relevant to schizophrenia) rather than positional candidates in regions implicated by linkage studies. Genes involved in dopaminergic and serotonergic neurotransmission have received particular attention as candidate genes based upon neuropharmacological studies, which suggest that abnormalities of both these systems may play a role in the aetiology of schizophrenia. However, it is becoming increasingly clear that other neurotransmitter systems, and in particular glutamatergic and GABAergic systems, are probably involved in the pathogenesis of schizophrenia, while neuropathological and neuroimaging studies provide some support for the importance of neuromodulation and neurodevelopment as pathological processes. Our widening concept of the possible mechanisms underlying the aetiology of schizophrenia is reflected in the choice of functional candidates being studied (Malhotra, 2001).

Numerous candidate gene analyses have been reported in schizophrenia, but no positive finding has received sufficient support from more than one group to suggest a true association with even a modest degree of probability, except perhaps for the serotonin 5-HT2a and dopamine D3 receptor genes discussed below.

Serotonin 5-HT2a Receptor Gene

The serotonergic system is a therapeutic target for several antipsychotic drugs. The first genetic evidence for its involvement in schizophrenia was a report of association with a polymorphism at nucleotide 102 in the HTR2A gene, which encodes the 5-HT2a receptor (Inayama *et al.*, 1996), whereby a point mutation results in a thymine-to-cytosine base change. This association was based upon a small sample of Japanese subjects. Firmer evidence for association subsequently emerged from a large multi-centre European consortium (Williams *et al.*, 1996) and a meta-analysis of all the data available in 1997 based upon more than 3000 subjects (Williams *et al.*, 1997).

If we assume that schizophrenia is homogeneous and that the association is correct, the odds ratio (OR) for the C allele is approximately 1.2 (95% confidence interval 1.07, 1.31). Given the difficulties and expense inherent in these types of studies some may question whether any priority should be given to finding such genes of small effect, though of course if a risk factor is common in the population then it can be associated with a high attributable risk even though the relative risk may be low. For example, in schizophrenia the population attributable fraction associated with possession of allele C of the T102 C polymorphism in 5-HT2A is 0.35 (Williams *et al.*, 1997).

Since the meta-analysis was undertaken, a few further negative reports have followed, none with the sample sizes (and thereby power) required to detect an association. Sample sizes of 1000 subjects are required for 80% power to detect an effect of

this size even at a 5% significance level. However, while the negative studies do not refute the putative association, the evidence presented even in the meta-analysis ($p = 0.0009$) is well short of genome-wide significance (estimated at around $p = 5 \times 10^{-8}$ by Risch and Merikangas, 1996). Admittedly, demanding genome-wide significance is inappropriate for such a strong candidate gene because the prior probability that it is involved in schizophrenia is greater than a gene selected at random. However, as there is no way of quantifying how much greater the prior probability is, we have no compelling alternative to genome-wide significance. Consequently, we have to surmise that the evidence tends to indicate association between 5-HT2a and schizophrenia, but that the burden of proof has not yet been met.

Another reason to be sceptical about the putative association is that there are no variants yet detected in the gene that clearly alter receptor function or expression, although there is some indirect evidence for the existence of a sequence variation elsewhere that alters 5-HT2a expression in some regions of the brain (Bunzel *et al.*, 1998).

Dopamine D2 Receptor Gene

The dominant neurochemical hypothesis of schizophrenia involves dysregulation of the dopaminergic system, and increased levels of striatal dopamine D2 receptors has been repeatedly reported in post-mortem studies, although it remains unclear how much of this is secondary to treatment with antipsychotic medication. Neuroimaging studies have provided conflicting results regarding D2 receptor levels, but nevertheless the strength of evidence implicating this receptor makes the DRD2 gene a promising candidate for genetic studies (Kahn and Davidson, 1995; Harrison, 1999). However, association analyses of the DRD2 gene to date have essentially been negative, although recently three studies have found an association with a polymorphism (−141C Ins/Del) in the promoter region of this gene that alters DRD2 expression *in vitro* (Arinami *et al.*, 1997; Ohara *et al.*, 1998; Jonsson *et al.*, 1999). Unfortunately, the largest single study of this polymorphism found no evidence for association (Li *et al.*, 1998). Furthermore, when the UK data from this study were combined with a large data set from Scotland, the allele that was associated with schizophrenia in the other three studies was actually significantly less common in cases than controls (Breen *et al.*, 1999). This finding has been interpreted as suggestive that the polymorphism tested in these studies is simply a marker for the true susceptibility variant (i.e. that the association is due to linkage disequilibrium). While it is reasonable to attribute reversal of allelic association to LD differences between samples of different ethnic origins, the explanation would be more convincing if the same allele was associated in both UK and Swedish samples. Furthermore, if LD is the explanation for the association, then the fact that this particular polymorphism is functional is no longer relevant. Further studies of this polymorphism are therefore required to clarify the possible role of this variant in the aetiology of schizophrenia.

Dopamine D3 Receptor Gene

The dopamine hypothesis has received somewhat stronger, although not robust, support from studies of the DRD3 gene, which encodes the dopamine D3 receptor. Association has been reported between schizophrenia and homozygosity for a Ser9Gly polymorphism in exon 1 of this gene (Crocq *et al.*, 1992). As expected, both positive and negative reports of association with this polymorphism have emerged, but unlike the situation with the DRD2 gene, sufficient data are available for meta-analysis. Based upon all available data from over 5000 individuals, Williams *et al.* (1998) concluded in favour of an association although the effect size was extremely small ($OR = 1.23$, 95% CI 1.09, 1.38) but nominally significant ($p = 0.0002$). For the same reasons outlined above regarding the 5-HT2a gene, the level of statistical evidence here, while supportive of a significant association, is not conclusive.

Anticipation and Trinucleotide Repeats

One class of mutation rather than a particular gene that merits specific mention is that of expanded trinucleotide repeats, whose hallmark is the phenomenon of anticipation, whereby a disease becomes more severe or has an earlier age at onset in successive generations. Numerous studies have now suggested that the pattern of illness in multiplex pedigrees segregating schizophrenia and other psychotic illnesses is consistent with anticipation, although ascertainment biases in these studies is difficult to rule out (O'Donovan and Owen, 1996). This hypothesis has received support from a number of studies reporting that large but unidentified CAG/CTG trinucleotide repeats are more common in patients with schizophrenia and other psychoses than in unaffected controls (e.g. O'Donovan *et al.*, 1995; Morris *et al.*, 1995), although these early findings have been followed by numerous failures of replication. Also, the specific loci responsible for around 50% of the anonymous CAG/CTG repeats detected in the previous studies have now been identified, but are not associated with psychosis (e.g. Vincent *et al.*, 1999; Bowen *et al.*, 2000). These data have tempered much of the enthusiasm for the CAG/CTG hypothesis, but it is still premature to discard it. Indeed two independent groups have recently detected the presence of proteins in a small number of schizophrenics that react with an antibody against moderate–large polyglutamine sequences (Ross, 1999). This is of relevance here because polyglutamine sequences are often encoded in DNA by CAG repeats, though it remains to be seen whether these proteins are involved in the disease rather than simply chance findings.

Interpreting Association Studies of Schizophrenia

Unfortunately association studies are prone to type I errors, the most likely reasons being the low prior odds of association and the multiple testing involved (Owen *et al.*, 1997; Risch and Teng, 1998), a problem that will be even more significant when genome-wide scans are undertaken. Additionally, association studies are heavily influenced by population structure, and confounding may occur due to population stratification, resulting in different allele frequencies at the marker locus in the cases and controls. This problem can be addressed by family-based association methods (Schaid and Sommer, 1994), but large enough samples of individuals with schizophrenia with all relevant family members willing to participate are difficult to collect (O'Donovan and Owen, 1999).

A further problem is that samples are often ascertained in widely differing and unsystematic ways, and any associations reported might therefore be with other confounding variables such as co-morbidity, or with modifying factors such as those influencing disease severity or age at onset. For example, genes involved in the monoamine system implicated in the aetiology of schizophrenia may help to determine drug response rather than contribute to the aetiology in any way. The design of studies using only incident cases may be required before explanations of this sort can be excluded.

It is important to note, however, that the overwhelmingly negative reports from association studies of schizophrenia cannot be considered as definitive exclusions of small genetic effects due to the possibility of type II (false negative) errors resulting from insufficient power of most association studies to reliably detect a small effect size. It is therefore very important that association studies that aim to test putative associations should be based upon large enough samples (usually several hundred to a thousand cases

with as many, if not more, controls) to provide meaningful tests of association. Even with larger samples though, if aetiological heterogeneity does exist in schizophrenia, the lack of biologically meaningful diagnostic tests means it is possible that conflicting studies contain different balances of unknown subtypes of the disease which might dramatically alter the power for excluding association. Similarly, if there are differences in the contribution of a given allele in different ethnic groups (arising from different allele frequencies or different allele frequencies at interacting loci), aetiological heterogeneity will again alter the power to find a true association. At present, there are no simple ways to take such possibilities into account other than to recognize their potential existence. Basing future studies on sound epidemiological principles will be essential to avoid some of the problems inherent in studies to date, and to maximize the potential for finding true associations in this disorder.

Cytogenetic Abnormalities

A third approach by which investigators have sought to locate susceptibility genes for schizophrenia has been to identify chromosomal abnormalities in affected individuals. Cytogenetic anomalies, such as translocations and deletions, may be pathogenic through several mechanisms; direct disruption of a gene or genes, indirect disruption of the function of neighbouring genes by a so-called position effect or an alteration of gene dosage in the case of deletions, duplications and unbalanced translocations. It is also possible for an abnormality merely to be linked with a susceptibility variant within a particular family.

There have been numerous reports of associations between schizophrenia and chromosomal abnormalities (Bassett, 1992; Baron, 2001) but with two exceptions none has as yet provided convincing evidence to support the location of a gene conferring risk to schizophrenia. The first strongly suggestive finding is a t(1;11) balanced reciprocal translocation found to co-segregate with schizophrenia in a large Scottish family (St Clair *et al.*, 1990). This cytogenetic abnormality results in a portion of chromosome 11 being translocated to chromosome 1 and vice versa, and which has recently been reported to directly disrupt three genes, of unknown function, on chromosome 1 (Millar *et al.*, 2000). Interestingly the breakpoint appears to be located close to the markers implicated in the two Finnish studies mentioned previously in the linkage section of this chapter (Hovatta *et al.*, 2000; Ekelund *et al.*, 2000). However, until mutations have been identified in other families or convincing biological evidence implicating this locus has been obtained, the mechanism by which the translocation confers risk to mental illness remains obscure.

The second finding of interest is the association between velocardio-facial syndrome (VCFS) and schizophrenia. VCFS, also known as DiGeorge syndrome, is associated with small interstitial deletions of chromosome 22q11. The phenotype of VCFS is variable, but in addition to characteristic core features of dysmorphology and congenital heart disease there is strong evidence that individuals with VCFS have a dramatic increase in the risk of psychosis, and in particular schizophrenia and allied disorders (Shprintzen *et al.*, 1992; Pulver *et al.*, 1994; Papolos *et al.*, 1996; Murphy *et al.*, 1999). With an estimated prevalence of one in 4000 live births, one can estimate that VCFS cannot be responsible for more than a small fraction (~1%) of cases of schizophrenia, and this estimate is in keeping with empirical data (Karayiorgou *et al.*, 1995). However, from the perspective of genetic research, the high rate of psychosis in VCFS may provide a short-cut to a gene within the deleted region which is involved in susceptibility to schizophrenia even in cases without a deletion. As we have mentioned already, evidence for linkage of a general schizophrenia susceptibility locus on 22q has been found, and although most studies suggest that this maps outside the VCFS region, linkage mapping in complex diseases is imprecise and modest evidence for linkage within the VCFS region has also been reported (Blouin *et al.*, 1998; Lasseter *et al.*, 1995; Shaw *et al.*, 1998). Overall, the combination of these findings supports the view that a susceptibility gene for schizophrenia exists within this region and efforts are currently under way to try and identify this gene.

Refining the Phenotype

The effectiveness of molecular genetic studies will depend upon the genetic validity of the phenotype. If we were better at defining schizophrenia, would we be better at finding genes? The first thing to note at this point is that the commonly used diagnostic criteria define phenotypes with high heritability. In principle, therefore, it should be possible to identify the genes predisposing to schizophrenia if sufficiently large samples are studied. However, perhaps genetic validity could be improved by focusing upon aspects of clinical variation such as age of onset or symptom profiles, or by identifying biological markers that predict degree of genetic risk or define more homogeneous subgroups.

Despite much work, it has not been possible to identify genetically distinct subtypes of schizophrenia. Instead, clinical variation is likely to reflect in part at least a combination of quantitative variation in genetic risk for the disorder and the effect of modifying genes which influence illness expression rather than the risk of illness *per se*. Examples of this phenomenon relating to age at onset and symptom pattern in schizophrenia have been discussed elsewhere (Owen *et al.*, 2000).

The search for trait markers aims to move genetic studies beyond the clinical syndrome by identifying indices of genetic risk that can be measured in asymptomatic individuals and/or by identifying markers of pathophysiological processes that are closer to the primary effects of susceptibility genes than clinical symptoms. Indeed it may be that there are no genes 'for' schizophrenia as such, but only those for other factors such as personality and IQ that increase risk of the disorder. Candidate trait markers for schizophrenia to date include schizotypal personality traits, measures of cognitive processing, brain-imaging abnormalities, brain-evoked potentials and abnormalities in eye movements (Cannon *et al.*, 2001; Holzman, 2000; Turetsky *et al.*, 2000; Egan *et al.*, 2000; Adler *et al.*, 1999), and this area of research is discussed further in Chapter XVII-10. However, it seems unlikely that this search for trait markers will provide a rapid solution to the problem of identifying susceptibility genes for schizophrenia. First, we will need to ensure that the measures used are stable and determine the extent to which they are affected by state. Second, to be of use in gene mapping, such measures will have to be practicably applied to a sufficient number of families or unrelated patients. Third, we will need to ensure that the traits identified are highly heritable, which will itself require a return to classic genetic epidemiology and model fitting.

Efforts to improve the selection of phenotypes are also concerned with enhancing the traditional categorical approach to defining psychiatric disorders, by identifying genetically valid phenotypes that can be measured quantitatively. These can be used in quantitative trait locus (QTL) approaches to gene mapping. QTL linkage (Kruglyak and Lander, 1995) is generally carried out in sib-pairs and is based on the principle that at a locus influencing a trait or at a linked marker locus sibs with more similar phenotypic scores should share more alleles identical-by-descent (ibd), while QTL association (Page and Amos, 1999) is based on samples of unrelated individuals, and seeks evidence of differences in phenotypic values according to allelic or genotypic differences at a locus. This approach could be applied to measures of schizophrenia proneness, though again state effects may pose difficulties, or to quantitative features of the illness such as age at onset, symptom profile or outcome which could reflect the degree of genetic loading, modifying

loci or a combination of the two. For example, there is strong evidence for a genetic contribution to variation in age of onset, with correlations of 0.76 for MZ and 0.26 for DZ pairs reported by Cannon *et al.* (1998). Attempts to identify genes that modify age of onset and other clinical variation within schizophrenia are under way, although there have been no replicated positive findings as yet (Kendler *et al.*, 2000; Brzustowicz *et al.*, 1997; Cardno *et al.*, 2001).

FUTURE DIRECTIONS

Functional Studies

The most important and the most obvious implication of identifying genetic risk factors for schizophrenia is that it will inspire a new wave of neurobiological studies from which new and more effective therapies will hopefully emerge. However, while the unequivocal identification of associated genetic variants will represent a great advance, many years of work will still be required before this is likely to translate to the bedside. An early problem will be to determine exactly which genetic variation amongst several in LD in a given gene is actually responsible for the functional variation. Even where a specific variant within a gene can be identified as the one of functional importance, functional analysis, in terms of effect at the level of the organism, is likely to be particularly difficult for behavioural phenotypes in the absence of animal models. Disorders that predominantly involve higher cognitive functions such as schizophrenia are difficult to model in animals although some features of the human phenotype, including enlarged cerebral ventricles and information-processing abnormalities such as defects in pre-pulse inhibition, can be detected in animals. An extra level of complexity, however, is the need to produce model systems, both *in vivo* and *in vitro*, that allow gene–gene and gene–environment interaction to be studied. For further details regarding the use of animal models in research into schizophrenia please refer to Chapter XVII-1.

Pharmacogenetics

Another rapidly expanding field within the realm of research into schizophrenia is that of pharmacogenetics, where underlying genetic variation is investigated as a cause for individual variation in response to antipsychotic drug treatment. Antipsychotic pharmacogenetic studies have focused mainly on the atypical agent clozapine, with some evidence for an association between polymorphisms in the 5-HT2a receptor gene and clinical response (Arranz *et al.*, 1998). Additionally, Arranz *et al.* (2000) studied the role of 19 neurotransmitter gene polymorphisms, and reported that a combination of six polymorphisms had a 77% success rate at predicting clozapine response, with a sensitivity of 95% for satisfactory response, although replication by prospective studies is required before one can envisage a use for this sort of information in clinical practice. Studies of genetic variation predicting side effects of antipsychotics are also under way, and there is some evidence to date for an association between a DRD3 polymorphism and antipsychotic-induced tardive akathisia and dyskinesia (Eichhammer *et al.*, 2000; Basile *et al.*, 1999).

Nosology

While the development of new therapies will take time, it is likely that the identification of susceptibility genes will have an earlier impact on psychiatric nosology. By correlating genetic risk factors with clinical symptoms and syndromes it should be possible to study heterogeneity and co-morbidity in order to improve the diagnosis and classification of psychosis, which will clearly facilitate all avenues of research into these disorders. Improvements in diagnosis and classification should enhance our ability to detect further genetic and environmental risk factors and thus a positive feedback between nosology, epidemiology and molecular genetics can be envisaged.

Genome-Wide Association Studies

In recent years there has been increasing interest in the possibility of systematic, genome-wide association studies that have the potential of allowing systematic searches for genes of small effect in polygenic disorders (Risch and Merikangas, 1996; Collins *et al.*, 1997; Owen *et al.*, 2000). Optimism has been fuelled by the fact that the most abundant form of genetic variation, the single nucleotide polymorphism (SNP), is usually bi-allelic and potentially amenable to binary, high-throughput genotyping assays, the most promising of which are at present micro-arrays (so-called DNA chips). Moreover, as the amount of sequence data accumulates through the work of the Human Genome Project, it has become possible to contemplate the construction and application of very dense maps of hundreds of thousands of SNPs (Wang *et al.*, 1998). Association could then be sought between the disease and a comprehensive catalogue of every variant that can alter the structure, function or expression of every single gene. At present this is not feasible technically or economically, and studies in the next few years will probably utilize SNPs from coding sequences that actually alter protein structure in a wide range of functional and positional candidate genes. However, given the difficulty in identifying functional SNPs in regulatory, rather than coding, regions of the genome, as well as our ignorance of the pathophysiology of schizophrenia, the expectation should be that most reported associations will be false, and this will only be resolved by replication in large well-characterized samples.

An alternative approach is to seek associations between markers and disease that are due to linkage disequilibrium between the markers and susceptibility variants. This would allow the whole genome to be systematically screened if dense enough marker maps could be applied. Although this approach is, at present, not widely applicable at a genome-wide level, smaller-scale studies focusing upon specific regions indicated by the results of linkage studies may allow loci to be mapped. However, several practical difficulties as well as uncertainties about these approaches remain (Owen *et al.*, 2000) and the era of genome-wide association studies is not yet at hand.

Molecular Epidemiology

The identification of genetic risk factors can be expected to provide a new impetus to epidemiological studies of schizophrenia by allowing researchers to investigate the ways in which genes and environment interact. Studies of this kind will bring together methodologies from genetics and epidemiology that have traditionally adopted somewhat differing analytical approaches (Sham, 1998). Treating susceptibility alleles as risk factors in an epidemiological context will allow estimates of effect sizes within a population to be made. Accounting for specific genetic effects will also facilitate the search for independent environmental factors, and the investigation of potential gene–environment interactions. Epidemiologically based studies are likely to reduce the effects of confounding (for example, by using incident cases of schizophrenia to guard against confounding by illness chronicity), while the inclusion of a prospective element to studies will counteract the tendency of patients to forget historical details, and the difficulty of making observed ratings retrospectively from case records. However, the price of improved scientific rigour is likely to be considerably more expensive studies, due to the longer period of study and the

larger number of investigators that will be required to ascertain the detailed data on the thousands of subjects that will probably be required. Further details about the study of gene–environment interactions in schizophrenia can be found in Chapter XVII-10.

Genetic Testing

Finally, one other implication of genetic epidemiology studies concerns genetic testing. Given that susceptibility to schizophrenia almost certainly depends upon the combined effects of predisposing and protective alleles at a number of loci as well as interactions with various environmental factors, the predictive value of genetic tests is likely to be low (Owen *et al.*, 2000). Although determining exact risk may be impossible, investigation of gene–environment interactions may allow for the introduction of lifestyle changes to reduce risk in individuals identified as having increased susceptibility to the disorder, and encourage closer medical supervision for early diagnosis, repeatedly shown to be an important prognostic factor in schizophrenia. Genetic testing could also help to optimize treatment choices by testing genes that are found to influence treatment responses in schizophrenia, leading to a greater individualization of treatment.

CONCLUSION

Research to date has largely excluded the possibility that genes of major effect exist in schizophrenia, even in a subset of families, although there is some evidence to suggest that allelic association in at least two genes, those encoding the 5-HT2a and DRD3 receptors, confer a small degree of susceptibility to this disorder. It is clear that over the next few years the completion of the human genome project and the identification of polymorphisms that affect disease risk will have a significant impact on our understanding of pathogenic mechanisms and encourage the development of more specific treatments for schizophrenia. The study of how these genes interact with each other and with non-genetic environmental factors is likely to be fascinating and productive, and we envisage that genetic studies will contribute substantially towards reducing the population impact of this disorder in the future.

Gene–Environment Interactions in Schizophrenia

Ming T. Tsuang, William S. Stone, Sarah I. Tarbox and Stephen V. Faraone

INTRODUCTION

Schizophrenia is a disorder with multiple phenotypes, in which clinical symptoms can manifest in a variety of combinations that differ from individual to individual. This phenotypic heterogeneity not only makes it difficult to determine the aetiology of the disorder, but also underscores the issue of whether schizophrenia has multiple genetic and environmental aetiologies. In the search for useful phenotypes, clinical symptoms can be misleading. For example, many disorders outside the schizophrenic spectrum share features of schizophrenia, including hallucinations and delusions, two core diagnostic staples. Moreover, psychotic symptoms can occur without an underlying psychiatric disorder present, for instance by exposure to various toxins or from head injury. Clinical symptoms, such as psychosis, may represent rather remote end states of the aetiological processes that produced them, and may actually confound the quest to characterize those processes. Between the initial liability for schizophrenia and the expression of clinical symptoms, multiple levels of biological and environmental modulation may alter the course and outcome of the disorder. In order to gain a clearer picture of the genetic and environmental events that produce both the liability to, and the actual manifestation of, schizophrenia, it is important to examine phenotypes that are closer to their genetic and biological aetiologies than are clinical symptoms. In this chapter, we will consider alternative phenotypic candidates for use in genetic studies, including physiological, anatomical and neuropsychological measures, as surrogates for classical clinical criteria. We will begin by reviewing environmental factors implicated in the aetiology of schizophrenia, followed by a discussion of how they might combine with genetic risk factors to produce 'schizotaxia', which is the predisposition to schizophrenia or schizophrenia-like conditions. Based on this conceptualization, phenotypic expressions of schizotaxia will be considered.

INFLUENCE OF ENVIRONMENTAL FACTORS

It is well established through family, twin and adoption studies that schizophrenia and schizophrenic spectrum disorders have underlying genetic aetiological components (see Chapter XVII-9). Although the risk of developing schizophrenia is associated strongly with the number of shared genes between a family member and an individual with schizophrenia, genetics are not the only determining factor in the aetiology of the disorder. Several lines of reasoning support this point. First, the degree of risk for family members does not approach that which would be predicted based entirely on the percentage of shared genes. For example, monozygotic twins are genetically identical and thus share 100% of their genes. If one twin has schizophrenia, however, the risk to the other twin is closer to 50%, rather than the 100% that would be expected if genetic factors accounted for the disorder completely. First-degree relatives, including dizygotic twins, share about 50% of their genes, yet their risk has been estimated to be between 9% and 16% (Gottesman, 1991; Gottesman, 1993). In addition, neither inbreeding nor reduced level of procreation appear to affect the incidence of schizophrenia, which conflicts with the pattern observed in primarily genetic disorders (Andreasen, 2000; Torrey and Yolken, 2000).

Second, although elevated risk in adopted-away offspring of schizophrenic parents points to genetic influence, mutual environmental factors still exist, including a shared uterine environment (in the case of a schizophrenic mother) and a shared post-natal environment before adoption. Moreover, even monozygotic twins, who share identical genes, experience different environments from the moment of conception. Prenatal environmental differences between identical twins can include blood supply and position in the womb; in addition, twins experience differences during delivery (e.g. birth order), regardless of whether complications arise. In the case of identical twins with one affected member, the genetic predisposition is present in both individuals but is expressed only in the twin who has also undergone certain environmental experiences.

Thus, the interaction between genetic liability and environmental factors plays an important role in determining outcome. This conclusion is also evident in studies of heritability, which vary across samples and methods of ascertainment. Kendler, for example, reported the results of twin studies with an average heritability of around 70% (Kendler and Diehl, 1993), although recent studies using *Diagnostic and Statistical Manual of Mental Disorders*, 3rd, 3rd revised and 4th editions (DSM-III, DSM-III-R, DSM-IV) (American Psychiatric Association, 1980, 1987, 1994) diagnostic criteria also showed heritability estimates between 80% and 86% (Cannon *et al.*, 1998; Onstad *et al.*, 1991). Although the value obtained in a specific study might be accurate, estimates vary because heritability is a function of the population studied (including its size), the environment, the phenotypic criteria used for diagnosis, the statistical model used, the effect sizes of relevant variables, and many other factors. This means that while differences between individuals can be understood largely in terms of genetic factors, estimates of heritability vary, and its contribution to the schizophrenia phenotype cannot be understood without taking into account the importance of environmental factors.

Environmental factors implicated in the development of schizophrenia range from biological to psychosocial in nature and include, among others, pregnancy and delivery complications, location of birth/residence, and family environment. A few representative examples of these are considered below.

During pregnancy, environmental factors that have a potential negative impact on the developing fetus and have been implicated as risk factors for schizophrenia include pre-eclampsia (resulting in reduced blood supply), exposure to toxins (e.g. alcohol, radiation), and exposure to viral infections, including measles, influenza, meningitis and the common cold (Tsuang and Faraone, 1995).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

The times of greatest vulnerability to the developing brain may include the second and third trimesters of pregnancy. During this period, environmental factors may disrupt neuronal migration of cells to the cortex, resulting in abnormal development of the prefrontal cortex, entorhinal cortex and hippocampus (Arnold and Trojanowski, 1996). Delivery complications associated with increased risk for schizophrenia include fetal hypoxia, ischaemia, extreme prematurity, low birth weight and dysmaturity (post-term birth). Seasonality of birth has also been implicated, with winter–spring births being associated with increased risk for schizophrenia (Jones and Cannon, 1998). Although it seems that this increase could be due to a higher incidence of maternal infection (e.g. influenza), there have been conflicting reports. For example, Battle *et al.* (1999) demonstrated in a large US statewide sample that the incidence of schizophrenia correlated significantly with winter births but not with statewide incidence of influenza or measles. However, they did not look specifically at rates of maternal infection.

Overall, pre-eclampsia has been implicated as the highest individual obstetric risk factor for schizophrenia (Jones and Cannon, 1998). Pre-eclampsia, leading to hypoxia during pregnancy, results in fetal malnutrition, including lack of oxygen, iodine, glucose and iron. Chronic hypoxia can result in restricted fetal growth and damage to brain regions, including the basal ganglia. Moreover, blood and oxygen deprivation due to pre-eclampsia during delivery can also result in injury to regions of the brain, including the hippocampus and cortex (Dalman *et al.*, 1999). Seidman *et al.* (2000a), utilizing the New England cohort of the National Collaborative Perinatal Project, demonstrated a relationship between obstetrical complications and neuropsychological deficits in children at 7 years of age. Low birth weight had the strongest association with neuropsychological impairments, followed by an index of inferred hypoxic insults, and then by maternal conditions suggesting chronic hypoxia. Jones and Cannon (1998) reviewed significant relationships between hypoxia during delivery and genetic risk factors in predicting enlarged ventricles in adult schizophrenics. Recently, Zornberg *et al.* (2000) reported results from a 19-year follow-up study of a large sample of individuals with a previously documented history of birth complications and matched controls. The individuals with a history of birth complications were classified according to whether the complications were related to hypoxic ischaemia. A significant relationship was reported between hypoxic ischaemia-related complications and increased risk for schizophrenia.

Zornberg *et al.* (2000) suggested that pregnancy and birth complications interact with genetic liability and increase the chance for developing schizophrenia in an already at-risk child. Consistent with this view, Cannon (1996) found a dose-dependent relationship between risk of schizophrenia and severity of perinatal hypoxia. In addition, birth complications were unrelated to the development of schizophrenia in a control low-risk group whose parents did not have schizophrenia. Pregnancy and birth complications themselves occur more frequently in schizophrenic mothers compared with normal controls (Geddes and Lawrie, 1995; Jablensky, 1995; Lewis and Murray, 1987; Tsuang and Faraone, 1995), which raises the level of risk for their (already vulnerable) children even further. Prenatal famine is another environmental contingency related to schizophrenia and other psychiatric disorders. Brown *et al.* (1999), for example, showed that conditions of famine at the time of conception were associated with subsequent elevations in rates of nonaffective psychoses, including schizophrenia, while famine in the second or third trimester was associated with subsequent elevation in rates of affective psychoses.

There is an ongoing discussion of urban birth as a potential risk factor for schizophrenia. Studies have reported an association between urban birth and later development of schizophrenia, and a correlation between population density and the incidence risk ratio (IRR) (Marcelis *et al.*, 1998; Torrey *et al.*, 1997). Potentially, the risk associated with urban birth could be due to complications during pregnancy or birth, although Eaton *et al.* (2000) demonstrated that increased risk due to urban birth was not associated with obstetric complications in individuals born in Copenhagen versus those born in rural areas of Denmark. It is possible that this effect could be one not of urban birth but of urban residence. In this case, the risk of developing schizophrenia could be due to environmental stressors inherent in city living that compound the risk to already genetically liable individuals (Marcelis *et al.*, 1998; Mortensen *et al.*, 1999).

Although the double-bind hypothesis of the schizophrenogenic mother whose contradictory messages produce schizophrenia in her child is no longer held widely, there are other factors within the family environment implicated as sources of potential risk. Kinney *et al.* (1997), using the Danish sample, found elevations of the thought disorder index (TDI) in biological relatives of schizophrenic patients compared with normal controls. In contrast, elevations of the TDI were not evident in the adoptive relatives of either schizophrenic or control subjects. Findings from the Finnish adoption studies (Tienari, 1991; Tienari *et al.*, 1994; Wahlberg *et al.*, 1997) were consistent with those reported by Kinney and colleagues. For instance, Wahlberg *et al.* (1997) demonstrated that symptoms of thought disorder in offspring of schizophrenic mothers were more probable when they had been raised by adoptive mothers who themselves showed elevated levels of 'communication deviance'. In contrast, offspring of schizophrenic mothers who were raised by adoptive parents with low communication deviance were less likely to show thought disorder. There was no relationship between thought disorder in control adoptees and communication deviance in the adoptive parents. In other words, these findings did not detect the presence of a schizophrenogenic environment for individuals who did not demonstrate a pre-existing genetic liability.

Additional family environmental factors that potentially interact with genetic risk include early absence of the father (Walker *et al.*, 1981), and biological factors within families, such as diet, frequently used medications and infectious agents (Torrey and Yolken, 2000). Malaspina *et al.* (2001) showed that increased paternal age was associated with elevated risk of schizophrenia and related disorders in offspring, but was not related to other psychiatric disorders. Walker *et al.* (1981) demonstrated in two groups of at-risk children that the group that experienced the loss of a parent had a higher rate of developing schizophrenia. Torrey and Yolken (2000) made a case for the transmission of infection to family members by house cats. In their view, viruses, bacteria, fungi, parasites, etc., carried by cats could have a greater impact on an already genetically vulnerable individual. This discussion underscores the point that genetic factors alone do not explain the development of schizophrenia, and that a multiplicity of interactions with the environment likely mediate the development and course of the disorder.

IMPACT OF GENE AND ENVIRONMENTAL INTERACTION: SCHIZOTAXIA

The mechanisms by which genetic and environmental factors interact to produce the liability for schizophrenia are not understood clearly, but they point to an interactive, neurodevelopmental process. For example, as discussed above, many genetic and environmental risk factors are apparent either before or around the time of birth (Jones and Cannon, 1998). In addition, children at risk for schizophrenia show difficulties in several areas, including motor, intellectual and social development (Erlenmeyer-Kimling, 2000). Severity of childhood deficits is also predictive of later schizophrenia. Furthermore, psychotic symptoms generally manifest after puberty, a time when ongoing brain development, hormonal changes and environmental stressors all co-occur.

Recently, we modified Meehl's use of the term 'schizotaxia' (Meehl, 1962) to describe this liability based on the theoretical premise that the neurobiological basis for schizophrenia is formed by the integrated effect of genes and adverse environmental risk factors. Meehl originally introduced the term 'schizotaxia' as a theoretical construct to describe the unexpressed genetic predisposition to schizophrenia. He proposed that individuals with schizotaxia would develop either schizotypy or schizophrenia, depending on the protection or liability afforded by environmental circumstances. Although he suggested later that schizotaxia need not progress into either of these more overt conditions in all cases (Meehl, 1989), he still hypothesized that most cases would progress to one of those outcomes. Although schizotypy eventually entered the psychiatric nomenclature in the form of schizotypal personality disorder, schizotaxia did not. Instead, it remained a term used by researchers to describe — in a generic sense — the liability to schizophrenia. Four decades of subsequent research with nonpsychotic relatives of schizophrenic patients, however, have provided a preponderance of evidence that schizotaxia is a clinically meaningful condition with distinct psychiatric and neurobiological features.

Our reformulation of schizotaxia (Faraone *et al.*, 2001) describes genetically vulnerable individuals who are probably exposed to early adverse events (e.g. obstetrical complications) that result in abnormal development of certain brain structures. As presented above, this liability presents from childhood as schizotaxia, which is expressed through a combination of cognitive, neurobiological and social skill deficits that vary in severity. For most individuals, the condition remains stable throughout their lifespan, but for some, a combination of the liability with later adverse environmental events (e.g. substance abuse or stressful psychosocial circumstances) may produce schizotypal personality disorder or psychosis. The effects of psychosis may then lead to chronic schizophrenia. That is, schizotaxia plus psychosis results in the DSM or *International Classification of Diseases* (World Health Organization, 1992) (ICD) syndrome of schizophrenia. In this view, however, psychosis itself may not necessarily relate to the specific aetiology of schizophrenia (see also Schizotaxia and alternative phenotypes for schizophrenia below). If this model is substantially accurate, then it follows that psychosis and the subsequent diagnosis of schizophrenia are events that occur well after the expression of the genetic liability to schizophrenia was first manifested, rather than at its onset. This view is consistent with the notion of an underlying continuum of genetic liability that has schizophrenia as only one of its possible outcomes.

Schizotaxia is a broader construct than schizophrenia. Our empirical studies suggest that the basic symptoms of schizotaxia occur in 20–50% of first-degree relatives of schizophrenic patients (Faraone *et al.*, 1995a; Faraone *et al.*, 1995b). In comparison, only about 10% of relatives will become psychotic, and less than 10% will develop schizotypal personality disorder (Battaglia *et al.*, 1995; Battaglia and Torgersen, 1996). These figures suggest that schizotaxia does not lead inevitably to schizotypal personality or to schizophrenia, but in most cases is a stable, long-term condition.

Recently, we described preliminary research diagnostic criteria for schizotaxia (Tsuang *et al.*, 1999) based on two features that occur frequently in nonpsychotic relatives of patients with schizophrenia: negative symptoms and neuropsychological deficits (Faraone *et al.*, 2001; Seidman, 1997; Tsuang *et al.*, 1991). All subjects were first-degree biological relatives of schizophrenic patients who met predetermined inclusion criteria (Tsuang *et al.*, 1999). The next step is to validate the proposed syndrome of schizotaxia. Consistent with guidelines advanced by Robins and Guze (1970), it will be necessary to assess the validity of the syndrome with converging evidence from multiple domains. Thus far, two lines of evidence support the proposed syndrome. First, concurrent validation of schizotaxia was obtained by comparing subjects who met our clinical criteria for schizotaxia with those who did not on independent measures of clinical function (Stone *et al.*, 2001). On each of these scales, irrespective of whether they were rated by the subjects or the investigators (blindly), the schizotaxic subjects showed poorer clinical or social function than did subjects who did not meet criteria for schizotaxia. These differences were not attributable to age, IQ, education, parental education, family genetic loading, gender or comorbid psychiatric disorders.

The second line of support for the validity of schizotaxia involves the response to treatment (Tsuang *et al.*, 1999). Six of the eight pilot subjects who met our criteria for schizotaxia agreed to receive a brief 6-week trial of low-dose risperidone (up to 2.0 mg per day) (see Tsuang *et al.*, 1999 for a report on the first four cases). During the risperidone trial, five of the six individuals reported increased cognitive abilities, and three of the six individuals reported greater levels of interest in, and enjoyment of, social activities. Objective assessments showed that five of six subjects demonstrated improvements in measures of anhedonia and asociality, and also showed substantial improvements in attention and working memory. The cognitive and clinical improvements in these individuals are encouraging, and a larger, double-blind study is under way to determine whether our initial findings can be replicated.

Schizotaxia and Alternative Phenotypes for Schizophrenia

Schizotaxia is an evolving concept. While our validation studies suggest that our current definition may provide a useful foundation for investigations into this condition, we assume that schizotaxia will eventually encompass additional clinical and neurobiological domains. One implication of this conceptualization is that schizotaxia may provide a more specific expression of the aetiological processes underlying schizophrenia than do clinical symptoms (e.g. psychosis), which appear later in the course of the disorder and which may be more general indicators of severe mental illness than of a particular condition (Tsuang *et al.*, 2000). In this context, several types of alternative phenotypic expressions merit consideration as candidate symptoms for schizotaxia. Examples of these are considered below.

Neuropsychological Deficits

Nonpsychotic relatives show a range of neuropsychological deficits (Cannon *et al.*, 1994; Erlenmeyer-Kimling, 2000; Faraone *et al.*, 2001; Green *et al.*, 1997; Park *et al.*, 1995). As in schizophrenia, deficits in executive functions, attention and working memory, and long-term declarative memory occur consistently (Faraone *et al.*, 2001; Faraone *et al.*, 1995a; Faraone *et al.*, 1995b), which is the reason for their inclusion in our criteria for schizotaxia. These cognitive deficits coexist with each other in relatives but not in control subjects (Toomey *et al.*, 1998), are stable over a 4-year follow-up period (Faraone *et al.*, 1999), are more prominent (e.g. in verbal declarative memory) in 'multiplex' relatives (i.e. more than one close biological relative with schizophrenia) than 'simplex' relatives (i.e. one affected relative) (Faraone *et al.*, 2000), and when present in childhood are predictive of schizophrenia-related psychosis in adulthood (Erlenmeyer-Kimling *et al.*, 2000).

Social Function

Poor social adjustment has been demonstrated in relatives of schizophrenic patients. Problems in social adjustment included poor peer engagement (especially with members of the opposite gender), immaturity and unpopularity with peers (Hans *et al.*, 2000). Moreover, Toomey *et al.* (1999) showed that compared with controls, relatives of schizophrenic patients exhibited deficits in perception

of nonverbal social cues when assessed with the profile of nonverbal sensitivity test (PONS). These deficits correlated significantly with slower reaction times on vigilance tasks, supporting earlier findings that suggest impairments in attention contribute to development of social deficits (Dworkin *et al.*, 1993; Erlenmeyer-Kimling and Cornblatt, 1992).

Psychophysiological Function

Nonpsychotic adult relatives of schizophrenic individuals demonstrate a diminished ability to filter sensory input from the environment. For example, relatives show difficulties in smooth pursuit eye-tracking (Levy *et al.*, 1994; Park *et al.*, 1995; Ross *et al.*, 1998a; Ross *et al.*, 1998b), pre-pulse inhibition (Braff *et al.*, 1999) and P50 suppression (Adler *et al.*, 1998), which are similar to deficits observed in schizophrenic patients (Clementz *et al.*, 1998; Friedman and Squires-Wheeler, 1994; Waldo *et al.*, 1994). Moreover, the likelihood of having a deficit in P50 suppression increases as the degree of biological relatedness to an individual with schizophrenia increases (Waldo *et al.*, 1995; Waldo *et al.*, 1991).

Neuroimaging

Imaging techniques also show structural brain abnormalities in nonpsychotic adult relatives that are similar to those found in schizophrenic patients. For example, structural magnetic resonance imaging (MRI) studies indicate that nonpsychotic relatives of schizophrenic patients have significant volume reductions in the hippocampus, right amygdala, putamen, left thalamus, cerebellum and brainstem, and significantly increased volumes in the pallidum, as compared with matched controls (Seidman *et al.*, 1997b).

Moreover, structural and functional abnormalities are associated with the psychophysiological and neuropsychological deficits often found in relatives. For example, degree of perfusions in the left inferior prefrontal and anterior cingulate cortex in relatives of schizophrenic patients showed significant correlations with verbal memory and P300 amplitude in the left inferior prefrontal cortex and with P300 latency in the anterior cingulate cortex (Blackwood *et al.*, 1999). Recently, Seidman *et al.* (2000b) showed that deficits in verbal declarative memory were associated with smaller left hippocampal volumes and with the degree of genetic loading for schizophrenia (i.e. it was greater in multiplex than in simplex relatives). In a study utilizing functional MRI, Seidman *et al.* (1997a) demonstrated that in comparison to matched controls, nonpsychotic relatives of schizophrenic patients were impaired significantly on working memory tasks with interference. The tasks produced activation in the lateral and medial frontal cortex, posterior parietal and prefrontal cortex, and thalamus in both groups, but compared with controls the relatives had a greater number of extraneous, bilateral activations during the tasks they performed worse on.

CONCLUSIONS AND FUTURE DIRECTIONS

A century of research shows that schizophrenia has a significant genetic component, but that environmental factors are also critically important in the expression and course of the disorder. Where do we go from here? Certainly, technological advances in molecular biology and other fields will facilitate the search for susceptibility genes for schizophrenia, which will clarify its genetic basis further. But it is also critically important that conceptual progress on the nature of the disorder keep pace. This is true in the area of diagnosis, and especially so in the attempt to understand how clinical symptoms are related to underlying aetiology.

Thus far, clinical diagnosis has predominated as the method of identifying and classifying schizophrenic individuals and their affected versus unaffected family members for research studies and clinical treatment. Although diagnosis has improved substantially in the last two decades, it is far from precise due to the variety and range of clinical expression of schizophrenia and related disorders. Moreover, attempting to classify relatives who carry the liability to schizophrenia but exhibit few, if any, clinical symptoms is even more challenging. Yet this is a goal that must be attained in order to progress in our understanding of schizophrenia's genetic and environmental determinants.

In this context, the conceptualization, validation and study of schizotaxia have important implications for future research and clinical treatment. First, as schizotaxia may provide a more specific expression of the aetiological processes underlying schizophrenia than do clinical symptoms (e.g. psychosis), this model could aid in the facilitation of future research. For example, family studies (e.g. linkage studies) could benefit from a more sensitive method of identifying relatives who carry the liability for schizophrenia. More generally, the use of alternative clinical symptoms, and of neuropsychological and neurobiological measures, underscores their potential importance in parsing out genetic and environmental influences on schizophrenia. Moreover, as susceptibility genes for schizophrenia are identified in schizotaxic individuals, specific biological products (e.g. proteins) of those genes factors will also become identifiable. Consequently, the identification of more specific genetic-environmental interactions will become possible, which may also open up new avenues for understanding how environmental factors affect the liability (in positive or negative directions) for schizophrenia.

Second, the components of schizotaxia provide new potential targets for the development of treatments aimed at modifying fundamental phenotypical expressions of schizophrenia. The treatment of schizotaxia in nonpsychotic relatives could serve to alleviate symptoms that are clinically meaningful but are overlooked in the absence of a valid diagnosis. Perhaps even more importantly, the successful treatment of schizotaxia might serve to facilitate longer-term strategies aimed at the prevention of schizophrenia itself. This would be the ultimate environmental modification of the liability to the disorder, and the one that will attract increasing attention in the coming years.

ACKNOWLEDGEMENTS

Preparation of this chapter was supported in part by the National Institute of Mental Health grants 1 R01MH4187901, 5 UO1 MH4631802 and 1R37MH4351801 to Dr Ming T. Tsuang and the Veterans Administration's Medical Research, Health Services Research and Development and Cooperative Studies Programs, by a NARSAD Distinguished Investigator Award to Dr Tsuang, and by a NARSAD Young Investigator Award to Dr Stone.

XVII-11

Gender Issues in Schizophrenia

David J. Castle and Robin M. Murray

This chapter concerns gender differences in schizophrenia. We start with an overview of the general differences between men and women that may be relevant to gender differences in schizophrenia. Differences between males and females with schizophrenia are then detailed, including epidemiology and clinical features, as well as aetiological factors. Finally, we offer an integration of these findings.

There are, of course, myriad differences between males and females in psychological and social characteristics. Here, we will concentrate on biological domains rather than psychosocial differences. Our justification for this is that the gender differences in schizophrenia seem to operate across cultures; therefore, specific cultural influences are unlikely to be of major effect in explaining such gender differences. Having said this, some psychosocial factors may be of importance in mediating certain differences between men and women with schizophrenia, and these are addressed at the end of the chapter.

GENDER DIFFERENCES IN THE HUMAN BRAIN

The brains of males and females differ from each other in subtle but important ways. The roots of such differences lie ultimately in genetic make-up; indeed, neural cultures from male and female brains show sex-specific morphological and functional characteristics even in the absence of sex hormones (Reisert and Pilgrim, 1991). Nevertheless, hormonal factors are of undoubted importance in mediating the effects of genes, particularly the masculinizing effects of testosterone, which, in humans, is secreted from the male fetal testes at around week 9 of intrauterine development. One of the effects of testosterone is, in essence, to slow the rate of development of the male brain. Thus, Taylor (1969) hypothesized that the male brain lags behind the female brain in rate of myelinization and establishment of neural connections; it appears that the most profound impact is on the left hemisphere.

Differential development of male and female brains also results in structural sex differences. Not only is the male brain generally larger than the female brain, but there are more specific differences. For example, the size of the preoptic nucleus of the hypothalamus is relatively larger in males than females (Swaab and Fliers, 1985). There also appears to be a difference in lateralization, with the male brain being more asymmetrical than the female brain. Thus, Wada *et al.* (1975) reported left–right asymmetry in the planum temorale more commonly in males then females. In rats, there are sex differences in lateralization of the hippocampal-dentate complex (Diamond, 1989). Witelson (1989), after extensive investigations of gender effects in size and shape of the corpus callosum, concluded that the isthmus of this bridge between the hemispheres tends to be larger in females; she went on to speculate that this was a reflection of greater bilateral representation of cortical functions in females. These differences translate into functional differences between the sexes in performance on lateralized neurocognitive tasks, with females tending to show less lateralization of function (McGlone, 1980).

The relatively slow development of the male brain may result in it being vulnerable for a longer period than the female brain to adverse neurodevelopmental insults. For example, Amato *et al.* (1987) showed that among low-birthweight infants, males are more likely to suffer from peri-intraventricular haemorrhage. Furthermore, males are more likely to suffer longer-term adverse consequences from such early insult, perhaps the greater laterality of functioning leaving the male brain less able to compensate for lateralized brain damage. Brothwood *et al.* (1986) found that low-birthweight males were more likely than their female counterparts to be impaired developmentally at the age of 2 years. It was also reported that children exhibiting minor neurological dysfunction at age 12 years were most likely to be males and to have suffered from preterm birth or other early environmental adversity, notably hypoxia. Grimm and Frieder (1985) found in rats that prenatal brain insult resulted in impaired performance on complex learning tasks in males but not in females.

Perhaps as a consequence of this relative vulnerability of the male brain, males are far more likely than females to suffer from a range of neurodevelopmental disorders, e.g. severe mental retardation, autism and Asperger's syndrome. Such disorders have the following as their most consistent characteristics (see Goodman, 1990):

- left-sided brain dysfunction, evidenced by increased rates of non-right-handedness;
- association with early brain insult;
- over-representation among individuals with brain abnormalities.

THE AGEING BRAIN

Not only do male and female brains develop differently, but they also age differently. For example, Murphy *et al.* (1996) showed that in comparison with female brains, the male brain exhibits greater loss of whole-brain and frontal and temporal volume with age, while female brains show more rapid loss in the parietal lobe and hippocampus. Also, female brains exhibit relatively more age-related decline in the thalamus and hippocampus. There is also some evidence that women are more prone to Alzheimer's disease, even once the longer survival of women is taken into account; this has been related to the effect on the female brain of withdrawal of oestrogen (Henderson, 1997). A similar explanation has been put forward to explain the excess of women among late-onset schizophrenia patients (see below).

Of possible relevance to schizophrenia is the evidence that rates of decline of brain dopamine D2 receptors differ between men and

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

women. Thus, males start life with a relative excess of dopamine D2 receptors but lose them more rapidly, such that by mid-life females have a relative excess (Wong *et al.*, 1994; Pohjalainen, 1998). Given that schizophrenia has often been regarded as a state of functional dopamine excess, this has potential clinical implications.

BEHAVIOURAL DIFFERENCES BETWEEN MALES AND FEMALES

Differences in behaviour between boys and girls are evident from early life. Boys are more likely than girls to exhibit overactivity and difficulties in concentration, while girls are more likely to exhibit fearfulness (Earls, 1987). Sex differences in socialization have also been noted, with girls being overall more sociable and interested in others, and boys being more likely to be content with solitary play (Garai and Scheinfeld, 1968). Some authors believe that these gender differences continue into adult life and form the basis for the greater frequency of negative symptoms in males, relative to females, with schizophrenia (see below). This line of reasoning implies that these characteristics of psychotic patients are merely a reflection of the behavioural characteristics of males and females in the general population.

GENDER DIFFERENCES IN THE EPIDEMIOLOGY OF SCHIZOPHRENIA

It is generally considered that the lifetime risk of schizophrenia is roughly equal between men and women. However, this belies the fact that male : female ratios are affected markedly by the diagnostic criteria that are applied. For example, Castle *et al.* (1993) showed, in a representative case register sample, that although the application of broad International Classification of Diseases, 9th edition (ICD-9) (World Health Organization, 1978) criteria result in a near even male : female ratio (1.08 : 1), application of the somewhat more stringent Research Diagnostic Criteria (RDC) criteria enhanced the sex differential (male : female ratio 1.15 : 1), and the even more stringent *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (DSM-IIIR) (American Psychiatric Association, 1987) criteria produced a male : female ratio of 1.35 : 1. Furthermore, age at onset affected the gender ratios profoundly. For example, whilst applying ICD-9 criteria generated a male : female ratio of 1.41 : 1 in subjects with an onset before the age of 45 years, applying DSM-IIIR criteria produced a ratio of 2.13 : 1 in this group. In subjects with an onset of illness after age 45 years, females predominated, irrespective of the diagnostic criteria applied (e.g. female : male ratios of 1 : 0.61 for ICD-9 criteria and 1 : 0.58 for DSM-IIIR criteria).

Numerous studies have demonstrated that the mean age of onset is earlier in males than females with schizophrenia; this has been reported in samples ascertained by widely differing methodologies and across a number of different sociocultural settings (see Castle, 2000). However, many studies report only mean age-at-onset differences between the sexes, and reliance on means can be criticized on the basis that male and female onset distributions are not distributed parametrically. Indeed, disparate studies from a number of different geographical settings have shown that the pattern of onset distribution is a complex one, and that the distributions for men and women are not isomorphic. For example, in a case register sample, Castle *et al.* (1998) showed that the male distribution encompasses at least two peaks, the predominant peak being of early onset (mode 21.4 years) and the other (lesser) peak manifesting in mid-life (mode 39.2 years). In females, the early peak (mode 22.4 years) is less dramatic, but the mid-life peak (mode 36.6 years) exceeds that for males. Furthermore, females show a further peak in late life (mode 61.5 years). These results have, in large part, been replicated independently (see McLachlan *et al.*, 1998).

Almost universally in the west, age of onset of schizophrenia is significantly earlier in males than females. This is also mostly the case for samples from the developing world, but there are several studies from India in which this gender difference disappears (Murthy *et al.*, 1998). The reason for this is unclear, but one suggestion has been that schizophrenia in India includes a greater proportion of brief psychotic conditions than in the west. A further exception to the earlier onset in males is in those cases of schizophrenia from families that are multiply affected by the disorder. Here, the gender difference in onset is diminished markedly and, in several studies, disappears (Walsh *et al.*, 1996). This might imply that the earlier age of onset is an environmental effect caused, for example, by the greater frequency of drug abuse in males or the effect of pregnancy and birth complications (Kirov *et al.*, 1999).

There has been considerable interest in gender ratios for schizophrenia in the very young and the very old. Since age at onset tends to be earlier in males across adult life, one might anticipate that very-early-onset (adolescent and preadolescent) schizophrenia should be more common in males. However, there remains some doubt about this. This may reflect in part the rarity of the disorder at this age and the difficulty in reaching a definitive diagnosis at this age. Furthermore, many of the larger case series are from specialist tertiary referral units and might well be biased and unrepresentative. In reviewing this area, Orr and Castle (in press) concluded that it is probable that in adolescent cases, males and females are roughly equally prone but that males predominate in cases of prepubertal onset.

There is no doubt about gender differences in prevalence of very-late-onset schizophrenia (i.e. onset after age 60 years). Castle (1999), in reviewing the epidemiology of late-onset schizophrenia, established male : female ratios for very-late-onset schizophrenia from a number of studies from different treatment settings and that had used different diagnostic criteria. All studies that had included both sexes had an excess of females, with male : female ratios ranging from 3.1 : 1 to 22.5 : 1. These findings are not simply a reflection of the relative longevity of females.

CLINICAL DIFFERENCES BETWEEN MALES AND FEMALES WITH SCHIZOPHRENIA

Overall, premorbid adjustment appears to be better in females than males who later develop schizophrenia. This superiority covers social and school and work functioning (reviewed by Seeman and Fitzgerald, 2000). Of course, such conclusions are based on grouped data and belie the heterogeneity in premorbid functioning in schizophrenia; indeed, some females with schizophrenia show marked developmental deviance. Partly, gender effects are confounded by age at onset, with an earlier onset being (in general) associated with worse premorbid functioning, but this does not explain away the entire gender effect (Preston *et al.*, in press).

In terms of symptoms, gender differences are confounded by the diagnostic issues alluded to above. In particular, females are more likely than males to exhibit affective symptoms and to be excluded when stringent diagnostic criteria for schizophrenia are applied. However, even after controlling for such factors, females with schizophrenia tend to show more affective features and fewer negative symptoms than their male counterparts (see Seeman and Fitzgerald, 2000).

The longitudinal course of schizophrenia tends to be more benign in females than males; this applies to hospitalization, social functioning and occupational outcome. Females also tend to show a better response to antipsychotic treatment, and require lower doses

of such medication, at least premenopausally (reviewed by Seeman and Fitzgerald, 2000).

AETIOLOGICAL PARAMETERS

Genetics

The most important and best established aetiological factor for schizophrenia is genetic predisposition. Although the mode of inheritance has not been established absolutely, biometrical and molecular genetic studies have all but ruled out the existence of major genes of large effect. Thus, the current consensus is that a number of genes of small effect interact with each other and with a number of small environmental effects to project the individual across the threshold for the expression of schizophrenia.

In terms of gender, a number of studies have assessed family loading for schizophrenia in males and females with schizophrenia, and found that the morbid risk of schizophrenia is greater in the relatives of females than males with schizophrenia (see Goldstein and Lewine, 2000). One study reported an excess of schizophrenia amongst relatives of female probands, but it also found that schizotypal personality disorder was over-represented in the families of males with schizophrenia. These relatives were also more likely to exhibit flat effect, putatively an expression of subsyndromal phenomenology of the disorder (see Goldstein, 1995).

Early Developmental Insult

Considerable evidence points to early developmental insult being important in the aetiology of at least some cases of schizophrenia. The putative mechanism is a disruption of the normal development of the brain at certain crucial phases, leaving the individual with aberrant neural networks at risk for the later manifestation of psychosis as the brain matures.

Apart from genetically mediated developmental mechanisms, the most robust findings in this area are those implicating pregnancy and birth complications. Several meta-analyses (Verdoux *et al.*, 1997; Geddes *et al.*, 1999) have shown that exposure to obstetric complications approximately doubles the risk of the disorder, and that such complications appear to be associated especially with schizophrenia of relatively early onset. In terms of gender, a number of studies suggest that pregnancy and birth complications are more common in males (Hultman *et al.*, 1999), but this is not a consistent finding (Verdoux *et al.*, 1997).

Intrauterine infections have been another putative candidate for early neurodevelopmental insult that raise the risk of later schizophrenia. Most of the evidence is based on population samples exposed to epidemics of influenza viruses. Such studies inevitably suffer from ecological bias, but nevertheless they are of interest. Few of these studies have examined gender differences explicitly, but those that have tend to show that the effect is more potent in females than males (reviewed by McGrath and Castle, 1995).

Early Head Injury

Another early developmental event of putative importance in the risk of schizophrenia is childhood head injury. Here, the literature is scant and confounded by the potential for preschizophrenic children to be more clumsy than their counterparts not at risk for later illness. One study (Nasrallah and Wilcox, 1989) reported early head injury to be a feature of males rather than females with later schizophrenia, but we are not aware of replication of this finding, and indeed the result needs to be interpreted in the context of an overall male predisposition to such injury. Recently, Neilsen *et al.* (submitted) examined the rates of head injury in 8288 Danes suffering their first episode of schizophrenia. After adjusting for the greater risk of other fractures in males, both concussion and head injury were found to be increased significantly in male but not female, subjects.

Illicit Substance Use

It is well established that people with schizophrenia show a high rate of use of illicit substances, particularly substances with a dopaminergic effect such as amphetamines, cocaine and cannabis, and that this is more the case for males than females with schizophrenia (Jablensky *et al.*, 2000). The latter is, at least in part, a reflection of the fact that in the general population, males are more likely than females to abuse drugs. However, it may also be that males with more severe illness are more likely to use substances to alleviate negative symptoms or to reduce side effects of antipsychotic medications. Furthermore, males with early-onset illness are likely to be particularly socially impaired and might use illicit substances to aid socialization. It is also generally accepted that such substances can exacerbate psychotic symptoms and worsen the longitudinal course of the disorder. However, cause and effect are difficult to disentangle.

There remains controversy as to whether illicit substances such as cannabis actually increase the risk of development of schizophrenia rather than simply precipitate relapse in those with an extant vulnerability. The only published study of which we are aware that can begin to answer this is the Swedish conscript cohort study of Andreasson *et al.* (1987). This study suggested cannabis use at conscription to predict later schizophrenia. No conclusions can be drawn about any gender effects because the cohort was exclusively male.

NEUROCOGNITION AND NEUROIMAGING

Males and females exhibit fairly consistent group differences on tests of neuropsychological functioning (see Kimura, 1992). Thus, males tend to perform better on tests requiring imaginal rotation of objects, navigating through a route, and target-directed motor skills; they also tend to excel in mathematical reasoning. Females, on the other hand, show relatively greater aptitude for test of perceptual speed, arithmetical calculation, recalling landmarks form a route, and certain precision manual tasks. Girls also generally outperform age-matched boys on tests of verbal fluency (McGee, 1982). These parameters underline the differences in organization and function of male and female brains, and are relevant to gender differences in schizophrenia in terms of both aetiological parameters and interpretation of neuropsychological findings in schizophrenia patients.

There is long-standing evidence that preschizophrenic boys show lower IQ than preschizophrenic girls (Aylward *et al.*, 1984), a difference reflective of the poorer performance of the former in a range of psychological and social functions. A number of studies of adult schizophrenia patients have also found that males show more severe neuropsychological impairment than females (Goldstein *et al.*, 1998). However, when schizophrenia is defined narrowly, neuropsychological differences between the sexes tend to disappear (Hill *et al.*, 2001).

Ames (1991) points out that in the normal population, adult females tend to be superior to their male counterparts on tests of verbal memory while males are superior on certain visuospatial tests. Since verbal memory is impaired in schizophrenia, it is possible to speculate that one reason for the greater susceptibility of males to severe schizophrenia (see below) could be that their lesser competence in verbal memory places them nearer the threshold for expressing the disorder.

There is a large and inconsistent literature on brain imaging in males and females with schizophrenia (Goldstein and Lewine,

2000). In general, it appears that male patients show more severe brain structural abnormalities; indeed, some studies have failed to show any differences in these parameters between female patients and controls. Thus, McDonald and Murray (2001), in a recent study of families where several members were affected with schizophrenia, found that the brain imaging differences between patients and controls, and relatives and controls, were accounted for wholly by the male patients and relatives, respectively.

INTEGRATION

We have reviewed gender differences in schizophrenia, pointing out those parameters that appear most consistently to differentiate the sexes. These include:

- an excess of males in strictly defined samples of schizophrenia patients;
- a difference in onset distributions, with males greatly over-represented amongst patients with an onset in early adult life, and females showing an excess in mid-life, and a massive female preponderance in very-late-onset schizophrenia;
- poorer premorbid functioning in males;
- more negative symptoms in males;
- more affective symptoms in females;
- a worse longitudinal course in males;
- a more favourable response to antipsychotic medication in females, at least before menopause;
- more impairment of neurocognitive functioning in males;
- possibly an excess of brain abnormalities in males;
- probably a higher morbid risk of schizophrenia in the relatives of females with schizophrenia;
- possibly an excess of early developmental insult in males.

How can we integrate these findings? As we noted in the introduction, we concentrate here on biological explanations for these gender differences, as most of the differences appear to operate across cultures, and thus psychosocial parameters are likely to exert only a modest modifying role in their determination. We consider the biological factors in two main domains, namely hormonal influences, and brain organizational and structural differences.

HORMONAL INFLUENCES

Pubertal and postpubertal hormonal differences between the sexes bear consideration in trying to explain gender differences in schizophrenia. For example, testosterone production in the nonpsychotic adolescent male probably accounts at least in part for the upsurge of aggressive, impulsive and risk-taking behaviours at that age. Arguably, this could result in males with schizophrenia causing more domestic and peer-related disruption, and cause them to come into contact with psychiatric services earlier than their less aggressive female counterparts. However, this is unlikely to be a major effect, given that the lag between first symptom onset (either prepsychotic or psychotic) and first psychiatric contact is much the same for both genders (see Hafner *et al.*, 1989).

Of more compelling interest in terms of hormonal effects is the putative protective effect of oestrogens in females. Oestrogens have been shown in animal and laboratory studies to block dopamine D2 receptors and to reduce haloperidol-induced cataplexy (Hafner *et al.*, 1991; Kulkarni and Fink, 2000). Clinical studies suggest that women with schizophrenia are more vulnerable to relapse at times in their menstrual cycle when endogenous oestrogen levels are low, whilst pregnancy, associated with high oestrogen levels, is believed to be a time during which women with schizophrenia enjoy relative wellness in terms of psychotic symptomatology (see Lewine and Seeman, 1995). The postpartum period, during which oestrogen levels plummet, is associated with a particular vulnerability to psychotic illness, even in women with no prior history of psychosis (Kendell *et al.*, 1987). Furthermore, Hafner *et al.* (1989) have suggested that the second peak in schizophrenia in females in mid-life (see above) is a consequence of menopausal fall in oestrogen levels and the removal of the protective effect on the dopamine system.

Seeman and Lang (1990) have therefore implicated the protective effect of oestrogen in explaining some of the gender differences in schizophrenia outlined above. This hypothesis gains some support from *in vivo* studies of the effects of oestrogen on schizophrenia symptoms. For example, Kulkarni *et al.* (1996) claim that the administration of oestradiol to psychotic women as an adjunct to antipsychotic medication results in an accelerated amelioration of psychotic symptoms.

There are, however, some shortcomings to the oestrogen hypothesis. These include the fact that childhood premorbid function is characteristically poorer in males than females who later develop schizophrenia, and this obviously cannot be accounted for by direct hormonal influences as it antedates puberty. The mid-life peak in onset of schizophrenia has never been shown to be correlated directly with oestrogen levels and, indeed, there is also a mid-life peak (admittedly less pronounced) in males. Also, the very-late-onset peak in females occurs many years after the menopause. It has also been found that in families with a high genetic loading for schizophrenia, the females do not show the usual later onset of the disorder relative to males (see above). Furthermore, the data pertaining to pregnancy being a time of psychiatric well-being for women with schizophrenia is equivocal, whilst the postpartum peak in psychotic disorders is due largely to affective psychosis rather than schizophrenia (reviewed by Barkla and McGrath, 2000).

It is probably reasonable to conclude, then, that oestrogenic effects may go some way towards explaining some of the clinical and epidemiological gender differences in schizophrenia, but they cannot account for the complexity of these differences and should be seen in conjunction with explanations based on differences in male and female brains, as outlined below.

BRAIN DIFFERENCES AS AN EXPLANATION FOR GENDER DIFFERENCES IN SCHIZOPHRENIA

We have expressed our belief that gender differences in schizophrenia can be understood, at least in part, by an appreciation of brain differences between the sexes (see Castle and Murray, 1991). Thus, the differential maturation of the male and female brain, and in particular the slowed left hemisphere maturation in males, renders the male brain prone to neurodevelopmental insult, as outlined above. The considerable evidence pointing to at least some forms of schizophrenia being consequent upon neurodevelopmental deviance (see Murray *et al.*, 1992) is thus integrated into a typology of schizophrenia based on gender.

Testing this hypothesis, Castle *et al.* (1994) and Sham *et al.* (1996) reported a latent class typology of schizophrenia where males were particularly vulnerable to an early-onset dementia praecox type of illness associated with poor premorbid functioning and negative symptoms, and putatively of neurodevelopmental aetiology. A later-onset schizoaffective subtype, with prominent mood symptoms, affected almost exclusively females, and was interpreted as being related aetiologically to the mood disorders (there was a family loading for depression in this subtype). A further later-onset subtype, with predominant paranoid ideation, affected men and women in roughly equal proportions.

This typology does not encompass very-late-onset schizophrenia-like disorder (late paraphrenia), whose vast female preponderance could be interpreted in the context of degenerative differences between male and female brains, as outlined above (see Castle, 1999).

Thus, a typological approach has some utility in understanding gender differences in schizophrenia, but any such explanatory model needs to be sufficiently adaptable to accommodate hormonal and psychosocial influences, which differentiate the sexes and which play a part in the determination of vulnerability to, and expression of, psychosis in men and women.

Schizophrenia and Other Psychotic Disorders: Therapeutic Armamentarium

Michael J. Travis

INTRODUCTION

Since the discovery of the antipsychotic effects of chlorpromazine in the early 1950s, we have entered an era of effective pharmacological treatment for schizophrenia and related psychoses. Since the initial 1952 report of reduction in agitation, aggression and delusional states in agitated psychotic patients, a wealth of placebo-controlled trials have established the efficacy of typical antipsychotic (neuroleptic) medication for acute schizophrenia (Davis and Androukis, 1986) and for maintenance in chronic schizophrenia (Gilbert *et al.*, 1995; Viguera *et al.*, 1997).

Antipsychotics have therefore been the mainstay of treatment in schizophrenia and related psychoses for four decades. The knowledge of the chemistry and pharmacology of these medications has led to a greater understanding of the neurochemical basis of psychosis.

In the last decade, the reintroduction of clozapine has led to a new optimism in the treatment of schizophrenia and related psychoses, and the development and introduction of a new generation of antipsychotics, the 'atypicals', which bring the possibilities of fewer side effects and greater efficacy in comparison with the original antipsychotics (typicals). Nevertheless, a proportion of psychotic patients will not respond to standard treatments.

This chapter will selectively review the available literature that can inform our rational use of medication to treat psychosis in the twenty-first century.

SCHIZOPHRENIA AND PSYCHOTIC DISORDERS

Just as schizophrenia is heterogeneous, so are the disorders in which psychotic symptoms can occur. In the absence of large-scale clinical trials in related psychotic disorders, such as persistent delusional disorder, this chapter will focus on the treatment of schizophrenia. There is compelling evidence that medications used to treat schizophrenia are truly antipsychotic rather than antischizophrenic and thus may be used to treat psychotic symptoms in any psychiatric disorder in which they occur.

CLASSIFICATION OF ANTIPSYCHOTICS

Antipsychotic drugs are not a homogeneous group, and there are various classes. The phenothiazines include those with aliphatic side chains, e.g. chlorpromazine, those with piperidine side chains, e.g. thioridazine and pipothiazine, and those with piperazine side chains, e.g. trifluoperazine and fluphenazine. Other classes include the butyrophenones (haloperidol and droperidol), the thioxanthenes (flupenthixol and zuclopenthixol), the diphenylbutylpiperidines (pimozide), and the substituted benzamides (sulpiride and amisulpride). The relevance of grouping the medications by chemical class comes when switching antipsychotics. Patients who do not respond to a medication belonging to one particular chemical class should be switched to a medication of a different chemical class. It is interesting to note from Table XVII-12.1 that each of the newer

Table XVII-12.1 Chemical classification of antipsychotic drugs

Type	Class	Example
Typical antipsychotics	Phenothiazines	
	Aliphatic side chain	Chlorpromazine
	Piperidine side chain	(Thioridazine), pipothiazine
	Piperazine side chain	Trifluoperazine, fluphenazine
	Butyrophenones	Haloperidol (droperidol)
	Thioxanthenes	Flupenthixol, zuclopenthixol
	Diphenylbutylpiperidines	Pimozide, fluspirilene
Atypical antipsychotics	Dibenzodiazepines	Clozapine
	Benzixasoles	Risperidone
	Thienobenzodiazepines	Olanzapine
	Dibenzothiazepines	Quetiapine
	Imidazolidinones	(Sertindole)
	Benzothiazolylpiperazines	Ziprasidone
	Substituted benzamides	Sulpiride, amisulpride (sulpiride is considered by some to be a typical antipsychotic)

Medications in brackets have been withdrawn in the UK.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

antipsychotic medications belongs to a different chemical class, such as dibenzodiazepine (clozapine) and the benzixasole (risperidone). In light of this, the emphasis is now changing to pharmacological rather than chemical classes when considering switching medications.

MECHANISM OF ACTION OF ANTIPSYCHOTICS

Dopamine

The observation from the early use of chlorpromazine that clinical improvement was often accompanied by parkinsonian-like symptoms led to a focus on dopaminergic mechanisms in the neurochemistry of schizophrenia and mechanisms of action for antipsychotics. In 1963, Carlsson and Lindqvist reported that antipsychotics increase turnover of brain dopamine and suggested that this was in response to a functional 'blockade' of the dopaminergic system. Creese *et al.* (1976) demonstrated that the affinity of a wide range of antipsychotics to dopamine D_2 receptors was proportionate to their clinical potency (Figure XVII-12.1).

Emission tomography has reinforced the accepted theory that antipsychotic efficacy is related to D_2 receptor antagonism, with 65% blockade a putative threshold for antipsychotic response (Kapur *et al.*, 2000). Nonetheless, the situation appears very complex in that non-responders to antipsychotics may still show high levels of striatal D_2 blockade (Farde *et al.*, 1992; Pilowsky *et al.*, 1992). Furthermore, the highly effective atypical antipsychotic clozapine produces far less striatal D_2 blockade than typical antipsychotics (Farde *et al.*, 1992; Pilowsky *et al.*, 1992; Broich *et al.*, 1998), often below the putative 65% threshold. These findings have yet to be explained fully.

Extrapyramidal side effects (EPS) have also been studied; a threshold of 80% D_2 occupancy has been shown repeatedly to be necessary to produce EPS (Farde *et al.*, 1995; Kapur *et al.*, 2000). It may be that high levels of serotonin 5-HT_{2A} receptor blockade, as seen with most of the newer antipsychotics, may be protective against EPS by altering this threshold (Kapur and Remington, 1996).

Recent neurochemical imaging studies have indicated that people with schizophrenia have an increased sensitivity of their dopaminergic neurons to amphetamine challenge (Laruelle *et al.*, 1999) (Figure XVII-12.2). Thus, it may be that in response to stress, such people will over-release dopamine, which may drive psychosis.

There are currently five types of dopamine receptors identified in the human nervous system (D_1 to D_5). D_1 and D_5 receptors are similar in that they both stimulate the formation of cyclic adenosine monophosphate (cAMP) by activation of a stimulatory G-coupled protein. D_2 to D_4 receptors act by activating an inhibitory G-protein, thereby inhibiting the formation of cAMP. D_2 receptors are more ubiquitous than D_3 or D_4 receptors. D_3 receptors are situated differentially in the nucleus accumbens, one of the septal nuclei in the limbic system and D_4 receptors are concentrated especially in the frontal cortex.

There are a number of different dopaminergic pathways or tracts (Figure XVII-12.3). The nigrostriatal tract projects from the substantia nigra in the midbrain to the corpus striatum. This tract has a role primarily in motor control, although the ventral striatum has a role in reward- and goal-directed behaviours. It is by blocking dopamine receptors at the termination of this pathway in the dorsal striatum that the parkinsonian side effects of antipsychotics arise. The mesolimbic/mesocortical tract has its cell bodies in the ventral tegmental area adjacent to the substantia nigra. This tract projects to the limbic system and neocortex, as well as the striatum. This dopaminergic innervation supplies fibres to the medial surface of the frontal lobes and to the parahippocampus and cingulate cortex, the latter two being part of the limbic system. It is thought that this tract is where antipsychotic medication exerts its beneficial effect. The third major pathway is the tuberoinfundibular tract. The cell bodies for this tract reside in the arcuate nucleus and periventricular

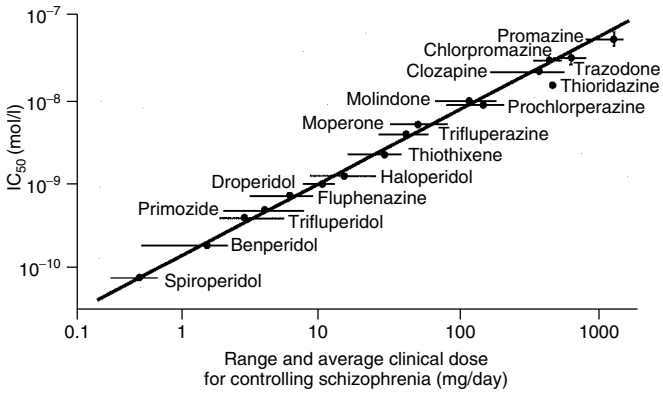

Figure XVII-12.1 Plot of the affinity of a wide variety of antipsychotic medications for the dopamine D_2 receptor against the average clinical daily dose used for controlling schizophrenia, an estimate of clinical potency. There is a direct relationship between these two indices. This replicated finding contributed to the use of high-dose antipsychotics on the assumption that giving higher doses would make an antipsychotic more potent by 'blocking' more receptors

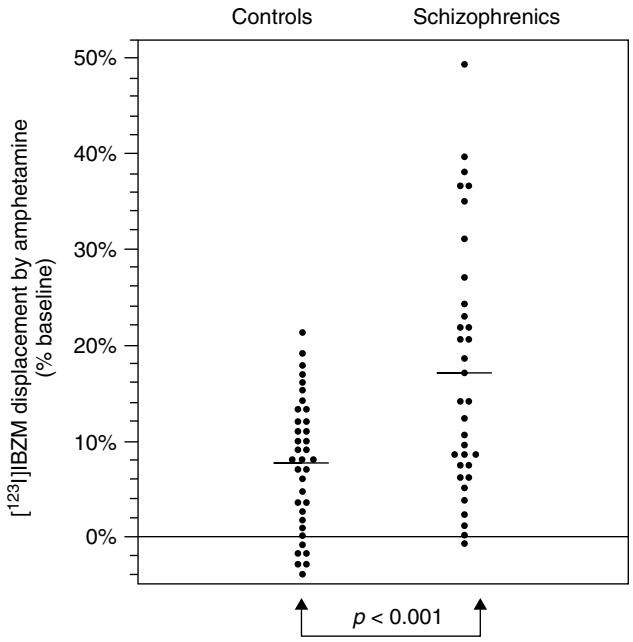

Figure XVII-12.2 Effect of amphetamine ($0.3\,mg\,kg^{-1}$) on [^{123}I]iodobenzamide ([^{123}I]IBZM) binding in healthy control subjects and untreated patients with schizophrenia. [^{123}I]IBZM is a tracer for D_2 receptors, which allows measurement of D_2 receptor availability (or binding potential) in humans *in vivo* using single photon emission tomography (SPET). The *y* axis shows the percentage decrease in [^{123}I]IBZM binding potential induced by amphetamine, which is a measure of the increased occupancy of D_2 receptors by dopamine following the challenge. Thus, these results indicate that when challenged with amphetamine, patients with schizophrenia release more dopamine than healthy controls

Figure XVII-12.5 Major serotonergic pathways in the human brain. Serotoninergic connections arising from the raphe nuclei are distributed ubiquitously throughout the cortical grey matter

area of the hypothalamus, and project to the infundibulum and, via the portal venous system, to the anterior pituitary. Dopamine acts within this tract to inhibit the release of prolactin. The blockade of these receptors by antipsychotics removes the inhibitory drive from prolactin release and leads to prolactinaemia.

Serotonin

The serotonergic hypothesis of schizophrenia predates the dopaminergic hypothesis and stems from the finding by Woolley and Shaw in 1954 that the hallucinogen lysergic acid diethylamide (LSD) acts via serotonin (5-hydroxytryptamine, 5-HT). Additionally, there is a neuroanatomical and functional interaction of 5-HT and dopaminergic systems such that blocking 5-HT_{2A} receptors enhances dopaminergic transmission (reviewed by Busatto and Kerwin, 1997). The newer atypical antipsychotics, in contrast with the typical antipsychotics, all have a higher affinity for the 5-HT_{2A} receptor than for the D_2 receptor. In terms of treatment response, there is a correlation of serotonergic neuroendocrine responses with symptomatic improvement on clozapine (Curtis *et al.*, 1995), and preliminary data suggest that allelic variations in the 5-HT_{2A} receptor gene vary with, and may predict, treatment response (Arranz *et al.*, 1995).

Previous studies with positron emission tomography (PET) and single positron emission tomography (SPET) have indicated that the atypical and newer antipsychotic medications, such as clozapine, risperidone, olanzapine and sertindole, all lead to almost complete occupancy of cortical 5-HT_{2A} receptors at clinically relevant doses (Farde *et al.*, 1994; Travis *et al.*, 1998; Kapur *et al.*, 1999) (Figure XVII-12.4). Full characterization of the effects of the older typical antipsychotics on 5-HT_{2A} receptors remains to be completed; however, preliminary data indicate that broad-spectrum typical antipsychotics, such as phenothiazines and thioxanthines, also lead to a significant occupancy (or reduction in receptor availability) of cortical 5-HT_{2A} receptors, but the level of occupancy is still significantly lower than that seen with the newer medications (Travis *et al.*, 1998).

More than nine distinct 5-HT receptors have been identified. The 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C} and 5-HT_3 subgroups have been studied most extensively. The major site of serotonergic cell bodies is in the area of the upper pons and midbrain. The classic areas for 5-HT-containing neurons are the median and dorsal raphe nuclei. The neurons from the raphe nuclei project to the basal ganglia and various parts of the limbic system, and have a wide distribution throughout the cerebral cortices in addition to cerebellar connections (Figure XVII-12.5). All the 5-HT receptors identified so far are G-protein-coupled receptors, except the 5-HT_3 receptor, which is a ligand-gated Na^+/K^+ channel.

Other Neurotransmitters that may be Involved in Antipsychotic Mechanisms of Action

Recent efforts have been directed towards finding an alternative neurochemical target in schizophrenia. The first of these that

should be considered is gamma aminobutyric acid (GABA). GABA appears to have a regulatory role on dopaminergic function. The balance of evidence would tend to suggest that GABA decreases dopaminergic firing. This links with human post-mortem data indicating that GABAergic reductions correlate with increased dopamine concentrations (reviewed by Benes, 1997 and Wassef *et al.*, 1999). Thus, it is possible that in schizophrenia there is a reduction in GABAergic function, which leads to a dysregulation of dopamine and the production of psychotic symptoms.

A more likely candidate, however, appears to be the glutamatergic system. Glutamatergic dysfunction, particularly at the level of the *N*-methyl-D-aspartate (NMDA) receptor, has also been implicated in the pathophysiology of schizophrenia. Drugs that are antagonistic at the NMDA receptor, such as ketamine and phencyclidine, produce in healthy volunteers the positive, negative and neurocognitive symptoms that are characteristic of schizophrenia (Krystal *et al.*, 1994). There is evidence that the propsychotic effects of these drugs may be mediated via an increase in the release of glutamate acting on non-NMDA receptors (Moghaddam *et al.*, 1997). If the function of NMDA receptors is decreased, this may remove the drive to inhibitory GABAergic neurons, which regulate the excitatory neurons acting on areas such as the frontal cortex and the limbic regions. Thus, with decreased inhibitory control, these neurons may increase firing in these areas and produce psychotic symptoms (Farber *et al.*, 1998). Reducing glutamate release at all glutamate receptors may also have a role in improving symptoms in schizophrenia and related psychosess.

SIDE EFFECTS OF ANTIPSYCHOTICS

Acute neurological side effects secondary to dopamine D_2 receptor blockade with typical antipsychotics include acute dystonia. This is characterized by fixed muscle postures with spasm, e.g. clenched jaw muscles, protruding tongue, opisthotonos, torticollis and oculogyric crisis (mouth open, head back, eyes staring upwards). Acute dystonia appears within hours to days; young males are most at risk. This side effect should be treated immediately with anticholinergic drugs (procyclidine 5–10 mg, benzotropine 50–100 mg i.m. or i.v.). The response is dramatic.

Medium-term neurological side effects due to D_2 blockade include akathisia and parkinsonism. Akathisia is an inner and motor (generally lower limb) restlessness. It is usually very distressing by the patient and can lead to increased disturbance. Treatment is by reducing the neuroleptic dose and/or giving propranolol, *not* with anticholinergics. Akathisia usually appears within hours to days.

Parkinsonism is due to blockade of D_2 receptors in the basal ganglia. The classical features are a mask-like facies, tremor, rigidity, festinant gait and akathisia. It appears after a few days to weeks, and treatment involves anticholinergic drugs (procyclidine, orphenadrine), reducing the neuroleptic dose, or switching to an atypical antipsychotic that is less likely to produce such extrapyramidal symptoms.

The chronic neurological side effects due to D_2 blockade are tardive dyskinesia and tardive dystonia. Tardive dyskinesia is usually manifested as orofacial dyskinesia, and the patient exhibits lip smacking and tongue rotating. Tardive dystonia appears as choreoathetoid movements of the head, neck and trunk. It appears after months to years. There is an increased risk of tardive dyskinesia in older patients, females, edentulous patients, and patients with organic brain damage. With chronic use of antipsychotics, 20% of patients will develop tardive dyskinesia. There is no clear relationship to duration, total dose of treatment, or class of antipsychotic used. Increasing the dose may alleviate symptoms temporarily, while reducing the dose may exacerbate symptoms. Clozapine, olanzapine and quetiapine have been shown to improve symptoms, while risperidone has a lower propensity to cause tardive dyskinesia (Beasley *et al.*, 1999).

The effect of D_2 blockade on the neuroendocrine system produces hyperprolactinaemia by reducing the negative feedback on the anterior pituitary. High serum levels of prolactin produce galactorrhoea, amenorrhoea and infertility.

The most life-threatening side effect of neuroleptic use is neuroleptic malignant syndrome (NMS). This is thought to be due to derangement of dopaminergic function, but the precise pathophysiology is unknown. Symptoms include hyperthermia, muscle rigidity, autonomic instability and fluctuating consciousness. It is an idiosyncratic reaction. The diagnosis is often missed in the early stages, but a raised creatine phosphokinase level is often seen. It can occur at any time. Mortality is 20% if untreated, and immediate medical management is required. Bromocriptine (a D_1/D_2 receptor agonist) and dantrolene (a skeletal muscle relaxant) are used to reverse dopamine blockade and for muscular rigidity, respectively. Management includes supportive treatment for dehydration and high temperature. Renal failure from rhabdomyolysis is the major complication and cause of mortality. NMS can recur on reintroduction of antipsychotics, therefore it is recommended to wait at least 2 months and then introduce a drug of a different class at the lowest effective dose.

Anticholinergic side effects of antipsychotics include dry mouth (hypersalivation with clozapine), difficulty in urinating or urinary retention, constipation, blurred vision and ejaculatory failure. Profound muscarinic blockade may produce a toxic confusional state.

The sedative effects of antipsychotics are, in part, produced by the blockade of histamine-1 receptors. Side effects secondary to alpha-adrenergic blockade include postural hypotension, cardiac arrhythmias and impotence.

Some side effects may be due to autoimmune reactions, such as urticaria, dermatitis and rashes. Dermal photosensitivity and a grey/blue/purple skin tinge are more commonly seen with the phenothiazines, as are the conjunctival, corneolenticular and retinal pigmentation sometimes reported. Cholestatic jaundice due to a hypersensitivity reaction is now seen rarely with chlorpromazine.

Weight gain is also seen frequently with a wide variety of antipsychotics. This may be due to increased appetite. Although the mechanism is unclear, it may be due to a combination of histamine-H_1 and 5-HT_{2C} receptor antagonism (reviewed by Malhotra *et al.*, 1993).

There are also idiosyncratic side effects related to individual drugs, which are discussed in the relevant sections below.

Cardiac Side Effects

Recently, concern has grown over the ability of antipsychotic medications to produce changes in cardiac conduction. QT_c interval prolongation is the most widely reported conduction deficit. This first came to attention after sudden deaths secondary to arrhythmias with pimozide were noted. The UK Committee for the Safety of Medicine's (CSM) advice regarding pimozide is that all patients should have an electrocardiogram (ECG) before starting treatment, and patients with a known arrhythmia or prolonged QT interval should not receive the drug. Sertindole, an atypical antipsychotic, was suspended voluntarily from sale by its manufacturers in 1997 after similar concerns. Most recently, the CSM has advised on restrictions regarding the use of thioridazine and droperidol as these medications produce the most profound QT_c prolongations (Reilly *et al.*, 2000).

The QT interval on the standard ECG represents the interval between the end of ventricular depolarization and the end of cardiac repolarization. The 'c' in QT_c indicates that the QT value quoted has been corrected for cardiac rate. It is thought that prolongation of this interval increases the risk of a potentially fatal ventricular arrhythmia known as torsade de pointes. The

mechanism of this is becoming clearer and implicates the blockade of the delayed rectifier potassium channel (Ikr). Blockade of this receptor in the heart prolongs cardiac repolarization and thus the QT_c interval. It is known that drugs associated most specifically with QT_c interval prolongation bind specifically to the Ikr (Yap and Camm, 2002).

Although there is little consensus as to what represents a 'normal' QT_c, it is generally accepted that a QT_c over 500 ms increases the likelihood of an arrhythmia. When interpreting data on medication-related QT_c prolongation, it is important to note that the mean daily QT_c intrasubject variability is 76 ms (Morganroth, 2002).

Other risks factors that increase the likelihood of QT_c prolongation include age over 65 years and coadministration of other drugs associated with cardiac arrhythmias, such as tricyclic antidepressants. Safety studies are ongoing with both the newer and the older medications, and preliminary data suggest that the newer medications do not differ significantly in their likelihood to prolong the QT_c interval.

EFFICACY OF ANTIPSYCHOTICS IN THE ACUTE PHASE OF TREATMENT

The best known large-scale clinical trial, which gives a good idea of the effect size to be expected, was carried out by the National Institute of Mental Health in the USA (National Institutes of Health, 1964). This study involved four treatment groups — chlorpromazine, thioridazine, fluphenazine and placebo — with 90 randomly allocated subjects in each group. The subjects were treated for 6 weeks. In this study, 75% of subjects in the chlorpromazine-, thioridazine- and fluphenazine-treated groups showed significant improvement, 5% failed to be helped, and 2% deteriorated. In the placebo group, only 25% of patients showed significant improvement, and over 50% were unchanged or worse.

As we mentioned earlier, the medications used to treat schizophrenia are effective against psychotic symptoms *per se*. This is illustrated by the study of Johnstone *et al.* (1988), who showed that pimozide was antipsychotic (i.e. reduced the positive symptoms of psychosis) in patients with 'functional' psychosis regardless of whether the patients had prominent manic or depressive symptoms or were euthymic. This proved that 'neuroleptics', as they were then called, were truly antipsychotic rather than just antischizophrenic, providing the rationale for their use to treat psychotic symptoms even in the absence of a clear-cut diagnosis of schizophrenia.

Davis and Andriukaitis (1986) performed a meta-analysis using the trials involving chlorpromazine, and investigated the relationship between dose and clinical effect. They noted that a threshold of 400 mg of chlorpromazine is required. This was based on the fact that in 31 trials using a dose of 400 mg or more of chlorpromazine per day, only one trial failed to show that chlorpromazine was less effective than the reference treatment, whereas in the 31 trials using a dose of less than 400 mg of chlorpromazine, 19 failed to show a significant effect.

PHARMACOTHERAPY AS MAINTENANCE TREATMENT IN SCHIZOPHRENIA

Although it is accepted widely that antipsychotic medication is the mainstay of treatment in acute schizophrenia, its role in long-term maintenance has been more contentious. Nevertheless, the importance of maintenance drug therapy in the treatment of chronic schizophrenia has been evident since the early 1960s.

Initial studies indicated that between one-half and two-thirds of patients with schizophrenia who were stable on medication relapsed following cessation of maintenance pharmacological therapy compared with 5–30% of patients maintained on medication (Caffey *et al.*, 1964; Hogarty *et al.*, 1974; Davis, 1975). Two more recent reviews have collated the information from trials in which antipsychotics were withdrawn from populations of patients with schizophrenia who had responded to medication (Gilbert *et al.*, 1995; Viguera *et al.*, 1997).

In a review of 66 studies from 1958 through to 1993, Gilbert *et al.* (1995) noted that the relapse rate in the medication withdrawal groups was 53.2% (follow-up 6.3–9.7 months) compared with 15.6% (follow-up 7.9 months) in the maintenance groups. There was also a positive relationship between risk of relapse and length of follow-up. Viguera *et al.* (1997) investigated the relationship between gradual medication discontinuation (from last depot injection or tailing off oral medication over 3 weeks or more) and abrupt oral medication discontinuation. They noted a cumulative relapse rate of about 46% at 6 months and 56.2% at 24 months follow-up in patients whose medication was stopped abruptly. They calculated that in patients whose medication was stopped gradually, the relapse rate at 6 months was halved. Fifty per cent of inpatients had relapsed by 5 months after cessation of medication, whilst in the outpatient group, relapse rates remained at less than 50% to 4 years follow-up.

Thus, findings from medication discontinuation studies have shown conclusively that, as a group, patients with schizophrenia fare better if they receive antipsychotic medication. However, prolonged use of antipsychotic medication, particularly the older typical antipsychotics, carries a high risk of adverse effects, particularly tardive dyskinesia. In order to attempt to minimize the risk of these events, much work has focused on the use of low-dose medication regimes.

Low-Dose Antipsychotics

The rationale underlying the use of low-dose strategies is that significantly lower doses of medication are required for maintenance as opposed to the acute treatment of schizophrenia. This assumes that all major treatment goals have been met by the time of dose reduction. The two major aims are to ensure that the stability of symptomatic improvement is at least maintained and to minimize the risk of neurological side effects and secondary negative symptoms caused by higher doses of, in particular, typical antipsychotics.

A number of trials have investigated the use of standard doses of depot antipsychotics (250–500 mg chlorpromazine equivalents) in comparison with continuous low-dose regimes (usually at least 50% less) (reviewed by Schooler, 1993 and Barbui *et al.*, 1996). On the whole, these studies have indicated that patients treated with lower doses of antipsychotics have a higher rate of exacerbation of psychotic symptoms and higher rates of relapse.

Intermittent or Targeted Medication

This treatment strategy is based on the assumption that patients can be maintained on intermittently administered low doses of antipsychotics. The antipsychotics are given either for only a few days per week, or only when the patient is exhibiting signs of relapse and then ceased on resolution of that relapse. To summarize the results from the main published studies (Herz *et al.*, 1991; Carpenter *et al.*, 1990; Jolley *et al.*, 1990; Gaebel *et al.*, 1993), it appears that patients receiving intermittent targeted therapy have a higher rate of relapse than those on continuous therapy, and may have a higher rate of rehospitalization. Interestingly, at 2 years there is little difference in social functioning or psychopathology between the two groups.

In light of the increased risk of relapse and hospitalization, neither low-dose nor intermittent targeted treatment is generally recommended.

NEWER ATYPICAL ANTIPSYCHOTICS

The reintroduction of clozapine in the early 1990s, and the subsequent release of several new, atypical antipsychotics, has increased optimism in the treatment of schizophrenia. The term atypical has become controversial, as the definition of what makes an antipsychotic atypical is contentious. The simple definition is that an atypical antipsychotic is one that when given to laboratory rats in doses equivalent to those used to treat psychoses in humans will not produce catalepsy (a dystonic reaction). However, a more useful definition is that an atypical antipsychotic is one that has a wide therapeutic range. The therapeutic range of an antipsychotic can be conceptualized as lying between two doses. The lower dose is the dose at which 50% of people receiving that medication will respond to treatment. The higher dose is the dose at which 50% of people receiving that medication will begin to develop mild EPS. Thus, this allows us to give the medication at a dose where response can be predicted but at which there is a low liability for EPS. A critical review of the clinical trial literature on older typical antipsychotics used at low doses found no convincing evidence that there is a low dose of typical antipsychotics that is effective but does not produce EPS, therefore they have a very narrow and unpredictable therapeutic range (Taylor, 2000). All of the newer antipsychotics reviewed below have, to a greater or lesser extent, a predictable, wide therapeutic range. As these newer antipsychotics are likely to be the mainstay of treatment for schizophrenia in the future, it is worthwhile considering them individually.

Clozapine

Clozapine, the prototypical third-generation antipsychotic, has been used since the 1960s for treatment of schizophrenia. After reports of several deaths from neutropoenia, it was withdrawn and then reintroduced with restrictions. In most countries, clozapine can be used only for patients unresponsive to two other antipsychotics given at an adequate dose for an adequate duration, or those with tardive dyskinesia or severe EPS, and then only with blood monitoring. Each patient has to be registered, and the drug is only dispensed after a normal white cell count. In the UK, a blood count should be performed every week for 18 weeks, then every 2 weeks for the next year, and thereafter monthly. Clozapine is contraindicated in patients with previous neutropoenia.

Important aspects of clozapine's pharmacology include its low affinity for the D_2 receptor in comparison with older antipsychotics. Clozapine has higher affinity at the D_1 and D_4 receptors, and also binds to the extrastriatal D_2-like receptor, the D_3 receptor. It is thought that the low incidence of extrapyramidal side effects is due to the low activity at the D_2 receptor. Clozapine also has antagonistic activity at the 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C} and 5-HT_3 receptors. Clozapine is also an antagonist at the alpha$_1$ (less so at the alpha$_2$) receptor, resulting in sedation and hypotension. Clozapine's antagonism of the histamine-H_1 receptor adds to its sedative effects and may be responsible for weight gain. Weight gain may also be attributed to clozapine's relatively high affinity for the 5-HT_{2C} receptor. Other side effects include hypersalivation, tachycardia, sedation and hypotension. More rarely, clozapine can produce seizures (approximately 1%) and blood dyscrasias (<1–2%). The risk of neutropoenia is 1–2% and, in most cases, is reversible. The majority of cases (83%) of neutropoenia occur within the first 20 weeks of treatment. Risk of agranulocytosis decreases to 0.07% after the first year of treatment. Agranulocytosis probably results from toxic and immunologic factors (reviewed by Travis, 1997). It is this latter, potentially fatal side effect that has led to the limits on the use of clozapine, and the requirement for blood monitoring in patients receiving the drug. Clozapine does not increase serum prolactin.

Clozapine is the most effective treatment for schizophrenic patients refractory to other therapies, and improves both positive and negative symptoms. In non-comparative studies, clozapine leads to an >15% improvement in baseline ratings in 30–70% of previously treatment-refractory patients after 2–6 months treatment (reviewed by Travis, 1997). In comparison with chlorpromazine (Kane *et al.*, 1988; Claghorn *et al.*, 1987; Conley *et al.*, 1988), haloperidol (Breier *et al.*, 1994) or fluphenazine (Pickar *et al.*, 1992), clozapine shows a 30–100% response rate over a 4–17% rate for the comparator when administered to patients resistant to previous treatment with classical antipsychotics (see Treatment Resistance in Schizophrenia below). A recent systematic review and meta-analysis of randomized trials of clozapine has confirmed the superiority of clozapine over typical antipsychotics in the management of schizophrenia (Wahlbeck *et al.*, 1999). Clozapine has been investigated in few randomized clinical trials of maintenance therapy due to the restrictions imposed on its use. In one of the few studies published, Essock *et al.* (1996) followed up a sample of 227 patients randomized to either clozapine or treatment as usual. They reported that those patients treated with clozapine had significantly greater reductions in side effects, disruptiveness, hospitalization and readmission after discharge. Furthermore, clozapine's clinical efficacy in relapse prevention is well established, naturalistically, at 1–2 years of treatment, and there have been reports of good maintenance efficacy for up to 17 years of treatment (for review, see Travis, 1997).

Risperidone

Risperidone has high affinity for the 5-HT_{2A} receptor, with a similar affinity at the D_2 receptor as most typical antipsychotics. In the acute phase of treatment, risperidone appears to be as effective as haloperidol in terms of improvement in positive and negative symptom scores (Marder *et al.*, 1997).

The optimal dose of risperidone appears to be 4–6 mg per day. At doses above 8–12 mg per day, risperidone can cause extrapyramidal side effects of tremor, rigidity and restlessness, with a similar frequency to classical antipsychotics. Risperidone increases serum prolactin, which may lead to sexual dysfunction.

Risperidone has been assessed for long-term efficacy and safety in a number of long-term, open-label studies. The earlier data of Mertens (1991), Bressa *et al.* (1991) and Lindstrom *et al.* (1995) suggested that long-term therapy with risperidone was associated with meaningful reduction in psychopathology, amelioration of EPS, and improved social functioning from baseline measures or against placebo.

More recently, a meta-analysis of 11 risperidone/conventional antipsychotic comparator randomized controlled trials was performed (Song, 1997). The author reports that slightly more patients on risperidone showed clinical improvement than with comparison antipsychotics (57% *v*. 52%) and used significantly less medication for EPS (29.1% *v*. 33.9%).

Olanzapine

A more broad-spectrum atypical antipsychotic, olanzapine has a side-effect profile similar to that of clozapine but with a higher incidence of EPS at doses above 20 mg per day. Olanzapine also demonstrates antagonistic effects at a wide range of receptors, but

has a higher affinity for D_2 and 5-HT_{2A} receptors than clozapine and a lower affinity at the D_1 receptor. In acute-phase studies, olanzapine is efficacious for positive and secondary negative symptoms (Tollefson *et al.*, 1997).

Standard-dose olanzapine (5–15 mg per day) is effective maintenance treatment for schizophrenia (Dellva *et al.*, 1997). Initial data from a meta-analysis of three studies using haloperidol-treated patients as a test group indicate that 80.3% of patients receiving olanzapine maintain their response at 1 year in comparison with 72% for haloperidol-treated patients (Tran *et al.*, 1998).

Quetiapine

Another broader-spectrum atypical antipsychotic, quetiapine has a similar receptor-binding profile to clozapine but with relatively lower affinity for all receptors and virtually no affinity for muscarinic receptors. Quetiapine is effective in acute-phase studies for the treatment of positive and secondary negative symptoms. Initial randomized controlled trials indicated that quetiapine (250–750 mg per day, $n = 96$) was more effective than placebo ($n = 96$) and that this efficacy was not seen at doses of less than 250 mg per day (Small *et al.*, 1997). In comparison with chlorpromazine, response rates to quetiapine were similar across all symptom domains (mean dose 407 mg quetiapine *v*. 384 mg chlorpromazine) (Peuskens and Link, 1997). Response rates between haloperidol and quetiapine-treated groups were also similar (Arvanitis and Miller, 1997). Further studies have replicated these findings (Copolov *et al.*, 2000).

In all of these studies, the rates of EPS with quetiapine are similar to those seen in placebo-treated groups and are significantly lower than those seen in conventional antipsychotic comparator groups. Most common side effects are somnolence and dry mouth. Quetiapine demonstrates a lower potential to cause weight gain than clozapine and olanzapine, and similarly does not increase serum prolactin (Rak *et al.*, 2000).

In the open-label extensions of the acute trials, 265 responders to quetiapine were considered suitable for 1 year's treatment. Of these, 33% were still on quetiapine at 12 months with a sustained level of symptomatic improvement (Rak and Raniwalla, 2000). This is similar to the continuation rates seen in similar trials with olanzapine.

Amisulpride

In contrast with the other novel antipsychotics, amisulpride only has effects on the dopamine D_2 and D_3 receptors, where it is a potent antagonist. In animal models at lower doses, amisulpride appears to bind preferentially to presynaptic D_2 receptors, and at projected therapeutic levels it also appears to be selective for limbic D_2 and D_3 receptors (Schoemaker *et al.*, 1997). It has a similar efficacy to haloperidol for positive symptoms in acute exacerbations of schizophrenia (Delcker *et al.*, 1990; Moller *et al.*, 1997b; Puech *et al.*, 1998; Carriere *et al.*, 2000), with a projected optimum dose in this group of 400–800 mg per day (Puech *et al.*, 1998). Some studies at this dose range have reported a significantly greater efficacy for amisulpride in comparison with placebo for treating the negative symptoms of schizophrenia (Moller *et al.*, 1997b; Carriere *et al.*, 2000).

In the studies mentioned above, amisulpride has a significantly lower incidence of EPS at doses below 1200 mg per day than haloperidol. Amisulpride may cause less weight gain than other atypical antipsychotics, but it increases plasma prolactin (Coulouvrat and Dondey-Nouvel, 1999; Rein *et al.*, 2000).

In a 12-month trial of amisulpride 200–800 mg per day ($n = 370$) versus haloperidol 5–20 mg per day ($n = 118$), amisulpride showed enhanced efficacy for positive and negative symptoms. Importantly, those patients treated with amisulpride had significantly greater improvement in quality of life and significantly fewer EPS. Long-term efficacy and relapse prevention were similar in the amisulpride- and haloperidol-treated groups (Colonna *et al.*, 2000).

Ziprasidone

Ziprasidone has a high 5-HT_{2A}/D_2 receptor blockade ratio and a similarly high affinity for the 5-HT_{2A} receptor as risperidone. It is an agonist at the 5-HT_{1A} receptor. Ziprasidone also has potent affinity for D_3 and moderate affinity for D_4 receptors. It exhibits weak serotonin and noradrenergic reuptake inhibition. Ziprasidone appears to have relatively low levels of side effects. These may include somnolence and headache, but results of full clinical studies remain to be published.

An initial clinical trial of ziprasidone versus haloperidol 15 mg per day over 4 weeks suggested that ziprasidone 160 mg per day was as effective as haloperidol at reducing positive symptom scores but produced fewer side effects (Goff *et al.*, 1998). In two placebo-controlled trials involving 139 and 301 patients over 4 and 6 weeks, respectively (Keck *et al.*, 1998; Daniel *et al.*, 1999), the pooled data indicated that ziprasidone 80–160 mg was consistently significantly more effective than placebo and lower doses of ziprasidone. Improvements in positive and negative symptoms were similar in magnitude to those seen in patients treated with risperidone, olanzapine or quetiapine. Interestingly, 160 mg of ziprasidone was associated with a greater than 30% decrease in depressive symptoms in the subgroup of patients with significant depression at the outset of the trials.

Ziprasidone has also been tested in a 1-year placebo-controlled trial in order to assess its utility for relapse prevention. A total of 294 patients were studied and randomized to placebo treatment or ziprasidone 40–160 mg per day. Of the 117 patients who were maintained on ziprasidone, at 6 months only 6% had experienced exacerbation of their symptoms compared with 35% of the 23 patients remaining on placebo; this compares favourably with the available data on the older antipsychotics (reviewed by Keck *et al.*, 2001).

Adverse Events with Atypical Antipsychotics

The issue of side effects or adverse events is linked closely to tolerability and acceptability and therefore to both compliance and relapse prevention. The most debilitating and obvious side effects of conventional antipsychotics are often motor effects. As described above, the newer antipsychotics demonstrate a lower propensity to cause EPS at clinically effective doses. These drugs may provide benefits for patients who suffer from akathisia and tardive dyskinesia.

Akathisia develops in 18–75% of patients treated with typical antipsychotics. Studies of patients treated with clozapine have indicated that over a 12-week period, there is a striking reduction in akathisia (Safferman *et al.*, 1992; Chengappa *et al.*, 1994), with rates of less than 10%. Moller *et al.* (1997a) have reported that risperidone at 4–8 mg per day produces a significantly lower incidence than haloperidol. Olanzapine-treated groups have improved akathisia ratings from baseline (Beasley *et al.*, 1997), and quetiapine shows similar akathisia rates to placebo and leads to improvements in akathisia ratings in switch-over studies (Small *et al.*, 1997; Arvanitis *et al.*, 1997). Similarly, in long-term studies, amisulpride shows a significantly lower rate of akathisia than haloperidol (8% *v*. 21%) (Colonna *et al.*, 2000), although in short term studies rates are similar, (Rein *et al.*, 2000).

It is in the area of tardive dyskinesias that clozapine appears to have its most marked effect. Liebermann *et al.* (1991) reported

a 50% reduction of symptoms over 28 months of treatment in 43% of patients, and Gerlach and Peacock (1994) reported a resolution of tardive dyskinesia in 54% of patients after 5 years of clozapine treatment. Furthermore, Tamminga *et al.* (1994) reported a significant difference in reduction of tardive dyskinesia scores in a clozapine-treated group versus a haloperidol-treated group; this difference began after about 4 months of treatment. There have also been case reports that show that switching to clozapine may be effective in reducing tardive dystonia (Shapleske *et al.*, 1996).

In risperidone-treated groups at <8 mg per day, there are EPS benefits that increase over time with a rate of tardive dyskinesia at approximately 0.3% per year (Lindstrom *et al.*, 1995). Additional evidence comes from the large-scale controlled studies of olanzapine, which has a 0.52% 1-year risk of tardive dyskinesia versus 7.45% for haloperidol (13.5 mg *v.* 13.9 mg) (Beasley *et al.*, 1999). These findings tie in with early studies on quetiapine versus haloperidol and ziprasidone versus placebo, which both show placebo rates of tardive dyskinesia (Arvanitis *et al.*, 1997; Keck *et al.*, 2001).

As has been described above, the rate of other side effects, such as weight gain and prolactinaemia, may vary between each of the newer drugs, although fully adequate comparison studies remain to be published.

NEGATIVE SYMPTOMS

Negative symptoms are usually separated into primary and secondary negative symptoms of schizophrenia. Primary negative symptoms are usually classified as the those that are due directly to, or are 'core' to, the psychotic illness process. Secondary negative symptoms are negative-type symptoms that mimic the core symptoms but that are due to enduring positive symptoms or are secondary to drug treatment induced EPS.

It is claimed that clozapine has an almost unique action against the negative symptoms of schizophrenia out of proportion to its effect on positive symptoms (Meltzer, 1990; Meltzer, 1991), but the evidence for this is by no means clear. Tandon *et al.* (1993) found that the improvement in negative symptoms covaried with the improvement in positive symptoms, and Hagger *et al.* (1993) found no improvement in negative symptoms. A more recent finding is that in comparison with haloperidol, clozapine has a significant effect on negative symptoms in patients with non-deficit schizophrenia but not in those with deficit schizophrenia, i.e. those with enduring negative symptoms (Breier *et al.*, 1994; Conley *et al.*, 1994). It has therefore been suggested that clozapine's seemingly beneficial effect on negative symptoms may simply be a reflection of its reduced tendency to cause extrapyramidal side effects (Kane *et al.*, 1994). The weight of current evidence suggests that clozapine has an excellent effect on the secondary but not primary negative symptoms (Carpenter, 1996). Indeed, all of the newer antipsychotics appear to have an effect on secondary negative symptoms, and all of the available trials have indicated a modest but significant advantage for the newer medications over conventional antipsychotics in negative symptom improvement on standard rating scales (Song, 1997; Tollefson *et al.*, 1997; Small *et al.*, 1997; Tandon *et al.*, 1997).

Additional to the effects at 400–800 mg per day, amisulpride at low doses (50–300 mg per day) may have a unique effect in patients with only negative symptoms. In comparison with placebo, these low doses of amisulpride produce significant reductions in negative symptoms scores with little change in positive symptom scores (Danion *et al.*, 1999; Boyer *et al.*, 1995; Paillere-Martinot *et al.*, 1995). However, in a study utilizing a different design but similar patient population, low-dose amisulpride was similar to low-dose haloperidol treatment in terms of negative symptom improvement (Speller *et al.*, 1997).

COGNITION

The older antipsychotics have limited impact on the neurocognitive deficits, which are a core feature of schizophrenia, are apparent at the onset of illness, and may deteriorate during the first few years of illness, although inconsistent long-term improvements have been noted (Meltzer *et al.*, 1996; Bilder, 1997). There has been increasing interest in the possible role that the newer antipsychotics may have in ameliorating these problems, which are linked to poor outcome and future unemployment. Clozapine may lead to improvements in attention, memory and executive function over 6–12 months (Lee *et al.*, 1994). Risperidone in comparison with haloperidol appears to improve frontal function and spatial working memory (Gallhofer *et al.*, 1996; Green *et al.*, 1997). Olanzapine improves a variety of measures of function, including psychomotor speed, verbal fluency and memory (McGurk and Meltzer, 1998). A preliminary study comparing quetiapine and haloperidol in a randomized double-blind trial demonstrated that patients treated with quetiapine showed significant improvements in overall cognitive performance, verbal fluency and verbal contextual memory (Velligan *et al.*, 1999). It is still not clear how relevant the modest improvements or impairments reported in these studies are to long-term outcome.

DEPRESSION AND BIPOLAR AFFECTIVE DISORDER

Patients with schizophrenia are significantly more likely than the general population to suffer from other psychiatric disorders, such as depression, and all antipsychotics are used to treat other psychotic disorders outside of schizophrenia. Clozapine has been reported to be effective in patients with treatment-resistant schizoaffective or manic illnesses (Zarate *et al.*, 1995; reviewed by Kimmel *et al.*, 1994). In one study, clozapine reduced baseline mania ratings by more than 50% in 72% of a group of patients suffering from either mania or schizoaffective disorder, and 32% had a significant improvement in brief psychiatric rating scale (BPRS) scores. The latter finding was more frequent in the bipolar patients and the non-rapid cycling patients (Calabrese *et al.*, 1996). In depressive disorders, clozapine has a more equivocal response. Although seemingly effective against depressive symptoms occurring comorbidly with schizophrenia (Meltzer and Okayli, 1995), there has been little work showing a particular use for clozapine in treatment-refractory depression (Banov *et al.*, 1994; Rothschild, 1996).

Conventional antipsychotics may both improve and contribute towards depressive symptoms. Clozapine reduces depressive features and suicidality (Meltzer and Okayli, 1995). Risperidone produces significantly greater reduction in anxiety/depression subscales in comparison with haloperidol (Marder *et al.*, 1997). Olanzapine has significant antidepressant effects in comparison with haloperidol (Tollefson *et al.*, 1998). Amisulpride (50 mg per day) has been compared with imipramine (100 mg per day) and placebo in patients with dysthymia and major depressive disorder. In this study ($n = 219$), both imipramine and amisulpride produced similar and significant improvements on all rating scales; the implications of this in patients with schizophrenia have yet to be elucidated (Lecrubier *et al.*, 1997).

TREATMENT RESISTANCE IN SCHIZOPHRENIA

Treatment resistance in schizophrenia is usually defined as a failure to show a clinical response to two antipsychotics from different chemical and pharmacological classes after each has been given for an adequate period of time at an adequate dose (reviewed by Conley and Buchanan, 1997 and Peuskens, 1999). It is estimated that at least 25% (Brenner *et al.*, 1990) and possibly up to 50%

Table XVII-12.2 Definition of treatment resistance in schizophrenia (Kane criteria)

Clinical history	• No good level of functioning over the last 5 years
(previous treatment)	• Received three periods of treatment in the preceding 5 years with antipsychotics of at least two different chemical classes for at least 6 weeks, with an equivalent of at least 1000 mg chlorpromazine daily without significant relief
Cross-sectional	• BPRS total score ≥45 (18 items, rated from 1 to 7 [absent to severe])
	• Rating ≥4 on at least two of the following BPRS items: conceptual disorganization, unusual thoughts, hallucinatory behaviour, suspiciousness
	• CG1 score ≥4
Prospective	• Failure to reduce BPRS score by ≥20%, plus either a post-treatment BPRS score of ≥35 or CGI ≥3 with haloperidol 60 mg daily for 6 weeks

BPRS, brief psychiatric rating scale; CGI, clinical global impressions scale.
From Kane *et al.* (1988) and Peuskens (1999).

(Peuskens, 1999) or more of patients with chronic schizophrenia would, at least partially, fulfil the criteria given below for treatment resistance.

The criteria used in the seminal clozapine versus chlorpromazine trial (Kane *et al.*, 1988) are often quoted as the gold standard in the definition of treatment resistance. An adequate dose of a typical antipsychotic is generally considered to be up to about 600–750 mg of chlorpromazine equivalent (Barnes and McEvedy, 1996), although it must be noted that most of the early trials in treatment-resistant populations adopted the criteria used in the Kane *et al.* (1988) seminal clozapine trial of >1000 mg of chlorpromazine equivalent. For the newer medications, the optimum or maximum therapeutic doses would appear to be about 6 mg per day for risperidone, 20 mg per day for olanzapine, 750 mg per day for quetiapine and 800 mg per day for amisulpride. Treatment non-response has been defined variously, one possible definition being a rating above 45 on the BPRS (18-item scoring 1 to 7) and/or a failure for the BPRS total score to improve by 20% during a treatment trial (Kane *et al.*, 1988). These criteria, however, emphasize positive symptoms, thus a broader definition has been applied more recently that also includes functional disability (Brenner *et al.*, 1990). An adequate duration of treatment is usually considered to be about 4–6 weeks (Kane and Marder, 1993) (Table XVII-12.2).

The most effective medication for treatment-resistant schizophrenia is clozapine; evidence for its effectiveness compared with typical antipsychotics is given above. If a patient fulfils the criteria for treatment resistance, they should be encouraged to take clozapine.

It is timely, however, to consider therapeutic options for patients who do not respond adequately to clozapine monotherapy and indeed for those treatment-resistant patients who are unwilling or unable to take clozapine.

Patients Who do not Respond Adequately to Clozapine

Between 30% and 60% of patients do not respond adequately to clozapine (Kane, 1992). Some patients gain benefit from clozapine but are still symptomatically or functionally impaired because of their schizophrenic illness. In these patients, it is worthwhile considering ways in which clozapine use can be optimized. This issue has been reviewed by Barnes and McEvedy (1996) and Chong and Remington (2000).

Dose and Duration

While there is still little evidence to suggest a linear relationship between clozapine plasma levels and response, more recent work (reviewed by Wagstaff and Bryson, 1995) has indicated that there is a minimum therapeutic plasma concentration, ranging between $350\,\mu g\,l^{-1}$ and $420\,\mu g\,l^{-1}$. Below these levels, 8–38% of patients respond, while above these levels 55–75% of patients respond (Miller 1996). Thus, although patients may respond at lower plasma levels and therefore lower doses of clozapine, there is evidence to suggest that a patient should not be considered to be a non-responder to clozapine unless they have had a period of treatment with plasma levels above $420\,\mu g\,l^{-1}$ for an adequate duration of time.

The optimal duration of a trial of clozapine remains controversial. The American Psychiatric Association recommends a minimal trial of 12 weeks; however, improvement and response have been noted as needing 6 months to occur (Conley and Buchanan, 1997). In the majority of the literature, 6 months of treatment is considered adequate to deem a patient treatment resistant, with the caveats in regard to plasma levels of clozapine.

Augmentation Strategies

The combination of clozapine with other medications is common. Between 30% and 40% of patients on clozapine receive an additional psychotropic medication (Peacock and Gerlach, 1994; Joffe *et al.*, 1996; Naber, 1992). There is little evidence, however, from controlled trials to guide rational combinations of medications.

Antipsychotics

The apparent low occupancy of dopamine D_2 receptors by clozapine (38–65%) (Farde *et al.*, 1992), even at high doses, may be below a putative threshold of occupancy required for full antipsychotic response. This threshold may be between 60% and 70% for haloperidol (Kapur *et al.*, 1999). It has therefore been speculated that for at least some patients, in addition to the broad pharmacology of clozapine, there may be a need for a higher degree of D_2 receptor occupancy to ensure successful treatment.

Friedman *et al.* (1997) augmented the therapy of seven clozapine-resistant schizophrenia patients with the selective, high-affinity D_2 receptor antagonist pimozide. They reported a significant mean BPRS score reduction of 27, and six of the seven patients had a marked response.

A double-blind, placebo-controlled, randomized study by Shiloh *et al.* (1997) augmented clozapine monotherapy with sulpiride 600 mg per day in 28 clozapine-resistant schizophrenia patients over 10 weeks. Although the clozapine–sulpiride group exhibited significantly greater improvements in positive and negative psychotic symptoms, about half of this group of patients exhibited a mean reduction of 42.4% and 50.4% in BPRS and SAPS, respectively whereas half showed almost no improvement at all (<5%).

McCarthy and Terkelsen (1995) described two patients with schizophrenia who improved when risperidone was added to clozapine. This was reinforced by an open trial of augmentation with up to 6 mg per day of risperidone in 12 patients (Henderson and Goff, 1996). In this study, ten of the patients showed a greater than 20% fall in their BPRS total scores. Pharmacologically, it is likely that any effect seen was secondary to enhanced D_2 receptor occupancy by risperidone, as both clozapine and risperidone produce high and equal occupancy of 5-HT_{2A} receptors at a range of clinical doses (Travis *et al.*, 1998).

Although slight increases in EPS were noted in some of these studies, these strategies were generally well tolerated, and although more evidence is needed, the addition of selective D_2 antagonists, such as sulpiride, pimozide and potentially amisulpride, to clozapine will be beneficial to some patients.

Antidepressants

The case report literature would tend to suggest that there is little benefit, and an increased risk of toxicity, if tricyclic antidepressants are added to clozapine (Chong and Remington, 2000). The evidence from the case report literature is more in favour of clozapine/selective serotonin reuptake inhibitor (SSRI) combinations, particularly fluvoxamine, although not without some increased risk of toxicity (reviewed by Chong and Remington, 2000). Unfortunately, the one extant controlled trial comparing fluoxetine ($n = 18$) with placebo ($n = 15$) failed to show any effect on psychosis or mood rating scales over 8 weeks (Buchanan *et al.*, 1996).

It is highly possible that both the beneficial and adverse effects of SSRIs in clozapine augmentation are simply the effects of increasing clozapine plasma levels (Hiemke *et al.*, 1994), as with the exception of citalopram all of the currently available SSRIs inhibit the metabolism of clozapine (Wetzel *et al.*, 1998a).

Mood Stabilizers

Lithium and clozapine combinations were reported to be effective in an 11-patient case series (Bryois and Ferrero, 1993) and in 23 of 27 patients with schizophrenia or schizoaffective disorder in a retrospective study (Bender *et al.*, 1996). There is also evidence from the case report literature that the combination is effective in treatment-resistant bipolar disorder (Puri *et al.*, 1995). However, there are no data from any prospective controlled trials. Adjunctive lithium has, anecdotally, been used in conjunction with clozapine to increase white cell counts in patients who have a white cell count below the threshold for clozapine administration (Blier *et al.*, 1998). There is no evidence, however, that this is safe in the longer term, and it is possible that in such patients lithium may mask a fulminant neutropoenia or agranulocytosis. Furthermore, there is some evidence that the combination may be neurotoxic (Blake *et al.*, 1992), although the literature on this is by no means clear (Naber *et al.*, 1992).

A combination of clozapine and carbamazepine has a potential increased risk of neutropoenia and agranulocytosis (Gerson and Meltzer, 1992), and there is evidence that carbamazepine may reduce plasma clozapine levels (Ereshefsky, 1996). There is also little evidence to suggest any therapeutic benefit, therefore there is little to recommend carbamazepine as an augmentation strategy in clozapine non-responders.

The combination of clozapine and valproate is more promising. Valproate has long been suggested to be the antiepileptic of choice in clozapine-related seizure disorders (Devinsky and Pacia 1994), and it appears to have little effect on plasma clozapine concentrations (Facciola *et al.*, 1999). There is also preliminary evidence of some clinical effectiveness. Kando *et al.* (1994), in a review of 55 patients, 17 of whom had schizophrenia and 23 had schizoaffective disorder, reported efficacy in 87% of their patients. However, these data would need to be replicated in a prospective controlled study before a recommendation for this drug combination could be given.

Although evidence for the effectiveness of lamotrigine augmentation is sparse, in a recent open-label, non-randomized case series of six outpatients with a partial response to clozapine, and in whom lamotrigine was prescribed (up to a maximum dose of 250 mg per day), there was a consistent, highly significant improvement in baseline BPRS scores (Dursun *et al.*, 1999).

Other Strategies

Electroconvulsive therapy (ECT) and clozapine combinations have not been the subject of any controlled studies. There is some case report literature indicating a beneficial effect in some patients with a low degree of toxicity (reviewed by Chong and Remington, 2000), but there is insufficient evidence to make a clear judgement.

Benzodiazepines are used relatively frequently in combination with clozapine, with one study reporting their use in up to 11% of patients (Faisal *et al.*, 1997) and another in up to 30% of patients (Peacock and Gerlach, 1994). There has been no assessment of the clinical effect of this combination, however. There has been concern about the toxicity, particularly in terms of the incidence of respiratory depression or collapse. Larger studies tend to show that this combination is no more toxic than clozapine monotherapy, but smaller case reports and case report series indicate that there is a risk of respiratory depression with this combination, thus doses should be titrated slowly (reviewed by Chong and Remington, 2000).

Treatment-Resistant Patients Unwilling or Unable to Take Clozapine

Changing Antipsychotic

There is little evidence to support changing a treatment-resistant patient who is unable to take clozapine to a typical antipsychotic, as response rates to these medications in this group are uniformly low. An exception to this is the possibility of reviewing the patient's treatment history and restarting them on the medication to which they have consistently shown a beneficial response in the past. Failing this, there are some data to support the potential use of some of the atypical antipsychotics in treatment resistance.

Risperidone

In an early, naturalistic, open-label study, 25 chronically hospitalized patients who were partial non-responders were switched to risperidone 6–16 mg per day from their previous treatment (mean 1265 mg per day chlorpromazine equivalent). In this cohort, who could also receive adjunctive medication, 36% had a reduction in total BPRS of 20% or more after 6 months of treatment (Smith *et al.*, 1996).

Using the Kane (1988) criteria with three previously ineffective trials of medication, Wirshing *et al.* (1999) recruited 67 subjects and randomized them to receive 6 mg per day of risperidone or 15 mg per day of haloperidol preceded by a 7–9-day placebo washout phase. Patients were held at this fixed dose for 4 weeks and then had 4 weeks flexible-dose medication (risperidone mean 7.5 mg per day, haloperidol mean 19.4 mg per day). At the end of the fixed-dose period, risperidone had produced significantly more improvement in the total BPRS score (24%) than haloperidol (10%) ($P = 0.03$). Interestingly, this difference had disappeared by the end of the flexible-dose period. Throughout the study, risperidone-treated patients had fewer EPS than haloperidol-treated patients. This evidence is supported partially by a trial comparing risperidone and clozapine (Bondolfi *et al.*, 1998). Although not employing strict Kane criteria, this group randomized 86 patients who had failed to respond adequately to at least two trials of conventional antipsychotics to either risperidone (mean 6.4 mg per day) or clozapine (mean 291.2 mg per day) for 8 weeks. This cohort did not have psychopathology ratings as high as patients in trials using Kane criteria and were thus relatively treatment resistant. The results of this study indicated that both risperidone and clozapine led to clinical improvement (defined as a 20% reduction from baseline in positive and negative syndrome scale (PANSS) total) in roughly 60% of patients, with no difference between groups but possibly a slightly faster onset of action in the risperidone-treated group. EPS did not differ between groups. Similar results were noted in a smaller trial using Kane criteria with treatment over 12 weeks, although in this study the authors noted that the clozapine-treated group appeared to be continuing to improve at endpoint while the risperidone-treated group was not (Lindemayer *et al.*, 1998). Other smaller, less rigorously conducted, retrospective trials have either had similar results (Wahlbeck *et al.*, 2000) or shown a superiority

for clozapine over risperidone (Sharif *et al.*, 2000). Thus, there is some evidence that risperidone may be useful in some patients resistant to treatment with conventional antipsychotic medication, but the dose of risperidone may be critical to this response and should probably be no higher than 6 mg per day.

Olanzapine

Breier and Hamilton (1999) analysed a subgroup of 526 patients with partial non-response (in this case, failure to respond to at least one rather than two antipsychotics) drawn from a larger clinical trial comparing olanzapine and haloperidol. In this group, the mean olanzapine dose was 11.1 mg per day and that of haloperidol was 10 mg per day. Both the last observation carried forward and the completer analysis showed superiority for olanzapine over haloperidol in improvements in negative symptoms and depression ratings. The analysis of those patients who completed the trial revealed a superiority for olanzapine over haloperidol in all symptom domains, with a response rate for olanzapine of 45% compared with 36% for haloperidol. Unfortunately, as the population studied does not fulfil traditional treatment-resistance criteria, these data are more supportive of the use of olanzapine as a second-line medication once one antipsychotic has failed.

In a study using traditional Kane criteria, Conley *et al.* (1998) compared olanzapine 25 mg per day with chlorpromazine 1200 mg per day. They also excluded patients who had previously not responded to clozapine. Furthermore, the patients underwent 6 weeks treatment with haloperidol (10–40 mg per day) before randomization to olanzapine or chlorpromazine (a 'run-in' phase). A total of 103 patients started the haloperidol phase, with one subject responding to haloperidol. Eighty-four subjects were randomized to one of the treatment arms for 8 weeks of treatment. In this study, 7% of patients responded to olanzapine and 0% responded to chlorpromazine, with no difference between groups in mean BPRS score at any point during the trial. This contrasts with the results from a study comparing directly olanzapine and clozapine (Tollefson *et al.*, 2001). The criteria for treatment resistance were similar to the Conley *et al.* (1998) trial, except that patients had to have received the two antipsychotics at doses of greater than 500 mg (rather than 1000 mg) of chlorpromazine equivalents, and patients who had previously not responded to clozapine or olanzapine were excluded. There was no run-in phase. Patients received 15–25 mg per day of olanzapine (mean 20.5 mg) or 200–600 mg per day of clozapine (mean 303.6 mg). Over 18 weeks of treatment, there was no difference between the two groups in terms of symptom reduction or clinical response. Both medications produced a significant improvement from baseline ratings, with a response rate for olanzapine of 38.2% and for clozapine of 34.5%. Clozapine produced significantly more constipation and sialorrhoea than olanzapine. The authors concluded that olanzapine was not inferior to clozapine in treatment-resistant schizophrenia. The contrasting results of these two studies may be explained by the Conley *et al.* patient group being more treatment resistant by virtue of having received a higher dose of typical medication before inclusion in the study. The absence of a clozapine wing in the Conley *et al.* study also makes it difficult to comment on the clozapine responsiveness of the patient cohort, although a subgroup from the study was subsequently treated with clozapine and 11 of 21 patients did respond (Conley *et al.*, 1998; Conley *et al.*, 1999). Another possibility is the duration of the studies. The Conley *et al.* study took place over 8 weeks rather than the 18 weeks in the Tollefson *et al.* study, thus potentially the olanzapine-treated subjects in the former were not given adequate time to respond. It must be noted, however, that the majority of responses in both groups in the Tollefson *et al.* study had already taken place by 8 weeks.

Further preliminary evidence for the use of olanzapine in treatment resistance is provided by two open-label studies. In the first study, 48 patients, the majority of whom in addition to traditionally defined treatment resistance had also failed to respond to clozapine (91.1%), or had been intolerant of it, were prescribed olanzapine 5–25 mg (mean 22 mg per day) for 18 weeks. Treatment was well tolerated, and it is reported that 55.6% of patients had a 20% or greater reduction in BPRS from baseline (Dossenbach *et al.*, 2000).

There is therefore some evidence to suggest that a trial of olanzapine would be useful for treatment-resistant patients with schizophrenia, particularly for those who are unwilling or unable to take clozapine, and perhaps for those who have previously received lower doses of typical antipsychotics.

Quetiapine

In a study of 288 patients with a partial response to 4 weeks of 20 mg per day fluphenazine, quetiapine at 600 mg per day showed benefits over haloperidol at 20 mg per day over 8 weeks. For inclusion in the fluphenazine run-in, patients had to score at least 15 on the positive subscale of the PANSS and were excluded if they were clozapine non-responders. The subjects had a total PANSS score of 88 at randomization. Fifty-two percent of patients responded to quetiapine (>20% reduction in PANSS total) versus 38% to haloperidol ($P < 0.05$). Again, the patients receiving quetiapine had significantly fewer EPS (Emsley *et al.*, 2000). Even though this study does not address the use of quetiapine in classical treatment resistance, it does provide evidence that quetiapine may be useful in patients who are unable to start clozapine.

Other Atypical Antipsychotics

As the time of writing, there is no evidence to recommend the use of other atypical antipsychotics in this group of patients.

Antidepressants

Depression is a common comorbid disorder with schizophrenia, although it is difficult to separate it from the EPS side effects of older antipsychotics or indeed from the negative symptoms of schizophrenia (Hirsch *et al.*, 1989; Siris *et al.*, 1988; Kibel *et al.*, 1993). This is reflected in the wide range of prevalence figures quoted (from 7% to 75%), although there is a generally accepted prevalence of about 25% (Siris, 2000). As we have seen, the newer atypical antipsychotics may have beneficial effects on mood in comparison with the older antipsychotics. However, studies before the introduction of these medications indicated that the majority of depressive symptoms associated with schizophrenia resolved with successful resolution of the psychosis (Koreen *et al.*, 1993). Nevertheless, it is likely that a substantial proportion of patients with schizophrenia will remain with depressive symptoms hampering their recovery.

Whilst there is no evidence that antidepressants have any antipsychotic efficacy, there is evidence from a number of studies that antidepressants may alleviate comorbid depressive symptoms in schizophrenia (Hogarty *et al.*, 1995; Siris *et al.*, 1994; Siris *et al.*, 1987; Prusoff *et al.*, 1979). There is little evidence to suggest which antidepressant should be used. Although the majority of studies have investigated the effects of tricyclic antidepressants (reviewed by Levinson *et al.*, 1999), recent studies have suggested that SSRIs may also have a beneficial effect (reviewed by Evins and Goff, 1996). It has been suggested by Siris (2000) that in the absence of florid psychosis, if a patient with schizophrenia is experiencing persistent episodes of depression, and the possible contribution of EPS to these symptoms has been addressed, then there is sufficient evidence to suggest that a 6-week trial with an antidepressant at normal therapeutic doses would be worthwhile.

Mood Stabilizers

Lithium

Early studies suggested that lithium might have a role in the treatment of schizophrenia (Alexander *et al.*, 1979; Zemlan *et al.*, 1984). Lithium as monotherapy, however, does not appear to be an effective antipsychotic in schizophrenia, and in comparison with pimozide in the pivotal Northwick Park Functional Psychosis Study (Johnstone *et al.*, 1988), it only had the effect of reducing elevated mood. Similarly, lithium protects against the euphoriant effects secondary to dexamphetamine administration in subjects with schizophrenia, but does not protect against its propsychotic effects (Van Kammen *et al.*, 1985). This lack of efficacy for lithium in schizophrenia is reinforced by the findings of Wilson (1993), who reported that lithium was an ineffective augmenter of haloperidol if patients with affective symptomatology were excluded. Schulz *et al.* (1999) studied a group of 41 patients with schizophrenia who had failed to respond to fluphenazine decanoate. The patients were then randomized to receive either lithium or placebo for 8 weeks in addition to their stable dose of fluphenazine. The BPRS total scores at baseline were in the region of 46. Lithium levels were maintained between 0.8 and 1.0 $mEq\,l^{-1}$. Interestingly, although both groups showed a significant reduction in BPRS total during the trial ($P = 0.0135$), there was no difference between the placebo- and lithium-treated groups. Furthermore, there was no reduction in measures of depressed mood. Thus, whilst there may be a role for lithium in patients with schizoaffective disorder, there is little evidence for its usefulness in schizophrenia *per se*.

Carbamazepine

Carbamazepine has similarly not been shown to be an adequate monotherapy in schizophrenia (Sramek *et al.*, 1988; Carpenter *et al.*, 1991). Its use as an adjunctive therapy to antipsychotics may, however, be justified. In a review by Schulz *et al.* (1990) of nine studies of carbamazepine adjunctive treatment, there was a general but nonspecific trend in favour of the effectiveness of carbamazepine. As half of the studies focused on patients with violent behaviour, this may have biased the use of carbamazepine for this group. However, a meta-analysis of all of the extant carbamazepine trials has suggested that there is no evidence that this medication is useful as an adjunct in schizophrenia (Leucht *et al.*, 2000). The authors suggest that a trial of carbamazepine could only be recommended for patients who had previously shown a response or who had confirmed abnormalities on EEG. It is important to note that carbamazepine is a powerful enzyme inducer and may reduce the plasma levels of coadministered antipsychotics by as much as 50–80% (Jann *et al.*, 1989). This implies that there is a potential for carbamazepine to cause patients with schizophrenia to relapse.

Valproate

Valproate (sodium valproate, divalproex, valproate semisodium) appears to be used increasingly frequently in the treatment of schizophrenia. From 1994 to 1998, for example, the adjunctive use of valproate nearly tripled in people with schizophrenia treated in New York state hospitals (Citrome *et al.*, 2000). Despite this, there has been no systematic evaluation of valproate's role in treatment-refractory schizophrenia. There is some evidence from case reports for the potential role of valproate in the control of aggression in schizophrenia (Wassef *et al.*, 1989; Morinigo *et al.*, 1989), and also, when used as an adjunct to haloperidol, in reducing the doses of sedative medication prescribed and the hostile belligerence demonstrated by patients with schizophrenia (Dose *et al.*, 1998). Recent data from two small, placebo-controlled trials have indicated that valproate enhances global antipsychotic response both in acute exacerbations of schizophrenia and in partially responsive patients not on clozapine (Wassef *et al.*, 1999; Wassef *et al.*, 2000).

Lamotrigine

Lamotrigine may be an effective augmenter in partially resistant patients as there is preliminary evidence for its efficacy in clozapine non-responders (Dursun *et al.*, 1999) (see above).

THE FUTURE

Despite the advances in schizophrenia pharmacotherapy since the early 1950s, there are still many limitations. EPS make the use of high doses of the older typical antipsychotics problematic and often unpleasant for those taking them. Lower doses of typicals and the newer atypical antipsychotics offer benefit the patients in terms of reductions in EPS, but the latter medications are not without their own unpleasant side effects.

Another failing in the pharmacotherapy of schizophrenia is that there are still 40–50% of patients with schizophrenia who do not have an optimal response to medication and some 20% who are resistant to all forms of treatment, including clozapine.

Future developments may include a new generation of antipsychotic drugs that are partial agonists (rather than antagonists) at D_2 and D_2-like receptors, such as aripiprazole (Lawler *et al.*, 1999). Early clinical trials with this medication show good efficacy with placebo rates of EPS (Carson *et al.*, 2001).

In conjunction with developments in trial methodology, combinations of neurochemical and functional imaging may help to elucidate the neural correlates of treatment response and resistance and allow more rational therapeutic decisions.

Pharmacogenetics may help to define further the parameters that predict response or non-response to particular medications by analysing the allelic variations for individual receptors that correlate with response (Arranz *et al.*, 2000).

Animal Models of Depression: A Diathesis/Stress Approach

Paul Willner and Paul J. Mitchell

INTRODUCTION

Animal models of depression are used both as screening tests to discover and develop novel antidepressant drug therapies, and as simulations for investigating various aspects of the neurobiology of depressive illness, including the neuropharmacological mechanisms mediating the effects of antidepressant treatments. These different functions of animal models have different and, to some extent, conflicting requirements.

A simulation of depression aims to mimic aspects of the clinical situation, and should embody a degree of complexity, to permit investigation of the validity of the model. In addition, if a model is to be used to investigate antidepressant actions, a slow onset comparable to the clinical time course is highly desirable, and the model should therefore exhibit differences (either in direction of response, or in response magnitude) between single (acute) and repeated (chronic or continuous) treatment regimes. By contrast, the only essential requirement for antidepressant screening tests is that they make accurate predictions of antidepressant activity. For practical reasons, they should also be cheap, robust, reliable and easy to use (Danysz *et al.*, 1991; Willner, 1991a), and for all of these subsidiary reasons, a screening test should in principle be as simple as possible. However, the view that such screening tests should also respond acutely has changed during the past decade, in line with the drive from the clinic to identify rapid-onset antidepressant treatments. By necessity this approach involves the assessment of drug action associated with chronic/continuous drug treatment regimes and an acute response is thus of little value. Appropriate screening tests to be used relatively early during drug development should therefore have the ability to identify the time course of drug action associated with repeated treatment schedules.

The present chapter is concerned primarily to evaluate the suitability of the available animal models as research tools, and we therefore focus initially on issues relating to the validity of the available models as simulations of depression.

VALIDITY

In line with current thinking, our assessment of the validity of animal models of depression addresses the three dimensions of predictive, face and construct validity (Willner, 1984, 1991a). The concept of predictive validity implies that manipulations known to influence the pathological state should have similar effects in the model. Face validity refers to a phenomenological similarity between the model and the disorder being modelled. Construct validity implies that the model has a sound theoretical rationale. Some reviewers have advocated the primacy of one of these approaches (predictive validity: Geyer and Markou, 1995; face validity: Weiss and Kilts, 1998; construct validity, Sarter and Bruno, Chapter III). In principle, we share Sarter and Bruno's position, that construct validity is the most important of the three dimensions. In practice, however, the construct validity of animal models of depression is difficult to determine, and therefore we favour a balanced approach in which a view of the validity of a model is formed only after considering all three sources of evidence. We therefore begin by reviewing briefly the three sets of validation criteria, as they apply to animal models of depression.

Predictive Validity

In practice, the predictive validity of animal models of depression is determined solely by their response to antidepressant drugs. A valid test should be sensitive and specific: it should respond to effective antidepressant treatments ('true positive' effects), including electroconvulsive shock (ECS), and should fail to respond to ineffective agents ('true negative' effects). A model with high predictive validity should therefore maximize identification of both 'true positives' and 'true negatives', but should minimize identification of 'false positives' and 'false negatives'. Furthermore, positive responses should occur at behaviourally selective doses (i.e. those which do not generally disrupt behaviour, or induce motor impairment) that are within or close to the clinical range, and should be demonstrable with a range of structurally diverse compounds. It should be recognized that no animal model has a 100% prediction rate although some complex experimental paradigms have approached this level of predictive ability. Part of the problem lies not so much with the preclinical model but with the fact that there are several grey areas in the clinical literature where it is not known whether certain drugs (e.g. anticholinergics) possess antidepressant activity or not. It is generally agreed that the most effective treatment for depressive illness is electroconvulsive therapy (ECT). A suitable starting point to test the validity of an animal model should therefore be to demonstrate a positive response to repeated ECS. Failure to respond appropriately to ECS would severely question the predictive validity of the model.

About 30% of depressed patients fail to respond to antidepressant drug treatment, while the response rate for ECT is slightly higher. The occurrence of refractory patients probably reflects the heterogeneity of depressive illness. Nevertheless, a model that did not respond to the benchmark tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), or the recently developed serotonin–noradrenaline reuptake inhibitors (SNRIs)

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

would not be taken seriously. This situation is unlikely to change in the absence of well-established therapies for tricyclic-resistant depression.

Beyond the clinically established antidepressant treatments (TCAs, monoamine oxidase inhibitors (MAOIs), SSRIs, SNRIs and some atypical antidepressants, such as mianserin) are a wide range of newer compounds for which antidepressant activity has been claimed, ranging from pharmacologically-selective compounds that are probably effective (e.g. α_2-adrenoceptor antagonists; ligands for serotonin (5-hydroxytryptamine; 5-HT) receptor subtypes including $5HT_{1A}$ receptor ligands that possess agonist activity (and partial agonists), ligands for 5-HT_{2A} and 5-HT_{2C} receptor subtypes, and *N*-methyl-D-aspartate (NMDA) receptor ligands), through preparations of mixed pharmacological activity (e.g. SSRI with selective 5-HT_{1A} receptor antagonist activity) to compounds of uncertain status (e.g. phosphodiesterase inhibitors, calcium antagonists, anticonvulsants). Even in the case of the SSRIs, whose antidepressant efficacy is beyond doubt, it is still uncertain whether their spectrum of activity is identical to that of the TCAs. Therefore, while a well-rounded description of an animal model of depression should include an account of its pharmacological profile broader than that provided by its response to traditional antidepressants, the contribution of these newer compounds to validation is limited.

To some extent, similar uncertainties exist in relation to drugs which are ineffective as antidepressants. The 'false positives' most commonly encountered in animal models of depression are psychomotor stimulants, anticholinergics and opiates. However, prior to the development of antidepressants, drugs from all three of these classes were regularly prescribed for the relief of depression (see Willner, 1985). Indeed, certain opiates (e.g. buprenorphine) have antidepressant activity (Emrich *et al.*, 1983), but anticholinergics and stimulants have never been properly assessed, as their use was discontinued prior to the introduction of blind clinical trials. Again, the uncertain status of these compounds to some extent undermines their value as definitive standards of negative control.

Finally, the response to antidepressant drugs is insufficient to define an animal model of depression. Some antidepressants are active in some animal models of anxiety and panic, following chronic treatment (Bodnoff *et al.*, 1988; Fontana *et al.*, 1989), and indeed, are increasingly seen as the drugs of choice in many forms of anxiety (see Den Boer, Chapter XIX-13). It is therefore crucial for establishing the predictive validity of an animal model of depression to demonstrate that the model does not respond to benzodiazepines.

Face Validity

To assess face validity, the extent of similarity between the model and the disorder is examined, on as wide as possible a range of symptoms and signs. However, not all symptoms of a psychiatric condition carry equal weight and for an animal model to be valid, a resemblance to the clinically defined core symptoms of the disorder carries more weight than a resemblance to any subsidiary symptoms (Abramson and Seligman, 1978). The most recent edition of the *Diagnostic and Statistical Manual* (DSM-IV) provides a framework within which to assess these similarities. However, not all of the clinical symptoms of depression can be modelled in animals; symptoms conveyed by subjective verbal report (e.g. excessive guilt, feelings of worthlessness, suicide ideation) are in principle excluded (Willner, 1984, 1990).

A DSM-IV diagnosis of major depression requires the presence of at least one of two core symptoms: loss of interest or pleasure (anhedonia) and depressed mood. Of these two core symptoms, anhedonia can be modelled in animals, but depressed mood cannot. In assessing the face validity of animal models of depression, anhedonia therefore assumes a central position. The problem here, however, is that anhedonia is also a core symptom of schizophrenia. Drug-induced reversal of anhedonia in animal models, while highly encouraging, should thus be considered in relation to DSM-IV criteria for both depressive illness and schizophrenia.

The subsidiary symptoms of depression in DSM-IV that are amenable to modelling in animals include psychomotor changes, fatigue or loss of energy (which might be modelled as decreased persistence), and disturbances of sleep or food intake. Interestingly, psychomotor activity, sleep and appetite may be increased or decreased, and diametrically opposite changes in locomotion have both been cited in support for the validity of a model. This lack of precision, together with the fact that the clinical phenomena of psychomotor retardation and agitation (which are considerably more complex than gross changes in locomotor activity) may even coexist (Nelson and Charney, 1981), suggests that simulations in which a change in locomotor activity is the major, or only, behavioural feature should not be taken too seriously. Unfortunately, it is precisely these behaviours that feature most prominently in many animal models of depression (Willner, 1991b).

Because the pharmacotherapy of depression typically requires chronic drug treatment, the validity of an animal model is called into question by an acute response to conventional (e.g. TCA) antidepressant treatment. There is some evidence of very early antidepressant responses in clinical studies designed explicitly to detect them (e.g. Frazer *et al.*, 1985; see also Willner, 1989a) but even so, repeated treatment is required for a full response. Acute treatment refers to a single bolus dose of drug and any acute treatment effects are usually observed within minutes or hours following the bolus dose. Multiple acute doses may be administered, over a short period, simply to increase levels of drug in the biophase without evoking secondary adaptive changes in neurotransmitter mechanisms. In contrast, chronic treatment refers to repeated bolus doses administered for extended periods (days, weeks, months). Chronic treatment effects may be associated with drug-induced adaptive changes in neurotransmitter-receptor-mediated systems, rather than increased drug levels in the plasma. Thus, in comparison to chronic treatment effects, an acute response in an animal model may be opposite, orthogonal (due to side effects, e.g. sedation) or absent. Irrespective of how it responds to acute antidepressant treatment, to be valid, an animal model of depression must respond to chronic treatment. Furthermore, since tolerance does not occur to the clinical effects of antidepressants, the response in the model must be maintained until the cessation of antidepressant treatment. This test has not been universally applied to animal models of depression, but in general, those models to which the test has been applied have passed it, though tolerance to antidepressant effects has been reported in some behavioural paradigms (e.g. Cuomo *et al.*, 1983; Niesink and van Ree, 1982).

Construct Validity

An evaluation of the theoretical rationale of an animal model requires a means of bringing the theoretical accounts of both the disorder itself and the disordered behaviour exhibited by the model into alignment. However, any evaluation of animal models of depression is intrinsically limited by the rudimentary state of theories of the pathology of depression. Indeed, there is little in the extensive literature describing neurochemical abnormalities or biochemical markers reportedly associated with depression that can be usefully employed to provide a theoretical standard against which to validate animal models. Even the most basic questions of whether the level of activity in monoaminergic systems is elevated or decreased in depression were and remain controversial (Willner, 1985).

Similar problems arise in relation to modelling the aetiology of depression. It is now clear that a variety of different factors

are implicated in the aetiology of depression: 'psychological' factors include undesirable life events, chronic mild stress, adverse childhood experiences, and personality traits such as introversion and impulsiveness; 'biological' factors include genetic influences, and a variety of physical illnesses and medications (see Akiskal, 1985, 1986; Willner, 1985 for reviews). However, for most of these factors, there is little theoretical understanding of the processes by which they influence the physiological processes underlying mood. In certain cases, the immediate precipitant of a depression may be clearly identified: for example, seasonal affective disorder (SAD) and post-partum depression. More usually, the pathogenesis of depression is better understood as the result of an accumulation of a number of different risk factors (Akiskal, 1985; Aneshensel and Stone, 1982; Brown and Harris, 1978). This point has been largely overlooked in the construction of animal models of depression, which in general have assumed a single causal factor. This may be counterproductive, since few of the identified aetiological factors appear sufficiently potent to precipitate depression in an otherwise risk-free individual.

Although attempts to assess the theoretical rationale of animal models are limited by this lack of theoretical structure at the clinical level, a number of generalizations are possible. The major group of animal models of depression are based on responses to stressors of various kinds, and are usually justified by reference to the role of stressful life events in the aetiology of depression (Brown and Harris, 1978, 1988; Lloyd, 1980). However, if very severe acute stress is used (e.g. Weiss *et al.*, 1982), the relevance of these procedures to depression, rather than, for example, to posttraumatic stress disorder (PTSD) is questionable. Furthermore, the adverse consequences of life events endure for a prolonged period of six to twelve months, in part by exacerbating ongoing life difficulties (Brown, 1989; Brown and Harris, 1988). Thus, life events should not be viewed as acute stressors (indeed, in the case of bereavement, a diagnosis of depression is explicitly excluded during the period of acute loss); from this perspective, it may be more appropriate to use chronic stress regimes, rather than acute stressors, to model the aetiological role of life events. Other factors have been identified that confer a long-lasting vulnerability to depression, in particular, an inadequate level of social support, which to a large extent arises from inadequate socialization (Aneshensel and Stone, 1982; Brown, 1989; Brown and Harris, 1978, 1988; see Willner, 1989b). From these starting points, a number of animal models of depression have been developed that are based on the adverse effects of social isolation. However, with the exception of some of the primate studies (see below), these models have largely ignored both the complexity of childhood social deprivation phenomena and the mediation of their effects through later social relationships.

Although assessment of the theoretical rationale of animal models of depression is limited by the paucity of theory, construct validity can also be evaluated at the level of constructs: that is, whether the behavioural phenomena are correctly described. This approach is best exemplified by the extensive experimental analysis of whether 'learned helplessness' is an appropriate term to describe the impairments of escape learning that follow exposure to inescapable electric shock (Seligman, 1975). The term 'learned helplessness' implies that the animals perform poorly because they have learned that their responses are ineffective in controlling their environment (Seligman, 1975). However, inescapable shock has a variety of other, simpler effects that could also explain many of the behavioural impairments, such as decreased locomotor activity (Anisman *et al.*, 1979; Glazer and Weiss, 1976) and analgesia (Lewis *et al.*, 1980). In addition, while inescapable shock results in 'cognitive' impairment (Jackson *et al.*, 1978) such behavioural effects arise from impairment at the level of attentional processing rather than 'helplessness' (Minor *et al.*, 1984). Thus, there are many reasons to question whether the learned helplessness procedure does in fact produce 'helplessness'.

Anhedonia is another construct that has been subjected to this kind of experimental attention. In this case, the question is whether the animals are failing to perform rewarded behaviour because they are insensitive to rewards or for some other reason. This question has been most extensively investigated in relation to the effects of chronic sequential exposure to a variety of mild stressors (chronic mild stress; CMS). CMS has been shown to cause an antidepressant-reversible decrease in the consumption of dilute sucrose solutions, which is hypothesized to reflect a decrease in the reward value of the sucrose (Willner, 1997; Willner *et al.*, 1987). Initial studies showed that, in contrast to the effect on dilute solutions of sucrose or saccharin, CMS did not decrease the intake of plain water, food pellets or concentrated sucrose solutions; thus the effects are not simply nonspecific changes in consummatory behaviour (Muscat and Willner, 1992). Some studies have suggested that decreases in sucrose intake reflect loss of body weight (e.g. Matthews *et al.*, 1995), but there is ample evidence (reviewed in Willner, 1997) to reject this suggestion, including the fact that the effects are seen in the absence of body weight changes. Furthermore, the effects of CMS are not confined to consummatory behaviours. CMS also attenuated or abolished place preferences established using a variety of natural or drug rewards. However, drug-induced place aversions were unaffected by CMS. Thus, the effect of CMS on place conditioning cannot be explained by nonspecific motivational impairments or a failure of associative learning (reviewed in Willner, 1997). Finally, CMS has also been shown to cause an increase in the threshold for brain-stimulation reward (Moreau *et al.*, 1992). Together, these results support the position that CMS causes a generalized decrease in sensitivity to rewards, and that under appropriate experimental conditions, decreases in sucrose intake provide a simple means of detecting this anhedonia.

These examples of successful experimental analyses of construct validity contrast sharply with a third example, the 'behavioural despair' test (Porsolt *et al.*, 1979). This term was introduced to describe the immobility seen in rats or mice forced to swim in a confined space, based on the assumption that when the animals adopted an immobile posture, they had 'despaired of' escaping. Unfortunately, this interpretation is not susceptible to experimental analysis. Consequently, although the test continues to be very widely used, the name 'behavioural despair' has been largely abandoned, and replaced instead by the theoretically neutral term 'the forced swim test'.

Heterogeneity of Depression

It has frequently been remarked (e.g. Fibiger, 1991) that the approach adopted in successive editions of the DSM, which identifies psychiatric disorders by the presence of a sufficient number of symptoms from a longer list, results in very different clinical presentations receiving the same diagnosis. However, discussion of the heterogeneity of depression is several decades older than the DSM system. It has been recognized since the 1920s that there are at least two forms of depression, but only one of them has enjoyed general agreement as to its nature (Willner, 1985). This is the syndrome that has been known, variously, as autonomous depression, endogenous depression, endogenomorphic depression and, more recently, melancholia. Because a consensus exists as to its existence and symptom profile, melancholia has emerged as the major subtype of depression, and its definition in DSM-IV is somewhat more restrictive than that of the parent syndrome, major depressive disorder.

Little attention has been paid to the question of subtypes of depression in the development of animal models, which have tended to focus either on an undifferentiated depressive state or on melancholia. Melancholia is defined, in DSM-IV (major depressive episode with melancholic features), by the presence of anhedonia,

which is also the only core symptom of major depression that is amenable to modelling in animals. Anhedonia may be readily modelled as decreased sensitivity to rewards, although, as noted above, this construct is considerably more complex than a simple decrease in the performance of a rewarded behaviour. In relation to the other symptoms that can be modelled, the diagnosis of melancholia specifies the direction of changes in appetite and sleep (decreased), although, as in the diagnosis of major depressive disorder, psychomotor changes could be in either direction (retardation or agitation). In many empirical studies, psychomotor retardation has emerged as the symptom most characteristic of melancholia, while psychomotor agitation tends to be more closely associated with psychotic features such as delusions of guilt (Nelson and Charney, 1981). Nevertheless, there is considerable overlap between these two groups of symptoms, and agitated melancholias are not uncommon. Unlike non-melancholic depressions, melancholia is characterized by a decrease in the latency to enter the first period of rapid eye movement (REM) sleep (Kupfer and Thase, 1983) and an increased activity of the hypothalamic–pituitary–adrenal (HPA) system, usually detected by the dexamethasone suppression test (DST) (Carroll, 1982). In a valid simulation of melancholia, these biological markers would be expected to coexist alongside decreased sensitivity to rewards. However, the specificity of both of these markers for melancholia is less than originally claimed.

Unlike melancholia, no consensus exists that non-melancholic depression is a homogeneous entity, and this issue has been extensively debated. Within the 'non-melancholic' spectrum, two syndromes have been described that are of interest in the present context. One of these is not recognized in DSM-IV, but has features which suggest that it might represent a coherent biological entity. This is a form of depression in which central 5HT activity is decreased, as indicated by low concentrations of the 5HT metabolite 5-hydroxyindole acetic acid (5-HIAA) in cerebrospinal fluid. These depressions are characterized by high levels of anxiety and agitation, and Van Praag (1994) has suggested that these symptoms are primary, with depressed mood as a secondary response to a failure to cope with the consequences. It has been suggested that some animal models of depression, which are characterized by high levels of locomotor activity and/or aggression, may represent models of this subtype. There is as yet little further evidence on which to judge the validity of these claims.

A second 'non-melancholic' subtype of depression is delusional depression (previously known as psychotic depression). Delusional depression (DSM-IV major depressive episode with psychotic features) is difficult to translate into behavioural terms, being differentiated from non-delusional depression only by a greater association with psychomotor agitation (Nelson and Charney, 1981). Delusional depressions are pharmacologically distinct in that they respond to ECT or combinations of TCAs with neuroleptics, but not to TCAs alone (Nelson, 1987). The development of an animal model that responds to ECS but not to TCAs has not yet been achieved.

Bipolar disorder is another well-defined diagnostic category for which there are no animal models. There are a number of animal models of mania (see Lyon, 1991), but the alternation of depressive-like and manic-like behaviours in an animal model has not yet been systematically addressed. Indeed, the episodic nature of unipolar depression (e.g. brief recurrent depression) also remains to be explored in animal models.

THE DIATHESIS/STRESS CONCEPT

It is widely assumed that individuals within the population vary in their risk of contracting psychiatric disorders, and that such disorders are typically precipitated by external or internal (e.g. hormonal) events. The term diathesis refers to a predisposition to contract the disorder, while the term stress refers simply to the precipitant (note that the term 'stress' is used here in a different sense from the usual). A predisposition to become depressed (a depressive diathesis) may arise in a variety of ways, which may involve different levels of explanation. For example, a number of genetic diatheses have been identified, particularly in relation to bipolar disorder (see Souery *et al.*, Chapter XVIII-10). Some early life experiences are also known to increase the risk for depression, particularly parental deprivation (Robertson and Bowlby, 1952). The mechanisms by which these experiences increase the risk of depression (and other psychiatric disorders) are largely unknown, but probably involve psychological and psychosocial constructs. For example, parental deprivation may decrease the ability to form close relationships, and so dilute the quality of social support available in later life. Early life experiences also determine characteristic styles of processing information in relation to the self. For example, the negative thinking that characterizes the depressed person is thought to reflect the activation of a negative 'cognitive schema', learned through adverse childhood experiences such as rejection, criticism, or living with a depressed parent (Beck, 1967).

It follows from the diathesis/stress concept that a person who has a weak depressive diathesis would only succumb to an intense stress, whereas a person with a strong depressive diathesis may succumb to minor or trivial stresses. As these minor events might be relatively common, a depressive diathesis might result in a chronic presentation that looks very similar to an acute major depressive episode. Indeed, there is a depressive (gloomy, pessimistic, introverted) personality type, and where the symptoms are intense and disabling, this is classified as a depressive personality disorder. (This syndrome, present in DSM-III-R, was removed from DSM-IV as a clinical diagnosis, but is retained for research purposes.) A depressive personality disorder can shade into dysthymia, a more intense and more variable presentation. The diagnostic criteria for dysthymia include a number of somatic symptoms that are absent in the criteria for depressive personality disorder, but DSM-IV comments: 'It remains controversial whether the distinction between depressive personality disorder and dysthymic disorder is useful. The research criteria given for this proposed disorder differ from the diagnostic criteria for dysthymic disorder by their emphasis on cognitive, interpersonal, and intrapsychic personality traits.' This emphasis means that the symptoms of depressive personality disorder fall outside the scope of animal models. Dysthymia, however, can be modelled in animals. Dysthymia may be present from early childhood, or may have a more definable later onset. In either case, the distinction between dysthymia and a major depressive episode rests largely on the fact that dysthymia is less intense, and of chronic duration. In other respects, major depression and dysthymia are very similar in their presentation (for example, DSM-IV specifies that there are even common abnormalities in sleep electroencephalogram (EEG) recordings). Indeed, the only significant differences are in some of the subjective symptoms that are not amenable to animal modelling, such as excessive guilt and suicidal ideation, which are less prominent in dysthymia.

Thus, depressive diatheses may present as 'silent' until activated by stress (e.g. a genetic risk factor that does not directly elicit depressive symptoms, or a tendency towards depressive thinking that is well controlled), as a sub-syndromal depressive condition, or as a chronic condition that is difficult to distinguish from a major depressive episode. Consequently, animal models of a depressive diathesis could appear either as essentially 'normal' animals that are more sensitive to a precipitant used to induce 'depressive' behaviour, or could present 'depressive' features in the absence of any specific experimental manipulation.

In surveying changes over time in the landscape of animal models of depression, the major recent development has been a growth in the number of models that are better thought of as models of a

predisposition to depression rather than as a depressive response to a precipitating event. We have therefore adopted this distinction as the organizing principle of this chapter. In the remainder of the chapter, we discuss first those models of depression that are based on exposure to adversity, and later, models that create or uncover a depressive diathesis. For the sake of completeness, we also mention briefly some of the pharmacological screening tests that were among the earliest animal models of depression to be developed.

MODELS OF DEPRESSION AS A RESPONSE TO ADVERSITY (i.e. STRESS)

A variety of adverse events have been used to produce animal models of depression, based on the observation that in general, the behavioural effects of stress are reversible by antidepressant drugs. However, the extent to which these effects meet the criteria for predictive validity, and the quality of the resulting models in terms of face and construct validity, varies greatly. For ease of presentation, we have grouped the models reviewed according to the nature of the stressor: acute experimenter-applied stressors; chronic experimenter-applied stressors; and models based on social stress and social isolation.

Acute Stress Models

Learned Helplessness Models

As noted earlier, the learned helplessness paradigm is based on the observation that animals exposed to uncontrollable stress (usually electric shocks) are subsequently impaired in learning to escape shock, an effect that is not seen in animals exposed to comparable, or indeed, identical, patterns of controllable shock. The protective effect of control appears to result from lower levels of fear (Jackson and Minor, 1988), which raises important questions about the relationship between depression and anxiety. Seligman (1975) proposed that exposure to uncontrollable stress provides the basis, in animals as in people, for learning that stress is uncontrollable (helplessness), and that this learning has a number of debilitating consequences, including depression. However, this interpretation has been the subject of considerable controversy, in both the human (Abramson *et al.*, 1978, 1989) and the animal literature (Minor *et al.*, 1984, 1988; Weiss *et al.*, 1982) and is probably incorrect (see above, and Willner, 1986, 1990). Nevertheless, the learning difficulties that follow exposure to uncontrollable shock are reversed with reasonable selectively by multiple acute, subchronic (3–5 days), treatment with TCAs or atypical antidepressants (Sherman *et al.*, 1982). SSRIs also appear to be effective, but only within a limited dose range (Martin *et al.*, 1989), as well as a number of other potential antidepressants such as 5-HT_{1A} receptor agonists (Giral *et al.*, 1988), β-adrenoceptor agonists (Martin *et al.*, 1986a), although some of these effects have been disputed (Christensen and Geoffroy, 1991), and extracts of St John's wort (*Hypericum perforatum*) (Gambarana *et al.*, 1999a; Kumar *et al.*, 2001). Interestingly, chronic, but not acute, treatment with lithium prevents the development of learned helplessness in rodents (Teixeira *et al.*, 1995). There are a few false positives, including the 5-HT_2 receptor antagonist, methysergide (Brown *et al.*, 1982), *p*-chlorophenylalanine (*p*CPA) (Edwards *et al.*, 1986) and piracetam (Cavoy *et al.*, 1988), while neuroleptics, stimulants, sedatives and anxiolytics are generally ineffective (Porsolt *et al.*, 1991; Sherman *et al.*, 1982).

The learned helplessness paradigm shows many symptomatic parallels to major depression — much so that it has been suggested that rodents subjected to uncontrollable shock could meet DSM diagnostic criteria (Weiss *et al.*, 1982)! However, the learned helplessness paradigm is implemented in a variety of different ways in different laboratories, and the version of the paradigm giving rise to the broadest range of symptoms (Weiss *et al.*, 1982) uses extremely high shock levels (4–6 ma) which are of doubtful relevance to depression. Furthermore, the effects of this regime largely dissipate within 2–3 days, and the effects of antidepressant pretreatment have not been studied using this procedure. The effects of antidepressants have typically been studied using shocks of a considerably lower intensity (1.0–1.5 ma) which cause a far less pervasive pattern of behavioural impairment.

Paradoxically, the effects of milder shock intensities are of longer duration, making it possible to interpose multiple acute (subchronic) drug treatment (typically for 3–5 days) between the initial uncontrollable shock session and the learning test. Furthermore, the duration of learned helplessness may be prolonged indefinitely by repeatedly exposing the subjects to the environment in which inescapable shock had occurred (Maier, 2001), which strengthens the face validity of this model of depression. However, a further problem is that different components of the learned helplessness syndrome may be related to different aspects of the induction procedure. For example, a long-term (7 weeks) suppression of home-cage locomotor activity has been reported following a single shock session (Desan *et al.*, 1988), but this effect is unrelated to shock controllability, and so clearly distinct from other learned helplessness phenomena (Woodmansee *et al.*, 1991). It is clear that the learned helplessness paradigm should more correctly be considered as a mixture of paradigms, and care should be taken in generalizing conclusions between them.

Among the consequences of low-intensity uncontrollable (but not controllable) shock is a poor performance of rewarded behaviour, which, as noted above, may be of particular relevance to melancholia. One manifestation of this effect is a long-lasting decrease in responding for brain-stimulation reward (intracranial self-stimulation; ICSS), in mice, which is specific to certain electrode placements, and therefore suggests a subsensitivity within part of the brain mechanism of reward, rather than, for example, a motor impairment (Zacharko *et al.*, 1983, 1987). Normal sensitivity to ICSS was restored by chronic, but not acute, treatment with TCAs (Zacharko and Anisman, 1991; Zacharko *et al.*, 1983). Interestingly, a long-lasting anhedonia is seen only if the animals are tested in the immediate aftermath of stress; otherwise the effect dissipates rapidly (Zacharko *et al.*, 1983). A related observation is that mild stressors, which are without effect in normal animals, may reinstate behavioural deficits resulting from an initial exposure to severe stress (Anisman and Zacharko, 1982). These studies suggest that it may be possible to develop conditioning models to explain how the risk of depression is elevated for several months in the aftermath of a stressful life event.

Another important observation is that uncontrollable electric shock has variable behavioural effects (most of which are antidepressant-reversible) in different inbred mouse strains. To take an extreme example, in the C57BL/67 strain, uncontrollable shock severely impaired subsequent learning to escape shock, but had no effect on responding for brain-stimulation reward, while the DBA/2J strain showed exactly the opposite pattern of deficits (Shanks and Anisman, 1988; Zacharko *et al.*, 1987). These studies may provide a starting point from which to investigate the physiological mechanisms underlying individual differences in responses to stress.

Vollmayr and Henn (2001) have recently described a procedure in which mild shocks induce learned helplessness in only some of the subjects, which may mimic the variable human predisposition for depressive illness. This procedure has been used as the basis for a selective breeding programme, which has produced a 'congenital learned helplessness' (cLH) and a 'congenital non-learned helplessness' strain. An impressive recent neuroimaging study of cLH rats reported that metabolism was decreased in dorsal frontal, medial orbital and anterior cingulated cortex, but increased in the subgenual region of the cingulated cortex (Shumake *et al.*, 2000); exactly these changes have been described in depressed patients (Drevets

and Raichle, 1998; Mayberg *et al.*, 1999). However, there are also anomalies: in particular, cLH rats show a decreased adrenocortical response to stress (King *et al.*, 2001). There is also uncertainty as to just what is being selected in the cLH breeding programme. cLH animals have been shown to exhibit stress-induced analgesia (King *et al.*, 2001), raising the possibility that an increase in pain threshold might provide a very simple explanation of their escape learning impairments. And given the separation of shock-induced escape deficits and anhedonia in inbred mouse strains (Shanks and Anisman, 1988; Zacharko *et al.*, 1987), there is no reason to assume that the cLH strain, which was bred by selecting on the basis of shock-induced escape deficits, would also exhibit shock-induced anhedonia.

There is a relatively extensive literature dealing with the neurochemical bases of stress-induced motor inactivation (see Maier, 1984; Willner, 1985). Briefly, the debilitating effect of uncontrollable stress on later performance may be reversed by agonists at μ-opioid, dopamine (DA), α_1- and β-adrenergic receptors or by anticholinergic drugs; conversely, helplessness may be simulated pharmacologically by drugs that reduce DA and/or noradrenalin (NA) function, or by drugs that increase cholinergic function (Anisman and Zacharko, 1982; Besson *et al.*, 1996, 1998, 1999). Any influence of DA neurotransmission on learned helplessness appears to be mediated by the D1 dopamine receptor (Gambarana *et al.*, 1995a, b). Furthermore, reduced catecholamine neurotransmission, either by inhibition of catecholamine synthesis with α-methyl-ρ-tyrosine (De Montis *et al.*, 1993) or by treatment with α_1- and β-adrenoceptor antagonists (as well as the opiate receptor antagonist naloxone) has been shown to block the therapeutic effect of TCAs (Martin *et al.*, 1986b). Similarly, blockade of NMDA-receptor-mediated neurotransmission also blocks TCA-induced reversal of learned helplessness (Meloni *et al.*, 1993). Gamma-aminobutyric acid (GABA) neurotransmission also seems to be involved in learned helplessness behaviour. Thus a long-term increase in $GABA_B$ neurotransmission is associated with exacerbation of learned helplessness, while the action of antidepressant drugs in this model is associated with a long-term reduction in $GABA_B$ neurotransmission (Nakagawa *et al.*, 1996a, b). In contrast, studies of the role of 5-HT in learned helplessness are inconsistent (see Willner, 1990). Some 5HT receptor agonists may reverse learned helplessness, while 5-HT lesions did not prevent the action of TCAs in this model (Soubrie *et al.*, 1986). The induction of behavioural depression/learned helplessness may be regulated, at least in part, by serotonergic input into the hippocampal CA3 subfield. Papolos *et al.* (1996) have shown that intracerebroventricular administration of an antisense oligonucleotide to the $5\text{-}HT_{2A}$ receptor reduced receptor density in the CA3 area and induced learned helplessness behaviour.

Forced Swim Test

In the forced swim test, rats or mice are forced to swim in a confined space. While mice are subjected to a single swim test following a single drug administration, rats are generally subjected to two tests, usually spaced 24 h apart, to generate increased immobility scores. The onset of immobility exhibited by rats in the second test is delayed by pretreatment with a wide variety of antidepressants, usually administered in a multiple acute (subacute) treatment schedule consisting of three injections over the time period between the two swim sessions. The fact that the forced swim test responds to acute drug treatment has been a frequent source of criticism. Small antidepressant effects may be present after a single high dose. Larger effects are observed after multiple acute treatments at lower doses, but these changes may simply reflect an elevation of brain drug concentrations.

Effective treatments include TCAs, MAOIs, most atypical antidepressants, the selective NA reuptake inhibitor, reboxetine (Connor *et al.*, 1999), $5\text{-}HT_{1A}$, $5\text{-}HT_{1B}$ and $5\text{-}HT_{2C}$ receptor agonists (Cryan and Lucki, 2000; O'Neill and Conway, 2001), extracts of St John's wort (*Hypericum perforatum*) (Butterweek *et al.*, 1997), ECS and REM sleep deprivation (Borsini and Meli, 1988; Porsolt, 1981; Porsolt *et al.*, 1991). The test is not usually sensitive to SSRIs (Borsini, 1995; Borsini and Meli, 1988; Connor *et al.*, 2000), although activity of these compounds has sometimes been reported, and this appears to reflect a subtle technical change, an increase in the water depth (e.g. Cryan and Lucki, 2000; van der Heyden *et al.*, 1991). There have also been a variety of other negative reports; nevertheless, some 90% of clinically active antidepressants are active in the forced swim test, with the proportion rising in studies using chronic drug treatment (Borsini and Meli, 1988; Porsolt *et al.*, 1991). It has been suggested that both serotonergic and noradrenergic systems may be involved in mediating antidepressant-induced reductions in immobility; serotonergic-mediated effects result from increased swimming time while noradrenergic-mediated effects reflect increased climbing behaviour (Detke *et al.*, 1995).

Reduced immobility scores have also been observed following treatment with neurosteroids (Reddy *et al.*, 1998), neuropeptide Y (Stogner and Holmes, 2000) and NMDA receptor antagonists (Panconi *et al.*, 1993; van der Bos *et al.*, 1992). The effect of NMDA receptor antagonists is to reduce calmodulin-mediated activation of nitric oxide (NO) synthase. Likewise, NO synthase inhibitors have been reported to be as effective in reducing immobility as imipramine (Harkin *et al.*, 1999a). In rat studies, selective antagonists for subtypes of the cholecystokinin (CCK) receptor have both been shown to reduce immobility score. However, these positive effects are dependent on time of drug administration. Thus, the CCK_A antagonist devazepide is only effective when given before the conditioning pre-test (Hernando *et al.*, 1996) while the CCK_B antagonist L-365,260 is effective when given immediately prior to the re-test (Hernando *et al.*, 1994). These observations suggest a role for CCK in behavioural adaptations to acute stress.

On the negative side, while the test successfully discriminates antidepressants from neuroleptics and anxiolytics (Porsolt *et al.*, 1977), false positives have been reported for stimulants, convulsants, anticholinergics, antihistamines, pentobarbital, opiates, a variety of brain peptides (see above) and a number of other drugs (Borsini and Meli, 1988; Porsolt *et al.*, 1991). Some false positive responses have been reported to disappear if chronic drug treatment is used, or the duration of the test is prolonged (Kawashima *et al.*, 1986; Kitada *et al.*, 1981), but the generality of these effects has not been established.

While the predictive validity of the forced swim test may be better than has sometimes been assumed, its face and construct validity are minimal. The only symptomatic resemblance to depression is an inability or reluctance to maintain effort. Interestingly, positive responses to antidepressant drug treatment (i.e. reduced immobility) are only observed if subjects are forced to swim in water at least 10 °C below core body temperature (P.J. Mitchell, personal observations) and consequently develop severe hypothermia. If mice are forced to swim in water maintained at body temperature then immobility still occurs, but the response to antidepressant treatment is abolished. These observations clearly implicate the importance of severe cold stress and the consequent induction of hypothermia in this model, which further weakens the parallel with depression.

The theoretical rationale of this test derives entirely from its supposed relationship to learned helplessness. However, the relationship between the two models is unclear. Prior inescapable, but not escapable, shock has been found to increase immobility in the forced swim test, (Nomura *et al.*, 1982; Weiss *et al.*, 1981), but in view of the consistent finding of decreased motor activity following inescapable shock (see Anisman and Zacharko, 1982), it would be surprising were this not the case. The reciprocal finding has not been demonstrated: forced swimming did not impair subsequent escape performance in a shock avoidance task in which

performance deficits are typically seen following inescapable shock (O'Neill and Valentino, 1982).

Nevertheless, the two tests do seem to share similar physiological substrates. Immobility in the swim test is also reversed by stimulating 5-HT_{1A}, 5-HT_{1B} and 5-HT_{2C} receptors (Cryan and Lucki, 2000; O'Neill and Conway, 2001; van der Heyden *et al.*, 1991), DA or α_1-adrenergic receptors or by anticholinergics, and potentiated by treatments that decrease the activation of DA (e.g. amisulpride: Papp and Wieronska, 2000) or NA systems or increase cholinergic transmission. Similarly, the therapeutic actions of antidepressants in this model are blocked by DA receptor antagonists and by treatments that reduce NA function, including neurotoxic destruction of the ascending NA pathways and α_1-adrenoceptor antagonists. As in the learned helplessness test, impairment of 5HT transmission neither increases immobility nor blocks its reversal by antidepressants (see Borsini and Meli, 1988; Willner, 1990).

Tail-Suspension Test

A number of variants of the forced swim test have been proposed. One of these, the tail-suspension test, has been claimed to be ethically superior to the forced swim test, as stress levels appear to be reduced (Porsolt *et al.*, 1986; Steru *et al.*, 1985). In this model, mice suspended by the tail show a temporal pattern of struggling followed by immobility, similar to that seen in the forced swimming test. Antidepressants, at strikingly low doses, have been shown to increase the duration of mobility and also, in an automated version of the test, to increase the power of the movements (though the latter effect is rather less convincing). Effective agents include TCAs, MAOIs and atypical antidepressants; the latter include mianserin, the selective NA reuptake inhibitor, reboxetine (Wong *et al.*, 2000), extracts of St John's wort (*Hypericum perforatum*) (Butterweek *et al.*, 1997), the NMDA receptor antagonist MK-801 (Panconi *et al.*, 1993) and, significantly, some (but by no means all) 5-HT uptake inhibitors (David *et al.*, 2001; Perrault *et al.*, 1992; but see also Fujishiro *et al.*, 2001; Teste *et al.*, 1993), which are usually ineffective in the forced swim test (see above). Immobility was also reduced by stimulant drugs, but was potentiated by neuroleptics or anxiolytics (Porsolt *et al.*, 1986; Steru *et al.*, 1985).

While it is tempting to see the tail-suspension test as a more sensitive version of the forced swim test, there are subtle differences between them, which are not at present understood but involve significant mediation by a noradrenergic-receptor-mediated mechanism(s) (Ferrari *et al.*, 1991). In particular, $5HT_{1A}$ receptor agonists are active in the forced swim test, but are ineffective in the tail-suspension test (Porsolt *et al.*, 1991), whereas the mixed 5-$HT_{1A/1B}$ receptor agonist RU 24969 was active in the latter. Like the forced swim test, the face and construct validity of the tail-suspension test are minimal.

Restraint Stress

Rats subjected to 2 h restraint stress exhibit hypolocomotion when examined in an open field 24 h later. Chronic treatment with desmethylimipramine (desipramine, DMI) or sertraline prior to restraint stress reverses the hypolocomotion (Kennett *et al.*, 1987). There is little basis on which to evaluate the validity of this model, which is included here simply to illustrate the generality of the reversibility of stress effects by antidepressants. Note, however, that, unlike the models described earlier, which respond to acute antidepressant treatment, this model requires chronic treatment.

Chronic Stress Models

Chronic Severe Stress

Repeated presentation of the same stressor usually leads to adaptation. However, adaptation can be prevented by presenting a variety of stressors in an unpredictable sequence. Katz and colleagues showed that three weeks of exposure to electric shocks, immersion in cold water, immobilization, reversal of the light/dark cycle and a variety of other stressors caused a decrease in the activating effect of acute stress in an open field test. However, the activating effect of acute stress was maintained in animals receiving daily antidepressant treatment during the chronic stress period; the effects of administering antidepressants after exposure to stress have not been studied in this model. A variety of antidepressant drugs, as well as ECS, were found to prevent the effect of chronic stress, but the MAOI tranylcypromine was ineffective. Various non-antidepressants failed to prevent the effect of stress. In addition to causing changes in open field activity, chronic stress also increased plasma corticosteroid levels. This effect showed the same spectrum of pharmacological sensitivity, with the exception that an anticholinergic was also effective (Katz *et al.*, 1981; see Willner, 1990 for review). Similar effects have also been reported in mice; corticosteroid levels and the response to an acute stress were normalized by TCAs, but not by the SSRI fluoxetine (Soblosky and Thurmond, 1986).

A further effect observed in rats after chronic stress was a failure to increase fluid consumption when saccharine was added to the drinking water, suggesting that chronic stress might cause anhedonia; this deficit was partially restored by imipramine (Katz, 1982). The chronic stress model has been used very little since the original series of publications, in part because the levels of severity employed raise serious ethical problems. However, a variant of the model has been devised which employs very mild stressors, and this model is described next.

Chronic Mild Stress (CMS)

The CMS model was developed in an attempt to achieve the same endpoints as the chronic stress model, but in a more ethically acceptable manner. The procedure involves relatively continuous exposure of rats or mice to a variety of mild stressors, such as periods of food and water deprivation, small temperature reductions, changes of cage mates, and other similarly innocuous manipulations. Over a period of weeks of chronic exposure to the mild stress regime, rats gradually reduced their consumption of a preferred dilute sucrose solution, and in untreated animals this deficit persisted for several weeks following the cessation of stress (Willner *et al.*, 1987, 1991). As discussed earlier (see the section on Construct Validity, above), a variety of studies have been performed to confirm that these effects reflect a generalized insensitivity to reward; in particular, chronic mild stress also impairs responsiveness to reward as assessed by different methods, including suppression of place preference conditioning (Papp *et al.*, 1991, 1992, 1993) and increased threshold for ICSS (Moreau *et al.*, 1992). Studies of the effects of the individual elements of the chronic mild stress regime revealed that one element, social housing (in animals usually housed individually), was particularly potent, but no individual element (including social housing) was either necessary to induce anhedonia or sufficient to maintain anhedonia for a prolonged period (Muscat and Willner, 1992).

Antidepressant treatment has no effect on sucrose consumption or ICSS threshold in non-stressed animals, but following the reduction of sucrose intake by stress, normal behaviour was gradually restored by chronic treatment (2–5 weeks) with a wide variety of antidepressants, including TCAs, SSRIs, a specific NA reuptake inhibitor (maprotiline), MAO-A inhibitors, atypical antidepressants such as mianserin, buspirone, and amisulpride, and ECS. Also effective were some agents of uncertain antidepressant status, such as antihistaminic and anticholinergic drugs. Ineffective drugs include the anxiolytic chlordiazepoxide, various neuroleptics, amphetamine and morphine (reviewed by Willner, 1997; Willner

and Papp, 1997). Fluoxetine, maprotiline and mianserin (but not chlordiazepoxide) were also found to restore the rewarding properties of food, as assessed in the place conditioning paradigm (Cheeta *et al.*, 1994; Muscat *et al.*, 1992). In contrast to the extensive array of drugs correctly classified in CMS experiments, very few false positives or false negatives have been reported.

The reversal of an established behavioural deficit during the continued presence of the stressor is an important feature of this model: if, as seems likely, chronic stress does play a role in the aetiology of melancholia (e.g. Aneshensel and Stone, 1982; Monroe *et al.*, 1985; Rodgers, 1991), its continued presence during antidepressant therapy would usually be the norm. Also important is the extended time course of antidepressant action, which makes it feasible to detect rapid onset of action. Many novel agents have been identified as potential antidepressants using the CMS procedure, and these include some that appear to act more rapidly than TCAs or SSRIs, including the D2/D3 receptor antagonist amisulpride (Papp and Wieronska, 2000), the glycine antagonist 1-aminocyclopropanecarboxylic acid (ACPC) (Papp and Moryl, 1996), the $5HT_{1A}$ receptor agonist BIMT-17 (D'Aquila *et al.*, 1997), and the SNRI venlafaxine (M. Papp, personal communication). Potentiation of antidepressant action by lithium and pindolol has also been reported (Sluzewska and Szczawinska, 1996a, b). In at least three instances (the D2/D3 receptor agonist pramipexole, the corticosterone synthesis inhibitor ketoconazole, and the catechol-*O*-methyl transferase (COMT) inhibitor tolcapone), the antidepressant effect of these compounds was demonstrated in the clinic only after these actions had been predicted in the CMS model (see Willner, 1997).

In addition to decreasing responsiveness to rewards, CMS also causes the appearance of many other symptoms of major depressive disorder. Behavioural changes in animals exposed to CMS include decreases in sexual, aggressive and investigative behaviours, and decreases in locomotor activity. These are seen during the dark phase of the light–dark cycle, which is the rat's active period; EEG measures of active waking are also decreased during the dark phase. In contrast, CMS did not cause the appearance of an 'anxious' profile in two animal models of anxiety, the elevated plus-maze and the social interaction test, suggesting that the behavioural changes are specific for depression. Animals exposed to CMS show an advanced phase shift of diurnal rhythms, diurnal variation, with symptoms worst at the start of the dark (active) phase, and a variety of sleep disorders characteristic of depression, including decreased REM sleep latency, an increased number of REM sleep episodes, and more fragmented sleep patterns. They also gain weight more slowly, leading to a relative loss of body weight, and show signs of increased activity in the HPA axis, including adrenal hypertrophy and corticosterone hypersecretion. Abnormalities have also been detected in the immune system, including an increase in serum, decreases in thymus weight, natural killer cell activity and reactivity to T-cell mitogens, and an increase in acute phase proteins that was reversed by chronic antidepressant treatment. Taken together with the generalized decrease in responsiveness to rewards, these parallels to the symptoms of depression, and in particular, to melancholia, are both extensive and comprehensive (reviewed by Willner, 1997). Indeed, it is arguable that the only symptoms of depression that have not been demonstrated in animals exposed to CMS are those uniquely human symptoms that are only accessible to verbal enquiry. Even without these symptoms, a rat exposed to CMS could, in principle, legitimately attract a DSM-IV diagnosis of either major depressive disorder or major depressive disorder with melancholic features.

Studies of the neural basis of the CMS-induced anhedonia have focused primarily on the mesolimbic DA system. The behavioural changes in animals subjected to CMS are accompanied by a decrease in D2/D3-receptor binding and D2-mRNA expression in the nucleus accumbens, and a pronounced functional subsensitivity to the rewarding and locomotor stimulant effects of the D2/D3 receptor agonist quinpirole, administered systemically or within the nucleus accumbens. All of these effects are also reversed by chronic antidepressant treatment (Dziedzicka-Wasylewska *et al.*, 1997; Willner and Papp, 1997). In other studies, animals successfully treated with antidepressants were treated acutely with D2/D3 receptor antagonists, at low doses that were without effect in non-stressed animals or in untreated stressed animals. This treatment reversed the effects of a wide variety of antidepressants on rewarded behaviour (Willner and Papp, 1997). These data argue strongly that an increase in D2/D3 receptor responsiveness may be responsible for the therapeutic action of antidepressants in this model (Willner and Papp, 1997). A similar reversal of SSRI action by the D2 antagonist sulpiride has been observed in a clinical study, as predicted from the CSM data (see Willner, 1997).

A recent CMS study suggests a neural mechanism that could mediate the negative information processing bias characteristic of depression (Beck, 1967). In this study, DA release in nucleus accumbens and prefrontal cortex was monitored by microdialysis following exposure to a palatable reward and a stressor (tail pinch). CMS markedly inhibited DA release in response to rewards, but potentiated responses to the stressor; and both of these effects of CMS were reversed by chronic treatment with the TCA, DMI (Di Chiara *et al.*, 1999).

While the CMS model has a great many positive features, and is probably the most valid animal model of depression currently available (see below), a major drawback is that the model has proven extremely difficult to implement reliably, and while many laboratories have succeeded in doing so, many others have not. The reasons for this lack of reliability have been extensively debated (see Willner, 1997), but as yet are unresolved.

Stress Induction and Mild Stress Maintenance

Tagliamonte and colleagues have described a model that represents a cross between learned helplessness and CMS. In this procedure, an altered state is first induced by acute exposure to a session of moderately intense inescapable tail shock, and then maintained, apparently indefinitely, by exposure to milder stressors (brief restraint, a small number of shocks, or exposure to the inescapable shock apparatus), presented at two-day intervals. This treatment resulted in an impairment of shock escape learning, as in learned helplessness, and a failure to learn a simple maze task reinforced by a highly palatable food (vanilla sugar), as in CMS. Both of these deficits were prevented by chronic pretreatment with TCAs or fluoxetine (De Montis *et al.*, 1995; Ghiglieri *et al.*, 1997). The stress procedure also decreased basal levels of extracellular DA in the nucleus accumbens shell, and this change also was prevented by chronic TCA treatment (Gambarana *et al.*, 1999b).

We noted earlier (see the section on Construct Validity, above) that the effect of severe life events to precipitate depression was best characterized as an acute severe stress followed by a chronic increase in mild stress. Stress induction followed by mild stress maintenance exactly parallels these processes, and is the only animal model of depression to do so. This procedure could potentially provide a more reliable and robust alternative to the CMS procedure, but few data are as yet available. In particular, while antidepressants have been shown to prevent the development of behavioural abnormalities, they have not as yet been shown to reverse an established deficit. Also, the portability of the procedure to other laboratories has not yet been demonstrated.

Withdrawal from Chronic Psychomotor Stimulants (Amphetamine and Cocaine)

A number of studies have reported that responding for ICSS was reduced in the days following withdrawal from chronic

amphetamine treatment. In these studies, amphetamine was administered to rats for between 4 and 10 days, typically using several administrations each day, at increasing doses (Barrett and White, 1980; Kokkinidis and Zacharko, 1980; Leith and Barrett, 1976; Simpson and Annau, 1977). The threshold for ICSS was elevated following amphetamine withdrawal, confirming that the rate reduction reflects a subsensitivity to brain-stimulation reward rather than a depression of motor activity (Cassens *et al.*, 1981; Leith and Barrett, 1980). After 14 days of amphetamine treatment, the decreased sensitivity to ICSS did not recover during 18 days of further testing (Leith and Barrett, 1980) reflecting subsensitivity of reward systems rather than simple depression of motor activity. In a single pharmacological study, this effect was alleviated by two days of imipramine or amitriptyline treatment, and with continued treatment, normal responding was restored (Kokkinidis *et al.*, 1980).

In a variant of this procedure, animals self-administer cocaine, rather than being administered amphetamine (Koob, 1989). In these experiments, the threshold for brain-stimulation reward, administered through electrodes in the posterior lateral hypothalamus, was obtained using a discrete trial procedure (Kornetsky and Esposito, 1981), which is sensitive to changes in reward value, but not to changes in motor performance (Markou *et al.*, 1989). Following 24 h of cocaine self-administration, ICSS thresholds were elevated for several hours (Koob, 1989), indicating that cocaine withdrawal induced a state of anhedonia. Acute administration of the DA receptor agonist bromocriptine restored ICSS thresholds to normal (Markou and Koob, 1989). Only one conventional antidepressant has been tested in this procedure: repeated administration of the TCA DMI was reported to shorten the duration of post-cocaine anhedonia (Markou *et al.*, 1992).

It has frequently been assumed that stimulant drug treatment is a form of stress, since in many respects stimulant treatment and stress appear to be interchangeable (Antelman *et al.*, 1980; Post, 1975). Indeed, withdrawal from chronic cocaine treatment in rats is associated with intense anxiety-related behaviour and extrahypothalamic-limbic corticotropin-releasing hormone (CRH) hypersecretion (Sarnyai *et al.*, 1995). The similarities between stress and stimulant withdrawal are thought to arise from the fact that, like stimulant drugs, stressors activate the mesolimbic and mesocortical DA projections (Blanc *et al.*, 1980). Independent of a relationship to stress, there is an obvious parallel between the effects of stimulant withdrawal and the depressions that frequently follow the cessation of chronic stimulant use (Watson *et al.*, 1972), although in the animal model, the time course is rather more compressed.

As the stimulant withdrawal models are based exclusively upon changes in ICSS behaviour, their construct validity depends largely on the assumption that brain-stimulation reward activates natural reward pathways (Hoebel, 1976). Although early studies suggested that ICSS had unusual properties compared to natural rewards (for example, rapid extinction), it was later recognized that these properties derive from differences in the experimental procedures typically employed (such as the delay of reinforcement); when such extraneous factors are equated, ICSS appears very comparable to a high-incentive natural reward presented under conditions of low drive (see Gibson *et al.*, 1965). These parallels, together with the observation that responding for ICSS performance is influenced by many of the factors that control responding for natural rewards, have justified the assumption that the ICSS electrode stimulates directly the neural substrates that are activated indirectly by natural rewards (Hoebel, 1976). A degree of caution is required, since although people implanted with ICSS electrodes report a variety of pleasurable sensations, they also report other reasons for stimulating, such as curiosity (Atrens, 1984; Valenstein, 1973). Nevertheless, the commonality of anatomical substrate between ICSS and other types of reward supports the use of this procedure as an animal model of hedonic behaviour (see also Koob, 1989; Wise, 1989). However, the relationship of drug-induced depressions to major depressive disorder is uncertain, and the validity of this model is therefore questionable.

Social Dominance Models

Parallels have often been noted between depressive and submissive behaviours (Gardner, 1982; Price, 1972), and a number of laboratories have attempted to model depression by using animals of low social rank. Subordinates, and those who have lost status as a result of defeat in social conflict situations, are at greater risk for psychopathology. Biological similarities between defeated animals and human depression have frequently been noted (see Gilbert and Allan, 1998; Henry, 1982; Toates, 1995), and there is considerable evidence that depressed individuals see themselves as inferior and behave submissively (reviewed by Gilbert and Allan, 1998). Indeed, social skills training, of which assertiveness training represents a major component, is used clinically as a psychotherapy for depression, which has been found to be as effective as TCA treatment (e.g. Hersen *et al.*, 1984). Like the chronic mild stress procedure, animal models based on social dominance employ realistic inducing conditions, which are of particular ecological relevance.

Social Defeat

Social defeat is a potent stressor, and repeated defeat is a form of chronic stress, which is associated with a decrease in aggressive behaviour (Albonetti and Farabollini, 1994). A single social defeat has been reported to produce a gradual, but long-lasting, increase in immobility in the forced swim test, which was prevented by chronic treatment with clomipramine (Koolhaas *et al.*, 1990). A similar model has been developed in submissive C57BL/6J mice: a single defeat by a dominant male mouse of the same strain was reported to cause a gradual increase over weeks in passive behaviour in response to a mild stressor, which could be antagonized by clomipramine; defeated animals also had higher immobility times in the forced swim test (Korte *et al.*, 1991). In a chronic version of a similar procedure, mice were housed in social contact, but were physically separated except for one daily 3-minute encounter. Again, increased immobility in the forced swim test was observed in repeatedly defeated animals, and this effect was prevented by chronic treatment with imipramine (Kudryatseva *et al.*, 1991), though in this study, imipramine did not normalize social behaviour in the defeated animals (Kudryatseva *et al.*, 1991).

In a modified rat model, defeat of dominant pair-housed rats by rats of a different, more aggressive strain resulted in the loss of dominant status relative to their previously submissive partners, which was restored by chronic imipramine treatment (Willner *et al.*, 1995). This loss of status was accompanied by the abolition of morphine-induce place conditioning, most likely reflecting a decrease in hedonic tone (Coventry *et al.*, 1997). This suggests that it may be appropriate to view submission models, potentially, as models of melancholia. However, more evidence is needed for any firm conclusion.

In a modified murine social defeat paradigm, subordinate mice subjected to repeated social defeat showed reduced growth compared to dominant subjects, together with citalopram-sensitive anxiogenic-like behaviour (Keeney and Hogg, 1999; Keeney *et al.*, 2001). The defeated mice exhibited a maintained increase in both core temperature and circulating corticosterone levels indicative of chronic stress, although social defeat had no effect on either ethanol consumption or immobility time measured in the forced swim test. Similarly, a single social defeat of Lewis rats resulted in hypophagia and weight loss, together with increased measures of anxiety,

and these effects were reduced following acute fluoxetine treatment (Berton *et al.*, 1999).

Overall, these various studies suggest that social defeat may in principle provide a valid and ecologically sound model of depression. However, a variety of procedures have been used, and at present, the data are not entirely consistent.

Social Hierarchy

Rats housed in closed groups develop a social hierarchy and the relative social position of each group member may be identified by assessing each individual's level of success during agonistic encounters with other group members. If rats are housed in triads then a social hierarchy consisting of a dominant, subdominant and subordinate develops. Chronic administration (2-week) of either clomipramine or mianserin to the subdominant animal results in an increase in that subject's rank position at the expense of the level of dominance enjoyed by the dominant group member (Mitchell and Redfern, 1992a). The increase in the social position of the antidepressant-treated subdominant rat is likely to be related to increased assertiveness expressed during social encounters. An attractive feature of this model is that daily assessment of social structure allows the time course of antidepressant-induced elevation of social position to be determined.

However, not all features of subordinate animals are necessarily of relevance to depression, and the relationship between social dominance and social competition is potentially problematic. In group-housed rats competing for limited access to a high-incentive reward, the performance of subordinate animals was improved by acute or chronic anxiolytic treatment (Gentsch *et al.*, 1990; Joly and Sanger, 1991), suggesting that the social competition test is relevant to anxiety rather than depression. Consistent with this view is the observation that chronic treatment with *m*-chlorophenylpiperazine (*m*CPP), a major metabolite of the antidepressant trazodone, which also possesses antidepressant activity, failed to increase the performance subdominant rats in a social competition test (Moledina *et al.*, 2000) at a dose previously shown to increase the aggressive behaviour of resident rats in a resident–intruder test (see below) (Mitchell and Redfern, 2000). However, the benzodiazepine anxiolytic diazepam, which improves performance in a social competition test, did not increase aggressive behaviour in dyadic encounters, after either acute or chronic administration (Mitchell and Redfern, 1992b). Further studies will be necessary to confirm this ineffectiveness of anxiolytics in social dominance tests.

The Resident–Intruder Test

Antidepressant treatment has consistently been shown to have profound effects on rat, but not necessarily mouse, social and agonistic behaviour. While acute treatment with pharmacologically disparate antidepressant drugs (including TCAs, MAOIs, SSRIs, SNRIs, 5-HT_{1A} receptor agonists and partial agonists, and 5-HT_{2C} receptor agonists) commonly reduces the aggressive behaviour of resident rats when confronted with an unknown conspecific intruder, chronic antidepressant treatment (including repeated ECS) increases such aggressive behaviour (Cobain *et al.*, 1994a, b; Mitchell and Fletcher, 1993, 1994; Mitchell and Forster, 1992; Mitchell and Hogg, 2001a, b; Mitchell and Redfern, 1992b, 1997a, b, 2000; Willner *et al.*, 1981). These observations are consistent with the view that aggression is the only type of rodent social behaviour consistently increased following chronic treatment with antidepressants (File and Tucker, 1986).

The fact that chronic antidepressant treatment increases aggressive behaviour appears at first sight to be incompatible with the use of SSRIs in the clinical treatment of impulsive aggression (Coccaro and Kavoussi, 1997; Evenden, 1999a; Fava and Rosenbaum, 1993). However, this is a clinical, rather than an experimental, paradox, since clinically, antidepressants both increase aggression in submissive depressed individuals (manifest as a reversal of intropunitive aggression and/or impaired sociability: see Dixon *et al.*, 1989; Kaplan *et al.*, 1961; Priest *et al.*, 1980) and decrease pathological aggression (e.g. Hollander, 1999; Vartiainen *et al.*, 1995). A resolution of this paradox may be that antidepressant treatment increases assertiveness, since this would increase low levels of social dominance while at the same time decreasing high levels of physical aggression. Hence, the ability of chronic antidepressant treatment to increase aggression in rats may reflect the increased assertiveness and associated externalization of emotions expressed during recovery from depressive illness. Such increased assertive/aggressive behaviour is consistent with the effects of such treatment in the social hierarchy model (see above). However, face validity of the resident–intruder model is reduced by the fact that the test involves 'normal' unmanipulated animals; non-depressed people do not respond to antidepressant treatment. Interestingly, and in contrast to the rat studies, the aggressive behaviour of male mice in resident–intruder studies is particularly sensitive to anxiolytic, rather than antidepressant, drug activity (e.g. Lumley *et al.*, 2000).

By programming daily dyadic encounters, the resident–intruder paradigm can be used to compare the rate of onset of antidepressant-induced elevation in aggression between antidepressant treatments and to assess the utility of potential adjuvant treatment to accelerate antidepressant-related changes in rodent behaviour. Indeed, the first published studies to demonstrate the ability of a selective 5-HT_{1A} receptor antagonist (WAY-100635) to accelerate time-dependent antidepressant-induced behavioural changes used the resident–intruder test (Mitchell and Redfern, 1997b).

Social Separation

The presumed aetiological role in depression of loss events, and particularly loss of a loved one, has led to the development of a number of animal models of depression based on separation phenomena.

Although the evolutionary proximity of primates has led some authors to consider primate separation models to be of particular importance (e.g. Everitt and Keverne, 1979), they have produced remarkably little of value. Precisely because of their evolutionary proximity, the use of primates sacrifices many of the advantages of animal models, such as the easing of ethical constraints, and the possibility of testing adequately sized groups of subjects.

Neonatal Isolation

The most familiar of these models involve non-human primates, either infants isolated from their parents, or juveniles isolated from their peer group. The separation response consists of an initial stage of 'protest', characterized by agitation, sleeplessness and distress calls, followed by 'despair', characterized by a decrease in activity, appetite, play and social interaction, and the assumption of a hunched posture and 'sad' facial expression (see Henn and McKinney, 1987; Suomi, 1976). These symptoms are strikingly similar to those of 'anaclitic depression' in institutionalized children (Robertson and Bowlby, 1952). However, while parental loss in childhood, and loss events such as bereavement in adults, are implicated in the aetiology of depression, they also increase the risk of a variety of other psychiatric and non-psychiatric disorders (Brown *et al.*, 1973; Schmale, 1973). The nature of the separation response is sensitive to the environment in which the experiments are carried out (e.g. Reite *et al.*, 1981; Suomi, 1976), and the incidence of 'depressive' behaviours may in some experiments be as low as 15% (Lewis *et al.*, 1976).

The few pharmacological studies using these models have not been impressive. Very few published studies have attempted to use antidepressant treatments to modify primate separation behaviour, and because of the expense of using primates, the size of experimental groups in most studies has usually been too small to provide reliable data. Chronic treatment with DMI (Hrdina *et al.*, 1979), imipramine (Suomi *et al.*, 1978), oxaprotiline (McKinney and Kraemer, 1989) and ECS (Lewis and McKinney, 1976) have been reported to reverse some, but not all, of the effects of separation in monkeys. Trifluoperazine, amphetamine and diazepam did not affect responses to social isolation in chimpanzees (Menzel *et al.*, 1963, Turner *et al.*, 1969), but some therapeutic effects of chlorpromazine were seen in rhesus monkeys (McKinney *et al.*, 1973). 'Depressive' — like behaviours in singly-housed rhesus monkeys are associated with decreased concentrations of NA in the cerebrospinal fluid, with relatively little effect on DA or 5HT (Kraemer *et al.*, 1989). Following a return to social housing, NA levels normalize, but the animals remain hypersensitive to pharmacological challenges of the NA system (Kraemer *et al.*, 1984a, b).

In fact, separation phenomena of 'protest' followed by 'despair' are present to some extent in many other species, including cats, dogs, rodents and precocial birds (Katz, 1981; McKinney and Bunney, 1969), and several of these phenomena have also been used as the basis for the development of animal models of depression. One of these, the reactivation of distress calling in one-week-old chicks, appears to perform relatively well as an antidepressant screening test (Lehr, 1989). The vocalizations of guinea-pig pups separated from their mothers also respond to antidepressants, and this test was used successfully to detect antidepressant-like activity of the Substance P neurokinin 1 (NK1) receptor antagonists (Rupniak *et al.*, 2000).

Adult Isolation

Chronic (4–6 weeks) isolation of adult rats has been found to cause a disruption of cooperative social behaviour (Berger and Schuster, 1982) reminiscent of the poor social performance of depressed people (Lewinsohn, 1974). In a single study of the effects of antidepressant treatment, the impairment of social cooperation in isolated rats was reversed by chronic treatment with either imipramine or fluoxetine, and the effect of imipramine in this model was abolished by the 5-HT antagonist metergoline (Willner *et al.*, 1989).

MODELS OF PREDISPOSITION TO DEPRESSION (i.e. DIATHESIS)

Depressive diatheses have been modelled genetically, genomically, developmentally and by brain lesioning. These areas are reviewed in turn.

Genetic Models

Selective Breeding for Muscarinic Hypersensitivity (FSL)

The Flinders Sensitive Line (FSL) rat is the result of selective breeding for sensitivity to the hypothermic effect of cholinergic agonists and is based on the hypothesis that central cholinergic systems are important in depression since increased cholinergic sensitivity has been reported in depressed patients. Although bred for cholinergic hypersensitivity, FSL animals also show a number of other pharmacological abnormalities, including serotonergic hypersensitivity and dopaminergic hyposensitivity (Overstreet and Janowsky, 1991). Relative to the control Flinders Resistant Line, FSL animals have a number of characteristics reminiscent of depression, including cholinergic supersensitivity, increased REM sleep and reduced locomotor activity, which is further pronounced following electric footshock (Overstreet, 1993). FSL animals also show greater immobility in the forced swim test (Overstreet and Janowsky, 1991). This behaviour was normalized by chronic treatment with a high dose of imipramine, and partly reversed by DMI or sertraline, but was not restored by chronic amphetamine or scopolamine (Overstreet, 1991; Overstreet *et al.*, 1995; Schiller *et al.*, 1992). FSL rats also exhibit a greater vulnerability to the suppressive effect of chronic mild stress on responsiveness to sweet reward (Pucilowski *et al.*, 1991, 1993) but behave normally in the elevated plus-maze, a putative animal model of anxiety (Overstreet, 1991).

While these observations are consistent with a depressive diathesis and greater behavioural responsiveness to stress, other data are not. FSL rats have markedly elevated levels of 5-HT, NA and DA in specific brain areas, which are normalized during chronic treatment with DMI (Zangen *et al.*, 1997, 1999), and hypothalamic levels of CRH and circulating levels of adrenocorticotrophic hormone (ACTH) are lower in FSL rats (Owens *et al.*, 1991), indicating reduced HPA axis activity, in contrast to the increased HPA axis activity observed in depression. Similarly, acute and chronic treatments with nicotine, a non-antidepressant, both exhibit an antidepressant-like effect on the behaviour of FSL rats in the forced swim test (Tizabi *et al.*, 1999), which was blocked by prior treatment with the nicotinic receptor antagonist mecamylamine (Tizabi *et al.*, 2000). It should be noted that the major pharmacological evidence supporting the FSL strain as a model of depression derives from studies using the forced swim test, which is itself of questionable validity.

The Roman Low-Avoidance (RLA) Strain

The Roman low-avoidance (RLA) rat strain has been selectively bred for poor avoidance in the shuttle box paradigm, while the Roman high-avoidance (RHA) counterparts have been selectively bred for their good performance in that task. Compared to RHA rats, the behaviour of RLA rats expressed in the open-field, elevated plus-maze and hole-board tests are consistent with high levels of emotionality (Escorihuela *et al.*, 1999) and reflect differences in response to or the ability to cope with stress. In contrast, RLA and RHA rats react similarly to social defeat (Meerlo *et al.*, 1997). This latter finding suggests that the RLA strain is likely to prove of limited relevance to depression.

The Fawn-Hooded Strain

The Fawn-Hooded (FH) rat strain exhibits hypercortisolaemia and blunted response to dexamethasone-induced suppression of cortisol secretion (Owens and Nemeroff, 1991) consistent with the hyperactivity of the HPA axis which is observed in depressive illness. The elevated levels of plasma cortisol are reduced by chronic treatment with the TCAs imipramine and clomipramine, and with the MAO-A inhibitor clorgyline (Aulakh *et al.*, 1993). FH rats also exhibit reduced growth rate consistent with an abnormality of the hypothalamic-somatotrophic (HSM) axis (Gomez *et al.*, 1999). FH rats exhibit increased immobility in the forced swim test in some studies (but not all; see Hall *et al.*, 1998a; Lahmame *et al.*, 1996) and increased ethanol intake and preference (Overstreet *et al.*, 1992). Furthermore, ethanol consumption in FH rats is increased by social isolation (Hall *et al.*, 1998b). Recent studies also indicate higher levels of anxiety in FH rats (Hall *et al.*, 2000; Kantor *et al.*, 2001) together with impaired social behaviour (Kantor *et al.*, 2000). These observations indicate that the FH rat may be a suitable model

of comorbid depressive illness, alcoholism and anxiety, but clearly, much more work would be needed to substantiate this conclusion.

Like FSL rats, FH rats exhibit cholinergic supersensitivity (Overstreet *et al.*, 1992). In contrast, FH rats exhibit functional hyposensitivity to a variety of 5-HT and NA receptor agonists (Aulakh *et al.*, 1994, 1996) reflecting altered serotonergic and noradrenergic function in the FH strain.

Genomic Models

HPA Transgenic

In depressive illness, the secretion of CRH from the paraventricular nucleus of the hypothalamus is under the control of a glucocorticoid-receptor-mediated inhibitory feedback system. Conditions of extreme, prolonged stress cause reduced sensitivity of the glucocorticoid receptor, thereby reducing the effectiveness of the feedback loop, resulting in hypercortisolaemia. A transgenic mouse strain expressing glucocorticoid-receptor antisense has been described which exhibits dysfunction of the HPA axis in a manner similar to that seen in depressive illness (Montkowski *et al.*, 1995; Pepin *et al.*, 1992a). Chronic treatment with antidepressants reduces plasma cortisol and ACTH levels (Montkowski *et al.*, 1995; Pepin *et al.*, 1992b), by increasing glucocorticoid-receptor mRNA expression (Barden, 1996), with a subsequent elevation of glucocorticoid-receptor activity resulting in increased sensitivity of the HPA axis to glucocorticoid negative feedback (Barden, 1999). However, while behavioural and neuroendocrine responses to stress are modified in transgenic mice (Farisse *et al.*, 1999; Linthorst *et al.*, 2000), the direction of these changes is inconsistent with a model of depressive illness: relative to wild-type controls, transgenic mice exhibit reduced immobility in the forced swim test and less anxiety-related behaviour on the elevated plus-maze but increased aggressive behaviour (Beaulieu *et al.*, 1993; Montkowski *et al.*, 1995). All of these changes are in the opposite direction to those expected.

5-HT Transporter Knockout

The serotonin reuptake transporter (5-HTT) is pivotal in the inactivation and control of serotonergic neurotransmission, and blockade of the serotonin transporter is the principal target of the TCA, SSRI and SNRI drugs. Investigations of subjects which lack the serotonergic transporter, while not a model of depression, may provide an insight into the adaptive mechanisms associated with a permanent lack of serotonin reuptake. Recent studies suggest that 5-HTT knockout mice show regional differences from wild-type mice in terms of 5-HT_{1A} receptor protein and mRNA expression (reduced in dorsal raphe, hypothalamus, amygdala and septum, but increased in hippocampus: Fabre *et al.*, 2000; Lanfumey *et al.*, 2000; Li *et al.*, 2000), which are associated with reduced functional sensitivity to the hypothermic effects of the 5-HT_{1A} receptor agonist 8-hydroxy-2-(di-*n*-propylamino)tetraline (8-OH-DPAT) (Li *et al.*, 1999). Similarly, 5-HT_{2A} receptor density is also reduced in 5-HTT knockout mice (Rioux *et al.*, 1999). Interestingly, the desensitization of 5-HT_{1A} autoreceptors in 5-HTT knockout mice is further enhanced by exposure to stressful conditions (Lanfumey *et al.*, 2000).

CRH Receptor Subtype Knockouts

CRH is a critical coordinator of the HPA axis and subtypes of CRH receptors, CRH-R1 and CRH-R2, are found throughout the central nervous system and peripheral tissue. CRH has higher affinity for the CRH-R1 receptor, while urocortin (a CRH-related peptide) exhibits 40-fold selectivity for the CRH-R2 receptor. CRH-R1 knockout mice exhibit anxiolytic-like behaviour, which may be due to impaired spatial recognition memory (Contarino *et al.*, 1999), together with characteristic responses to stress (Timpl *et al.*, 1998) indicative of disrupted HPA axis (Smith *et al.*, 1998). In contrast, CRH-R2 knockout mice exhibit increased anxiety-like behaviour and are hypersensitive to stress (Bale *et al.*, 2000).

Tachykinin Receptor Knockout

The NK1 receptor is expressed in brain areas associated with the control and management of depressive illness, anxiety, stress and sensitivity to the rewarding properties of food and drugs of abuse. Indeed, antagonists at the NK1 receptor have been suggested as potential antidepressant drugs with a novel mode of action (Froger *et al.*, 2001; Rupniak *et al.*, 2000, 2001). The NK1 receptor knockout mouse is not an animal model of depression. Rather, these mice show behavioural changes similar to those elicited by antidepressants in normal mice, including a decrease in neonatal vocalization following maternal separation, decreased aggressive behaviour in the resident–intruder test, and decreased immobility in the forced swim and tail-suspension tests (Rupniak *et al.*, 2001). NK1 receptor knockout mice also exhibit a loss of the rewarding properties of morphine, together with reduced physical response to opiate withdrawal, but their response to cocaine is unchanged (Murtra *et al.*, 2000), suggesting that this may reflect a specific interaction with opioid systems, rather than a general effect on brain reward mechanisms.

Developmental Models

Neonatal Antidepressant Treatment

Neonatal treatment of rat pups with the TCA clomipramine has been reported to cause a spectrum of symptoms reminiscent of depression, including decreases in sexual and aggressive behaviour, a shortening of REM sleep latency, and subsensitivity to ICSS. Treated animals were also hyperactive in some tests (Vogel *et al.*, 1990, 1996). Animals were typically tested when mature, at ages that varied between tests. Most of the behavioural and sleep abnormalities were present on first testing at approximately 3 months; however, the ICSS abnormalities were absent at 4–5 months, but present at 6–8 months. ICSS was not tested in older animals, but some other abnormalities appeared to normalize at around 11 months (Vogel *et al.*, 1990). These effects are probably not specific to clomipramine, since neonatal treatment with DMI, zimeldine or the SSRI Lu 10-134-C has also been reported to increase immobility in the forced swim test in adult rats (Hansen *et al.*, 1997; Hilakivi and Hilakivi, 1987; Velazquez-Moctezuma and Diaz Ruiz, 1992), while neonatal treatment with the SSRI citalopram similarly reduces adult aggressive behaviour (Manhaes de Castro *et al.*, 2001). Zimeldine, like clomipramine, but not DMI, also disrupts adult rat sleep patterns by shortening the duration of REM sleep bouts (Frank and Heller, 1997). In contrast, neonatal treatment with scopolamine, a cholinergic receptor antagonist, suppressed REM sleep, as observed with neonatal clomipramine treatment, but unlike clomipramine, facilitated adult male sexual behaviour. These results suggest that the neonatal clomipramine-induced reduction in male sexual behaviour is not due to early REM sleep deprivation (Velazquez-Moctezuma *et al.*, 1993).

As yet, information concerning the pharmacological responsiveness of this model is minimal: some effects of imipramine and REM sleep deprivation have been reported, but the numbers of subjects tested were too low to allow reliable conclusions to be drawn (Vogel *et al.*, 1990). While this model appears to have good face validity, in terms of the range of symptoms displayed and the insidious onset of anhedonia, the mechanisms by which neonatal antidepressant treatment has adverse effects in mature animals are unknown. In particular, it is unclear what, if any, is the relationship between

neonatal antidepressant treatment and the aetiology of depression in humans. The extent to which the symptoms can be reversed by antidepressants is uncertain. Nevertheless, these studies raise the disconcerting possibility that a breast-fed infant could develop a susceptibility to melancholia by ingesting TCAs prescribed to the nursing mother for the relief of post-partum depression.

Prenatal/Neonatal Stress

Prenatally stressed (PS) rats (where the dam is subjected to repeated footshock during the early stages of pregnancy) exhibit elevated activity of the HPA axis and defensive behaviour before weaning, and the heightened defensive behaviour, as well as exaggerated behavioural, physiological and neuroendocrine responses to stressful stimuli, persists into adulthood (Takahashi *et al.*, 1992; Ward *et al.*, 2000; White and Birkle, 2001). Current behavioural data suggest similarities between the behavioural profiles of PS rats and the anxiogenic changes in behaviour induced by yohimbine and idazoxan (White and Birkle, 2001); these data indicate high levels of anxiety in PS rats. However, female, but not male, PS mice exhibit an antidepressant-reversible increase in immobility time in the forced swim test, indicating that PS might induce a gender-dependent increase in the risk of depression-like behaviour (Alonso *et al.*, 1999; 2000).

Neonatal stress in non-human primates has been shown to induce hypersecretion of CRH (Coplan *et al.*, 1996) and abnormal social behaviour in adulthood, indicative of enhanced response to stressors (Clarke and Schneider, 1993). Similarly, neonatal stress in rat pups, achieved by maternal separation, also increases CRH levels in adulthood (Ladd *et al.*, 1996).

Waiting Behaviour

Two procedures have been described in which antidepressants increase the ability of rats to withhold responses. They are not based on developmental — or indeed, any other — manipulations, but they do involve constitutional predispositions, and are reported at this point for convenience.

In one paradigm (differential reinforcement of low rate-72 s; DRL-72) premature responding delays the delivery of reward, and the ability of drugs to improve performance in this model has been claimed to be an efficient antidepressant screening test (Seiden *et al.*, 1985), although this has been disputed (Pollard and Howard, 1986). In the second paradigm, a larger reward may be earned by waiting; again, the improvement of performance in this model appears to be a specific property of a wide range of antidepressants (Bizot *et al.*, 1988a). Drugs which possess 5-HT_{1A} receptor agonist activity are antidepressant-like in both of these waiting paradigms (Archer, 1991; Bizot *et al.*, 1988b; Kostowski *et al.*, 1992; Richards *et al.*, 1994), and in the DRL-72 test, antidepressant effects were blocked by a 5-HT receptor antagonist (Marek *et al.*, 1989). The relevance of these behaviours to depression is unclear. In a different schedule designed to examine accurate estimation of time intervals, acute treatment with antidepressant drugs (imipramine, clomipramine and zimeldine) failed to modify timing accuracy (Bayley *et al.*, 1998) suggesting that improvement in performance on DRL schedules, including SSRIs (Sokolowski and Seiden, 1999), is most likely due to reduced rate of lever-pressing rather than improved timing.

Clinical evidence strongly suggests that similar disorders of 5-HT function cut across diagnostic boundaries, and are expressed as 'pathologically impulsive behaviour' rather than as any particular disorder (Soubrie, 1986; Willner, 1989b). Indeed, mice lacking the 5-HT_{1B} receptor (5-HT_{1B} knockout mice) exhibit more impulsive aggressive behaviour, drink more ethanol and acquire cocaine self-administration faster than wild-type mice (Brunner and Hen, 1997; Scearce-Levie *et al.*, 1999), which reflects (in part at least) reduced 5-HT function (Evenden, 1999b), and may provide an animal model of addiction and motor impulsivity. In vervet monkeys (*Cercopithecus aethiops sabaeus*) there appears to be a clear inverse relationship between serotonin turnover and social impulsivity (Fairbanks *et al.*, 2001). The inability to withhold responses in the two rodent 'waiting' models may constitute instances of impulsive behaviour, and as such, the effect of antidepressants in these paradigms may not relate specifically to depression.

The constitutional predisposition referred to earlier is that antidepressant effects in the DRL vary considerably between rats of different strains, or rats of the same strain obtained from different suppliers (Balcells-Olivero *et al.*, 1998).

Lesion Model

Olfactory Bulbectomy

The other major animal model of depression is based on the destruction of the olfactory bulb in rats, which disrupts the limbic-hypothalamic axis. Bulbectomized (OB) animals display a variety of behavioural changes, including irritability, hyperactivity, and an impairment of passive avoidance learning (Cairncross *et al.*, 1979). Recent observations suggest that OB rats exhibit increased reactivity together with a reduced rate of habituation to novel stimuli (Mar *et al.*, 2000) together with changes in the immune system and NA, DA, 5-HT, GABA, cholinergic and glutaminergic neurotransmitter systems (Kelly *et al.*, 1997). They also show an elevation of circulating corticosteroid levels (as do stressed animals), which appears to be an increased corticosteroid response to stress rather than an increase in basal levels (Broekkamp *et al.*, 1986). These changes are reversed by antidepressants, including compounds with 5-HT_{1A} receptor agonist activity (Borsini *et al.*, 1997; McGrath and Norman, 1999), SNRIs (McGrath and Norman, 1998) and selective NA reuptake inhibitors (Harkin *et al.*, 1999b) in addition to the TCAs. The most specific antidepressant effect is the reversal of the passive avoidance learning deficit (Cairncross *et al.*, 1979; Van Riezen and Leonard, 1990), although attenuation of hyperactivity in the open field is nowadays the most commonly used behavioural predictor of antidepressant activity (Kelly *et al.*, 1997). However, while all TCA and atypical antidepressants appear to be effective in this test, MAOIs are not (Jesberger and Richardson, 1986). While repeated administration of TCAs is necessary to normalize behaviour in this model, a limited number of studies suggest that some SSRIs act after acute treatment (Joly and Sanger, 1986; Lloyd *et al.*, 1982). Recent studies suggest that the OB rat model of depression is insensitive to the potential rapid-onset antidepressant action induced by concomitant treatment with 5-HT_{1A} receptor antagonists (Cryan *et al.*, 1998, 1999). The implication that the model involves primarily serotonergic mechanisms is supported by the observation that the effects of subchronic treatment with imipramine and mianserin were reversed by acute administration of the 5-HT_2 receptor antagonist metergoline (Broekkamp *et al.*, 1980).

Although pharmacologically specific for antidepressants, the face validity of the olfactory bulbectomy model appears slight. Unlike the stress models, the bulbectomized rat resembles an agitated hyposerotonergic, rather than a retarded, depression (Lumia *et al.*, 1992), but beyond hyperactivity, it is difficult to discern any further points of behavioural resemblance. Indeed, increased irritability and aggression together with exaggerated reactivity to auditory and tactile stimulation may reflect additional septal damage. Nevertheless, bulbectomized rats do resemble depressed humans on a surprisingly wide range of peripheral neurochemical and immunological markers, such as abnormalities of platelet 5HT transport and neutrophil phagocytosis (Leonard, 1991).

PHARMACOLOGICAL SCREENING TESTS

Finally, we mention briefly some older tests, now little used, based on interactions between antidepressants and a range of other pharmacological agents. Generally speaking, the predictive validity of these tests is poor, and their face and construct validity as simulations of depression is minimal or zero.

Reserpine and Tetrabenazine Reversal

The rationale behind the reserpine model of depression is from clinical observations of patients treated with reserpine for hypertension who subsequently developed signs of depressive illness. Later observations indicated that the symptoms induced by reserpine in laboratory animals (including ptosis, hypothermia and sedation) were due to depletion of central monoamines. It is generally accepted that an ability to reverse the reserpine syndrome is due to reduced inactivation of central monoamines, either by inhibiting monoamine reuptake or by inhibiting the enzyme monoamine oxidase. Indeed, the classical TCAs in use today were developed on the basis of their positive effects in this model. False negatives include iprindole, mianserin, rolipram and SSRIs, while false positives include stimulants, anticholinergics and analgesics. This model possesses little or no face or construct validity to depression. Even so, it is still used in drug development although its use is largely limited to confirmation of pharmacological activity, in relation to monoamine reuptake inhibition (Rogoz *et al.*, 1999a, b; Wong *et al.*, 2000) and MAOI activity (e.g. Caille *et al.*, 1996; Iwata *et al.*, 1997; Kato *et al.*, 1998).

Tetrabenazine is chemically related to reserpine and likewise depletes central, although not peripheral, stores of NA and 5-HT. It therefore similarly induces sedation and hypothermia. Consequently the validity profile of this model is no better than that of reserpine. It is still used in drug development but, again, simply to confirm pharmacological activity (e.g. Darias *et al.*, 1999; Ferris *et al.*, 1995).

5-HTP Potentiation

5-Hydroxytryptophan (5-HTP) is the immediate precursor of 5-HT, and the consequences of 5-HTP loading in animals are behaviours associated with 5-HT excess (hypothermia, sedation, head-twitch response), which may be potentiated by drugs which attenuate 5-HT inactivation. As with other pharmacological screening tests this model has no validity as a model of depression, and is largely employed in mechanistic studies to confirm pharmacological activity (Ferris *et al.*, 1995; Porsolt, *et al.*, 2000).

Yohimbine Potentiation

Yohimbine preferentially inhibits presynaptic α_2-adrenoceptors, so increasing the release of NA and causing behavioural excitation and increased heart rate and blood pressure. A combination of increased NA release together with reduced NA inactivation following antidepressant treatment results in a lethal cocktail and it is this phenomena that is employed in this test. Almost all antidepressants potentiate the lethal effects of yohimbine, but how such effects are related to depressive illness is unclear, and the test has no validity as a model. As with other pharmacological screening models, the use of yohimbine potentiation is primarily limited to mechanistic studies (e.g. Eguchi *et al.*, 1997).

Apomorphine and Clonidine Antagonism

On acute treatment, some antidepressants, including TCAs, NA reuptake inhibitors, the SNRI venlafaxine (Redrobe *et al.*, 1998) and β-adrenoceptor agonist drugs, antagonize the hypothermia induced by a single high dose of apomorphine (Puech *et al.*, 1981). On chronic treatment, TCAs, MAOIs and some atypical drugs antagonize the hypolocomotion and/or hypothermia induced by a single dose of clonidine (e.g. Kostowski and Malatynska, 1983; Kostowski and Obersztyn, 1988; von Voigtlander *et al.*, 1978). False positives in both cases include the psychostimulants amphetamine, *p*-chloro-methyl-amphetamine (PCA) and L-dihydroxyphenylalanine (L-DOPA), while MAOIs, SSRIs and atypical drugs are generally inactive (Maj *et al.*, 1986; Pawlowski and Mazela, 1986).

Potentiation of Apomorphine- and Clonidine-Induced Aggression

Acute treatment of rats with apomorphine or of mice with clonidine increases aggressive behaviour. Prior chronic, but not acute, treatment with antidepressants usually potentiates apomorphine- or clonidine-induced aggression (Maj, 1984; Maj *et al.*, 1979, 1980, 1981, 1982). False negatives in these tests include the SSRIs (e.g. Matto *et al.*, 1998a), while false positives include examples of 5-HT antagonists and neuroleptics (Maj, 1984; Maj *et al.*, 1982). The aggressive behaviour induced by daily administration of apomorphine was attenuated by acute treatment with trazodone at non-sedative doses, which had little or no effects on forced swim behaviour or on levels of anxiety, while chronic treatment with trazodone slowed the development of apomorphine-induced aggression (Rudissaar *et al.*, 2001). Other studies (e.g. Matto *et al.*, 1998b) suggest that 5-HT reuptake inhibition has no major effect on apomorphine-induced aggressive behaviour. Available data for clonidine-induced aggression are rather equivocal (e.g. Rogoz *et al.*, 1999a, b) although this behaviour was potentiated by venlafaxine (Maj and Rogoz, 1999). The predictive validity of these tests is limited, and their face and construct validity, non-existent.

EVALUATION

Table XVIII-1.1 presents a summary of the models surveyed, showing our evaluation of each model against the accepted validation criteria. (The pharmacological screening tests are excluded, as they have little or no validity on any of the criteria.) The first three columns score each model on a scale of 0 to 3, using the following scoring system:

0	no positive evidence, or no excess of positive evidence over negative
+	small amount of positive evidence or small excess of positive evidence over negative
++	moderate amount of positive evidence or large excess of positive evidence over negative
+++	large amount of positive evidence, with little or no negative evidence

(A score of 3 does not, however, imply, that there is no room for improvement.) The fourth column presents an overall validity estimate arrived at by summing across columns 1–3.

It should be borne in mind that these judgements to some extent reflect the authors' subjective impressions, and they should not be taken too seriously.

With this caveat, we draw the following conclusions:

1. Easily ahead of the pack, the CMS model scores a maximum 9, against a highest score of 5 for any of the other models. We reiterate, however, that this strength is to some extent offset by the limited reliability of the procedure.

Table XVIII-1.1 Evaluation of animal models of depression

Animal model	Validity				Evaluation		Sensitivity to chronic drug treatment
	PV	FV	CV	Sum	Depression	Melancholia	
Stress models							
Acute stress models							
Learned helplessness	++	++	+	5	++	++	+
Forced swim	++	0	0	2	+	0	0
Tail suspension	++	0	0	2	+	0	0
Restraint stress	+	+	0	2	+	0	+
Chronic stress models							
Chronic severe stress	+	++	+	4	++	+	++
Chronic mild stress	+++	+++	+++	9	+++	+++	+++
Induction and maintenance	+	++	++	5	++	++	0
Psychostimulant withdrawal	+	+	+	3	+	+	+
Social dominance models							
Social defeat	+	+	+	3	+	+	+
Social hierarchy	+	++	++	5	++	0	+++
Resident–intruder	+++	+	+	5	++	0	+++
Social isolation models							
Neonatal isolation	+	++	+	4	++	0	+
Adult isolation	+	+	+	3	+	0	+
Diathesis models							
Genetic models							
Muscarinic hypersensitivity (FSL)	+	++	0	3	+	+	0
Roman Low-Avoidance	0	0	0	0	0	0	0
Fawn-Hooded	+	+	0	2	+	0	+
Genomic models							
HPA transgenic	+	0	+	2	+	0	+
5-HT transporter knockout	0	0	0	0	0	0	0
CRH receptor subtypes knockouts	0	0	0	0	0	0	0
Tachykinin receptor knockout	0	0	0	0	0	0	0
Developmental models							
Neonatal antidepressant treatment	0	++	+	3	+	0	0
Prenatal/neonatal stress	0	+	0	1	0	0	0
Waiting behaviour	++	0	0	2	+	0	0
Lesion model							
Olfactory bulbectomy	++	+	+	4	++	0	++

PV, predictive validity; FV, face validity; CV, construct validity; sum = PV + FV + CV.
See text for an explanation of the scoring system.

2. High overall scores (4–5) are achieved by models from all of the groups classified as 'stress' models, but by only one of the 'diathesis' models, olfactory bulbectomy.
3. This means that the genetic, genomic and developmental models all require further development. In the case of genomic models in particular, it would not be surprising to see this achieved rapidly.
4. Good predictive validity can be achieved in the absence of face and construct validity. Thus, scores of 2/3 for predictive validity are awarded to the forced swim, tail-suspension and waiting behaviour models, which score 0 elsewhere. (Note, however, that the high score for the forced swim test refers to the modification of this procedure introduced by Lucki and colleagues [e.g. Cryan and Lucki, 2000; Detke *et al.*, 1995], which responds to SSRIs. We would only award 1/3 to the traditional version of this test.)

The next two columns present estimates of the overall validity of each model, on a scale of 0–3, in relation to major depressive disorder, and to melancholia. We must emphasize that a score of +++ means only that a model performs better than those scored ++, which in turn perform better than those scored +; there is no implication that a model receiving a score of 3 cannot be improved. We also note that in some cases (e.g. social defeat) the low score reflects a paucity of positive evidence, rather than the presence of negative evidence. In making the overall estimates, we have weighted face and construct validity a little more highly than predictive validity. In estimating validity with respect to melancholia we have weighted the available information in relation to the specific feature of melancholia. Again, the CMS model stands out as the only model receiving a +++ rating in both categories. Seven further models perform relatively well as simulations of depression (score ++): learned helplessness, chronic severe stress (note, however, that ethical considerations would usually rule this model out of use), the induction and maintenance model, social hierarchy, resident–intruder test, neonatal isolation, and olfactory bulbectomy. Two of these models, learned helplessness and induction and maintenance, also perform well as models of melancholia. It should also be noted that the simple metric used to compute the overall ratings does not take account of discrepancies between the different components of the assessment. In particular, the ++ rating for the resident–intruder model derives largely from the excellent predictive validity of this model, face and construct validity being very limited.

The final column evaluates each model against the criterion that is central to current efforts in drug development, sensitivity

to chronic drug treatment, by which we mean that the model responds to chronic, but not acute, treatment with conventional antidepressants. The importance of this feature is that only when a model displays a gradual onset of action is it possible to detect a more rapid onset. The estimates in the table are conservative, in the sense that some of the models (e.g. induction and maintenance) have the capability, potentially, to demonstrate a gradual onset of action, since they have an extended time course, but this has not yet been investigated. The three models for which the clearest evidence for gradual onset of action has been obtained are CMS, social hierarchy and the resident–intruder test.

SIMULATIONS OF DEPRESSIVE ILLNESS VERSUS DRUG SCREENING TESTS

While the focus of this chapter has been on the development of simulations of depression, to be used as research tools, many of the same behavioural models are also used for drug development purposes. The universal use of cheap, quick drug screening tests by the pharmaceutical industry since the beginning of the 1970s resulted in a large array of antidepressant drugs being discovered, all of which have pharmacological and therapeutic profiles qualitatively similar to that of the archetypal TCA, imipramine, or MAOI, isoniazid. Unfortunately, the success of such acute treatment screening tests (e.g. the pharmacological procedures reviewed, or the forced swim test) not only restricted the development of animal models with improved face and construct validity, but has also largely been responsible for delaying the development of animal models in which antidepressants are active only following their chronic administration. The majority of models used routinely as antidepressant screening tests, and which respond acutely to drug treatment, are of no value in the drive to identify rapid-onset antidepressant drugs and are of limited or minimal validity as simulations of depression (cf. Willner, 1984). Generally, the use of drug screening models has simply resulted in the identification of further 'me-too' compounds (compounds of novel chemical structure whose acute pharmacological profile is similar to that of compounds already available to the clinician), provides no information on speed of onset of desirable drug activity, has been of very limited use in furthering our knowledge of the mechanisms associated with the psychopathology of depressive illness or adaptive changes associated with the recovery process from depression, and has largely failed to identify novel mechanisms and targets for future drug discovery.

In order to ascertain whether views within the pharmaceutical industry are changing, one of us (P.W.) conducted a small survey, which was carried out in the summer of 1999. A total of 28 questionnaires were sent out to companies with a known interest in CNS pharmacology, asking about the use of 12 named behavioural tests in antidepressant development, and the respondent's level of confidence in the outcome of each test. Assurances were given about anonymity, confidentiality and the absence of any commercial interest on the part of the investigator. Fourteen replies (50%) were received, of which twelve provided usable data. Six tests were reported to be in routine use by six or more (i.e. >50%) of the respondents: forced swim test in rats and mice, tail-suspension test, CMS; DRL-72s, and social separation. The first five of these tests are evaluated here (Table XVIII-1.1) as providing reasonably good predictive information, while varying considerably in their validity as simulations of depression. (The sixth test, social separation, performs less well, but it was realized subsequently that different companies were using very different tests under this general heading, none of which alone met the 50% criterion.)

Confidence in a positive outcome that a novel agent detected by the model would be an effective antidepressant in clinical trials was rated on a scale of 0 (not at all confident) to 6 (totally confident). All of the models achieved a mean rating of 3, with the exception of CMS, which was rated 5. It would appear that drug industry scientists are well aware of the literature summarized in Table XVIII-1.1.

It has traditionally been a major consideration in the design of antidepressant screening tests that they respond to acute or subacute drug administration. As a direct consequence, they are incapable, by virtue of their design, of responding to the major current challenge of discovering new antidepressants that have a shorter onset of action. By contrast, it is implicit in their protracted time course that chronic realistic animal models do have the capacity to detect a rapidly acting novel antidepressant. In fact, most pharmaceutical companies have now abandoned the high-volume, random screening approach in favour of the development of a small number of compounds specifically designed to meet predetermined pharmacological criteria. In such a programme, the place of behavioural screening methods shifts from the discovery phase to the development phase, and the logistical disadvantages of using complex, chronic models are small, relative to the costs of testing an ineffective drug in the clinic.

WHERE NEXT?

We conclude with some comments on likely future developments in this area. The greatest immediate contribution of animal models of depression is likely to be in relation to the elucidation of the mechanisms of action of antidepressant drugs. Thirty years of clinical experience has given rise to two widely accepted axioms: that only rarely do antidepressants cause discernible clinical improvement within the first two weeks of treatment, and that they are devoid of mood-elevating effects in normal human subjects. The clinical requirement for chronic treatment regimes has led to a considerable literature describing the effects of chronic antidepressant administration in normal animals, and numerous changes in pre- and/or postsynaptic receptor function have been reported, in a variety of systems. These descriptive studies are an essential first step towards establishing mechanisms of antidepressant action. However, the inability to determine which of the many effects of antidepressants are responsible for their therapeutic actions constitutes a fundamental limitation of this approach, which has not been widely recognized. The development of chronic animal models, in which an abnormal state is induced and maintained for a prolonged period during which 'therapy' can be administered, provides a powerful methodology for investigating these problems.

Although they have as yet made little impact, it is to be expected that genomic models will play a significant role in these developments. However, it will be important not to lose sight of the fact that genetic and genomic models are mostly of relevance to depressive diatheses. Studies in which valid and realistic models of depressive diatheses are combined with valid and realistic stress models are awaited with interest.

XVIII-2

Monoaminergic Transmitter Systems

Alexander Neumeister and Dennis S. Charney

INTRODUCTION

There is considerable evidence available in the literature supporting the idea that brain monoamine systems play a key role in the pathogenesis of affective disorders, in particular depression. These hypotheses have primarily taken the form of proposing abnormal regulation in serotonin (5-HT) (Coppen, 1967) and the catecholamines norepinephrine (NE) (Bunney and Davis, 1965; Schatzberg and Schildkraut, 1995) and dopamine (DA) (Kapur and Mann, 1992)in depression. Early studies have focused largely on levels of monoamines and their receptors and have stimulated several theories about the pathophysiology of depression, including the monoamine deficiency and receptor sensitivity hypotheses. However, we have to acknowledge today that these hypotheses have not provided us with an ultimate explanation about the role of monoamines in depression. Nor can the pathophysiology of depression be explained simply by dysregulation of 5-HT and/or NE or DA transmission. Recent advances in molecular and cellular neurobiology have offered new insights into mechanisms possibly involved in the pathophysiology of depression, and also into the mechanisms of action of antidepressant treatment modalities (for reviews see Duman *et al.*, 1997; Manji *et al.*, 2001; Sulser, 1989). These studies have shown that chronic antidepressant treatment regulates intracellular signal transduction pathways and the expression of specific target genes.

The purpose of this chapter is to provide a concise review of clinical studies on the role of 5-HT and NE transmission in depression. However, several caveats need to be considered. First, depression is not a homogeneous disorder, and classifying a given patient with depression is a clinical decision and remains a subjective interpretation of a syndrome, even though the decision should be based on established diagnostic criteria such as DSM-IV criteria (American Psychiatric Association, 1994). However, identifying homogeneous groups of patients with depression has proven to be a virtually impossible task. This might explain some of the variability of biological findings in depression and the lack of consistent replication of many intriguing findings. Second, almost all patients being studied in clinical studies have been exposed to different pharmacological and non-pharmacological treatments before entering studies. This may confound the results of clinical and preclinical studies. Finally, there is no methodological homogeneity in processing experimental samples and assays. It is remarkable that despite these methodological problems a number of neurochemical findings have been replicated in the past in patients with depression and have provided researchers with insight into the underlying biology of this devastating illness.

SEROTONIN

Serotoninergic neurons are located in the brainstem where they can project to virtually every part of the central nervous system, often modulating neuronal responses to other neurotransmitters. As a result of this widespread projection pattern, 5-HT is known to be involved in the regulation of a wide variety of functions, including mood, anxiety, aggression, sleep, arousal, appetite and sexual function. However, it has to be acknowledged that the precise details of the mechanisms involved are not fully understood. Interest into the potential role of 5-HT in the pathophysiology of psychiatric disorders was spurred by the observation that hallucinogens such as lysergic acid diethylamide and psilocybin inhibit the peripheral actions of 5-HT. This led to the hypothesis that brain serotonergic function might be altered in patients with psychiatric disorders (Gaddum and Hameed, 1954; Wooley and Shaw, 1954). Further evidence for the importance of serotonergic mechanisms in depression was inferred by the observation that imipramine improved mood and boosted psychomotor activity (Kuhn, 1958). This initial observation of the antidepressant properties of imipramine led to more intensive testing in clinical trials of this compound and later the other tricyclic antidepressants and monoamine oxidase inhibitors for the treatment of depression. The results from these clinical trials, indicating that the action of antidepressant drugs involves enhancement of brain serotonergic activity, and further evidence for dysfunction at multiple levels in the serotonergic system of depressed patients culminated in the 'serotonin hypothesis' of depression (Maes and Meltzer, 1995). Whether this serotonergic dysfunction is the primary cause of depression or is a necessary risk factor remains unclear and is the subject of intensive research.

Seasonality of Serotonergic Function

One factor that has to be considered when evaluating the potential role of 5-HT in depression is the seasonal variation in central and peripheral 5-HT function in humans. There is considerable evidence in the literature suggesting a seasonal variation in several phenomena, such as mood, feeding behaviour and suicide, and that these phenomena may be related to changes in central and peripheral 5-HT function (Maes *et al.*, 1995). In healthy subjects and non-psychiatric patients several studies have described seasonal variations in central and peripheral 5-HT function. Studies of humans distinguish whether measures are static (e.g. biochemical levels in body fluids or blood elements) or dynamic (e.g. neuroendocrine responses to pharmacologic challenges).

Several lines of evidence based on static measures support the hypothesis of seasonal fluctuations of 5-HT function in humans: (1) hypothalamic 5-HT concentrations in human post-mortem brain specimens are decreased in winter after values peak in autumn (Carlsson *et al.*, 1980), (2) levels of plasma tryptophan, the precursor of 5-HT, show a bimodal seasonal pattern (Maes *et al.*, 1995), (3) platelet 5-HT uptake and ^{3}[H]-imipramine binding show a seasonal pattern, albeit with some differences in seasonal peaks and troughs (Arora and Meltzer, 1988; DeMet *et al.*, 1989; Tang

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

and Morris, 1985; Whitaker *et al.*, 1984), (4) levels of 5-HT and its metabolites in cerebrospinal fluid show seasonal fluctuations, varying with latitude and population studied (Asberg *et al.*, 1981; Brewerton *et al.*, 1988), (5) serum melatonin concentrations demonstrate summer and winter peaks in healthy males (Arendt *et al.*, 1977), and (6) recently Neumeister *et al.* (2000) reported *in vivo* a significant reduced availability of hypothalamic 5-HT transporter sites in winter compared with summer in healthy female subjects (Figure XVIII-2.1).

There are few reports in the literature about seasonal variations in 5-HT function using dynamic measures. Joseph-Vanderpool *et al.* (1993) report a seasonal variation in behavioural responses to the administration of *meta*-chlorophenylpiperazine (mCPP) in patients with SAD, with higher 'activation/euphoria' scores in SAD patients during winter compared with summer or after successful light therapy. More recently, Cappiello *et al.* (1996) demonstrated a seasonal variation in neuroendocrine (prolactin) responses to intravenous tryptophan administration in unipolar, non-melancholic depressed patients. Interestingly, seasonality was more pronounced in female than in male patients. No such seasonal variability was found in bipolar, melancholic or psychotic patients or in healthy controls.

Altogether, substantial evidence is published in the literature arguing for a seasonal variation of central and peripheral 5-HT function in patients suffering from depression and also in healthy controls. Thus, we can hypothesize that seasonality of central and peripheral 5-HT function is physiological. It is not clear whether seasonal 5-HT fluctuations may represent a predisposing factor for depression with and without a seasonal pattern. It has to be said that the variability in the specific seasonal peaks and nadirs reported by different research groups reflects the use of different study designs, methodologies, sample sizes and measures of 5-HT function. Consequently, further studies are needed to clarify the role of seasonal variations in central and peripheral 5-HT function in the regulation of human behaviour and in the pathogenesis of mood disorders.

Tryptophan-Depletion Studies

The situation regarding how to evaluate the potential role of 5-HT in depression has been hampered by the fact that, until recently, it has not been possible to measure brain 5-HT directly, which means that researchers had to rely on indirect evidence for the involvement of this transmitter in the pathogenesis of depression and its role in antidepressant treatment modalities. Over the past few years, neurotransmitter depletion paradigms have provided another means of examining the potential role of 5-HT systems in the pathophysiology of depression and their role in pharmacological and non-pharmacological treatment modalities for depression.

The aim of tryptophan depletion is to lower brain 5-HT by depleting its precursor tryptophan. Most of the tryptophan in plasma is protein-bound, with only about 5% being left free and available to be transported into the brain across the blood–brain barrier by an active protein shuttle for which five other large amino acids (valine, leucine, isoleucine, phenylalanine and tyrosine) also compete. Once in the brain, the initial step in the biosynthesis of 5-HT is the conversion of L-tryptophan to 5-hydroxytryptophan, a reaction catalysed by the rate-limiting enzyme tryptophan hydroxylase (Fernstrom, 1983). The Michaelis constant for tryptophan hydroxylase is higher than tryptophan concentration in the brain, suggesting that under physiological conditions the activity of this enzyme is limited by the availability of the substrate (Friedman *et al.*, 1972). Animal studies have shown that the synthesis and content of 5-HT in rat brain vary in parallel with brain tryptophan concentrations (Fernstrom and Wurtman, 1971). Moreover, it has been shown that increase in brain tryptophan concentration raises 5-HT release *in vitro* (Auerbach and Lipton, 1985; Schaechter and Wurtman, 1989) and *in vivo* (Carboni *et al.*, 1989; Sharp *et al.*, 1992), although some studies disagree with these findings (Elks *et al.*, 1979; Marsden *et al.*, 1979). In summary, the concentration of brain 5-HT depends upon the availability of its precursor tryptophan.

Preclinical data show that the acute administration of a tryptophan-free amino acid mixture of essential amino acids produces a rapid and substantial decrease in plasma tryptophan levels, associated with a decrease in brain tryptophan, brain 5-HT and 5-HIAA levels in rats (Gessa *et al.*, 1974). Studies in humans show profound decreases of plasma tryptophan levels (Bell *et al.*, 2001; Moore *et al.*, 2000; Neumeister *et al.*, 1997b) and cerebrospinal fluid levels of 5-HIAA (Carpenter *et al.*, 1998; Moreno *et al.*, 2000b; Williams *et al.*, 1999) after oral administration of an amino acid mixture without tryptophan (Table XVIII-2.1).

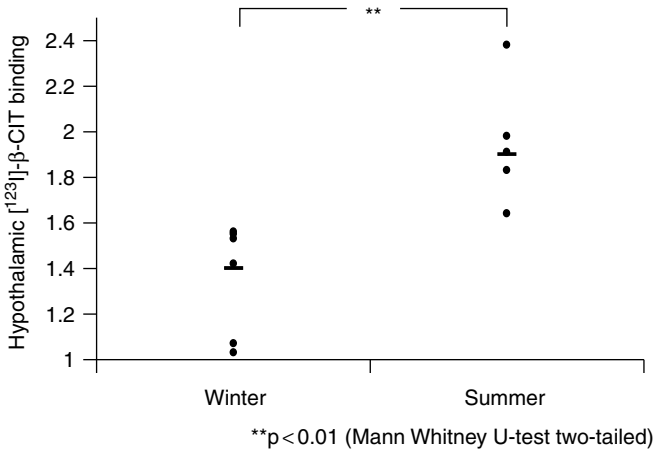

Figure XVIII-2.1 Hypothalamic serotonin transporter availability is significantly reduced in winter compared with summer in healthy female controls, as studied *in vivo* using [^{123}I]-β-CIT single photon emission computed tomography (SPECT) (Neumeister *et al.*, 2000)

Table XVIII-2.1 Amino acids used for tryptophan depletion versus sham depletion

Makes one beverage	
L-Alanine	5.5 g
Glycine	3.2 g
L-Histidine	3.2 g
L-Isoleucine	8.0 g
L-Leucine	13.5 g
L-Lysine	11.0 g
L-Phenylalanine	5.7 g
L-Proline	12.2 g
L-Serine	6.9 g
L-Threonine	6.9 g
L-Tyrosine	6.9 g
L-Valine	8.9 g
L-Methionine	12.0 g
L-Arginine	19.6 g
L-Cysteine	10.8 g
During sham depletion the beverage contains additional amino acid:	
L-Tryptophan	2.3 g

Three mechanisms appear to be responsible for the transient decrease in brain 5-HT activity during tryptophan depletion: (1) the amino acid mixture (Table XVIII-2.1) that is given to the subjects during tryptophan depletion stimulates protein synthesis in the liver, which uses up plasma tryptophan, (2) the amino acid mixture contains large amounts of the other neutral amino acids, which compete with tryptophan for the transport across the blood–brain barrier and thus restrict uptake of tryptophan into the brain and (3) a recent study showed an increase of plasma neopterin levels induced by tryptophan depletion (Stastny *et al.*, submitted). It has been shown that increased neopterin levels may facilitate catabolism of free plasma tryptophan, possibly via an interferon γ-induced activation of the tryptophan-cleaving cellular enzyme indoleamine 2,3-dioxygenase (Mellor and Munn, 1999). These mechanisms lead to the rapid and substantial, albeit transient, reduced synaptic availability of 5-HT in the brain.

The value of a depletion paradigm depends on whether the method is reliable, reversible and specific. All three issues have been addressed in several studies and have shown that the tryptophan-depletion method fulfils all three requirements for a meaningful research tool (Delgado *et al.*, 1990; Ellenbogen *et al.*, 1996; Moja *et al.*, 1989; Smith *et al.*, 1987). In particular, studies in monkeys (Young *et al.*, 1989) and humans (Moreno *et al.*, 2000b; Neumeister *et al.*, 1998c) showed that tryptophan depletion did not change the metabolism of other neurotransmitters, whereas levels of tryptophan and 5-HIAA in plasma and cerebrospinal fluid, respectively, were lowered. Thus, if the effects of tryptophan depletion can be attributed to changes in a transmitter system in the brain, it is probably 5-HT systems that are affected.

Tryptophan-Depletion Studies in Healthy Subjects

Studies of tryptophan depletion in healthy subjects have shown conflicting results. Healthy male subjects with their baseline ratings of depression in the upper normal range exhibit a transient worsening of their mood during tryptophan depletion, although never amounting to clinical depression (Smith *et al.*, 1987; Young *et al.*, 1985). In contrast, healthy male subjects who were euthymic at baseline and who were rigorously screened for any psychiatric or somatic illness remained unaffected by tryptophan depletion (Abbott *et al.*, 1992). Healthy male controls with a multigenerational family history for major affective disorders reported a greater reduction in mood induced by tryptophan depletion than healthy controls without a positive family history (Benkelfat *et al.*, 1994). Tryptophan-depletion studies in female subjects with no personal history of depression showed an increased risk to develop depressive symptoms during tryptophan depletion. In some tryptophan-depletion studies in healthy female controls family histories of affective disorders were assessed and were positive (Klaassen *et al.*, 1999), negative (Ellenbogen *et al.*, 1996; Klaassen *et al.*, 1999), or unknown (Weltzin *et al.*, 1995). These studies showed consistently an increased risk for an exacerbation of depressive symptoms during tryptophan depletion with more pronounced effects when the family history for affective disorders is positive. This is supported by a recent study in unaffected relatives of patients with bipolar affective disorders, who experience a transient lowering of their mood after tryptophan depletion (Quintin *et al.*, 2001). However, another study reported no mood-lowering effects of tryptophan depletion in healthy females with a negative family history of depression (Delgado *et al.*, 1989), and several studies report no mood-lowering effects of tryptophan depletion in healthy female subjects (Salomon *et al.*, 1997; Voderholzer *et al.*, 1998).

Other studies have focused on the memory and cognitive effects of tryptophan depletion, and have shown that tryptophan depletion impairs long-term memory formation and interferes with the process of memory consolidation (Riedel *et al.*, 1999; Schmitt *et al.*, 2000). It is noteworthy that tryptophan depletion did not affect other measures of frontal functioning. Sleep disturbances represent another key symptom of depression, so studies have been conducted to determine whether tryptophan depletion is capable of inducing sleep abnormalities, including changes in sleep continuity or architecture. Studies reported reduced REM latency after tryptophan depletion (Bhatti *et al.*, 1998; Moja *et al.*, 1979), but not unequivocally (Voderholzer *et al.*, 1998). The combination of tryptophan depletion plus administration of the 5-HT1A receptor agonist ipsapirone produced a significant suppression of REM sleep whereas tryptophan depletion alone did not significantly alter any REM sleep measure (Moore *et al.*, 2001). This differs markedly from the consistent tryptophan-depletion-induced REM-disinhibiting effect seen in medicated depressed patients. Another area of interest is whether reduced 5-HT activity during tryptophan depletion results in increased aggression since reduced brain serotonergic activity is believed to be associated with aggressive behaviour. It was shown that tryptophan depletion induces a rise in ratings of aggression in subjects with high-trait aggression but has little effect in those with low-trait aggression (Bjork *et al.*, 2000). Another study found an association between decreased serotonergic transmission and increased aggression in women who have been studied during the late luteal phase of their menstrual cycle (Bond *et al.*, 2001). Significantly, acute ethanol consumption may be associated with a decrease in tryptophan availability, and may induce aggressive behaviour in susceptible individuals (Badawy *et al.*, 1995).

Behavioural responses to tryptophan depletion in healthy subjects show a high variability. There are subgroups of subjects who appear to be at a greater risk to develop depressive symptoms during tryptophan depletion. Possible explanations include a positive family history of depression, gender and possibly high, albeit not reaching the levels of clinical depression, baseline ratings of depression. Studies that have included men and women have reported a gender difference, with a tendency for tryptophan depletion to produce more prominent mood-lowering effects in women, despite similar effects of tryptophan depletion on plasma tryptophan levels. This suggests that women may be more susceptible to the effects of tryptophan depletion than men. This is of particular interest considering the results of a positron emission tomography study of humans showing gender differences in 5-HT metabolism, with tryptophan depletion producing greater biochemical effects in women than in men (Nishizawa *et al.*, 1997). However, it has to be acknowledged that uptake of alpha-methyl L-tryptophan is not clearly established as a reliable indicator of 5-HT synthesis.

An intriguing finding is the association between the allelic distribution of the serotonin transporter gene promoter polymorphism (5-HTTLPR) and the behavioural responses to tryptophan depletion in a group of healthy women with and without family history of depression (Neumeister *et al.*, in press). The study showed subjects with the short allele of the 5-HTTLPR at increased risk to develop depressive symptoms during tryptophan depletion relative to subjects who are homozygous for the long allele. Future epidemiological studies will have to confirm the relevance of this finding, and will answer the clinically and scientifically relevant question as to whether the short allele of the 5-HTTLPR polymorphisms is associated with an increased risk for developing depression, as the authors had hypothesized. Brain imaging studies may be helpful in studying the underlying neural processes.

Tryptophan-Depletion Studies in Depression

To test the hypothesis that decreased 5-HT function is associated with depression, several studies were performed including untreated, symptomatic depressed patients prior to initiation of an antidepressant treatment (Delgado *et al.*, 1994; Neumeister *et al.*,

1997c; Price *et al.*, 1997, 1998). It was hypothesized that tryptophan depletion would lead to an exacerbation of the depressive syndrome. However, the results of these studies were somewhat unexpected. Consistently, it was shown that tryptophan depletion did not exacerbate depressive symptoms in these subjects. Remarkably, in two studies (Delgado *et al.*, 1994; Price *et al.*, 1998) some patients showed an improvement of their condition on the day after tryptophan depletion. The failure to aggravate depression by depleting brain 5-HT can be explained by the hypothesis that brain 5-HT function is already maximally dysfunctional in depressed patients and thus further lowering of 5-HT activity has no further effects on depressive symptoms. Alternatively, it can be hypothesized that disturbed 5-HT function does not explain the biological basis of depression, and that there is no direct relationship between severity of depressive symptoms and brain 5-HT function. A possible explanation for the improvement in symptoms the day after tryptophan depletion is an upregulation of postsynaptic 5-HT receptors because of the decreased release of 5-HT at the synapse during tryptophan depletion. Typically, 5-HT levels are restored the day after tryptophan depletion and the net effect is an enhancement of brain 5-HT function, resulting in an improvement of the patient's condition.

A recent study (Berman *et al.*, in press) evaluated whether combined tryptophan depletion and catecholamine depletion compared with tryptophan depletion and sham depletion would aggravate the depressive syndrome in unmedicated, symptomatic depressed patients. The authors report a progressive decrease in Hamilton depression scores in both groups with no difference between the combined monoamine-depletion group and the tryptophan-depletion group. This finding that simultaneous disruptions of 5-HT function and catecholamine function do not exacerbate depressive symptoms in untreated symptomatic depressed subjects supports the hypothesis that monoamines have an indirect role in regulating mood in actively depressed patients.

Intensive research using tryptophan depletion has been done during the past few years to study the role of 5-HT in the mechanism of action of antidepressant drugs, and non-pharmacological treatments for depression, such as light therapy and sleep deprivation. The hypothesis of these studies was that antidepressant treatments lead to an enhancement of brain 5-HT function and that tryptophan depletion will disrupt the antidepressant effects. This has now been tested in multiple studies, and researchers have found that tryptophan depletion reverses the antidepressant effects of antidepressant medications, in particular of agents with a predominantly serotonergic mode of action (Aberg-Wistedt *et al.*, 1998; Bremner *et al.*, 1997; Delgado *et al.*, 1990, 1999; Spillmann *et al.*, 2001). It should be noted, however, that tryptophan depletion causes clinically relevant symptoms only in about 50–60% of the patients, and one study reported no mood effects of tryptophan depletion at all (Moore *et al.*, 1998). However, the majority of studies clearly demonstrated that the depressive symptoms evoked by tryptophan depletion were often similar to those the patients had experienced during their depressive episode. As noted above, the behavioural responses to tryptophan depletion were substantially more prominent in subjects who had been successfully treated with selective 5-HT reuptake inhibitors (SSRIs) relative to the responses in those subjects who had responded to a treatment with noradrenergic antidepressants (Delgado *et al.*, 1999; Miller *et al.*, 1996a). This finding, and the finding that catecholamine depletion predominantly induces a depressive relapse in subjects treated with noradrenergic antidepressants, suggests that enhanced serotonergic or noradrenergic transmission is necessary to maintain the antidepressant responses to SSRIs or noradrenergic agents, respectively (Figure XVIII-2.2). Other variables that may affect the reoccurrence of depressive symptoms during tryptophan depletion are the length of the remitted state of the patient, with a greater likelihood of depressive symptom exacerbation when the duration of remission

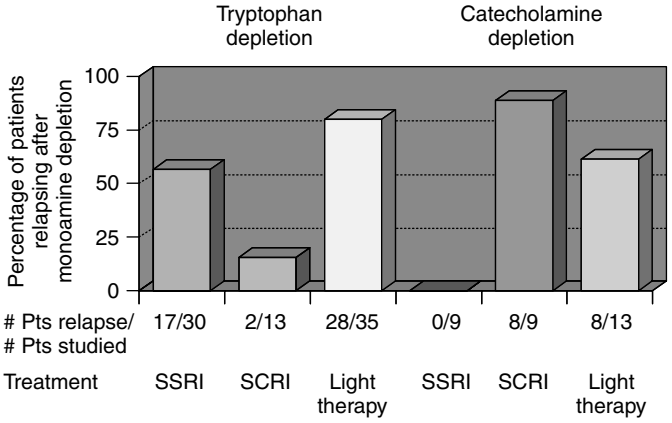

Figure XVIII-2.2 Tryptophan depletion induces a depressive relapse predominantly in patients remitted on selective serotonin reuptake inhibitors (SSRIs), but not in patients remitted on selective catecholamine reuptake inhibitors (SCRIs). In contrast, catecholamine depletion induces an exacerbation of depressive symptoms in patients remitted on SCRIs but not in patients remitted on SSRIs. Patients remitted on light therapy show a depressive relapse in both, tryptophan depletion and catecholamine depletion

is short, the number of previous depressive episodes, and the pattern of response to the antidepressant treatment. Patients who responded to treatment with placebo seem to be less vulnerable to the effects of tryptophan depletion than 'true' drug responders. This suggests that antidepressants induce biological changes in the neuron that make the subjects less vulnerable to acute changes in brain 5-HT function.

Non-pharmacological, albeit biologically based, treatments for depression include light therapy and sleep deprivation. Light therapy is the treatment of first choice for patients suffering from seasonal depressions during autumn and winter, and has been shown to be effective in non-seasonal depression when given in conjunction with other antidepressant treatment modalities (Neumeister *et al.*, 1999b). Tryptophan depletion (Neumeister *et al.*, 1997a, 1998c) and catecholamine depletion (Neumeister *et al.*, 1998c) reversed the antidepressant effects of light therapy, suggesting that both transmitter systems are involved in the mechanism of action of light therapy. Several lines of evidence suggest that sleep deprivation exerts its antidepressant effects by enhancing serotonergic transmission. To test this hypothesis, patients who responded to a single night of total sleep deprivation underwent tryptophan depletion or sham depletion (Neumeister *et al.*, 1998b). It was expected that tryptophan depletion would reverse the antidepressant effects of sleep deprivation. Unexpectedly, tryptophan depletion did not reverse the antidepressant effects of sleep deprivation, but rather prevented the otherwise naturally occurring depressive relapse after the recovery night. The authors concluded that it seems to be unlikely that serotonin alone mediates the antidepressant effects of sleep deprivation; however, serotonergic mechanisms may play an important role.

The effects of tryptophan depletion in formerly depressed, fully remitted patients, off medication is of particular interest to understand the role of 5-HT in the pathogenesis of the disorder. It might be expected that these subjects are specifically vulnerable to the depressiogenic effects of tryptophan depletion. The majority of the studies (Moreno *et al.*, 1999; Neumeister *et al.*, 1998a; Smith *et al.*, 1997) reported a depressive relapse induced by tryptophan depletion whereas subjects remained well during sham depletion. However, two studies found no exacerbation of depression during tryptophan depletion (Lam *et al.*, 2000; Leyton *et al.*, 1997). These discrepancies may be explained by the differing

length of remission among the different studies, and by differing study populations. Furthermore, a recent study in remitted depressed patients shows, similar to the effects of antidepressant treatment, that tryptophan depletion is associated with a decrease in 5-HT_2 receptor binding (Yatham *et al.*, 2001). This might have explained the failure of tryptophan depletion to exacerbate depressive symptoms in this study. The depressive relapse induced by tryptophan depletion in remitted patients off therapy suggests that at least a subgroup of patients with depression remain vulnerable to changes in 5-HT function. Interestingly, two studies showed that the majority of subjects who relapsed during tryptophan depletion experienced further depressive episodes in the near future (Moreno *et al.*, 2000a; Neumeister *et al.*, 1999a). Thus, tryptophan depletion may be capable of predicting the future course of depression.

Altogether, tryptophan-depletion studies have been shown to provide a way of examining the role of 5-HT in the pathophysiology of depression and the mechanism of action of antidepressants. The behavioural responses to tryptophan depletion provide insight into the underlying biology of depression, and suggest that serotonergic mechanisms may play a key role in the disorder. Many questions remain unanswered but tryptophan depletion may be a research tool to study gene–environment interactions in the future, and therefore may lead to further understanding of the processes involved in the pathophysiology of depression.

Serotonin 1A Receptor Function in Depression

Most 5-HT receptors belong to the family of G protein-coupled receptors (GPCRs), a large group of proteins that transduce signals through coupling to guanine nucleotide-binding regulatory proteins. Serotonin receptors are classified into seven groups according to their ligand-binding affinity profiles, molecular structures and intracellular transduction mechanisms. The human 5-HT_1 receptor subfamily includes 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E} and 5-HT_{1F} receptors. Multiple lines of evidence suggest that 5-HT_{1A} receptor functions are abnormal in depression. The data supporting this hypothesis have been obtained by assessing neuroendocrine and temperature responses to 5-HT_{1A} receptor agonists in depressed subjects versus healthy controls (Lesch, 1992), measuring 5-HT_{1A} receptor density in brain tissue acquired post-mortem (Bowen *et al.*, 1989; Lopez *et al.*, 1998) and examining 5-HT_{1A} receptor functions in rats following administration of antidepressant drugs (Artigas *et al.*, 1996; Chaput *et al.*, 1991; Haddjeri *et al.*, 1998).

Human 5-HT_{1A} receptors are expressed presynaptically on 5HT cell bodies in the raphe (somatodendritic autoreceptors) and postsynaptically in other brain regions (Azmitia and Whitaker-Azmitia, 1991). In humans and monkeys, the density of 5-HT_{1A} receptors is very high in the raphe and parts of the hippocampal formation, high in hypothalamus, insula, temporal, cingulate and ventral prefrontal cortices, moderately high in occipital and parietal cortices, and very low in the cerebellum, striatum, thalamus and white matter. In the cortex, hippocampus and amygdala postsynaptic 5-HT_{1A} receptors are located on pyramidal cells and interneurons, and stimulation of these receptors generally inhibits glutamate-mediated depolarization of parent neuron (Azmitia and Whitaker-Azmitia, 1991; Sprouse and Aghajanian, 1988).

5-HT_{1A} autoreceptors constitute an important control point for serotonergic activity in the brain. Stimulation of presynaptic 5-HT_{1A} autoreceptors similarly inhibits the 5-HT neuron firing in the raphe, reducing 5HT release, and can reduce 5HT synthesis via inhibition of tryptophan hydroxylase (Briley and Moret, 1993; Chaput and de Montigny, 1988; Chaput *et al.*, 1986; Sprouse and Aghajanian, 1988). Postsynaptic 5-HT_{1A} receptors are also abundantly expressed by astrocytes and some other glia (Azmitia *et al.*, 1996). These 5-HT_{1A} receptors are expressed by the majority of astrocytes in frontal and limbic cortex, but essentially none of the astroglia in striatum, thalamus or cerebellum (Whitaker-Azmitia *et al.*, 1993). Stimulation of astrocyte-based 5-HT_{1A} sites causes astrocytes to acquire a more mature morphology and to release the trophic factor S-100B, which promotes growth and arborization of serotonergic axons (Whitaker-Azmitia and Azmitia, 1989; Whitaker-Azmitia *et al.*, 1990). S-100B is primarily released by astroglia in the developing brain, when it plays a role in the development of the serotonergic system. S-100B also plays a role in maintaining the cytoskeleton in adult animals by promoting tubulin polymerization and inhibiting PKC-mediated breakdown of microtubules (Azmitia, 1999). In addition, stimulation of neuron-based 5-HT_{1A} receptors inhibits PKA-mediated disassociation of the proteins comprising the tubulin polymers of the cytoskeleton. Administration of 5-HT_{1A} receptor antagonists, antibodies to S-100B or agents that deplete 5-HT all produce similar losses of dendrites, spines and/or synapses in adult and developing animals, effects which are blocked by administration of 5-HT_{1A} receptor agonists or SSRIs. The role of postsynaptic 5-HT_{1A} receptor function in maintenance of the cytoskeleton has led to the hypothesis that a reduction of 5-HT_{1A} receptor function may comprise a risk factor for the neuropathological abnormalities identified in limbic and paralimbic cortical areas in mood disorders (reduced cortex volume, reduced synaptic proteins, increased neuronal density, reduced glial counts) (Drevets, 2000; McEwen, 1999).

5-HT_{1A} Receptor Imaging in Depression

Positron emission tomography (PET) studies obtained *in vivo* show evidence of reduced pre- and postsynaptic 5-HT_{1A} receptor binding in depression. Drevets and colleagues (Drevets *et al.*, 1999) demonstrated that the mean 5-HT_{1A} receptor binding potential (BP) was reduced in the mesiotemporal cortex and raphe in unmedicated depressives relative to controls using PET and [*carbonyl*-^{11}C]WAY-100635. A similar reduction was evident in the parietal cortex, striate cortex and left orbital cortex/ventrolateral prefrontal cortex. These data were consistent with those of Sargent *et al.* (2000), who found decreased 5-HT_{1A} receptor BP in unmedicated depressives relative to healthy controls in the raphe, mesiotemporal cortex, insula, anterior cingulate, temporal polar cortex, ventrolateral prefrontal cortex and orbital cortex. A subgroup of the subjects were scanned both pre- and post-paroxetine treatment, and 5-HT_{1A} receptor BP did not significantly change in any area.

These data were compatible with 5-HT_{1A} receptor agonist challenge results showing that unmedicated depressed subjects have blunted hypothermic and adrenocorticotropin (ACTH) and cortisol release in response to ipsapirone or buspirone, relative to healthy controls (Lesch, 1992). The degree of blunting correlated with depression severity (Rausch *et al.*, 1990). Since 5-HT_{1A}-receptor-stimulation-induced hypothermia and ACTH/cortisol release are thought to distinguish pre- and postsynaptic 5-HT_{1A} receptor stimulation, respectively, in humans and rats, these findings were compatible with the PET data implicating both pre- and postsynaptic 5-HT_{1A} receptors in depression. Abnormally decreased 5-HT_{1A} receptor BP in depression may reflect either downregulation of receptor density or a reduction in the number of brain cells expressing 5-HT_{1A} receptors. The likelihood that abnormal 5-HT_{1A} receptor binding in primary mood disorders is accounted for by differences in nonspecific binding is reduced by the high selectivity of [*carbonyl*-^{11}C]WAY-100635 for 5-HT_{1A} receptors. Furthermore, reduced [^{11}C]WAY-100635 binding in depression is not expected to reflect a compensatory response to abnormal 5-HT release, or an effect of endogenous 5-HT concentrations on radiotracer binding. The 5-HT_{1A} receptor density and mRNA expression appear insensitive to reducing 5-HT transmission by lesioning the raphe or administering PCPA, or to pharmacologically

induced increases in 5-HT concentrations. Moreover, in baboons administration of agents which increase 5-HT release, including fenfluramine, citalopram, and amphetamine, does not alter [^{11}C]WAY-100635 binding (Parsey *et al.*, 1998). The insensitivity to endogenous 5-HT is partly related to the ~50-fold greater 5-HT$_{1A}$ receptor affinity of WAY-100635 relative to endogenous 5-HT (based upon K_D).

Altogether, reductions in 5-HT$_{1A}$ receptor binding in depression may reflect alterations in the cellular elements that express these receptors, or in the factors that downregulate genetic expression of these receptors. Preclinical and clinical data suggest that 5-HT$_{1A}$ receptors play a key role in the regulation of brain 5-HT activity and thus may be a target for novel antidepressant and antianxiety drugs with a more directed mechanism of action and possibly with a more favourable side effect profile.

NORADRENALIN

There is much data available supporting the hypothesis of a noradrenergic deficiency in depression (Delgado, 2000; Heninger *et al.*, 1996). The original catecholamine deficiency hypothesis of depression proposed that depression is a result of decreased catecholaminergic activity, whereas mania is associated with a relative excess (Schildkraut, 1965). In early reports urinary levels of MHPG were found to be significantly lower in patients with unipolar depression relative to healthy controls. However, these findings have not been consistently replicated. The original concept that depression is associated with decreased levels of catecholamines (for overview see Schatzberg and Schildkraut, 1995) as assessed with measurements of norepinephrine and its metabolites in peripheral samples has been invaluable in developing concepts of the biological mechanisms underlying depressive disorders and has served as a rich source from which researchers have generated testable experimental hypotheses. A recent study showing pronounced and sustained central hypernoradrenergic function in depression with melancholic features (Wong *et al.*, 2000) supports these early observations. New techniques such as brain imaging or depletion paradigms have provided new insight into the role of catecholaminergic mechanisms in the pathophysiology of mood disorders. Such studies have confirmed initial hypotheses that have suggested a pivotal role for noradrenergic systems in the pathophysiology of depression.

Catecholamine Depletion Studies

Of various methods employed for modifying the functions of sympathetic nervous systems, a unique and successful one has been the inhibition of catecholamine biosynthesis by α-methyl-para-tyrosine (AMPT) (Engelman *et al.*, 1968a; Sjoerdsma *et al.*, 1965). AMPT decreases norepinephrine and dopamine levels via inhibition of tyrosine hydroxylase, a rate-limiting enzyme in the synthesis of both transmitters (Widerlov and Lewander, 1978). AMPT is adequately absorbed from the gastrointestinal tract and the degree of inhibition achieved in man approximates the values, which could be predicted from the plasma levels of the drug (Engelman *et al.*, 1968b). In clinical investigations, AMPT (in dosages ranging from 1 g per day to 4 g per day) leads to profound decreases in urinary excretion of catecholamine metabolites and cerebrospinal fluid levels of the dopamine metabolite homovanillic acid (HVA) with no change in the 5-HT metabolite 5-hydroxyindoleacetic acid (5-HIAA) (Brodie *et al.*, 1971; Engelman *et al.*, 1968a; Sjoerdsma *et al.*, 1965). A maximal reduction of catecholamine metabolites during AMPT treatment occurs after 2–3 days of treatment (Bunney *et al.*, 1971; Engelman *et al.*, 1968b). It has been shown that about 20% of the urinary MHPG is derived from the central nervous system pool (Potter *et al.*, 1984).

Catecholamine Depletion Studies in Healthy Subjects

In order to evaluate the role of catecholamines in regulation of mood, anxiety and alertness, and its potential role in the pathogenesis of psychiatric disorders, it is also important to study the effects of catecholamine depletion in healthy volunteers. Treatment with AMPT has been shown to induce pronounced increases in sleepiness and mild increases in negative mood and anxiety, when administered to healthy male controls (McCann *et al.*, 1995). Significantly, replacement of catecholamine stores with L-DOPA reversed the effects of catecholamine depletion, and was associated with a more rapid recovery from AMPT's effects than when subjects were treated with AMPT alone. Another study of the same group comparing the psychological effects of AMPT alone versus AMPT plus 40.5 hours of total sleep deprivation (McCann *et al.*, 1993) suggests that catecholamines may be involved in mood changes during sleep deprivation. Combined treatment with AMPT and sleep deprivation led to significant increases in negative mood, whereas no treatment alone produced consistent mood changes. With the use of a different methodology to deplete catecholamines, by administering an amino acid mixture deficient of phenylalanine and tyrosine, Leyton and colleagues (Leyton *et al.*, 2000b) induced lowered mood and energy and increased irritability scores in a group of healthy women. Interestingly, the behavioural changes induced by catecholamine depletion were similar to those found during tryptophan depletion in the same group of subjects. In both conditions, the behavioural effects were more pronounced following exposure to aversive psychological events. Another study suggests that acutely decreased catecholamine transmission may disrupt mechanisms mediating alcohol self-administration (Leyton *et al.*, 2000a). Altogether, these studies support the role of catecholamines in a variety of human behaviours and also suggest that disturbed catecholamine transmission may predispose humans to various psychiatric disorders, including depression and different anxiety disorders.

Catecholamine Depletion Studies in Depression

The role of norepinephrine and dopamine in the pathogenesis of depression and in the mechanisms of action of antidepressant drugs have been subjects of intensive research during the past decades. A comprehensive overview of catecholaminergic function in depression is beyond the scope of this chapter. The purpose of the present chapter is to show the biochemical and behavioural effects of catecholamine depletion in depressed patients in different states of their illness, and their implications in our understanding of the pathogenesis of depression and its treatment. In the initial studies performed by Bunney and colleagues at the National Institute of Health (Bunney *et al.*, 1971) the authors demonstrated the antimanic effects of AMPT in a small group of manic patients, whereas three of four unipolar psychotic depressed patients showed an increase of depression on AMPT. However, small sample sizes and the lack of a control group or a placebo condition limit the interpretation of these initial findings. More recent studies addressing these methodological shortcomings showed that drug-free, untreated, symptomatic depressed patients had significant increased visual analogue ratings of 'tired' and decreased ratings of 'energetic'. However, there was no alteration in mood reported by the authors (Miller *et al.*, 1996b). This finding suggests that a simple norepinephrine or dopamine deficiency hypothesis is insufficient to explain the neurobiological basis of depression. Rather, the role of noradrenergic systems needs to be considered in relationship

to many other neurobiological factors that may be involved in the pathogenesis of depression. An alternative explanation could be that during a depressive state the catecholamine systems are already maximally dysfunctional and thus further manipulations do not worsen the condition of the patient.

Studies of the effects of AMPT on patients remitted on antidepressants or remitted depressed patients off medications provided further insight into the pathogenesis of depression and mechanisms of action of different antidepressants. Depressed patients in remission and on noradrenergic antidepressants (desipramine and mazindol) experienced a depressive relapse during catecholamine depletion, whereas those patients whose remissions were maintained with the selective 5-HT reuptake inhibitors (SSRIs) fluoxetine and sertraline remained well during catecholamine depletion (Miller *et al.*, 1996a). The administration of AMPT induced core symptoms of depression, such as depressed mood, loss of interest, anhedonia, cognitive disturbances, and sense of worthlessness and failure. Another study reported the reoccurrence of depressive symptoms induced by catecholamine depletion in a group of patients with seasonal affective disorder/winter type remitted on light therapy (Neumeister *et al.*, 1998c), supporting recent findings of reduced dopaminergic function in untreated patients with winter depression (Neumeister *et al.*, 2001). These findings disagree with a small study of three depressed patients with a favourable treatment response to imipramine (Shopsin *et al.*, 1975). However, beside the sample size of that study being small and there being no control situation, it has to be considered that imipramine is a potent 5-HT reuptake inhibitor as well as a norepinephrine reuptake inhibitor. The findings that catecholamine depletion disrupts the antidepressant effects of catecholaminergic, but not serotonergic, antidepressants, whereas tryptophan depletion reverses the antidepressant effects of serotonergic antidepressants, but not catecholaminergic antidepressants (Delgado *et al.*, 1999), argue against a single monoamine-related mechanism of action of antidepressants. However, such studies suggest that enhanced catecholamine function is important to maintain response to noradrenergic antidepressants, and enhanced serotonergic function is important to maintain response to serotonergic antidepressants.

State-related changes in catecholamine function have been described in depressed subjects, whereas enduring abnormalities have been less reliably identified. Recent catecholamine depletion studies in fully remitted, medication-free, formerly depressed subjects showed a depressive relapse in these subjects during catecholamine depletion, but not during sham depletion (Berman *et al.*, 1999; Lam *et al.*, 2001). The authors argue that the reoccurrence of depressive symptoms during catecholamine depletion may represent a reliable marker for a history of depression, and may well be a trait marker for the disorder. Further studies are needed to clarify the importance of these findings.

α_2-Adrenergic Receptors

Neurotransmission in the noradrenergic system is mediated by a number of different neurotransmitter receptors whose function has been implicated in either the pathophysiology of depression or in the mechanism of action of antidepressants (Duman and Nestler, 1995). The α_2-adrenergic receptors (α_2-AR) have been the focus of considerable research on their role in the pathophysiology of depression. The α_2-ARs are a heterogeneous group of receptors that bind to the naturally occurring ligands epinephrine and norepinephrine (O'Dowd *et al.*, 1989; Venter *et al.*, 1989). α_2-ARs mediate their functions through the G_i class of G proteins (Lefkowitz and Caron, 1988; Limbird, 1988). The α_2-ARs are located on nerve terminals and on the cell bodies and/or dendrites, and participate in local and neuronal feedback inhibition (Cedarbaum and Aghajanian, 1977; Hein *et al.*, 1999; Langer, 1997; Miller, 1998; Stjarne, 1989). Activation of these receptors by endogenous ligands or α_2-agonists, e.g. clonidine, decreases noradrenalin release and the firing rate of the neurons (Engberg and Eriksson, 1991; Hein *et al.*, 1999; MacDonald *et al.*, 1991) and results in bradycardia, hypotension, hypothermia, locomotor inhibition, anxiolysis, analgesia and sedation (Aantaa and Scheinin, 1993; Altman *et al.*, 1999; Hein *et al.*, 1999; Lakhlani *et al.*, 1997; Puke and Wiesenfeld-Hallin, 1993; Rohrer and Kobilka, 1998; Ruffolo *et al.*, 1993; Sallinen *et al.*, 1999). Clonidine is a partial agonist at brain α_2-ARs, but also has high affinity for non-adrenergic imidazoline-binding sites. It has been shown that the distribution of non-adrenergic [^{3}H]-clonidine binding sites is correlated but distinct from that of α_2-ARs, and that the affinity of these sites is distinct from α_2-AR sites (Piletz *et al.*, 2000). Blockade of α_2-ARs by α_2-antagonists, e.g. yohimbine, increases the firing rate and responsiveness of neurons to stimulation (Simson and Weiss, 1987; Tjurmina *et al.*, 1999) and promotes release of noradrenalin (Freedman and Aghajanian, 1984; Grossman *et al.*, 1991; Scheinin *et al.*, 1988; Starke *et al.*, 1975). It has to be acknowledged that interpretation of data from yohimbine challenge studies is complicated by mixed drug effects due to the blockade of both pre- and postsynaptic α_2-ARs in the hypothalamus and presynaptic D_2 dopaminergic autoreceptors in the pituitary (Meltzer *et al.*, 1983). In addition, yohimbine exhibits affinity to 5-HT_{1A} receptors, although yohimbine is tenfold selective for human α_{2A}-ARs versus human 5-HT_{1A} receptors (Newman-Tancredi *et al.*, 1998). In addition to these α_2-auto-AR, α_2-heteroreceptors have been identified, which are located elsewhere than on noradrenergic neurons. These heteroreceptors are involved in the regulation of release of a variety of neurotransmitters, including serotonin (Gobert *et al.*, 1997, 1998; Mongeau *et al.*, 1993; Raiteri *et al.*, 1990), dopamine (Gobert *et al.*, 1997, 1998; Trendelenburg *et al.*, 1994), and histamine (Gulat-Marnay *et al.*, 1989). Activation of α_2-ARs by α_2-agonists reduces the turnover of norepinephrine, serotonin and dopamine in the brain.

It has been demonstrated that α_2-ARs mediate a variety of physiological functions and pharmacological effects in the central nervous system, mainly by inhibiting neuronal firing and release of noradrenalin and other neurotransmitters. A wide range of functions in peripheral tissues is also mediated by α_2-ARs, including regulation of noradrenalin release from sympathetic nerves, smooth muscle contraction, platelet aggregation, insulin secretion, glomerular filtration and energy metabolism (Ruffolo *et al.*, 1993).

The α_2-ARs have been the focus of considerable research on their role in the pathogenesis of depression (Charney *et al.*, 1981; Cohen *et al.*, 1980; McKenna *et al.*, 1992; Piletz *et al.*, 1986; Smith *et al.*, 1983). An increase in the density of platelet α_2-ARs has been reported in drug-free depressives. Also, the platelet aggregation response has been reported as being enhanced in depression. The findings of increased α_2-AR density in depression, both in the central nervous system and in the periphery, have not been consistently replicated. Blunted growth hormone responses have been reported in depressive patients in different states — untreated, treated with antidepressants, and when being remitted. This argues that alterations in α_2-AR function may be a trait characteristic in at least a subgroup of depressed patients.

SUMMARY

The data obtained from studies evaluating the role of monoamines in the pathophysiology of mood disorders, in particular depression, and in antidepressant treatments provide evidence that monoamines do not have a direct effect on regulating mood, but rather have a modulator role on other neurobiological systems. However, there is substantial evidence that adequate monoaminergic activity in the brain is necessary to achieve and maintain an antidepressant response to antidepressant treatments. Future research

should try to further increase our knowledge about the interactions between serotonergic and noradrenergic transmitter systems and other neurobiological systems. This may become of clinical relevance since preclinical studies have revealed potential molecular and anatomic sites that could contribute to the development of future generations of antidepressant agents.

XVIII-3

Evidence for GABAergic and Glutamatergic Involvement in the Pathophysiology and Treatment of Depressive Disorders

Gerard Sanacora

The majority of neurons in the brain use either γ-aminobutyric acid (GABA) or glutamate as their primary neurotransmitter. In effect these two neurotransmitters serve to regulate the excitability of almost all neurons in the brain. Therefore, it is not surprising that they are implicated in a broad range of both physiological and pathophysiological events related to brain function. Although the past three decades of research has emphasized the role of the biogenic amines and hypothalamic–pituitary–adrenal (HPA) axis in the neurobiology of mood disorders, emerging evidence now suggests that the amino acid neurotransmitter systems also contribute to the pathophysiology and pharmacological treatment of depression.

Newly developed neurochemical imaging techniques and advances in molecular pharmacology are now providing novel methods to study the amino acid neurotransmitter systems. Through the use of these modalities and novel pharmaceutical agents we are now beginning to uncover the extent to which these ubiquitous systems are related to depression and other mood disorders. In the following pages we will examine the evidence supporting the involvement of the GABAergic and glutamatergic systems in the neurobiology of mood disorders.

EVIDENCE SUPPORTING GABAERGIC CONTRIBUTIONS TO THE NEUROBIOLOGY OF DEPRESSION

Dysregulation of GABAergic neurotransmission is increasingly implicated in the neurobiology of mood disorders (Lloyd *et al.*, 1989; Petty, 1995; Sanacora *et al.*, 2000; Shiah and Yatham, 1998). Supporting evidence comes in the form of (1) animal studies showing stress-related changes in GABAergic function, and the ability of GABA modulating agents to alter animal models of depression, (2) demonstration of GABAergic abnormalities in depressed patients, and (3) GABAergic effects of antidepressant and mood stabilizing medications.

GABA and Animal Models of Stress and Depression

Multiple lines of evidence suggest stress is a major precipitating factor in the development of depressive episodes. Existing animal studies suggest that stress-related effects on the GABAergic neurotransmitter system may contribute to this relationship. Several studies have found decreased cortical $GABA_A$ receptor function following exposure to short-term stress in various rodent models (Biggio *et al.*, 1984; Concas *et al.*, 1988; Sanna *et al.*, 1992; Serra *et al.*, 1991). Additionally, stressful early life events can result in long-lasting changes in $GABA_A$ receptor function that appear related to altered expression of adult behaviours (Caldji *et al.*, 2000). Lower GABA concentrations, synthesis rates, and neurotransmitter uptake have also been reported in acute stress paradigms (Acosta *et al.*, 1993; Borsini *et al.*, 1988). Chronic stress produced similar changes in GABAergic function, including decreases in brain GABA concentrations, glutamic acid decarboxylase (GAD) activity, GABA uptake, and regional $GABA_A$ receptor binding (Acosta and Rubio, 1994; Insel, 1989; Weizman *et al.*, 1989). Interestingly, the time course of these events corresponds to changes in neuroactive steroid concentrations, which may serve as endogenous mediators of homeostatic function by maintaining GABAergic regulation during prolonged stress (Barbaccia *et al.*, 1996, 1997).

The role of GABA in the regulation of the HPA axis is now drawing increasing attention (Barbaccia *et al.*, 1996, 1997; Boudaba *et al.*, 1996; Calogero *et al.*, 1988; Owens *et al.*, 1991). Local circuits from within the hypothalamus provide a rich supply of GABAergic innervation directly on to the corticotropin-releasing hormone (CRH) containing parvocellular region of the paraventricular nucleus (PVN) (Herman and Cullinan, 1997). These stress-activated PVN-projecting GABAergic pathways appear to play a prominent role in modulating the HPA axis response to stress (Bowers *et al.*, 1998). Disruption of this system could be related to the abnormal HPA stress responses commonly observed in mood-disordered individuals.

The ability of GABA modulating agents to alter the expression of stress responses and animal models of depression further suggest a role for the inhibitory neurotransmitter system in the neurobiology of mood disorders. Initial studies by Sherman and Petty demonstrating the ability of intrahippocampal GABA injections both to prevent and reverse the induction of learned helplessness provided the initial link to the GABAergic system (Sherman and Petty, 1980). Other studies demonstrating decreased Ca^{++}-dependent GABA release from the hippocampus of helpless animals, and inhibition of imipramine's 'antidepressant-like' effects on learned helplessness behaviour by intrahippocampal administration of the GABA antagonist bicuculline (Petty and Sherman, 1981), provided additional evidence that GABA-mediated mechanisms are associated with the development of depression-like behaviours in this model.

Transient GABA reductions were reported in several brain regions following the initial session of the forced swimming test (FST) (Borsini *et al.*, 1988), another frequently used animal model of depression and a test of antidepressant activity. Similar to the actions of other antidepressant agents, GABA agonists reduce

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

the immobility time during the forced swimming test (Borsini *et al.*, 1986; Poncelet *et al.*, 1987). Inhibiting GABA breakdown by administering the GABA-transaminase (GABA-T) inhibitor amino-oxyacetic acid prior to the first forced swim session elevated GABA levels, and decreased immobility time (Borsini *et al.*, 1988), suggesting that the immobility time associated with the FST is mediated in part through the GABAergic system.

Like the learned helplessness and FST models, the olfactory bulbectomized rat, another commonly used behavioural model of depression, also appears sensitive to modulation by GABA mimetics. The passive avoidance deficit (Lloyd *et al.*, 1983, 1987), muricidal behaviour (Delini-Stula and Vassout, 1978) and open field behaviour (Leonard, 1984), measures frequently used as tests of antidepressant-like activity, are all reversed following the administration of GABA agonists. In other studies $GABA_B$ binding was demonstrated to be significantly decreased in the frontal cortex of these animals (Lloyd *et al.*, 1987). GABA mimetics also produce antidepressant-like activity in other tests of antidepressant activity such as the paradoxical sleep and 5-HTP head twitch (for review see Lloyd *et al.*, 1989).

Evidence of GABAergic Abnormalities in Mood Disorder Patients

There are several forms of evidence suggesting possible widespread abnormalities of GABAergic function to mood disorders. However, the most convincing evidence linking the GABAergic system to the neurobiology of mood disorders are the studies showing decreased GABA in the plasma, cerebrospinal fluid (CSF) and cerebral cortex of depressed individuals.

CSF

Gold and colleagues first reported decreased CSF GABA levels in mood disorder patients (Gold *et al.*, 1980). They found significantly lower CSF GABA concentrations in mood disorder patients compared to a group of subjects undergoing a neurological evaluation and a group of psychotic subjects. A second CSF study (Post *et al.*, 1980) reported a non-significant trend toward lower GABA levels in 16 depressed patients, compared to 8 manic patients and 41 healthy comparison subjects. A third study (Gerner and Hare, 1981) highlighted the complexities of CSF GABA studies. It compared CSF GABA levels from groups of depressed, schizophrenic, manic and anorexia nervosa patients to the levels of healthy comparison subjects using two samples of CSF. Consistent with the initial study by Gold *et al.*, only the depressed subjects exhibited lower CSF GABA than the healthy comparison subjects when the sample was obtained from the first 12 cm^3 collected. However, when the second aliquot of CSF (15–26 cm^3, the same as in the Post *et al.*, study) was used, the trend was no longer statistically significant (Gerner *et al.*, 1984). Gerner later replicated the findings of decreased GABA concentrations in a larger study measuring CSF levels in 41 depressed patients and 38 controls. Consistent with the previous studies, lower CSF GABA levels were not observed in patients diagnosed with schizophrenia or mania. A Japanese study also reported significantly lower CSF GABA levels in depressed patients compared to a mixed group of healthy comparison subjects and hospitalized patients without neuropsychiatric illness (Kasa *et al.*, 1982). A later study by Roy and collaborators (Roy *et al.*, 1991b) also found lower CSF GABA levels in patients with a current depressive episode. However, when they controlled for age and gender there was no significant difference. Only the subgroup of patients with unipolar

Table XVIII-3.1 Review of CSF GABA studies in depression

	Comparison subjects				Depressed patients		
Reference	CSF Sample (cc)	Sample size	Gender	CSF GABA level (pmol ml^{-1}) mean ± SEM	Sample size	Gender	CSF GABA level (pmol ml^{-1}) mean ± SEM
Gold *et al.* (1980)	0–10	20 (neurologic patients)	M = 4 F = 16	218 ± 26	MDE = 17 UP = 10 BP = 5 ETOH = 1 OBS = 1	M = 1 F = 16	122 ± 10*

Gerner and Hare (1981)	1–12 15–26	29 (healthy)	M = 14 F = 15	183 ± 12 200 ± 11	MDE = 24 UP = 19 BP = 5	M = 11 F = 13	134 ± 5* 172 ± 10
Zimmer *et al.* (1981)	1–6	6 (surgical patients)	Not specified	360 ± 29	DS = 6 (sub-type not specified)	M = 3 F = 3	280 ± 45
Kasa *et al.* (1982)	5–10	24 (mixed group of healthy subjects and hospital patients without neurologic and psychiatric disorders)	Not specified	138 ± 12	MDE = 13 (sub-type not specified)	M = 11 F = 2	96 ± 39*
Gerner *et al.* (1984)	0–12	38 (healthy)	M = 18 F = 20	190 ± 5	MDE = 41 Up = 30 BP = 10	M = 18 F = 23	140 ± 6*
Roy *et al.* (1991b)	1–10	20 (healthy)	M = 8 F = 12	145 ± 10	MDE = 25 UP = 18 BP = 7	M = 4 F = 21	119 ± 33

Note: *Sig. $P < 0.05$. M = male, F = female, MDE = major depressive episode, DS=depressive syndrome, UP = unipolar depression, BP = bipolar depression, OBS = organic brain syndrome, ETOH = alcohol related.

melancholic depression had significantly lower GABA levels than all other groups. Finally, a study by Zimmer and colleagues reported a non-significant decrease in CSF GABA levels with depressive mood states in a small group of poorly defined subjects (Zimmer *et al.*, 1980).

In summary, all of the CSF studies to date have found at least a trend toward decreased GABA concentrations in depressed subjects (see Table XVIII-3.1). A meta-analysis of this data (Petty *et al.*, 1993c) revealed a highly significant difference between depressed and comparison subjects. Interestingly, the finding appears to be relatively specific to depression. No significant differences were observed in schizophrenic, anorectic or manic subjects (Gerner and Hare, 1981; Gerner *et al.*, 1984; Gold *et al.*, 1980; Post *et al.*, 1980). In further support of this specificity, Roy and colleagues (Roy *et al.*, 1991a) reported CSF GABA levels to be selectively decreased in depressed alcoholic patients compared to non-depressed alcoholics. Unfortunately, lack of diagnostic specificity in these early studies and the grouping of unipolar and bipolar patients into a common class does not allow for tests of further specificity. The fact that none of the studies examined remitted patients also leaves the state versus trait dependence issue unresolved.

Plasma Levels

There are several reports of decreased plasma GABA levels in individuals with affective disorders, with the majority of studies from a single laboratory (Berrettini *et al.*, 1982a, 1986; Petty and Schlesser, 1981; Petty and Sherman, 1984; Petty *et al.*, 1990, 1992, 1993b). In general, these findings suggest a trait-dependent reduction in plasma GABA levels in patients with mood disorders. This is best noted by a markedly increased percentage of individuals having plasma GABA concentrations below 100 pmol ml^{-1}. Unlike the CSF studies, there is no clear evidence of specificity between active episodes and remitted states, or between depressed and manic states. However, the group of patients with the lowest GABA levels had more severe melancholic-like symptoms. Similar to the CSF studies, the lower GABA concentrations were somewhat specific to mood disorders. No change in plasma GABA was observed in patients with schizophrenia, generalized anxiety disorder, eating disorders or panic disorder (Petty and Sherman, 1984; Goddard *et al.*, 1996; Roy-Byrne *et al.*, 1992; Petty, 1994 for review see). However, lower plasma GABA levels were seen in alcoholism (Petty *et al.*, 1993a), Parkinson's disease (Manyam, 1982) and premenstrual dysphoric disorder (Halbreich *et al.*, 1996).

Post-Mortem and Biopsy Studies

Post-mortem studies consisting mostly of depressed suicide victims have not provided consistent evidence of GABAergic abnormalities. No significant differences were found in $GABA_B$ binding in a post-mortem sample of 16 suicide victims compared to 20 controls (Arranz *et al.*, 1992). This is consistent with earlier post-mortem studies that showed no change in $GABA_B$ binding sites in depressed suicide victims (Cross *et al.*, 1988). $GABA_A$-benzodiazepine binding was increased by 18% in the frontal cortex of 21 depressed suicide victims compared to 21 age- and sex-matched controls (Cheetham *et al.*, 1988).

Biopsy and post-mortem data on GABA concentrations also remains inconclusive, an outcome that may be due in part to the dramatic post-mortem increase in the activity of GABA's primary synthetic enzyme GAD. A negative correlation was found between GABA concentrations and severity of depression in a study measuring GABA levels from cortex removed during psychosurgery (Honig *et al.*, 1988). However, Korpi *et al.* (1988) found no significant differences in brain GABA levels of suicide victims. Similar inconsistencies are seen regarding GAD activity levels. An early study reported significantly lower rates of GABA synthesis in several brain regions from elderly depressed patients compared to control subjects (Perry *et al.*, 1977). Consistent with this, a single study found lower plasma GAD activity in depressed patients (Kaiya *et al.*, 1982). However, Cheetham *et al.* (1988) found no significant differences in GAD activity in depressed suicide victims, and a more recent study reported a significant increase in the expression of the GAD_{67} isoform of the enzyme in the prefrontal cortex of depressed patients (Toth *et al.*, 1999). No differences were found in the one study investigating the activity of GABA-T activity in depressed and non-depressed suicide victims (Sherif *et al.*, 1991), although lower platelet GABA-T activity was found in euthymic medication-free bipolar patients (Berrettini *et al.*, 1982b). Recent studies by Rajkowska and colleagues suggest that mood disorders are associated with reduced numbers of neurons in layer II in regions of the frontal cortex (Rajkowska *et al.*, 1999), and preliminary findings further demonstrate an associated reduction of calbindin-immunoreactive neurons in layer II depressed subjects (Personal Communication Dr. Rajkowska).

In vivo Brain Studies of GABA

Advances in magnetic resonance spectroscopy (MRS) have made it possible to measure GABA concentrations *in vivo*. Using this methodology, decreased GABA concentrations were demonstrated in the occipital cortex of depressed subjects (Figure XVIII-3.1) (Sanacora *et al.*, 1999a). In two other preliminary studies the occipital GABA concentrations were found to be normalized following treatment with either electroconvulsive therapy (Sanacora *et al.*, 1999b) or selective serotonin reuptake inhibitor (SSRI) medications (Sanacora *et al.*, 2002). Since these initial MRS studies were limited to the occipital cortex it is difficult to determine the pathophysiological significance of the findings. However, in light of the previous reports that consistently demonstrated decreased GABA concentrations in the plasma and CSF of depressed patients, the studies suggest that widespread alterations of GABAergic function are associated with major depression. In a single preliminary report using SPECT imaging of radiolabelled Iomazenil to examine benzodiazepine binding, no significant difference was observed between depressed subjects and a historical group of healthy control subjects despite the presence of lower occipital cortex GABA concentrations (Kugaya *et al.*, 2001).

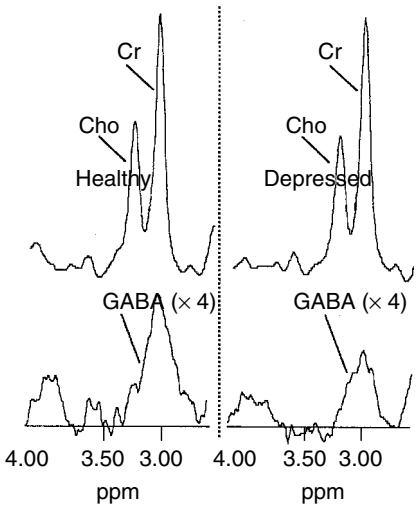

Figure XVIII-3.1 *In vivo* 1H-MRS spectra from representative healthy and depressed subjects. The relative differences in occipital cortex GABA between these two subjects is illustrated by the size of the GABA peaks on the spectra

Pharmacological Challenges

The use of pharmacological challenge studies to investigate GABAergic involvement in depression has yielded inconsistent findings. Administration of the $GABA_B$ agonist baclofen is known to increase growth hormone secretion from the anterior pituitary (Koulu *et al.*, 1979; Müller, 1987). Two studies have shown this effect to be blunted in depressed individuals, suggesting altered $GABA_B$ function in depression (Marchesi *et al.*, 1991; O'Flynn and Dinan, 1993). However, two other studies found no significant difference between healthy comparison and depressed subjects in response to a baclofen challenge (Davis *et al.*, 1997; Monteleone *et al.*, 1990).

Findings Related to Endogenous Modulators of GABA Function

Neuroactive steroids are metabolites of progesterone and deoxycorticosterone that interact with the $GABA_A$/benzodiazepine receptor complex. Decreased plasma levels of several neuroactive steroids possessing potentiating effects on the $GABA_A$ receptor were observed along with a concomitant increase in two neurosteroids that may act as functional GABA antagonists in depressed individuals (Romeo *et al.*, 1998). Treatment with antidepressant medication appears to reverse this disequilibrium. This effect of antidepressant medications on neuroactive steroid concentrations is consistent with an earlier rodent study demonstrating increased neuroactive steroids concentrations in response to fluoxetine treatment (Uzunov *et al.*, 1996), and may contribute to the mechanism of antidepressant action by altering GABAergic transmission. Furthermore, the involvement of neuroactive progesterone metabolites in the pathophysiology of depression also suggests one possible explanation for the elevated rates of depression in the post-partum period (O'Hara *et al.*, 1984), and elevated rates of depressive symptoms in the late luteal phase of the menstrual cycle (Rubinow *et al.*, 1984).

Genetic Studies

Attempts to examine the relationship between the GABAergic system and mood disorders using genetic analysis studies are yet to yield convincing evidence (Table XVIII-3.2). Puertollano and colleagues reported an association between manic-depressive illness and tetranucleotide repeat polymorphisms at the GABRB1 gene in a study of a subpopulation of Spanish females (Puertollano *et al.*, 1997). Oruc *et al.* (1996) failed to detect a significant association with GABRA1 and GABAR3 and bipolar disorder. A third study by Serretti and colleagues (Serretti *et al.*, 1998) also failed to find an association between depressive symptomatology and the GABRA1 gene in a group of unipolar and bipolar depressed patients. Petty and colleagues recently provided preliminary evidence suggesting that regulation of plasma GABA levels may be under the control of a single gene, inherited in a recessive manner (Petty *et al.*, 1999). This is consistent with an older study that showed a statistically significant correlation between plasma GABA concentrations of depressed subjects and first-degree relatives (Petty, 1994).

GABA's Role in the Treatment of Mood Disorders

The delayed clinical response to tricyclic antidepressants (TCA), SSRI and monoamine oxidase inhibitors (MAOI) suggests that other neurotransmitter systems in addition to the monoamines may be involved in the mechanism of antidepressant action. Several studies have sought to examine the possible involvement of the GABAergic system in this regard.

Receptors

Chronic administration of all three classes of antidepressants (TCA, SSRI, MAOI) and ECT have been reported to enhance $GABA_B$ receptor binding in animal studies (for review see Lloyd *et al.*, 1987). However, contrasting findings have also been reported (Cross and Horton, 1988; McManus and Greenshaw, 1991; Monteleone *et al.*, 1990; Szekely *et al.*, 1987). The upregulation of $GABA_B$ receptors appears dependent on chronic administration of antidepressant medications, as no changes were seen after acute administration. Interestingly, other neuroleptic, anxiolytic and psychostimulant medications failed to show similar effects (Lloyd *et al.*, 1987), but mood stabilizing agents such as sodium valproate, carbamazepine and lithium did enhance $GABA_B$ binding (Motohashi *et al.*, 1989).

Using the olfactory bulbectomized rat model Joly and colleagues (Joly *et al.*, 1987) reported that only desipramine 'responders' displayed a significant increase in $GABA_B$ receptor binding, thus suggesting a functional relationship between the increase in $GABA_B$ receptors and behaviour. Interpretation of the above findings is complicated by a recent study by Beck and colleagues suggesting that the potency of $GABA_B$ transmission is decreased following chronic fluoxetine treatment in selected subfields of the rat hippocampus as measured by baclofen-stimulated hyperpolarization (Beck *et al.*, 1997).

There are two reports of long-term antidepressant administration resulting in downregulation of $GABA_A$ receptors (Suranyi-Cadotte *et al.*, 1984; Suzdak and Gianutsos, 1985). However, these finding were not replicated in a later study (Kimber *et al.*, 1987), and increased numbers of benzodiazepine receptors were found in selected areas of rat brain following chronic administration of sertraline (Giardino *et al.*, 1993). Chronic administration of

Table XVIII-3.2 Summary of findings in depressed subjects

	Levels relative to controls	Comments	References
Plasma GABA	↓	Consistent findings of low plasma GABA with one exception.	Petty (1994), Petty and Schlesser (1981), Petty *et al.* (1992), Rode *et al.* (1991)
CSF GABA	↓	4 of 7 studies found significantly lower GABA concentrations, others reported trend toward lower GABA in depression.	Gerner and Hare (1981), Gerner *et al.* (1984), Gold *et al.* (1980), Kasa *et al.* (1982), Post *et al.* (1980), Roy *et al.* (1991b), Zimmer *et al.* (1981)
Brain GABA	↓	Inconsistent findings with limited post-mortem studies, *In vivo* MRS study highly significant	Honig *et al.* (1989), Korpi *et al.* (1988), Sanacora *et al.* (199b)
GABAergic neurons	↓	Single study results	Rajkowska *et al.* (1999) (Personal Communication Dr. Rajkowska)

imipramine, phenelzine and buspirone resulted in altered $GABA_A$ receptor subunit patterns in rat brains (Tanay *et al.*, 1996), but no consistent pattern of change was observed.

GABA Levels

Several older studies found elevated GABA levels and enhanced GABA release in rat brains following high-dose acute administration of TCAs and MAOIs, and daily electroconvulsive shock (Bowdler *et al.*, 1983; Korf and Venema, 1983; Patel *et al.*, 1975; Perry and Hansen, 1973; Popov and Matthies, 1969). However, other studies found GABA levels to be generally unaltered by antidepressant administration (Olsen *et al.*, 1978; Pilc and Lloyd, 1984). More recent studies consistently find the MAOI phenelzine to increase GABA levels in the rat brain (Baker *et al.*, 1991; McKenna *et al.*, 1994; McManus *et al.*, 1992). The increased GABA levels do not appear the direct result of changes in synthetic or catabolic enzyme gene expression since phenelzine produced no effect on the steady-state levels of mRNAs that encode for GABA-T, GAD_{65} or GAD_{67} (Lai *et al.*, 1998). However, the elevated brain GABA levels do appear in part related to the anxiolytic properties of the drug in animal models (Paslawski *et al.*, 1996). The true relevance of the elevated GABA levels to phenelzine's antidepressant actions remains unknown. Seemingly in contrast to the above findings, Giardino and colleagues (Giardino *et al.*, 1996) found chronic sertraline treatment to decrease GAD expression in several rat brain regions. As mentioned above, recent MRS findings suggest that GABA concentrations in the occipital cortex are elevated following treatment with antidepressant agents.

Effectiveness of Mood Stabilizers and Antidepressants with GABAergic Activity

GABA Analogues

Several studies suggest that compounds that enhance GABAergic transmission possess antidepressant properties. As noted above, GABA agonists have antidepressant-like activity in several animal models used to assess antidepressant action (Lloyd *et al.*, 1989). These findings prompted clinical investigation of GABA-enhancing drugs as antidepressants. Due to the pharmacological limitations of many of these compounds, their use in clinical trials is limited. However, progabide and fengabine (SL 79229) are two GABA-mimetic compounds that reached clinical trials as antidepressant agents. Both of these compounds appeared to be effective antidepressants in multiple controlled clinical trials, in some reports having equal efficacy to TCAs (for compilation of studies see Bartholini *et al.*, 1986). However, development of these compounds was halted due to unfavourable side-effect profiles, and no recent work has been reported as a follow-up to these initial studies.

Benzodiazepines and Anticonvulsants

The benzodiazepine class of $GABA_A$ agonists appear to be ineffective as antidepressant agents in general (Schatzberg and Cole, 1978; Tiller *et al.*, 1989). However, the efficacy of the triazolobenzodiazepine alprazolam remains contested (Petty *et al.*, 1995). Interestingly, valproic acid, a compound that appears to increase GABAergic transmission through multiple mechanisms (Löscher, 1993), has proven mood stabilizing properties (Bowden *et al.*, 1994), and possible efficacy in unipolar major depression (Davis *et al.*, 1996). Other anticonvulsants (gabapentin and topiramate) with GABAergic activity have recently attracted attention as possible mood stabilizing, and antidepressant drugs (Brown *et al.*, 1999; Post *et al.*, 1997). However, the clinical effectiveness of these treatments awaits further study.

In conclusion, the evidence supporting the hypothesis that the GABAergic system contributes to the mechanism of action of antidepressant medications remains preliminary and contestable.

GLUTAMATE

Given that glutamate is the principal excitatory neurotransmitter in the mammalian brain it is likely to contribute to a wide array of both normal and abnormal brain functions. Its involvement has been previously implicated in the pathophysiology of several neurodegenerative disorders as well as schizophrenia, obsessive compulsive disorder and alcohol dependence (Carlsson, 2001; Danbolt, 2001; Tsai and Coyle, 1998). Supporting evidence for glutamate's role in the pathophysiology of mood disorders comes from (1) animal studies showing stress-related changes in glutamatergic function, and its possible relationship to excitotoxicity, (2) demonstration of glutamatergic abnormalities in depressed patients, (3) glutamatergic effects of antidepressant and mood stabilizing medications and (4) the effectiveness of glutamate modulating agents in the treatment of depression.

Stress-Related Effects

Glutamatergic neurotransmission appears intimately involved in a stress-responsive cascade of events that result in neurotoxicity (Sapolsky, 2000). Stress has been shown to increase synaptic glutamate concentrations in the hippocampus and prefrontal cortex (Moghaddam, 1993; Moghaddam *et al.*, 1994), and to alter glutamate receptor function in the hippocampus and hypothalamus (Bartanusz *et al.*, 1995; Nowak *et al.*, 1995b). If this model is correct, stress-responsive neurotoxicity may help explain several recent findings demonstrating altered hippocampal and cortical morphology (Bremner *et al.*, 2000; Sheline *et al.*, 1996) and histology (Ongür *et al.*, 1998; Rajkowska *et al.*, 1999), associated with major depression. In support of this hypothesis, studies using glutamate transporter GLT-1 knockout mice with excessive synaptic glutamate have demonstrated pathological destruction of hippocampal neurons (Tanaka *et al.*, 1997).

Other data suggests that glutamatergic activity is closely tied to the stress-responsiveness of the paralimbic–HPA axis, and that glutamate is capable of stimulating CRF release into the portal circulation (Cratty and Birkle, 1999; Feldman and Weidenfeld, 1997; Ziegler and Herman, 2000). Consistent with glutamate's proposed role in the regulation of the stress response, *N*-methyl-D-aspartate (NMDA) receptor antagonists reduce immobility time on the FST (Maj *et al.*, 1992) and prevent many of the behavioural deficits associated with chronic stress (Ossowska *et al.*, 1997).

Evidence of Glutamatergic Abnormalities in Mood Disorder Patients

Plasma

Studies regarding plasma levels of glutamate in mood disorders remain inconclusive. An early study by Kim and colleagues (Kim *et al.*, 1982) reported elevated glutamate levels in a group of depressed patients, but could not separate the effect from the use of antidepressant medications. Altamura and colleagues (Altamura *et al.*, 1993) also initially reported elevated plasma glutamate levels in a group of mood disorder patients but in a later study found no significant differences in plasma glutamate concentrations comparing unmedicated patients with major depression to healthy controls (Altamura *et al.*, 1995). However, employing a linear discriminant analysis, the group did find a highly significant separation between major depressed subjects and normal volunteers,

using glycine, glutamate and taurine as discriminatory variables. In more recent studies, Mauri and colleagues (Mauri *et al.*, 1998) found elevated plasma and platelet levels of glutamate in depressed patients compared to controls, but Maes *et al.* (1998) found no difference in serum glutamate levels from depressed patients compared to age- and sex-matched controls. Interestingly, however, they did find significantly reduced serum glutamate levels following a 5-week period of treatment with antidepressants.

CSF

Very few CSF studies have addressed the glutamatergic system in relation to depression. Levine and colleagues used MRS technology to demonstrate significantly higher CSF glutamine concentrations in the CSF of 18 hospitalized patients with acute unmedicated severe depression compared to 22 control subjects (Levine *et al.*, 2000). In a second study, Hiraoka and colleagues (Hiraoka *et al.*, 1989) reported that mean CSF glutamine levels in functional psychosis (schizophrenia, manic-depressive illness and other psychoses) did not differ from those of neurotic patients, patients with cerebrovascular disorders or patients with metabolic neuropathy.

Brain

A single study examining neurosurgical samples from chronically depressed subjects did not find a significant difference in frontal cortex glutamate concentrations (Francis *et al.*, 1989). Another study also failed to find any significant difference in the binding of a non-competitive antagonist to the NMDA receptor among depressed suicide victims and an age-matched comparison group (Holemans *et al.*, 1993). However, Nowak and colleagues reported that the proportion of high-affinity, glycine displaceable [3H]CGP-39653 binding to glutamate receptors was reduced in age- and post-mortem interval-matched suicide victims (Nowak *et al.*, 1995a).

In vivo measures of excitatory amino acids in the brain can be made with the use of 1H-MRS. Using standard clinical field strength magnets, the visibility of these metabolites are limited by several factors that make it extremely difficult to assign unequivocal resonance peaks. This has led to the use of a combined measure termed Glx that contains glutamate, glutamine and GABA, of which the greatest proportion reflects the glutamate concentration. In one of the more unique studies, Cousins and Harper used this methodology to demonstrate temporary decreases in Glx levels coinciding with a patient's transient experience of suicidal depression following Taxol and Neupogen chemotherapy (Cousins and Harper, 1996). More recently, Auer and colleagues (Auer *et al.*, 2000) reported decreased Glx measures in the anterior cingulate cortex of severely depressed subjects. A preliminary study by Michael and colleagues also showed a similar decrease in baseline anterior cingulate Glx levels that later increased following treatment with ECT (Michael *et al.*, 2001). Interestingly, no decrease was seen in a group of bipolar depressed subjects participating in this study. Consistent with the idea that Glx measures may differ between unipolar and bipolar depressed patients, elevated levels of Glx were found in both the frontal lobe and basal ganglia of depressed bipolar children compared to a control group (Castillo *et al.*, 2000).

Glutamatergic Effects of Antidepressant and Mood Stabilizing Agents

A growing body of research suggests that the NMDA class of glutamate receptors may be involved in the mechanism of action of antidepressants (Skolnick, 1999). Downregulation of the glycine-B site of NMDA receptors appears to be a common feature of current antidepressant treatments. As shown in Figure XVIII-3.2, tricyclics, serotonin reuptake inhibitors, electroconvulsive stimuli and bupropion selectively reduced the potency of glycine to inhibit [3H]-5,7-dichlorkynurenic acid (5,7-DCKA) binding to the glycine-B site of the NMDA receptor, a change consistent with downregulation of NMDA receptor function (Paul *et al.*, 1994). In this study, the NMDA antagonist ketamine did not modify sensitivity to glycine, although it directly reduced NMDA receptor function through blockade of the calcium channel within the NMDA receptor complex. The tricyclic antidepressant desipramine, which has direct NMDA receptor antagonism at therapeutic doses (Reynolds and Miller, 1988; White *et al.*, 1990), reduces the potency of glycine to displace 5,7-DCKA binding similarly to other antidepressants and it additionally reduces the density of 5,7-DCKA binding sites (Paul *et al.*, 1994). Interestingly, pretreatment of mice with desipramine was shown to significantly reduce NMDA-induced biting and scratching behaviour (Mjellem *et al.*, 1993).

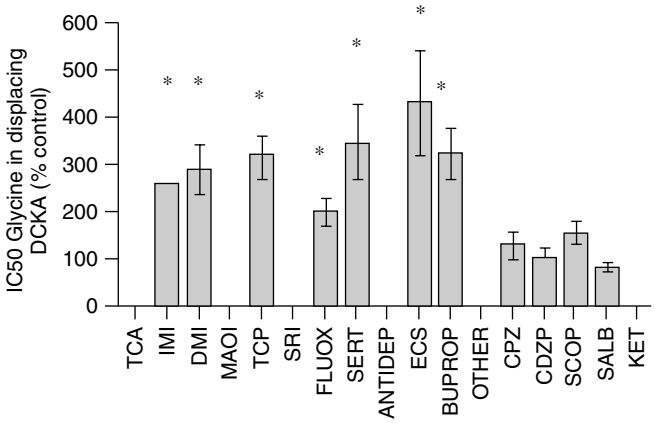

Figure XVIII-3.2 Graph demonstrating the general ability of various antidepressant treatments to reduce the potency of glycine in displacing DCKA binding on NMDA receptors. Adapted from Paul *et al.* (1994)

Several mood stabilizing compounds also appear to attenuate glutamatergic function. Repeated administration of lithium, the prototype mood stabilizer, may promote the uptake of glutamate from the synapse (Dixon and Hokin, 1998), attenuate the function of glutamate receptors (Nonaka *et al.*, 1998) and reduce the function of intracellular signalling cascades that are activated by the binding of glutamate to its receptors (Manji and Lenox, 1999). Anticonvulsant and voltage-sensitive calcium channel antagonist mood stabilizers appear to reduce glutamate release (Cunningham and Jones, 2000), and to inhibit intracellular signalling downstream from glutamate receptors (Manji *et al.*, 1999).

NMDA Antagonist as Antidepressant Agents

Animal Studies

A growing body of preclinical research suggests that NMDA glutamate receptor antagonists exhibit antidepressant-like effects in animal models. Non-competitive NMDA antagonists (amantadine and memantine), competitive NMDA receptor antagonists (CGP 37849) and glycine-B partial agonists (ACPC) have antidepressant-like effects in several tests, including the Porsolt swim test (Moryl *et al.*, 1993; Przegalinski *et al.*, 1997), the tail suspension test (Trullas and Skolnick, 1990) and the chronic mild stress paradigm (Ossowska *et al.*, 1997; Papp and Moryl, 1994).

The mechanisms through which NMDA receptor antagonism exerts this effect are not yet clear. However, several possible pathways exist. For example, NMDA antagonists are known to downregulate β-adrenergic receptors, in a manner similar to

other antidepressants (Wedzony *et al.*, 1995). NMDA receptor antagonists also enhance serotonergic function (Lejeune *et al.*, 1994; Pallotta *et al.*, 1998) by several mechanisms, including increasing the number of 5-HT1A receptors (Wedzony *et al.*, 1997). Alternatively, the mechanism may be the result of a more direct effect on cortical excitability in critical regions of brain activity.

Treatment of Humans with Glutamate Modulating Agents

In humans, the antidepressant activity of NMDA receptor antagonists has received little rigorous evaluation. Initial studies by Crane suggested that D-cycloserine (DCS), an antibiotic developed to treat tuberculosis with indirect NMDA receptor antagonist-like effects mediated through the glycine-B site, possessed antidepressant activity (Crane, 1959, 1961). He reported beneficial effects with respect to depressed mood, insomnia and reduced appetite in depressed tuberculosis patients treated with DCS in doses of 500 mg per day. Interestingly, the rapid onset of antidepressant activity was a striking feature of DCS effects in these patients.

Case reports and preliminary studies suggest that amantadine, a low-affinity non-competitive antagonist of the NMDA receptor, has clinical efficacy in treating depressive symptoms provide additional evidence of the antidepressant activity of NMDA receptor antagonists (Dietrich *et al.*, 2000, Ferszt *et al.*, 1999, Huber *et al.*, 1999). Memantine, a related non-competitive NMDA receptor antagonist, also shows signs of behavioural improvement across a number of dimensions in patients with neuropsychiatric disorders, including mood and motor activity (Ambrozi and Danielczyk, 1988; Görtelmeyer and Erbler, 1992).

Most recently, a placebo-controlled pilot study suggested that the administration of single doses of ketamine 0.5 mg kg^{-1}, intravenously, had antidepressant effects in depressed patients (Berman *et al.*, 2000). Ketamine infusion produced mild psychosis and euphoria that dissipated within 120 minutes, while the antidepressant effects of ketamine infusion emerged over the first 180 minutes and persisted over 72 hours (Figure XVIII-3.3).

Although the clinical evidence supporting the antidepressant efficacy of NMDA antagonists remains limited, if effective, NMDA antagonists may show unique onset rapidity of clinical efficacy.

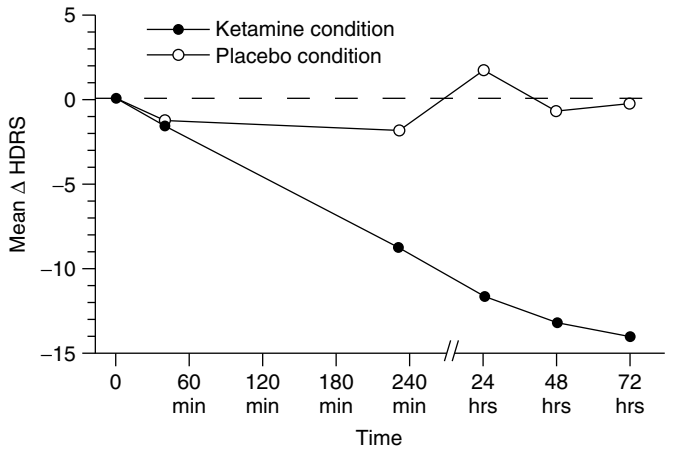

Figure XVIII-3.3 Graph illustrating the decrease in depressive symptom severity as measured by the Hamilton depression rating scale (HDRS) in seven subjects following either administration of placebo (open circle) or ketamine (closed circle) over a 72-hour period. Adapted from Berman *et al.* (2000)

CONCLUSION

Increasing evidence from several lines of research suggests that the major amino acid neurotransmitter systems contribute to the pathophysiology of mood disorders and the mechanisms of antidepressant and mood stabilizing actions. Relatively recent advances in magnetic resonance spectroscopy, along with an increased understanding of amino acid physiology and pharmacology, have now made it possible to begin our investigation into the role these systems may play in the pathophysiology and treatment of mood disorders.

The convergence of this evidence with other studies showing glial deficits and neuronal atrophy associated with stress and depression suggests that a common link may exist. Mismatches between inhibitory and excitatory drive are likely to promote atrophy and neurotoxicity, and may also be related to the reports of altered energy metabolism and cortical excitability that are commonly associated with mood disorders.

XVIII-4

Peptidergic Transmitter Systems

Jeffrey H. Meyer

Peptides refer to short proteins consisting of chains of less than 100 amino acids. There are as many as 250 peptide neurotransmitters in the brain (see Table XVIII-4.1 for a partial list). Some, such as corticotrophin-releasing factor, have been extensively investigated with respect to mood disorders, but most have not.

Peptides may function as neurotransmitters, neuromodulators and neurohormones. Neurotransmitters are synthesized in presynaptic neurons, and are released after depolarization by presynaptic neurons in sufficient amounts to have effects upon postsynaptic neurons. Neurotransmitters have immediate effects upon postsynaptic neurons and are removed by the synaptic cleft. Neuromodulators have longer term effects upon neurons. For example, a neuromodulator may stimulate a receptor coupled to an effector that influences a second messenger, leading to a cascade that changes ongoing cellular functioning. Neurohormones are similar to neuromodulators except that neurohormones are released into blood, cross the blood–brain barrier, and then bind to receptors.

In this chapter, abnormalities of peptidergic transmitter systems in mood disorders are reviewed. Abnormal peptidergic functioning may involve neurotransmitter, neuromodulator and neurohormone effects. There will be some discussion regarding the role of specific peptidergic transmitter systems in clinical treatment.

OPIOIDS

It is well known that opioid agonist administration can influence mood, and cause analgesia in humans. Given that these behavioural states are dysregulated during depressive episodes, there has been some interest in measuring abnormalities of opioid receptors during mood disorders.

Table XVIII-4.1 A partial list of peptides in the central nervous system

Adrenocorticotrophic hormone
Androgens
Bradykinin
Calcitonin
Cholecystokinin
Corticotrophin-releasing hormone
Cortisol
Oestrogens
Glucagon
Growth hormone
Insulin
Nerve growth factor
Neuropeptide Y
Opioids
Oxytocin
Somatostatin
Substance P
Vasoactive intestinal peptide
Vasopressin

The major classes of opioid receptors are delta (δ), kappa (κ), and mu (μ). Two reports have found an increase in μ opioid receptor density in multiple brain regions of suicide victims (Gabilondo *et al.*, 1995; Gross-Isseroff *et al.*, 1990). The earlier study sampled depressed patients. In the later study, the diagnosis was not always known; however, among those in which the diagnosis was known, most had depression. These reports are consistent with preliminary, *in vivo*, imaging investigations. There is one published abstract reporting an increase in μ opioid receptor binding potential in an [^{11}C] carfentanil positron emission tomography study of depression (Zubieta *et al.*, 1995). The binding potential is proportional to receptor density and affinity (Meyer and Ichise, 2001; Mintun *et al.*, 1984).

Increased μ opioid receptor density should enhance the effects of endogenous opioids and it may seem counterintuitive that increased μ opioid receptor density is observed in depressive episodes. It is possible that these findings may be secondary to lower endogenous opioids or other abnormalities that affect the regulation of this receptor (Law and Loh, 1999).

CHOLECYSTOKININ (CCK)

Cholecystokinin is a family of short-chain peptides which bind to CCK receptors. CCK receptors are categorized into CCK_A and CCK_B receptors. CCK is of interest in mood disorders because anxiety symptoms often occur comorbidly with depressive episodes, and peptides that have CCK_B receptor agonist properties provoke panic attacks (Bradwejn and Koszycki, 1994; Rehfeld, 2000). A second reason for the interest in CCK in mood disorders is that CCK can modulate the release of dopamine in the nucleus accumbens and influence reward behaviours in animal models (Vaccarino, 1994).

Studies sampling CCK in cerebrospinal fluid tend to find no differences between depressed and healthy subjects (Gerner and Yamada, 1982; Gjerris and Rafaelsen, 1984; Gjerris *et al.*, 1984; Rafaelsen and Gjerris, 1985). One study associated state anxiety level with several CCK peptides in a large sample of depressed patients (Lofberg *et al.*, 1998). It has been reported that CCK receptors are increased in frontal cortex of young suicide victims (Harro *et al.*, 1992). The most common diagnosis of a suicide victim is a major depressive episode and major depressive disorder (Barraclough *et al.*, 1974; Robins *et al.*, 1959) so it may be that this abnormality occurs during depressive episodes. Post-mortem investigations of CCK have found no changes in entorhinal cortex concentrations in depressed subjects (Perry *et al.*, 1981) and no changes in several cortex and limbic regions in suicide victims (Kleinman *et al.*, 1985).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

These findings suggest that most CCK peptides are not globally altered during depressive episodes. They do not clarify whether CCK peptides may be altered in small, specific subregions such as the shell of the nucleus accumbens. Thus it is theoretically possible that CCK peptides may have a role within specific neurochemical brain circuits and contribute to pathological behaviour such as impaired reward.

Even if it is eventually found that CCK peptides do not contribute to the pathophysiology of depression, CCK antagonists might be considered as possible treatments to enhance reward or reduce anxiety. The main barrier to the clinical development of such compounds is that they often do not penetrate the blood–brain barrier (Wilson *et al.*, 2001).

CORTICOTROPHIN-RELEASING FACTOR

Corticotrophin-releasing factor (CRF) binds to CRF_1 and CRF_2 receptors. Hypersecretion of CRF is known to occur during depressive episodes. Evidence for this includes increased cerebrospinal fluid CRF in depressed patients (Banki *et al.*, 1987; France *et al.*, 1988; Nemeroff *et al.*, 1984) as well as several findings in suicide victims. In suicide victims, cerebrospinal fluid CRF was increased, and CRF receptor density was decreased in multiple brain regions (Arato *et al.*, 1989; Hucks *et al.*, 1997; Nemeroff *et al.*, 1988). These findings suggest that CRF is higher throughout the central nervous system during depressive episodes (Nemeroff *et al.*, 1988).

Increased CRF appears to affect other hormones during depressive episodes. The adrenocorticotrophic hormone (ACTH) response to CRF is blunted (Hartline *et al.*, 1996; Pariante *et al.*, 1995) and the decreased ACTH responsiveness to CRF can be considered a consequence of chronically excessive CRF stimulation. Since CRF stimulates ACTH and ACTH stimulates cortisol secretion, the increased cortisol secretion observed during depressive episodes is most likely attributable to increased CRF during depressive episodes.

In addition to effects upon ACTH and cortisol secretion, CRF may influence anxiety systems and have specific behavioural effects during depressive episodes. CRF has been implicated in stress response behaviours in animal models. Stressors increase the synthesis of CRF and CRF administration increases stress-related behaviours (Gray and Bingaman, 1996; Lightman *et al.*, 1993). Some of these effects may be consequent to CRF release in the hypothalamic–pituitary axis because exploratory behaviours are reduced after CRF administration to the hypothalamus (Menzaghi *et al.*, 1993).

CRF release in the amygdala may also contribute to these stress behaviours. Stress paradigms appear to activate CRF releasing neurons in the amygdala and CRF administered to the amygdala increases stress behaviours (Gray and Bingaman, 1996; Honkaniemi, 1992). CRF-containing neurons in the amygdala project to other limbic regions that contribute to the stress response (septum, hypothalamus, vagal nucleus) (Gray and Bingaman, 1996).

Glucocorticoids suppress CRF by providing negative feedback to the secretion of CRF, and this feedback is impaired during depression (Carroll, 1976; Carroll *et al.*, 1976). It has been postulated that one mechanism of antidepressants is to enhance this inhibitory feedback upon CRF secretion by increasing glucocorticoid receptor expression (Barden *et al.*, 1995; McQuade and Young, 2000). A number of antidepressants, including desipramine, imipramine, moclobemide and lithium, increase mRNA of type II glucocorticoid receptors (Barden *et al.*, 1995; McQuade and Young, 2000; Pepin *et al.*, 1989).

Another interesting direction of clinical treatment is the use of CRF antagonists to treat mood disorders. An open trial of a CRF_1 antagonist in patients with depressive episodes reported promising results with good tolerability and a reasonable response rate (Zobel *et al.*, 2000).

CORTISOL

Cortisol is a peptide that binds to both glucocorticoid and mineralocorticoid receptors. Increased cortisol levels in the serum and cerebrospinal fluid may be the most replicated finding in depressive episodes (Holsboer, 2000). It has also been demonstrated that cortisol secretion is resistant to inhibition by dexamethasone during depressive episodes (Carroll, 1976; Carroll *et al.*, 1976). Adrenal gland size is also reported to be enlarged during depressive episodes (Nemeroff *et al.*, 1992; Rubin *et al.*, 1995, 1996).

In animal models, it has been demonstrated that increased stress may result in a number of changes in cells within the hippocampus: decreased number of granule cells, decreased neurogenesis of granule cells, increased death of neurons, and atrophy of neuronal dendrites (Duman *et al.*, 2000; Fuchs and Flugge, 1998; Sapolsky, 2000). It is thought that cortisol is in part responsible for mediating these effects because stress raises cortisol levels and some of these hippocampal changes occur after high doses of glucocorticoids (Fuchs and Flugge, 1998; Sapolsky, 2000).

There are several observations of changes in depression that have been attributed to increased stress and/or increased glucocorticoids because they resemble such effects observed in the hippocampus in animal models (Duman *et al.*, 1997; Fuchs and Flugge, 1998; Sapolsky, 2000). Post-mortem investigation of both unipolar and bipolar illnesses reports decreased neuronal size, and neuronal and glial densities in some cortex layers within Brodmann's area 9 of the prefrontal cortex (Rajkowska *et al.*, 1999, 2001). Hippocampal volume as measured using structural magnetic resonance imaging (MRI) is reported to be lower in major depressive disorder (Bremner *et al.*, 2000; Sheline *et al.*, 1996, 1999).

Increased stress during depressive episodes may be causing increased cortisol. The increased cortisol during depressive episodes could then be contributing to the post-mortem and MRI changes reflecting cell loss (Bremner *et al.*, 2000; Rajkowska *et al.*, 1999, 2001; Sheline *et al.*, 1996, 1999). Increased cortisol is not specific to mood disorders and can be found in other psychiatric illnesses, most notably bulimia. Even so, the effects of high cortisol may be an important part of the pathophysiology of this illness.

VASOPRESSIN AND OXYTOCIN

Arginine vasopressin (AVP) is a neuropeptide and hormone which binds to V_1, V_2 and V_3 receptor subtypes. V_3 (also known as V_{1B}) receptors can be found in the anterior pituitary and are of particular interest in mood disorders (Thibonnier *et al.*, 1998, 2001). V_1 receptors are mostly in vasculature and V_2 receptors are mostly renal (Thibonnier *et al.*, 1998, 2001). The reason why AVP has been investigated in mood disorders is that it participates in stress responses and modulates the hypothalamic–pituitary cortisol axis. In rodent models, vasopressin secretion is increased after immobilization and novelty stress, and especially after repeated immobilization stress (Bartanusz *et al.*, 1993; Chen and Herbert, 1995; Gibbs, 1986; Ivanyi *et al.*, 1991). These findings are consistent with a report that stressful events can increase vasopressin secretion in humans (Meyerhoff, 1990).

Vasopressin can enhance the function of the hypothalamic–pituitary axis to secrete cortisol. Vasopressin facilitates CRF-stimulated ACTH production. The mechanism for enhancing the effect of CRF may involve increased production of CRF itself and/or increased synthesis of CRF_1 receptors (Aguilera *et al.*, 2001; Bartanusz *et al.*, 1993; Gibbs, 1986).

Since increased CRF secretion occurs during depressive episodes, investigators have been interested in assessing whether increased AVP secretion may contribute to increased CRF secretion observed during depressive episodes. Serum and cerebrospinal fluid levels during depressive episodes are not consistently different from those of healthy subjects (Inder *et al.*, 1997; Legros and Ansseau, 1992; Legros *et al.*, 1993; Pitts *et al.*, 1995; van Londen *et al.*, 1997); however, one study did correlate CRF levels with AVP levels during depressive episodes (Pitts *et al.*, 1995). Within specific brain structures such as the paraventricular nucleus of the hypothalamus and the suprachiasmatic nucleus, increased numbers of AVP secreting neurons are reported (Purba *et al.*, 1996; Zhou *et al.*, 2001). While the role of the latter finding is still unclear, the increased numbers of AVP secreting neurons in the hypothalamus may be important: increased arginine vasopressin release could facilitate activation of the hypothalamic–pituitary axis for cortisol production.

Oxytocin (OT) may have a similar role to AVP in major depressive disorder. The role of this peptide during stress and its influence upon ACTH secretion appear to be similar to AVP (Callahan *et al.*, 1992; Gibbs, 1986; Ivanyi *et al.*, 1991). OT secretion is increased during stressful conditions and OT can facilitate CRF stimulation of ACTH (Callahan *et al.*, 1992; Gibbs, 1986; Ivanyi *et al.*, 1991).

Since increased CRF secretion occurs during depressive episodes, investigators have been interested in assessing whether increased OT secretion also occurs during depressive episodes. Cerebrospinal fluid and serum measures of OT are not consistently abnormal during depressive episodes (Legros and Ansseau, 1992; Legros *et al.*, 1993; Pitts *et al.*, 1995; van Londen *et al.*, 1997). There is one report of increased OT cell numbers in the paraventricular nucleus of the hypothalamus during depressive episodes (Zhou *et al.*, 2001). It is possible that OT will have a role as a facilitator of CRF stimulation during depressive episodes.

NEUROPEPTIDE Y

Neuropeptide Y is a 36-amino acid neurotransmitter with five receptor subtypes. There are some reports that neuropeptide Y is reduced in the cerebrospinal fluid and plasma of patients with depressive episodes (Hashimoto *et al.*, 1996; Nilsson *et al.*, 1996; Westrin *et al.*, 1999; Widerlov *et al.*, 1988). Neuropeptide Y is also reported to be lower in the prefrontal cortex of suicide victims (Widdowson *et al.*, 1992). Neuropeptide Y mRNA was reported to be lower in the prefrontal cortex of subjects with bipolar disorder (Widdowson *et al.*, 1992) and a post hoc analysis showed increased Y_2 mRNA expression in layer IV of the prefrontal cortex in suicide victims (Caberlotto and Hurd, 2001).

An interesting argument has been made that neuropeptide Y may be inadequately inhibiting CRF secretion during depressive episodes (Antonijevic *et al.*, 2000). The role of neuropeptide Y in mood disorders is still an area of ongoing investigation.

SUBSTANCE P

Substance P is classified with the tachykinin family and binds to neurokinin (NK_1) receptors. There is only limited evidence to suggest that there are abnormalities of the function of this peptide in mood disorders: one study found an elevation of substance P and/or substance P related peptides in cerebrospinal fluid of patients with major depressive disorder, and a second found no difference in substance P levels in major depressive disorder or bipolar disorder (Berrettini *et al.*, 1985; Rimon *et al.*, 1984). One study found no difference in substance P concentrations in a number of different brain regions in suicide victims as compared to healthy subjects (Kleinman *et al.*, 1985). One study found no overall difference in NK_1 density in the anterior cingulate gyrus in patients with a history of unipolar or bipolar disorder (Burnet and Harrison, 2000). In this study a secondary analysis found a decrease in the ratio of NK_1 density between superficial and deep layers in patients with a history of unipolar disorder. Further studies are needed to replicate this post hoc finding, to determine if there are substance P or NK_1 receptor abnormalities in other brain regions, and to address whether any such changes are related to the specific state of illness, i.e. depressive episode.

Although substance P might not play a role in mood disorders, NK_1 antagonists may have useful antidepressant properties. In behavioural models in animals, NK_1 antagonists reduce stress-induced vocalizations, enhance memory performance and reduce anxiety behaviours (Hasenohrl *et al.*, 2000; Kramer *et al.*, 1998). In addition, NK_1 antagonists promote cell growth and survival, and enhance recovery from lesions (Barker, 1996). All of these properties would seem favourable for the treatment of depressive episodes.

One clinical trial of an NK_1 antagonist found a similar rate of antidepressant response as compared to paroxetine and a significantly better response rate than placebo (Kramer *et al.*, 1998). Replication of this finding will be important as the placebo response rate was very high in this study.

NEUROTROPHINS

Brain-derived neurotrophic factor (BDNF) is a peptide within the family of neurotrophins and it binds to the tyrosine kinase receptor trkB. Neurotrophins and BDNF are released in the brain after damaging process such as seizures, hypoglycaemia and ischaemia (Lindvall *et al.*, 1994). Under such conditions, BDNF and neurotrophins demonstrate neuroprotective effects, and contribute to the formation of new synapses (Lindsay *et al.*, 1994; Lindvall *et al.*, 1994).

Neurotrophins are involved in processes of neuronal plasticity that occur in response to changes in perceptual stimuli (Thoenen, 1995). It is possible that processes which interfere with neurotrophin function will interfere with neuronal plasticity. This may be very relevant to stress during depressive episodes as it has been demonstrated that elevated stress may decrease hippocampal BDNF levels in animals (Duman *et al.*, 1997).

Neurotrophins may mediate some therapeutic effects of antidepressants. Long-term antidepressant (serotonin and norepinephrine reuptake inhibitors, monoamine oxidase inhibitors) administration to animals increases the expression of BDNF and trkB (Duman *et al.*, 1997). This finding may be relevant to clinical treatment of depression: a recent post-mortem study found elevated BDNF levels in the cerebellum in antidepressant-treated patients with major depressive disorder (Bayer *et al.*, 2000).

CONCLUSIONS

The relationship between peptides and mood disorders is a new frontier that bears further investigation. Studies of peptides in mood illnesses in humans have mostly sampled unipolar depression, and the relevance of these investigations to bipolar disorder is not known. The relationship between most peptides and mood disorders has not been studied.

Some peptides, such as CRF, may play a role in behavioural symptoms of depression, whereas peptides such as cortisol and NGF may contribute to pathological changes observed. Intervening with treatments to reverse abnormalities of these neuropeptides should result in new therapeutic opportunities for mood disorders.

Other peptides (such as substance P) may have no role in the pathophysiology of the illness, yet their antagonists could influence either symptoms or pathology and have important therapeutic properties. Most current antidepressant medications share considerable commonality because they bind to monoamine receptors or influence monoamines. For treatment-refractory patients, new classes of antidepressants could be extremely important.

Neuroendocrinology of Mood Disorders

Dorothy K.Y. Sit and Anthony J. Rothschild

INTRODUCTION

The major mood disorders are associated with specific, highly reproducible neuroendocrine alterations, and conversely, certain endocrine disorders (e.g. hypothyroidism and Cushing's disease) are associated with higher than expected rates of mood disturbances. Neuroendocrine abnormalities have been thought to provide a 'window on the brain', revealing clues regarding the pathophysiology of central nervous system dysfunction. This neuroendocrine strategy is based on extensive research which indicates that the secretion of peripheral endocrine hormones is largely controlled by the respective pituitary trophic hormone. The pituitary hormones are in turn regulated by hypothalamic release and release-inhibiting hormones. Mood disorders are associated with multiple alterations, specifically of the hypothalamic–pituitary–adrenal (HPA), hypothalamic–pituitary–thyroid (HPT) and growth hormone axes. In this chapter, we review the research on the alterations of these axes and also discuss the roles of melatonin, dehydroepiandrosterone, parathyroid hormone and gonadal hormones in the pathophysiology of mood disorders.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Introduction

Hypercortisolism has been prevailingly linked to the hormonal stress response found in patients experiencing affective disorders, especially in depression. Stressful life events may trigger a psychiatric condition in susceptible individuals, perhaps indicating a response of the HPA axis. Current research, however, is now aimed at understanding the mechanism by which the HPA axis may be causally linked to the pathophysiology of mood disorders. A growing body of preclinical and clinical research continues to provide information on the close ties between abnormalities in the HPA axis and various regions of the brain, with their subsequent influence to alter function of crucial neurotransmitters (and their receptors), relevant to the development of affective disorders.

HPA Axis Function

Corticosteroids and Mood Effects

Cortisol and the HPA axis play a crucial role in the stress response system, acting as an important interface between the central nervous system and the peripheral endocrine response system (Holsboer, 2001). Each hormone in the HPA axis cascade, as well as the other neuropeptides, possesses important effects not only on behaviour and emotions, but have significant roles in modulating the immune, endocrine and autonomic nervous systems. Cortisol enhances the availability of glucose, the main nutrient for all cells, including those found in the brain. Hypercortisolism, as a reflection of a hyperactive HPA axis state, now is postulated to be causally linked to the pathophysiology of depression.

Patients with depression and documented hypercortisolism often present with vegetative changes, such as sleep disturbance and energy reduction, decreased attention and cognition, psychosis, suicidality, anxiety, psychomotor disturbances or decreased libido (Wolkowitz, 1994). More recent literature hypothesizes that current antidepressants stimulate corticosteroid receptor expression, causing enhanced negative feedback on the HPA axis restoring appropriate corticotropin-releasing hormone (CRH) and cortisol levels. By reducing the levels of circulating cortisol, mood and vegetative symptoms may improve.

Historically, medically ill patients who were prescribed steroids such as prednisone, dexamethasone, cortisone and other synthetic corticosteroids for various medical conditions reportedly developed behavioural and emotional changes, such as mood lability, depression, hypomania, memory and attention changes, or psychosis. Those treated with exogenous corticosteroids seem to present with hypomania, while those with an underlying condition that produces increased endogenous steroids present with depression (Plihal *et al.*, 1996). Patients with Cushing's syndrome (non-adrenocorticotropic hormone [ACTH] related) and disease (increased ACTH) develop depression at similar incidence rates, even though the disease origins are different, implying that cortisol contributes to the development of psychiatric symptoms (Murphy, 1991).

Of note, patients with Addison's disease, an immune-related disorder leading to adrenocortical insufficiency, may also develop depression which responds to cortisol and other hormone replacement therapy (Leigh and Kramer, 1984). DeBattista *et al.* (2000) reported on 22 patients with non-psychotic depression who were randomly assigned to a one-day treatment with either ovine CRH, hydrocortisone or saline. Depression rating scales given immediately prior to treatment and the day following treatment demonstrated a rapid and robust reduction in depressive symptoms. Arana *et al.* (1995) and Dinan *et al.* (1997) described brief open-label trials using high-dose dexamethasone for the treatment of depression, reporting significant symptom improvement. On the otherhand, Wolkowitz *et al.* (1996) found the contrary, albeit in a very small sample size of five patients. Wolkowitz and Reus, (1999) postulated that both anti-glucocorticoid treatment and brief high-dose steroid treatment may have similar effects on the HPA axis, such as lowering of cortisol levels through upregulation of brain corticosteroid receptors; altering levels of the other adrenal steroid hormones; and increase in ACTH levels (after dexamethasone's initial inhibitory effect on ACTH production is worn off).

The HPA Axis, Serotonin, and Hippocampal Pathophysiology

It appears that corticosteroids influence brain function through the modulation of gene expression, and direct cell membrane effects

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

(McEwen *et al.*, 1979). The mechanisms by which hypercortisolism leads to affective disorders, such as depression, may be explained by effects of increased CRH, enhanced secretion of ACTH from the pituitary, increased adrenal steroid output, and impaired response to negative feedback at the levels of the hypothalamus, pituitary, adrenals and hippocampus. The hippocampus is implicated in its role of regulating the HPA axis. This stems from findings of increased expression of mineralocorticoid (type I) and glucocorticoid (type II) receptors in the hippocampus (Jacobson and Sapolsky, 1991), along with evidence of increased HPA stress reactions after hippocampal damage, and hippocampal glucocorticoid receptor blocking (Feldman and Conforti, 1980; Sapolsky *et al.*, 1984). In fact, type I receptors are predominantly found in the hippocampus, while type II receptors are distributed in many regions of the brain, including the hippocampus (Joels and Dekloet, 1992; McEwen *et al.*, 1992).

The hippocampus is densely distributed with serotonin 1A receptors, and there is early evidence that interactions between corticosteroids and the 5-HT 1A receptor (Lopez *et al.*, 1998; Meijer *et al.*, 1998) may contribute to the pathophysiology of affective disorders. In fact, 5-HT 1A receptor density reduction and downregulation appear to be mediated by the mineralocorticoid receptors (Meijer *et al.*, 1997), while adrenalectomy appeared to reverse the decrease in hippocampal 5-HT 1A receptor levels (Lopez, 1998).

With the advent of more suitable positron emission tomography (PET) imaging tracers, decreased pre- and postsynaptic binding of 5-HT 1A receptors in depressed patients have been detected. Serotonin 2A receptors demonstrated equivocal results, perhaps due to the heterogeneity of depressive disorders and varying severity of presentations. Much data also indicate a decreased density in serotonin transporters in the brains of depressed patients (Ellis and Salmond, 1994). Post-mortem studies of suicide victims examining postsynaptic 5-HT 1A receptor density in the hippocampus and frontal cortex reported inconsistent results (Lowther *et al.*, 1997; Stockmeier *et al.*, 1997). The reports of increased 5-HT 1A receptor sites among individuals who have completed suicide may suggest that these receptors are more regulated by steroid levels in the hippocampus and, less so, in other parts of the brain. Also, tracers used in PET studies of patients (antagonistic action binding to receptors in high- and low-affinity states) differ from those used in post-mortem studies (agonist action with high-affinity binding).

MRI studies of depressed patients showed decreased hippocampal size, correlating with lifetime duration of illness and treatment resistance (Shah *et al.*, 1999; Sheline *et al.*, 1999). McEwen (2000) summarized the possible causes for hippocampal atrophy, and noted evidence of its reversibility after treatment. Reduction in the volume of Ammon's horn or dentate gyrus may occur secondary to reduced dendrite branching, impaired neurogenesis, decreased neuronal survival rate or permanent neuron loss. Atrophy of other areas of the brain, such as the prefrontal cortex (Drevets *et al.*, 1997) and amygdala (Sheline *et al.*, 1998), has been linked to depressive disorders. Glial cell loss appears to contribute to atrophy of the prefrontal cortex, amygdala and possibly hippocampus, which has also been associated with depression.

For further details, Fujita *et al.* (2000) completed an excellent review of the literature on the role of the hippocampus in depression pathophysiology.

The D-fenfluramine challenge test is used in studies as an indirect indicator of central serotonergic functioning, by measuring the prolactin (PRL) response to D-fenfluramine (serotonin releasing agent) exposure. O'Keane *et al.* (1992) reported that a fenfluramine-induced prolactin response was augmented after antidepressant treatment with medications including tricyclic agents and serotonin reuptake inhibitors, as have other groups (Charney *et al.*, 1984; Kasper *et al.*, 1990; Maes *et al.*, 1991; Price *et al.*, 1989). Shapira *et al.* (1993) found that an increased prolactin response to D-fenfluramine occurred after lithium treatment for depression, which persisted even after medication cessation.

On the other hand, in a double-blinded randomized control trial comparing patients before and after treatment with two SSRIs, fluoxetine and fluvoxamine, Kavoussi *et al.* (1999) observed a lack of enhancement of the PRL response after an 8-week period of treatment. This group postulated that study patients may have been less severely depressed, and free of Axis I and II comorbidities. Indeed, certain patients had normal PRL responses to D-fenfluramine even prior to the intervention. They explained that SSRI treatment may have prevented D-fenfluramine uptake into presynaptic neurons, thus lessening the release of 5-HT from these neurons, and thereby reducing the PRL response. Lastly, the question was raised that the action of certain SSRIs, such as fluvoxamine, may preferentially downregulate 5-HT 2 receptors (Spigset and Mjorndal, 1997). Recent literature has suggested that the PRL response to D-fenfluramine may be mediated by the 5-HT2 Rec (Coccaro *et al.*, 1996).

Mannel *et al.* (1997) found the fenfluramine test not to be a useful tool for the prediction of therapeutical outcome, upon measuring PRL and cortisol responses in euthymic patients (combination of unipolar, bipolar and schizoaffective diagnoses), treated on long-term lithium or carbamazepine prophylaxis. However, they observed a trend that blunted cortisol release in response to the FEN challenge seemed to occur in those responding to lithium or carbamazepine treatment, which may reflect better mood stabilization.

Dopamine and the HPA Axis

As described in the previous section, psychotic depression appears to be associated with hypercortisolaemia and activation of the dopamine system (Schatzberg and Rothschild, 1988; Schatzberg *et al.*, 1985) while suppression of glucocorticoid (GC) release reduces dopamine activity (Piazza *et al.*, 1996). In plasma homovanillic acid (HVA) (metabolite of dopamine) studies, there is evidence of increased central dopamine activity (Aberg-Widtedt *et al.*, 1985; Devanand *et al.*, 1985; Sweeney *et al.*, 1978), while others have found the absence of effect (Wolkowitz *et al.*, 1987). Plasma HVA is derived from peripheral noradrenergic neurons and limits interpretation of these results. Measures of CSF HVA levels may be more suggestive of presynaptic dopamine activity (Pitchot *et al.*, 1992), but psychomotor activity may interfere with CSF HVA measurements (van Praag *et al.*, 1975).

Other groups have administered dopamine agonists (APOmorphine), to observe prolactin and growth hormone responses, as an indirect indicator of dopamine receptor activity in depressed patients (Duval *et al.*, 2000) and depressed, suicidal patients (Pitchot *et al.*, 2001). Results are interpreted with difficulty due to their indirect indication of central neurotransmitter activity at the hypothalamic level.

Of interest, Cyr *et al.* (2001) reported their findings in transgenic mice bearing blocked GC receptor expression, compared to control mice. They were able to show increased amphetamine-induced locomotor activity, with increased concentrations of striatal dopamine and its metabolites, dihydroxyphenylacetic acid and HVA. Transgenic mice exhibited increased D1 and D2 receptor binding. Upon exposure to amitriptyline, increased dopamine-specific transporter binding occurred (restoring dopamine uptake into synaptosomes), and upon exposure to fluoxetine, reduced striatal D1 and D2 receptor levels were observed. These results seem to indicate that increased GC levels in these transgenic mice was associated with hyperactive dopamine activity, and corrected following antidepressant exposure.

Measures of HPA Axis Function

Dexamethasone-Suppression Test (DST)

The cortisol response to challenge with the exogenous corticosteroid dexamethasone is measured to determine the intact function of the HPA axis response, by suppressing cortisol release. Patients with psychiatric disorders, particularly major depression, often fail to suppress their cortisol production, or will escape from suppression abnormally early. According to the DST protocol published by Carroll *et al.* (1981), dexamethasone 1.0 mg was administered at 11 p.m., and blood samples for serum cortisol were taken the following day, at 8 a.m., 4 p.m. and 11 p.m. The greatest sensitivity was obtained when all three samples were collected (Rush *et al.*, 1996). For convenience, outpatients are usually tested in the afternoon, thus losing sensitivity of the test results. Carroll *et al.* (1981) defined the criterion for a normal response to the DST as a cortisol level of $5.0\,\mu g\,dl^{-1}$, using the modified Murphy competitive protein finding technique (Murphy, 1968). Rubin *et al.* (1987) suggested a cortisol level cut-off of $3.5\,\mu g\,dl^{-1}$, with the more specific radioimmunoassay (RIA) technique. Rush *et al.* (1996) reported that a limit of $4.0\,\mu g\,dl^{-1}$, would achieve a 96% specificity of the DST. Rothschild *et al.* (1982) described how cortisol levels with a threshold of $15\,\mu g\,dl^{-1}$ would attain a high specificity and high predictive value for psychotic depression, and may be more clinically useful in confirming this particular diagnosis.

Interestingly, depressed patients found to be DST cortisol suppressors have higher plasma dexamethasone concentrations than DST non-suppressors (Carson *et al.*, 1988), with dexamethasone plasma levels rising with treatment (Holsboer *et al.*, 1986b). This may indicate a hypercortisolaemic induction of liver enzymes, to augment dexamethasone metabolism (Holsboer *et al.*, 1986a).

Other Measures of HPA Activity

Salivary cortisol has proven to be an accurate and valid measure of free cortisol (Kirschbaum and Hellhammer, 1994), and is closely correlated with serum and plasma cortisol levels before and after the DST. Normal values may range from 1 to $25\,nmol\,l^{-1}$. Difficulties in interpreting salivary cortisol results arise from the use of different cut-off values in different laboratories, and measurements made at different times of the day.

The 24-hour urinary-free cortisol (UFC) sample appears to closely reflect circulating unbound plasma cortisol production, and is a helpful indicator of adrenal cortical activity (Carroll *et al.*, 1976). Total creatinine is also determined, as a measure of renal function. Normal UFC excretion is $40-50\,\mu g$ in 24 hours, versus $>90\,\mu g$ in 24 hours in the (non-psychotically) depressed.

Finally, age may be an important contributing factor to increased cortisol levels, determined in the DST (Halbreich *et al.*, 1984), although others have not found this to be a significant factor (Schweitzer *et al.*, 1991). In certain studies, the population of older adults who have documented cognitive decline exhibit higher levels of 24-hour UFC, with women more than men demonstrating memory impairments (as tested by verbal free recall and spatial recognition performance, implying encoding deficits) associated with increased UFC (Seeman *et al.*, 1997).

The DST and Mood Disorders

Schatzberg *et al.* (1983) reported that using a plasma cortisol level cut-off of $15\,\mu g\,dl^{-1}$, the frequency of DST non-suppression in the group with psychotic depression (PD) was greater than in those with non-PD (71.4% versus 58.1%). Rothschild *et al.* (1982) examined patients with schizophrenia and psychotic symptoms, to compare DST responses of PD patients. None of the schizophrenic patients had DST non-suppression, while half of the PD patients showed elevated post-dexamethasone cortisol levels, $>14\,\mu g\,dl^{-1}$. A meta-analysis of 14 studies, carried out by Nelson and Davis (1997), found the DST non-suppression rate at 64% in PD patients, versus 41% in non-PD patients. In addition, there was no difference in the rate of DST non-suppression among the endogenously depressed versus those with non-endogenous depression (39% versus 36%). Patients with psychotic depression exhibit the most replicable findings of DST non-suppression, in addition to elevated post-dexamethasone cortisol levels and high levels of 24-hour UFC. Schatzberg *et al.* (1985) and Schatzberg and Rothschild (1988) hypothesized that in certain depressed patients, the hypercortisolaemic state enhanced dopamine activity, leading to psychotic symptoms.

Cassidy *et al.* (1998) reported on the cortisol responses to DST in bipolar manic patients, and although the sample size was small, mixed manic patients seemed to exhibit greater degrees of non-suppression than pure manic patients do. With disease remission, cortisol suppression became restored. Cassidy's (1998) study also summarized the literature published on the effects of mania on DST non-suppression, reporting the frequency to be from 0% to 70%. Drawing conclusions here may be difficult, due to numerous methodologic differences, such as the dexamethasone dose chosen and time of blood draw.

As for dysthymic disorder, the rate of DST non-suppression falls between that observed in patients with major depression and healthy controls. Howland and Thase (1991) reported on a meta-analysis of ten studies comparing DST results in patients with dysthymic disorder, major depression and other psychiatric diagnoses. They found that 14% of dysthymic individuals, 59% of major depressive patients and 6% of healthy controls demonstrated DST non-suppression, with no significant difference reported between the rate in dysthymics and that in controls. Interestingly, Ravindran *et al.* (1994) found the rate of non-suppression in the DST in dysthymic patients was 7%, and the non-suppressors proved to be more successful responders to antidepressant therapy (with fluoxetine).

DST and Outcome of Mood Disorders

Deshauer *et al.* (1999) observed the pattern of DST cortisol response, in a four-year follow-up study, of 19 completely remitted, unipolar depressed and bipolar disorder patients on lithium prophylaxis. Those with initial DST non-suppression demonstrated persisting HPA dysregulation (more females than males), despite symptom remission. Ribeiro *et al.* (1993) reported on a meta-analysis of long-term outcomes of depressed patients, describing those with DST non-suppression at post-treatment evaluations to have poorer outcomes.

Rothschild *et al.* (1993) found significant positive correlation between higher cortisol activity at one-year post-treatment, and impaired social and occupational functioning as measured by the Social Adjustment Scale — Self Report (SAS-SR) (Weissman *et al.*, 1978). Likely, impaired functioning was linked to cognitive deficits associated with the hypercortisolaemia. Belanoff *et al.* (2001) provide an excellent review on the effects of cortisol on cognition. Chronic hypercortisolaemia has been linked to neurotoxic effects, especially in the hippocampus, which possesses numerous glucocorticoid receptors (McEwen *et al.*, 1991). Preclinical evidence from rat and primate studies suggested evidence of hippocampal neuron loss (Sapolsky *et al.*, 1990). Cushing's syndrome patients, who have an endogenous overproduction of cortisol, demonstrated depressive symptoms, impaired cognition and decreased hippocampal volume (Starkman *et al.*, 1992). Of interest, after treatment of patients with Cushing's disease (microsurgical resection of pituitary adenomas), the hippocampal volume was increased by up to 10% (Starkman *et al.*, 1999). Further discussion on the HPA axis and hippocampal function will follow below.

DEX/CRH Test

Heuser *et al.* (1994) summarized their experience with the dexamethasone (DEX) suppression/CRH challenge test, to assess HPA axis abnormalities, by first pretreating patients with DEX 1.5 mg orally at 23 : 00 h the previous night. This is followed the next day with administering human CRH (hCRH) 100 μg intravenously, with blood samples drawn for serum cortisol and ACTH every 15 minutes from 14 : 00 to 18 : 00 h. This group reported that from a sample of 140 psychiatric patients with various diagnoses, including major depression, mania, panic disorder and schizophrenia, cortisol and ACTH release were significantly greater than healthy controls. The sensitivity of this test was 80% for major depression, exceeding that of the standard DST, which reportedly has sensitivity of 44% from a meta-analysis of available data (Arana and Forbes, 1991), depending on age, depression severity and DEX dose. Normal controls demonstrated suppression of ACTH and cortisol release.

With this test, DEX suppresses the HPA axis at the pituitary level, but does not suppress the release of CRH or vasopressin from the hypothalamus. Depressed patients may have altered glucocorticoid feedback regulation, such that pre-administered DEX was paradoxically unable to suppress ACTH and cortisol release after the hCRH bolus. In animals exposed to chronic stress conditions, vasopressinergic regulation of the pituitary–adrenal system takes over (de Goeij *et al.*, 1992). Likewise, psychiatric illness may lead to an increased hypothalamic CRH and vasopressin production, resulting in augmented ACTH and corticosteroid release, and a transient CS receptor desensitization.

Thus in a DEX-pretreated depressed patient, ACTH release in response to administered CRH would be greater than in a control patient, because of synergistic action between the CRH given and the increased available vasopressin (von Bardeleben *et al.*, 1985). Limitations include the cumbersome nature of the test, which requires intravenous administration of both DEX and human CRH, and frequent blood monitoring thereafter; and although the test is fairly sensitive for depression, the specificity remains low.

Rybakowski and Twardowska (1999) used this test to compare 16 bipolar and 24 unipolar depressed patients, with 20 healthy controls, finding that HPA dysregulation was more pronounced in patients with bipolar depression, as shown by significantly higher cortisol levels during the acute episode and in remission. Holsboer *et al.* (1995) reported that healthy probands at high risk for psychiatric disorders developed an increase in plasma cortisol response to the DEX/hCRH challenge test, at levels between depressed patients and the controls without family history.

The results of the DEX/CRH test, administered to inpatients with depression at the time of treatment initiation and at time of discharge, seemed to suggest that those individuals with increased cortisol response at discharge time exhibited a higher risk of relapse in the next six months, versus those with low cortisol responses (more appropriate response) (Zobel *et al.*, 1999), although this report did not report the average length of hospitalization for observed patients.

Of interest, Holsboer *et al.* (1995) and Krieg *et al.* (2001) (in the Munich vulnerability study) described their findings of cortisol response to the DEX/CRH challenge in apparently healthy relatives of patients being treated for acute major depression. In the Krieg study, those relatives with increased cortisol response exhibited higher scores on psychometric scales measuring 'rigidity' and 'autonomic lability', and 32% of first-degree healthy relatives had depression-like features in other neuroendocrine and polysomnographic (EEG) measures. Their prospective study continues to monitor these relatives, in order to determine whether these measures are able to predict risk for developing affective disorders in the relatives of patients already being treated.

CRH

Corticotrophin-releasing hormone is a neuropeptide with numerous sites of action in the endocrine, autonomic and immune systems, modulating various behaviours, e.g. anxiety-related behaviour, food intake, reproduction, arousal and motor function. CRH is released from the paraventricular nucleus (PVN) of the hypothalamus into portal vessels, and triggers release of ACTH from the anterior pituitary. From preclinical evidence, it is postulated that CRH behaves as a neurotransmitter, which acts at different sites in the brain to exert neuroendocrine and behavioural effects. CRH activates the HPA axis to cause increased corticosteroid release. Increased cortisol levels feed back into a circuit via three possible routes: negative feedback at the level of the PVN neurons and anterior pituitary (Swanson and Simmons, 1989), positive feedback at the level of the central nucleus of the amygdala (CeA) and the dorsal PVN (Swanson and Simmons, 1989), and negative feedback through the ventral hippocampus to the bed nucleus of the stria terminalis (BNST) (Herman *et al.*, 1992).

CRH projections from the central nucleus of the amygdala, PVN and BNST terminate in the locus ceruleus (Van Bockstaele *et al.*, 1998), and may be responsible for enhanced arousal to stressors with an emotional component, as well as affect attention. CRH interacts with serotonin at the level of the raphe nuclei (Price *et al.*, 1998), to influence behaviours and emotions (via serotonin innervations in the forebrain). CRH may also affect dopamine neurons in the substantia nigra, thereby modulating dopaminergic activity in the striatum.

For more detail, Steckler and Holsboer (1999) provide an excellent overview of preclinical data pertaining to CRH receptor subtypes and their link to emotion and other affective conditions. The activation of CRH receptors allows CRH to exert its influence on behaviour. Importantly, two receptors have been found thus far, CRH1 and CRH2. In preclinical studies, CRH2-alpha is expressed more in subcortical regions of the brain (lateral septum, ventromedial hypothalamus, dorsal raphe nucleus), and may be more responsible for behaviours such as feeding, reproduction and defence. CRH2-beta is expressed in non-neuronal tissue, such as the choroid plexus, arterioles, cardiac and skeletal muscle (Steckler and Holsboer, 1999). CRH1 receptors are found in the pituitary, cerebellum and frontal cortex, and seem to modulate the cognitive processes, e.g. attention, executive function, emotional experience, and perhaps learning and memory.

Urocortin is a neuropeptide that is 45% homologous to CRH, which binds more potently to the CRH2-alpha receptor, than CRH (Donaldson *et al.*, 1996). Binding of the different CRH receptor subtypes likely activates different functions. However, urocortin does not appear to mediate ACTH release from the anterior pituitary at baseline, after induced stress and adrenalectomy, according to preclinical studies (Turnbull *et al.*, 1999).

Ongoing basic and clinical research studies are being undertaken to further understand the effects of glucocorticoids on CRH gene expression, and the implications of CRH on fear and anxiety. Much continues to be reported on the neurobiology of stress and anxiety, including HPA dysregulation secondary to stress, and the resulting predisposition to or development of abnormal autonomic, CNS, neuroendocrine and immune system responses. Important reports and reviews include Schulkin *et al.* (1998), McEwen (2000), Thrivikraman *et al.* (2000) and Liu *et al.* (1997).

CRH, ACTH and Cortisol Responses in Mood Disorders

Symptoms of stress activation and melancholic depression have common features such as anxiety and fear, constricted affect, stereotyped thinking, including guilt preoccupations, pessimism for the future, and sense of worthlessness. There may be evidence of physiological hyperarousal, autonomic and neuroendocrine activation,

along with inhibited appetite, libido, and growth and reproduction (Gold *et al.*, 1988). Early studies by Gold *et al.* (1984), Holsboer *et al.* (1984) and Nemeroff *et al.* (1984, 1988) implicated CRH in the hypercortisolaemia found in depression: Gold and colleagues, in their study of HPA responses to ovine CRH, to glucocorticoid antagonists such as mifepristone, arginine vasopressin and to continuous infusions of CRH; Nemeroff and colleagues, in reporting elevated cerebrospinal fluid (CSF) CRH levels in depressed patients, and later describing reduced CRH receptors in the cerebral cortex of post-mortem suicide victims; and Holsboer and colleagues, in replicating findings of pituitary inhibition by hypercortisolaemia.

Norepinephrine (NE) is a neurotransmitter with numerous functions, inhibiting feeding, grooming and sleep behaviours. It activates the amygdala to enhance the coding of emotionally connected memories. NE inhibits medial prefrontal cortex functions, such as shifting mood states, developing novel versus well-rehearsed behaviours, and inhibiting the HPA axis and brainstem autonomic activity (Arnsten *et al.*, 1999; Gold and Chrousos, 1999). NE appears to stimulate the HPA axis, under chronic stress situations. Sympathetic inputs to the adrenal system are activated, thus sustaining hypercortisolaemia (Gold and Chrousos, 1999). CRH may also play a role in the learning and storage of fear responses in the amygdala. Rodent and primate research have shown that central administration of CRH activates the HPA axis, leading to sympathetic nervous system activation (Britton *et al.*, 1982; Brown *et al.*, 1982; Sirinathsinghji *et al.*, 1983; Sutton *et al.*, 1982).

Wong *et al.* (2000) postulated that melancholic depression activated a stress response via the NE-locus ceruleus and CRH systems. A study of 10 melancholic, depressed, medication-free patients and 14 healthy controls found that depressed patients exhibited elevated CSF NE (even during sleep), indicating central noradrenergic activation in depression.

The observation of elevated plasma cortisol may have resulted from possible direct NE activation of hypothalamic CRH neurons (Calogero *et al.*, 1988), NE activation of the amygdala and, subsequently, the HPA axis (Goldstein *et al.*, 1996), NE inhibition of the medial prefrontal cortex, which inhibits the HPA axis (Arnsten *et al.*, 1999), and sympathetic modulation of adrenal secretion during stress (Arnsten *et al.*, 1999). In fact, increased cortisol has been documented to directly activate brainstem noradrenergic neurons via CRH (Wong *et al.*, 2000). On the other hand, this study reported that CSF CRH levels and plasma ACTH levels were within 'normal' range. This actually represents inappropriately elevated levels of CSF CRH and plasma ACTH, in the setting of hypercortisolaemia (Kling *et al.*, 1991), thus indicating a possible dysfunction in the glucocorticoid negative feedback on hypothalamic CRH neurons, or an override of the negative feedback by CSF NE excitation.

Earlier, Gold *et al.* (1995) linked similar depressive states, those of atypical depression, seasonal affective disorder and depression accompanying Cushing's disease. Such patients usually describe symptoms of lethargy, fatigue, hypersomnia, hyperphagia and increased mood reactivity. It was postulated that with chronic hypercortisolism, these patients developed a central, hypothalamic CRH deficiency, with low ACTH levels, and a blunted response to exogenous CRH.

Vieta *et al.* (1999) compared the ACTH and free cortisol response to hCRH in 42 lithium-treated bipolar manic and hypomanic patients in remission with 21 healthy controls, and reported high baseline and peak ACTH levels in the patients. At six months follow-up, using stepwise logistic regression, the measured ACTH area under the curve, after CRH stimulation, documented a significant prediction of manic relapse with a sensitivity of 56% and specificity of 92%. After a 12-month follow-up, again enhanced ACTH response was found and the ACTH AUC predicted mania with sensitivity 75% and specificity 91%. Gold *et al.* (1984) did not find significant difference between remitted bipolar and healthy control patients (and between manic euthymic bipolar patients); however, samples sizes were small.

Heim *et al.* (2001) reported on HPA axis responses to provocation challenge tests (CRH stimulation and ACTH stimulation tests) in survivors of childhood abuse, finding that women with a history of abuse but without major depression exhibited greater ACTH responses to ovine CRH. Depressed women with and without histories of abuse both exhibited blunted ACTH responses, likely indicating CRH receptor downregulation, secondary to intrinsic chronic CRH hypersecretion from the hypothalamus. In addition, the women with abuse histories and major depression exhibited more comorbid post-traumatic stress disorder (PTSD) and recent chronic mild stress than the same cohort, without major depression. Heim *et al.* (2000) also reported on autonomic responses and ACTH and cortisol levels, after psychological laboratory stress exposure, to similar cohorts of women with a history of childhood abuse. Here, women with abuse histories, regardless of coexisting depressed mood, exhibited increased ACTH but normal cortisol responses, compared with healthy controls and depressed women without childhood abuse.

CRH Antagonists in Treatment of Depression and Anxiety Disorders

Holsboer (1999) argued that a number of clinical conditions, including anxiety, depression and alcohol withdrawal, are accompanied by an exaggerated stress response, and that certain psychiatric conditions, such as psychotic depression, seem to exhibit enhanced dopamine neurotransmission secondary to elevated cortisol. The longer-term administration of the antidepressant trimipramine appeared efficacious in treating psychotic depression, via suppression of the HPA system (Holsboer-Trachsler *et al.*, 1994). Preclinical studies to decrease CRH1 receptor function by blockade, or suppression of synthesis through receptor gene deletion, have resulted in decreased anxiety in stressed animal models. Therefore, it would seem appropriate and promising to explore the development of modalities to block the central hyperdrive mechanism of the HPA axis, inferred to be responsible for the production of anxiety and depressive symptoms (such as suppressing CRH gene activation and release, and inducing CRH receptor blockade).

In rodents, CRH1 seems to modulate anxiety, possibly through its regulation of the HPA axis, as demonstrated by the anxiolytic effects of CRH1 antagonists (Arborelius *et al.*, 2000). This study reported that in rats, chronic administration of the CRH1 antagonist CP-154,156 decreased CRH production in the paraventricular nucleus of the hypothalamus, rather than alter the synthesis of CRH1 receptors, and did not cause adrenal insufficiency.

Zobel *et al.* (2000) described the effects of administering the CRH1 receptor antagonist R121919, to 20 patients for the treatment of major depression, over a period of 30 days. Patients were randomized to two groups; one group received the lower dose of 40 mg per day, and the second group was started on 40 mg per day and titrated up to 80 mg per day. At the end of the study, depression and anxiety scores improved significantly. At the same time, CRH1 receptor blockade did not seem to impair the release of ACTH and cortisol, as shown by results of CRH challenge tests given both before and after the study.

CRH1 antagonists appear to shorten the time of onset of antidepressants, exerting antidepressant effects, and may also be beneficial in treating insomnia, which frequently accompanies anxiety and mood disorders. There are concerns, however, that in the setting of a hyperactive HPA axis (as found in depression), the CRH receptors may be downregulated or desensitized, thus resulting in the blunted ACTH response to CRH (Holsboer, 1999). Upon exposing the depressed patient to CRH1 antagonists, which would block the already desensitized CRH receptors, cognitive

impairment may be induced or worsened, because of the interaction of CRH with the cholinergic systems, at the cortical level.

There are many other possible applications for CRH1 receptor antagonists, not only for treatment of depression, but also for the treatment of substance abuse (especially drug-seeking behaviour), anxiety disorders (including PTSD) and eating disorders. Further preclinical and clinical studies to clarify the function of these receptors and their subtypes, as well as the effect of various neuropeptides on receptor activity, are needed.

Anti-Glucocorticoid Agents

Cushing's patients, managed with either surgical intervention, or anti-glucocorticoid agents such as ketoconazole, metyrapone and aminoglutethimide, remit from depression up to a rate of 70% (Nieman *et al.*, 1985; Sonino *et al.*, 1993). Wolkowitz *et al.* (1999a) reported on their double-blind trial using ketoconazole versus placebo for the treatment of depression over a four-week period, and reported significant improvements in depressive symptoms, in those patients with an underlying hypercortisolaemic state. Ghadirian *et al.* (1995) reported the use of the three anti-glucocorticoid agents mentioned above in the treatment of depression, in an open-label, two-month trial. They described 60% of the patient sample with a greater than 50% reduction in depression symptomatology, and 50% with sustained remission at eight months follow-up. Most recently, the anti-progesterone and anti-glucocorticoid agent mifepristone, also known as RU-486, has been found to rapidly reverse symptoms in patients with primary psychotic depression (see Belanoff *et al.*, 2001 for review) and psychotic depression secondary to Cushing's syndrome (Van der Lely *et al.*, 1991).

The HPA Axis and PTSD

Quite recent literature has been published on the HPA responses in adult survivors of child abuse, thus adding important information to already present literature documenting HPA axis changes in male combat veterans and Holocaust survivors, with PTSD. As in depression, patients with PTSD hypersecrete CRH, as proven by elevated levels of CRH found in the cerebrospinal fluid (Baker *et al.*, 1999). On the other hand, there is evidence suggesting that PTSD patients possess an HPA axis with an exaggerated negative feedback mechanism.

For example, male combat veterans have decreased 24-hour UFC excretion (Mason *et al.*, 1986; Yehuda *et al.*, 1990) and lower plasma cortisol levels measured in the morning and throughout the day (Boscarino, 1996; Yehuda *et al.*, 1994). Likewise, Holocaust survivors demonstrated lower 24-hour UFC (Yehuda *et al.*, 1995).

Other studies report combat veterans with higher baseline plasma cortisol levels than controls, but no differences in baseline plasma ACTH levels, in the ACTH response to stress as well as in the cortisol response to stress (Liberzon *et al.*, 1999). Surprisingly, prepubertal children with PTSD demonstrate elevated 24-hour UFC, as compared to healthy controls and children with only a primary anxiety disorder. Combat veterans also exhibited greater plasma cortisol suppression to lower doses of dexamethasone (Yehuda *et al.*, 1995).

Heim *et al.* (2000) measured the HPA axis response (afternoon plasma ACTH and cortisol levels) and autonomic response (heart rate) to a standardized psychosocial laboratory stressor, consisting of an anticipation and preparation phase, followed by 10 minutes of public speaking and mental arithmetic task performance before an audience. Women with a history of childhood abuse exhibited increased pituitary–adrenal and autonomic responses, particularly those with concurrent major depression. This increased reactivity may occur from CRH hypersecretion, as a persisting consequence of past abuse, and may predispose such individuals to developing certain affective disorders. If this is the case, it may also suggest a choice of therapy, such as the use of CRH antagonists for treatment of depression in this patient population.

Heim *et al.* (2001) elaborated on the above study, by comparing a cohort of adult survivors of childhood abuse (with and without major depression) to healthy controls, by measuring plasma ACTH and cortisol responses to the ovine CRH challenge, and plasma cortisol responses to the ACTH challenge. They discovered that abused women without depression exhibited greater than usual ACTH responses to the exogenous CRH, contrasting with both non-abused and abused women with depression, who demonstrated blunted ACTH responses to CRH. In the ACTH stimulation test, abused women without depression had lower baseline and stimulated plasma concentrations, as compared to healthy controls, and to non-abused and abused women with depression. Newport and Nemeroff (2000) provide an excellent review of the neurobiology of PTSD.

Combining current clinical and preclinical data from rat (Plotsky *et al.*, 1993), and primate studies (Coplan *et al.*, 1996), early life stress may cause alterations at the adrenal level leading to an underlying hypocortisolaemic state, as found in patients with PTSD. Second, childhood trauma may also result in the development of a hyperreactive HPA axis towards stress in adulthood, with an underlying sensitization of the anterior pituitary to CRH. This may lead to increased CRH release in times of stress, perhaps contributing to pituitary downregulation and observed hypocortisolism. At the same time, abused women with depression may have developed an override of this pituitary downregulation, explaining their blunted ACTH response to the CRH challenge. Further preclinical and clinical studies are necessary to confirm and clarify the meaning of the above findings.

DEHYDROEPIANDROSTERONE AND DHEA(S)

Dehydroepiandrosterone (DHEA) and its sulphated metabolite, DHEA(S), are adrenocortical steroids, which serve as the precursor to testosterone and oestrogen. Circulating plasma and CSF levels peak in the mid-20s, and decline with age, reaching a nadir at age 65–70 years (Azuma *et al.*, 1993), when age-related illnesses increase substantially. DHEA(S) appears to decrease in settings of medical illness as well as with chronic stress (Spratt *et al.*, 1993), in contrast to cortisol, which tends to increase or remain unchanged. In fact the plasma ratio of DHEA(S) to cortisol falls with chronic stress and increasing age (Fava *et al.*, 1989; Goodyer *et al.*, 1998; McKenna *et al.*, 1997; Reus *et al.*, 1993; Wolkowitz *et al.*, 1992).

Hypotheses for mechanism of action of DHEA, from preclinical studies, include: transformation of this compound to testosterone or oestrogen (which both have mood enhancing effects), the effect of DHEA on increasing the bioavailability of gonadal steroids (Barrett-Connor *et al.*, 1999; Morrison, 1997; Morrison *et al.*, 1998; Yaffe *et al.*, 1998a), antagonistic effects on cortisol production (Browne *et al.*, 1992; Osran *et al.*, 1993), GABA antagonistic effects (Friess *et al.*, 1995; Majewska, 1992; Spivak, 1994; Steffensen, 1995; Yoo *et al.*, 1996), GABA inverse agonist effect of DHEA(S) (Friess *et al.*, 1995; Majewska, 1992), which may then cause a secondary increase in other GABA agonist neurosteroids, potentiation of NMDA neurotransmission (Bergeron *et al.*, 1996) and of NMDA-induced hippocampal release of norepinephrine (Majewska, 1995; Monnet *et al.*, 1995) and lastly, increased serotonin and dopamine brain levels (Abadie *et al.*, 1993; Murray and Gillies, 1997; Porter and Svec, 1995). DHEA(S) has been reported to increase hippocampal cholinergic function (Rhodes *et al.*, 1996, 1997), and enhance neuronal excitation (Carette and Poulain, 1984; Diamond *et al.*, 1995; Meyer and Gruol, 1994; Spivak, 1994).

In human studies, depression has been linked to lowered levels of DHEA(S) (Legrain *et al.*, 1995; Yaffe *et al.*, 1998a), with

lower morning DHEA : cortisol ratios being reported in depressed patients (Osran *et al.*, 1993). Goodyer *et al.* (1996) found DHEA hyposecretion in morning measurements, with cortisol hypersecretion in evenings to be significantly correlated with the diagnosis and severity of depressive episodes in children and adolescents. Among post-partum women, Buckwalter *et al.* (1999), found higher DHEA levels were associated with less depression, interpersonal sensitivity and better short-term memory function; it was hypothesized that DHEA might play a role in regulating mood and cognition in pregnancy, although this remains to be tested.

More recently, Michael *et al.* (2000) reported on decreased levels of salivary DHEA in adults with major depression, with lower morning DHEA correlating with improved Hamilton Depression Scale (HAM-D) scores. This is suggestive that DHEA(S) changes reflect actual mood changes, rather than a simple medication-related effect. In this study, they recruited individuals with current major depression (mostly on antidepressants), remitted depression and still taking antidepressants, and a normal control group. Interestingly, the remitted patients demonstrated DHEA levels between the group with depression and the control group. In the data analysis, when depressed patients on treatment were separated from those patients not taking medications, there was no significant effect on DHEA levels; however, numbers were not large. Further studies on the possible interrelated effects of DHEA and cortisol are implicated, especially in light of preclinical literature reporting the actions of DHEA to antagonize damaging effects of steroids on hippocampal neurons (Kimonides *et al.*, 1999), the antidepressant effects of DHEA (Wolkowitz *et al.*, 1999b) and the ability to predict the course of adolescent depression from cortisol/DHEA measurements (Goodyer *et al.*, 1998).

Low plasma DHEA(S) has been reported with anxiety (Diamond *et al.*, 1989), perceived stress (Labbate *et al.*, 1995), cynicism and hostility (Fava *et al.*, 1987; Littman *et al.*, 1993). In contrast, higher DHEA(S) has been associated with more 'expansive personality ratings' (Hermida *et al.*, 1985) and healthier psychological profiles (Fava *et al.*, 1992). Other literature describe contrary findings, with depressed patients exhibiting increased urinary or serum DHEA(S) levels (Heuser *et al.*, 1998; Tollefson *et al.*, 1990) or unchanged levels (Fava *et al.*, 1989; Reus *et al.*, 1993; Shulman *et al.*, 1992).

Increased DHEA to cortisol ratios have also been found in panic disorder patients (Fava *et al.*, 1989). Herbert *et al.* (1996) reported that adolescents with depression and comorbid panic or phobic disorder did not exhibit low DHEA levels in morning samples.

Studies have explored the link between higher DHEA(S) levels and improved cognition and general functioning, especially among the elderly (Berkman *et al.*, 1993; Berr *et al.*, 1996; Cawood and Bancroft, 1996; Flood and Roberts, 1988; Kalmijn *et al.*, 1998; Ravaglia *et al.*, 1996, 1997; Reus *et al.*, 1993). Other studies report no effect or contrary findings, with the absence of association between DHEA(S) and cognition in women (Yaffe *et al.*, 1998b) or inverse association between DHEA(S) and declining cognition in female versus male nursing home patients (Morrison *et al.*, 1998, 2000) and female versus male Alzheimer's disease patients (Miller *et al.*, 1998).

Open-label studies showed that treatment with DHEA resulted in mood improvement, and increased interest, energy and activity levels, in healthy subjects (Morales *et al.*, 1994) and depressed patients (Wolkowitz *et al.*, 1997). Wolkowitz *et al.* (1999b) performed a double-blinded trial with 22 depressed patients, who were either already on antidepressants (with persisting depressive symptoms) or were medication-free. Patients were randomized to DHEA 90 mg per day or placebo for six weeks. Greater than 50% decreases in Hamilton Depression Rating Scale, with documented statistical significance, were reported in 5 of 11 patients treated with DHEA, compared to none of the 11 patients treated with placebo. This is a preliminary study, and larger scale trials may provide more useful information. For dysthymic patients, Bloch *et al.* (1999) treated non-medicated patients in a 12-week double-blinded placebo-controlled study, with DHEA (90 mg daily for three weeks, then increased to 450 mg daily for another three weeks), or placebo for six weeks and was able to show a robust antidepressant response with DHEA.

GROWTH HORMONE, PROLACTIN, AND OTHER ANTERIOR PITUITARY ABNORMALITIES

Alterations in the production of other anterior pituitary hormones, including growth hormone and prolactin, are associated with mood alterations. This would include conditions of over- and underproduction of such hormones.

Growth Hormone

The pulsatile release of growth hormone (GH) is regulated by the stimulatory effect of GH releasing hormone (GHRH), and the inhibitory effect of somatostatin (which itself is regulated by insulin-like growth factor-I) (Scanlon *et al.*, 1996). The secretion of GH can be increased in response to falls in blood glucose level, exercise, sleep, stress and alpha-adrenergic agonists; its release may be inhibited by beta-adrenergic agonists.

Overproduction of GH frequently occurs secondary to pituitary adenoma, rarely, hyperplasia, and results in acromegaly in adults and gigantism in children. Physical manifestations include skeletal overgrowth, especially of the hands, feet, skull and lower jaw, symptoms of headache, decreased libido, kyphosis and joint pains, and the development of hypertension, hypogonadism and diabetes mellitus (Lishman, 1998). Patients may present with psychiatric disorders, such as depression (Fava *et al.*, 1993; Ferrier, 1987). However, Abed *et al.* (1987) failed to confirm an increased rate of depression when compared with the general population.

GH deficiency causes growth failure and short stature in children, with psychiatric sequelae, including distorted body image and low self-esteem. In adults, decreased sense of well-being (Holmes and Shalet, 1995), anhedonia, fatigue and social isolation may improve from hormone replacement with recombinant GH (Degerblad *et al.*, 1990).

Neuroendocrine researchers use GH as an indirect indicator of neurotransmitter function (Porter *et al.*, 1998). Studies of children, adolescents and adults with major depression found altered responses of GH to clonidine (alpha-2 agonist)(Dolan and Calloway, 1986) and L-tryptophan (serotonin precursor) (Price *et al.*, 1991), possibly suggesting reductions in alpha-2 adrenergic and serotonin receptor functions.

Birmaher *et al.* (2000) reported a decreased GH response to GHRH in acutely depressed and recovered children and adolescents, as compared to healthy controls. Dahl *et al.* (2000) also reported low GH response to GHRH in acutely depressed children, as well as those in remission. Coplan *et al.* (2000) reported on ten-year follow-up data of now young adults, with and without major depression; those adults with lifetime depression exhibited lower levels of GH in the 100 minutes before sleep onset, in adolescence; those with a history of suicide attempts during adolescence had greater 24-hour GH release. Chronically elevated levels of corticosteroids may inhibit neurotransmitter actions, in addition to directly affecting pituitary secretion of GH, as reported by Watson *et al.* (2000).

Prolactin

Prolactin, which is secreted by the anterior pituitary gland, is under tonic inhibition from dopamine released by the hypothalamus (Lishman, 1998). Serotonin, acetylcholine, thyrotrophin-releasing hormone (TRH), oestrogen, endogenous opiates, stressors and nipple

stimulation all promote prolactin release (Rafuls *et al.*, 1987). Symptoms of hyperprolactinaemia commonly arise from prolactin-secreting adenomas, and may result in amenorrhea, galactorrhea, infertility and impotence (more in men). In addition, psychiatric manifestations, such as depression, anxiety and irritability, may occur. Mood changes appear to respond better to treatment with dopamine agonists (such as bromocriptine) to reduce prolactin levels, rather than antidepressants, which seem to be less effective (Fava, 1993). Diagnosis is made from serum screening for prolactin elevation, and confirmed with imaging studies. Transsphenoidal resection or radiotherapy to remove or shrink the adenoma are other possible treatment options.

Prolactin responses to dopamine agonists are used to indirectly measure serotonin activity, as was discussed earlier in the chapter.

HYPOPITUITARISM

This is a state which can be caused by pituitary tumours (craniopharyngioma in children), post-partum ischaemic necrosis of the anterior pituitary gland (Sheehan's syndrome) or, very rarely, secondary to a basal skull fracture (Lishman, 1998). Symptoms often exist for an extended period of time prior to diagnosis, and can include weakness, fatigue, cold sensitivity, decreased libido, amenorrhea, impotence and weight loss. Facial expressions are diminished, and the development of depression, irritability, apathy, somnolence, memory impairment and metabolic changes can occur before the onset of delirium. This presents secondary to concurrent infection, and manifests with hypoglycaemia, hypotension and hypocortisolaemia. Differential diagnosis should include hypothyroidism, Addison's disease (hyperpigmentation would be prominent), delirium, dementia and anorexia nervosa (AN) (apathy and somnolence are usually not found in cases of AN). With hormone replacement therapy, including cortisol or prednisolone, thyroxine and gonadal hormones, symptoms typically resolve.

PARATHYROID HORMONE (PTH)

The parathyroid glands are situated on the thyroid but function discretely from the thyroid axis. The synthesis and release of PTH is modulated by serum calcium levels, in which elevated calcium inhibits PTH release, while low serum calcium causes increased PTH synthesis and release. Increased serum phosphate causes an increase in PTH release (by decreasing serum calcium levels, such as in cases of renal failure). The commonest cause of hyperparathyroidism is the benign adenoma of a parathyroid gland; it is rarely associated with multiple endocrine neoplasia (MEN type I — associated with pancreatic and pituitary tumours, or MEN type II — associated with thyroid cancer and pheochromocytoma) (Lishman, 1998). Mood symptoms are a frequent presentation, with reports of up to two-thirds of patients experiencing psychiatric changes (Petersen, 1968). These can include amotivation, depression, lethargy, memory impairment, irritability and explosive outbursts (Petersen, 1968). Patients may complain of anorexia, nausea, headache, thirst and polyuria. Physical symptoms of renal calculi, bony deformities and fracture, myopathy of proximal muscles, hypotonia and corneal calcifications may develop (Lishman, 1998). Laboratory abnormalities associated with hyperparathyroidism include elevated serum calcium levels and low serum phosphate, (serum albumin values will need to be considered). Radioimmunoassay of parathyroid hormone levels will confirm diagnosis. Alkaline phosphatase is raised secondary to bony involvement; renal calculi, and calcifications in the caudate and frontal lobes may be identified on imaging. Occasionally, EEG will exhibit widespread slow activity, along with paroxysms of frontal delta waves (Lishman, 1998). Surgical resection of the adenoma improves most symptoms, but depression and other psychiatric manifestations may require treatment with psychotropic medications for complete symptom resolution.

Hypoparathyroidism can occur following neck surgery, and after thyroidectomy (occurring in up to 50% of these patients). Symptoms frequently arise from chronic tetany; signs and symptoms may include perioral, hand and feet numbness and tingling, muscle cramps, limb stiffness, carpopedal spasms, and even laryngeal stridor. Presenile cataracts, seizures, macrocytic anaemia, and prolonged QT interval are other possible manifestations (Brown, 1984). Psychiatric changes occur in up to 50% of these cases, as reported by Denko and Kaelbling (1962), and may present with delirium, difficulty concentrating, emotional lability and cognitive impairment. Other symptoms include depression, anxiety, irritability and social isolation. Psychosis, obsessions and derealization rarely occur (Denko and Kaelbling, 1962; Rafuls *et al.*, 1987). Calcium and vitamin D replacement successfully treat the above symptoms.

MELATONIN AND AFFECTIVE DISORDERS

Melatonin is an indolamine derivative of serotonin, produced in the pineal body, and secreted into the bloodstream and cerebrospinal fluid. Melatonin receptors are found in the hypothalamus, cerebellum and pineal body itself. Secretions usually peak at night and reach a nadir during the daytime. Melatonin appears to lower body temperature at night and increase sedation (Shafii and Shafii, 1990).

Nurnberger *et al.* (2000) attempted to replicate observations made in the past (Lewy *et al.*, 1980; Wetterberg *et al.*, 1981; Wetterbuerg *et al.*, 1979), that bipolar patients exhibit supersensitivity to the suppression of melatonin production by light, as this may be a marker for genetic vulnerability for affective disorders (Nurnberger *et al.*, 1988). Results from Nurnberger's more recent study observed no difference in light-induced melatonin suppression among bipolar, unipolar and healthy patients. Cortisol levels were similar in all three groups of patients. Lithium and propranolol did not produce any effect, despite past research documenting beta-adrenergic influence on melatonin production (Connolly and Lynch, 1983). Among bipolar I patients, they were able to document significantly lower melatonin levels on nights with light exposure, as well as a later peak time for melatonin on dark nights. On the other hand, both Lam *et al.* (1990) and Whalley *et al.* (1991) were not able to confirm that bipolar patients exhibited increased light sensitivity. Indeed, medication effects may account for these differences, and further study would be merited.

HYPOTHALAMIC–PITUITARY–THYROID AXIS AND MOOD DISORDERS

Thyroid dysfunction has been reported to affect up to 6% of the general population, with psychiatric patients exhibiting higher rates of abnormal thyroid metabolism, and women demonstrating a higher incidence than men (Whybrow, 1995). Joffe and Levitt (1993) have edited an excellent text on this topic, with more detailed overview on such related issues.

Historically, links between thyroid diseases and psychiatric disorders include Caleb Parry's (1825) report that 'nervous affectations' seemed to often occur with thyroid disorders. Gull (1873) reported observations of myxoedema resulting in psychosis. Later, the Clinical Society of London (1888) reported that 36% of myxoedematous patients developed 'delusions and hallucinations', and Asher (1949) coined the description 'myxoedema madness'. Robert Graves (1940) reported the case of a woman with 'symptoms ... suppose to be hysterical', who developed 'tachycardia, weakness, exophthalmos, and thyromegaly'.

Hypothyroidism

Hypothyroidism can be classified according to the level of dysfunction in the HPT axis, primary hypothyroidism referring to abnormal function of the thyroid gland (accountable for 95% of cases), secondary hypothyroidism as pituitary dysfunction, and tertiary hypothyroidism as hypothalamic dysfunction (Gharib and Abboud, 1987). Idiopathic, autoimmune, iatrogenic (psychotropic culprits, such as lithium and carbamazepine) and iodine deficiency causes explain most cases of hypothyroidism. Hashimoto's thyroiditis, an immune-related condition, is associated with elevated TSH and decreased thyroid hormone release, producing thyroid gland enlargement.

Primary hypothyroidism is subdivided into three grades. Grade I is characterized by increased levels of thyroid-stimulating hormone (TSH), decreased free thyroxine index (FTI) and an increased TSH response to thyrotrophin-releasing hormone (TRH), along with clinical findings such as weight gain, dry skin, hoarse voice, cold intolerance, fatigue, constipation, menstrual disturbances, psychomotor retardation and cognitive disturbances. Grade II hypothyroid patients have increased TSH, normal FTI, increased TSH response to TRH, but few clinical findings. Patients with Grade III hypothyroidism present with normal TSH, normal FTI, but an increased TSH response to TRH stimulation, with a clinically euthyroid presentation (Evered, 1973; Wenzel *et al.*, 1974). Traditionally, Grades II and III hypothyroidism are considered 'subclinical' forms, but ongoing reports of clinical psychiatric sequelae from these states, e.g. major depression, may imply the contrary (Haggerty and Prange, 1995; Joffe and Levitt, 1993).

The thyroid axis interacts closely with the sympathetic nervous system, with thyroid hormones potentiating central and peripheral sympathetic–adrenergic activity (Emlen *et al.*, 1972). Hypothyroidism is associated with a decrease in the number and activity of beta-adrenergic receptors, in particular. Thyroid hormones affect second-messenger systems, such as the phosphoinositol and adenyl cyclase pathways, which may influence alpha and beta adrenoreceptor activity. There appears to be a reduction in messenger RNA coding for the beta-adrenergic receptors responding to epinephrine and norepinephrine, as shown in rat studies (Gross *et al.*, 1980; Mason *et al.*, 1987; Sandrini *et al.*, 1991).

Lithium acts to inhibit the conversion of thyroxine (T4) to triiodothyronine (T3), and inhibit iodine uptake, thyroid hormone production and thyroid secretion by the thyroid gland (Burrow *et al.*, 1971; Carlson *et al.*, 1973). Patients treated with lithium may develop decreased total T4, decreased free T3, increased TSH, exaggerated TSH response to TRH challenge, anti-thyroid antibodies, and clinical evidence of hypothyroidism and/or goitre. Lithium appears to suppress thyroid function, albeit on a temporary basis. It is usually a reversible condition upon cessation of this medication (Joffe and Levitt, 1993). It would likely be prudent to screen the above laboratory tests prior to initiation of lithium, and intermittently throughout the course of treatment.

Carbamazepine has reportedly been shown to decrease thyroid function in patients treated for seizure disorders and affective illness (Ericsson *et al.*, 1985; Larkin *et al.*, 1989; Tanaka *et al.*, 1987). This occurs more often in responders than non-responders of the medication, is unrelated to the mean dose or blood level of the anti-epileptic (Roy-Byrne *et al.*, 1984), and may be a result of a reduced TSH response to TRH (Joffe *et al.*, 1984). On the other hand, valproic acid has not been demonstrated to affect thyroid function (Ericsson *et al.*, 1985; Larkin *et al.*, 1989).

Lastly, electroconvulsive therapy may cause a rise in serum TSH, during treatment, and may be correlated with seizure length (Aperia *et al.*, 1985a, b; Papakostas *et al.*, 1991). Phototherapy has not been shown to affect thyroid function tests (Bauer *et al.*, 1993; Joffe, 1991).

Hyperthyroidism

Hyperthyroidism is commonly caused by Graves' disease, an autoimmune process associated with increased circulating thyroid hormones, and with higher incidence in females than males (6 : 1 ratio). Toxic multinodular goitre, a non-malignant condition in which thyroid nodules produce excessive thyroid hormones, and overtreatment of hypothyroidism are other possible causes for hyperthyroidism. This results in physical, cognitive and affective symptoms, including increased motor activity (tremulousness, tremor, restlessness), tachycardia, weight loss, anorexia, heat intolerance, menstrual irregularities, exophthalmos, mood lability, distractibility and decreased concentration, impaired short-term memory, and, in extreme conditions, frank delusions and hallucinations (Kamlana and Holms, 1986; MacCrimmon *et al.*, 1979). A small minority of patients, especially the elderly, presents with contrasting symptoms of apathy, lethargy, depression and social isolation (Peake, 1981). Complaints of depressed mood and anxiety may occur (Wilson *et al.*, 1962).

Hyperthyroidism is diagnosed by decreased TSH (<0.2), elevated total T4 and elevated free T3. The TRH challenge test can be used to prove a hyperthyroid state, by administering 500 μg TRH intravenously, and measuring TSH levels at baseline, and every 15 minutes, for the first hour. Usually, women and men show peak values of $>6\,\mathrm{uU\,ml^{-1}}$, following the challenge test; men older than 40 years tend to exhibit a rise of $>2\,\mathrm{uU\,ml^{-1}}$. In the absence of pituitary disease, suppressed TSH response indicates thyrotoxicosis; if TSH response to the TRH challenge is within normal limits, a hyperthyroid condition is unlikely.

Joffe and Singer (1987) reported no change in thyroid function in depressed patients treated with phenelzine; however, monoamine oxidase inhibitors cause increased circulating catecholamines, and it may be suggested to avoid this class of medication in patients with a history of hyperthyroidism. Thyroid hormones activate the sympathetic nervous system, including the autonomic nervous system and central adrenergic inputs. These effects have long been recognized in the cardiovascular system (Harrison, 1964). Of note, hyperthyroidism may increase myocardial sensitivity to catecholamines, leading to cardiac toxicity in those patients with increased serum thyroid levels and elevated catecholamines (Larsen and Ingbar, 1992).

There have also been noted associations between hyperthyroidism and tricyclic antidepressant toxicity (Prange *et al.*, 1969). Hoeflich *et al.* (1992) were not able to observe adverse effects on thyroid function in depressed patients (both responders and non-responders) treated with either maprotiline or fluvoxamine for four weeks. Shelton *et al.* (1993) compared the thyroid function of depressed patients treated with desipramine or fluoxetine, reporting 26% of study patients exhibited baseline abnormalities in thyroid levels, and a small but statistically significant increase in total T4 in those treated with desipramine, and a decline in T3 in those who responded to fluoxetine but not desipramine. McCowen *et al.* (1997) found that sertraline may adversely affect thyroid function.

Mood Disorders and Thyroid Function

Depression

Although patients with unipolar major depression commonly present in euthyroid states, at ranges in both upper and lower limits of normal, various other abnormalities have also been reported. These may include elevated T4 levels, decreased serum T3, blunted TSH response to TRH challenge, and evidence of subclinical hypothyroidism (Joffe and Levitt, 1992; Sullivan *et al.*, 1997). According to Kirkegaard and Faber (1998), this normalized in responders to treatment with fluvoxamine after

only one month, suggesting interactions between the hypothalamic–pituitary–thyroid (HPT) axis and serotonin neurotransmission. Linnoila *et al.* (1979) and Kirkegaard and Faber (1981) reported increased serum levels of reverse T3 (the hormonally inactive form of T3) in acutely depressed individuals, with return to normal values upon recovery from depression, thus implying a state-dependent change.

Up to 15–20% of depressed patients exhibit subclinical hypothyroidism (Haggerty and Prange, 1995), with women patients more at risk for impaired thyroid function (Gold *et al.*, 1981). Prange and Loosen (1984) reported 25–33% of major depressive patients show blunted TSH response to TRH challenge. This could suggest a feedback mechanism involved in a chronically activated HPT axis (Banki, 1988), a response to a transient thyroxaemic condition (Loosen and Prange, 1982) or a response to hypercortisolaemia associated with depression (Re *et al.*, 1976).

Frye *et al.* (1999b) were not able to predict TRH hypersecretion and subsequent pituitary downregulation (with blunted TSH release) in patients with depression.

Of interest, there exist numerous reports of increased prevalence of anti-thyroid antibodies among depressed patients, 8–20% (Gold *et al.*, 1982; Haggerty *et al.*, 1991; Joffe, 1987; Nemeroff *et al.*, 1985) versus 5% in the general population (Tunbridge and Caldwell, 1991). The clinical significance remains unclear, since this is often accompanied by normal serum thyroid concentrations.

More recently, Joffe's group (Joffe, 1999; Joffe and Marriot, 2000) examined the relationship between basal thyroid hormone levels and the long-term course of depression and stage of treatment-resistant depression (Thase and Rush, 1995), reporting that time to recurrence of major depression was inversely related to T3 but not to T4 levels, supporting past findings that peripheral thyroid levels do not necessarily correlate with antidepressant treatment resistance (Vandoolaeghe *et al.*, 1997).

Also, the blunting of the TSH response to TRH challenge has been reported in acute and abstinent alcohol-dependent patients (Loosen, 1988; Loosen *et al.*, 1992), as well as in panic disorder patients (Fishman *et al.*, 1985; Stein and Uhde, 1988).

Bipolar Disorders

Whybrow and Prange (1981) hypothesized that mobilization of thyroid hormones in the CNS would augment recovery from depression, and, conversely, excessive mobilization would increase the risk of mania in certain individuals. In addition, thyroid hormones may have a central neuromodulatory role, through its actions on central beta-adrenergic receptors (Whybrow and Prange, 1981). However, measurements of peripherally measured hormone levels may not be an accurate reflection of central activity. Manic patients can develop a relative hyperthyroxinaemia with a slightly increased total or free T3/T4 (Bauer and Whybrow, 1988). Lee *et al.* (2000) reported on their study of 46 bipolar manic patients, followed for their thyroid indices, at baseline and one and six months after lithium treatment. Despite the absence of a placebo control group, they found that a reduction in free T4 levels and free T3 levels correlated with a drop in psychotic symptoms, as measured by the Brief Psychiatric Rating Scale (Overall and Gorham, 1962) scores, after one month of lithium treatment. In fact, a progressive reduction in TSH levels was documented throughout the six months of treatment. These observational results seem to support but not necessarily confirm Whybrow and Prange's theory.

Around 10–15% of patients with bipolar disorder are classified with the rapid-cycling subtype (experiencing four or more affective episodes yearly) (American Psychiatric Association, 1994), with women representing up to 80–95% of the patients categorized to this subtype. Various studies report both association and lack of association between hypothyroidism and rapid-cycling bipolar disorder (Cho *et al.*, 1979; Cowdry *et al.*, 1983; Joffe, 1988; Wehr, 1988). Bauer and Whybrow (1990) reported evidence of overt, mild and subclinical hypothyroidism in this sub-group. Gender (female sex) and length of treatment with lithium may be predisposing factors to developing thyroid abnormalities; Bartalena *et al.* (1990) found decreased total and free serum thyroid hormone levels in female bipolar patients, whether or not they were rapid-cyclers, and there was no difference between these two groups, in anti-thyroid antibody titres, presence of goitres and thyroid hormone indices.

Chang *et al.* (1998) reported an increase in mean TSH, and decreased T4 levels, in mixed manic patients, as compared to patients with pure mania, but no significant differences in T3 concentration or in previous exposure to lithium, agreeing with past reports that mixed mania may be more commonly associated with thyroid dysfunction. Frye *et al.* (1999a) found that lithium-treated bipolar patients, with lower free T4 concentrations, exhibited more affective episodes and greater severity of depression, but again causal links remain unclear.

Thyroid Treatment Modalities for Psychiatric Conditions

Major Depression

TRH is a neuropeptide produced by the hypothalamus, which regulates the thyroid axis by controlling the secretion of TSH and thus regulating thyroid hormone synthesis and release. Kastin *et al.* (1972) and Prange *et al.* (1972) reported antidepressant effects from TRH administered intravenously to patients with unipolar depression. However, numerous studies attempting to replicate these results demonstrated minimal or no benefit (Kiely *et al.*, 1976; Mountjoy *et al.*, 1974; Vogel *et al.*, 1977).

T3, a metabolite of T4 with a shorter half-life, appears to be the more biologically active form of thyroid hormone. It has been used as monotherapy treatment of depression, but there is little data supporting its efficacy (Feldmesser-Reiss, 1958; Flach *et al.*, 1958). Stern *et al.* (1991, 1993) performed double-blinded trials on ECT patients with unipolar, bipolar and schizoaffective depressions, who were pretreated with T3, and found improvements in mood and cognition. On the other hand, it is possible that cognitive improvements resulted from a reduction in the number of ECT treatments necessary for remission of the acute episode in those receiving T3 (Joffe and Sokolov, 1994; Sackeim, 1994).

T3 has been most studied as an adjuvant to antidepressant therapy. At doses of 25–50 μg per day, T3 was reported to accelerate the response to antidepressants (Prange *et al.*, 1969; Wheatley, 1972), and convert non-responders to responders (see Aronson *et al.*, 1996 for meta-analysis). Joffe *et al.* (1993) reported that T3 augmentation appeared equally efficacious as lithium, with both medications proving to be more useful than placebo. In fact, two-thirds of tricyclic antidepressant (TCA)-resistant patients responded successfully to T3 augmentation. Of interest, Joffe and Singer (1990) reported on a double-blind trial comparing T3 with T4 augmentation (in the absence of a placebo), and found that T3-treated patients responded at a higher rate than T4-treated individuals (53% versus 19%). Targum *et al.* (1984) reported on the use of T4 augmentation for TCA-resistant depressed patients, but also diagnosed a number of the study patients to have baseline subclinical hypothyroidism.

Case reports on the association of T3 augmentation with the development of angina exacerbation and paroxysmal atrial fibrillation in elderly patients (Cole *et al.*, 1993; Gitlin, 1986) warrant that caution be used when prescribing thyroid hormones.

Bipolar Disorders

A higher prevalence of hypothyroidism has been found in both the rapid- and non-rapid-cycling patients (Bartalena *et al.*, 1990; Joffe

et al., 1988; Wehr *et al.*, 1988), as discussed above. In a small sample sized study, Baumgartner *et al.* (1994) treated refractory bipolar patients (non-rapid-cycling) with T4, given 250–500 μg daily, and found significant response to T4, as measured by frequency of relapse and length of hospitalization. However, a significant portion of the study patients was described to also have subclinical hypothyroidism.

The use of T4 at doses up to 500 μg per day has been studied in the treatment of rapid-cycling bipolar disorder, with variable responses, from complete remission to minimal improvement (Bauer and Whybrow, 1990; Leibow, 1983; Stancer and Persad, 1982). Such therapy has been reportedly well tolerated, but there remain concerns about iatrogenically induced hyperthyroid states, and the accompanying risk, albeit theoretical, e.g. osteoporosis. Whybrow (1994) followed up patients from the 1990 study with serial bone densitometries, and discovered a net increase in bone density. However, these patients were also treated with lithium, and it is plausible that lithium may be protective against osteoporosis (Whybrow, 1994). Replication studies using larger numbers of patients, preferably with blinded and randomized controlled trials, are necessary.

GONADAL HORMONES AND MOOD DISORDERS

This topic is covered in greater detail in Chapter XVIII-12. However, this is an area that is being avidly studied in both preclinical and clinical settings. Important data continues to be published on the neurobiological mechanisms of action of these hormones — oestrogen (McEwen *et al.*, 1979), luteinizing hormone (Meller *et al.*, 2001), follicular-stimulating hormone and androgenic steroids (Weber *et al.*, 2000).

Progesterone along with its 5alpha-reduced metabolites, pregnanolone and allopregnanolone, has demonstrated anxiolytic, hypnotic and anaesthetic actions through GABA-A receptor modulation, thereby increasing chloride ion neuronal membrane permeability and reducing neuron excitability (Finn and Gee, 1994; Freeman *et al.*, 1993; Majewska, 1992; Majewska *et al.*, 1986; Wang *et al.*, 1996). Pregnenolone sulphate and dehydroepiandrosterone sulphate (DHEAS) (both 3beta-hydroxy-5-ene steroids) act on GABA-A receptors via *N*-methyl-D-aspartate (NMDA) receptor-mediated intracellular calcium influx across neuronal membranes (Bicikova *et al.*, 2000). Evidence is being gathered to support the roles of gonadal hormones in modulating dopaminergic (Woolley and McEwen, 1994), serotonergic (Biegon, 1990; Biegon *et al.*, 1983), noradrenergic (Biegon *et al.*, 1983) and other neurotransmitter systems.

Bloch *et al.* (2000) investigated the possible role of gonadal steroid level changes in post-partum depression (PPD). Hormonal changes in pregnancy and parturition were artificially simulated in healthy, euthymic, non-pregnant women, with and without history of PPD. Findings suggested a differential sensitivity to the mood-destabilizing effects of gonadal steroids in women with a history of PPD. A year earlier, Buckwalter *et al.* (1999) published their findings on 19 women who were followed during and after pregnancy. Steroid hormone levels were compared to patients' cognitive functioning and mood symptoms. During pregnancy, higher progesterone levels seemed to be associated with greater mood disturbances (particularly with obsessive-compulsive type symptoms), and higher DHEAS with better mood. Two months after delivery, higher testosterone levels was more associated with greater mood disturbances. While cognitive changes (particularly, verbal memory) were documented during pregnancy, they occurred independent of mood changes. Young *et al.* (2000) found that in comparing a sample of 25 depressed with 25 non-depressed women (all premenopausal, aged 20–49), the depressed women exhibited lower oestradiol levels, and a shorter half-life of the luteinizing hormone. Study limitations included a small sample size, and the fact that patients were enrolled at random phases of the menstrual cycle. Attempts were made to control for cycle variability by matching each depressed patient with a control patient, who was similar in age and in menstrual cycle day. This is one example of the intrinsic difficulty facing researchers investigating gonadal hormones and their links to various psychiatric and cognitive conditions.

Further literature has been published on the use of gonadal steroids in treating mood and anxiety disorders, focusing on their efficacy in treating post-partum affective disorders (Gregoire *et al.*, 1996; Sichel *et al.*, 1995), premenstrual syndrome and premenstrual dysphoric disorders (Magos *et al.*, 1986; Watson *et al.*, 1989), and perimenopausal and menopausal depressions (Best *et al.*, 1992; Ditkoff *et al.*, 1991; Limouzin-Lamothe *et al.*, 1994; Oppenheim, 1983; Schneider *et al.*, 1977; Wiesbader and Karzrok, 1938). Lastly, a body of data is accumulating on the effects of the gonadal steroids on mood and aggressive disorders in men (Pope *et al.*, 2000).

Soares *et al.* (2001) reported on their 12-week, double-blind, randomized, placebo-controlled trial of 17beta-oestradiol transdermal patch (100 μg) for the treatment of perimenopausal women with major depression, dysthymic disorder or minor depression for 50 women. Remission from depression was reported in 68% of treated women, versus 20% in the placebo-treated group. Results may be considered difficult to interpret, due to small sample size, broad diagnostic entry criteria (both minor and major depressive disorders) and vague exclusion criteria. The study did attempt to address safety concerns of the transdermal oestrogen patch, referring to published studies of the use of this patch in women with severe PMS (Smith *et al.*, 1995) and post-partum depression (Ahokas *et al.*, 1999). On the other hand, they did not refer to safety data on the use of the patch for perimenopausal women. A last possible concern would be the use of unopposed oestrogen therapy in patients with intact uteri. Albeit the study was limited to only 12 weeks, the risk of endometrial cancer increases by a factor of eight to ten in women who use unopposed oestrogen for at least ten years (Grady *et al.*, 1995).

Among the postmenopausal population in the United States, approximately 38% use hormone replacement therapy (Keating *et al.*, 1999). Manson and Martin (2001) provided an excellent review on this topic, addressing the conundrum of such widespread use of HRT, despite the lack of conclusive data regarding benefits and risks of such treatment, since much collected data were from observational studies. The safety issues of prescribing hormone replacement are closely following along, with recent literature seeking to answer concerns of increased risk for venous thrombosis in women on low-dose oral contraceptives (Vanderbroucke *et al.*, 2001), risk of endometrial cancer recurrence in HRT patients (Suriano *et al.*, 2001), safety of HRT in breast cancer survivors (O'Meara *et al.*, 2001) and possible risk for developing ovarian cancer in women already on HRT (Rodriguez *et al.*, 2001). All of these issues must be carefully considered in the face of potentially increased use of gonadal steroids in the treatment of psychiatric disorders. However, literature on the use of oestrogen and progesterone for treatment of perimenopausal and postmenopausal symptoms is now reporting that a lower dose of combination therapy is equally efficacious (Archer *et al.*, 2001; Utian *et al.*, 2001).

The cognitive benefits of oestrogen and oestrogenic-receptor modulators are also being actively studied. LeBlanc *et al.* (2001) performed a systematic review and meta-analysis on 29 studies and reported difficulty in combining studies on cognition, due to the heterogeneous nature of the study designs. They did perform a meta-analysis on the observational studies, finding that HRT may decrease the risk of dementia (summary odds ratio of 0.66), but reiterated concerns of methodological limitations in most studies. Mulnard *et al.* (2000), of the multi-centred Alzheimer's Disease

Cooperative Study, reported on their randomized, double-blinded, placebo-controlled trial conducted between 1995 and 1999, on 120 women with mild to moderate AD. It was found that oestrogen replacement given for a one-year period did not slow disease progression, nor did it improve global, cognitive or functional outcomes of patients in the study, and acknowledged the need for much more research. Yaffe *et al.* (2001) reported that use of the selective oestrogen-receptor modulator raloxifene (for treatment of postmenopausal women with osteoporosis), over a three-year period, did not improve cognitive scoring.

Gender Differences and Age-Related Changes in the HPA Axis

Seeman *et al.* (2001) tested the hypothesis that women exhibit greater age-related HPA axis reactivity to challenge (using a standardized 30 minute cognitive challenge). A group of 26 younger subjects (9 men and 17 women), in their 20s were compared to 14 older subjects (7 men and 7 women) in their 60s. Baseline salivary cortisol levels were measured and repeated during and following a battery of cognitive tests. These tests were administered in a fast-paced, time-limited fashion, and designed to increase both HPA and sympathetic nervous system activity. Results from previously published data showed that older age was associated with higher baseline cortisol (Deuschle *et al.*, 1997; van Cauter *et al.*, 1996); women exhibited shorter nocturnal nadirs, higher morning cortisol levels, and higher mean 24-hour readings (van Cauter *et al.*, 1996). Postmenopausal women showed greater HPA reactivity to CRH challenge (Heuser *et al.*, 1994) and less feedback inhibition (blunted ACTH decline) in response to cortisol infusion, at the level of the pituitary. In the younger age group, some studies reported that men tended to exhibit greater cortisol response (Kirshbaum *et al.*, 1992), while others found no significant gender difference (Gallucci *et al.*, 1993; Stoney *et al.*, 1987; Streeten *et al.*, 1984).

The question of the possible role gonadal hormones may play in shifting the HPA axis of older women to greater reactivity was raised, since higher oestrogen levels have been linked to decreased blood pressure (von Eiff, 1971) and decreased HPA reactivity (Bonen *et al.*, 1991; Marinari *et al.*, 1976). This may be counteracted in settings of higher progesterone levels (Kirshbaum *et al.*, 1999). On the other hand, hormone replacement therapy has been linked to blunted cortisol responses to cognitive and physical stress tests in postmenopausal women (Lindheim *et al.*, 1992, 1994). In addition to the lack of feedback inhibition to cortisol in older women, a greater increase in the ACTH response to CRH or vasopressin challenge has also been observed (Born *et al.*, 1995). Preclinical studies have suggested oestrogenic regulation of the hippocampus and hypothalamus, due to the presence of oestrogen receptors in these regions (Teyler and DiScenna, 1986), oestrogenic regulation of synaptogenesis in the CA1 region of the hippocampus (McEwen *et al.*, 1994) and induction of other electrical activity and membrane changes in the hippocampus and hypothalamus by oestrogen (Foy *et al.*, 1982; Minami *et al.*, 1990; Wong and Moss, 1991).

SUMMARY

Numerous factors may contribute to the pathophysiology of mood disorders, including the pathophysiology of the brain's adaptation to stress, (allostatic load) (McEwen and Stellar, 1993; Sterling and Eyer, 1988), the possible role of chronic stress on hippocampal damage and dysfunction (which may result in psychiatric symptoms) (McEwen, 2000), as well as the effects of genetic predisposition and developmental stresses (Liu *et al.*, 1997). It remains challenging and at times, controversial, to draw firm conclusions from observations of the endocrine abnormalities associated with mood disorders. The stress effect arising from these psychiatric conditions can precipitate significant and widespread metabolic/endocrine changes ('state' markers). Researchers are now attempting to differentiate this from causal factors ('trait' markers) for such endocrine changes, to determine which are associated with the pathophysiological mechanisms of mood disorders.

Psychophysiology of Mood Disorders

Silvana Galderisi

INTRODUCTION

Mood disorders are markedly heterogeneous with respect to signs, symptoms, course, response to therapeutic interventions and outcome. Attempts at reducing heterogeneity by subgrouping subjects on the basis of clinical aspects is a valuable strategy; however, the scarce impact on everyday practice of most clinical subtypes underscores its limitation. External validation of clinical subtypes (demonstrating that they are characterized by different psychophysiological patterns) has been an important goal of psychophysiological research in mood disorders. Several other conceptual strategies can be identified throughout the reviewed literature: the search for trait or state markers, the attempt at clarifying pathogenetic mechanisms of the observed dysfunctions, and the identification of early predictors of course, outcome or response to different therapeutic interventions.

On the whole, however, the field has suffered from the lack of unifying hypotheses and systematic research, which is reflected in the fact that relevant reviews, including the present one, are organized according to the different techniques applied in the investigations. Moreover, evaluation and comparison of different findings is often hampered by poor characterization of studied populations with respect to relevant or confounding variables such as symptoms, clinical subtypes, medication (or other therapeutic intervention) history, or substance abuse or dependence.

This chapter is organized in two main sections, peripheral and central measures, each including several subsections dealing with specific measures or techniques.

As previous excellent reviews of the topic are available (Goodwin and Jamison, 1990; Henriques and Davidson, 1989; Zahn, 1986), an attempt has been made to cover the relevant literature with particular attention to more recent findings. Furthermore, since some readers might be unfamiliar with specific technical issues, when deemed appropriate a brief definition and description of the psychophysiological measures or techniques discussed in the section is provided.

PERIPHERAL PSYCHOPHYSIOLOGICAL INDICES IN RESEARCH ON MOOD DISORDERS

Disturbances of several physiological functions, such as sleep, appetite, sexual drive, sweat secretion and chronobiological rhythms, are commonly found in mood disorders and indicate a dysregulation of the autonomous system in affected subjects. Despite the large number of studies focusing on autonomic measures, much remains to be done to characterize this dysregulation. Investigations based on the concomitant evaluation of several autonomic parameters are promising; their integration with central measures, as well as with neuroendocrine and neurochemical measures, may contribute greatly to progress in this field of research.

Electrodermal Activity

Electrodermal activity (EDA) has been largely investigated as a measure of tonic and phasic arousal. Different variables can be evaluated, including the skin conductance level (SCL; the tonic level, generally measured after a resting period, before the first stimulus presentation), the spontaneous skin conductance responses (SSCRs; nonspecific fluctuations of activity independent of external stimuli), the skin conductance orienting responses (SCORs; related to external stimuli) and habituation (reduction in response to repeated stimulation). For each of these indices the eventual asymmetry pattern can be assessed.

Low baseline EDA has been frequently found in depressed patients when compared with healthy subjects. Such a reduction has been observed for both SCL and SCORs (Dawson *et al.*, 1977, 1985; Iacono *et al.*, 1983; 1984; Schnur *et al.*, 1995; Storrie *et al.*, 1981; Ward *et al.*, 1983; Zahn, 1986). Negative or discrepant findings have also been reported: Toone *et al.* (1981) found no difference between unmedicated subjects with depression and healthy comparison subjects; Albus *et al.* (1982) found higher SCL in drug-free depressed patients as compared with controls; Levinson (1991) reported higher SCL and a trend toward more SSCRs in a group of depressed patients (including schizoaffective depressed subjects), and interpreted the finding as the result of a hyperarousal condition. Faster habituation of the SCOR has been demonstrated in depressive patients (Frith *et al.*, 1982; Thorell, 1987). However, findings have been inconsistent (Miquel *et al.*, 1999; Storrie *et al.*, 1981). Methodological issues might partly account for the observed discrepancies, while the confounding role of clinical heterogeneity in tested populations is not strongly supported by available findings. In fact, the reduction of EDA activity and reactivity in subjects with mood disorders appears rather independent of subjects' clinical characteristics. Low SCL has been found in both medicated and unmedicated depressed subjects (Iacono *et al.*, 1983; Storrie *et al.*, 1981; Thorell *et al.*, 1987; Ward and Doerr, 1986), in unipolar and bipolar patients (Williams *et al.*, 1985) and in acutely ill depressed and manic patients, as well as after clinical recovery associated with antidepressant treatment or electroconvulsive therapy (Dawson *et al.*, 1977; Storrie *et al.*, 1981), in both suppressors and non-suppressors to the dexamethasone suppression test (DST) (Williams *et al.*, 1985), and in subclinically depressed versus non-depressed college students (Gehricke and Shapiro, 2001). However, EDA reduction seems to be even more pronounced in endogenous patients and in patients with symptoms of inhibition (Dawson *et al.*, 1977; Lader and Wing, 1969; Thorell *et al.*, 1987; Williams *et al.*, 1985).

EDA stability across different clinical subtypes of affective disorders has prompted research on its potential diagnostic utility. Reduced SCL as a diagnostic index of depression was investigated by several authors (Dawson *et al.*, 1985; Iacono *et al.*, 1983; Ward

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

et al., 1983), who reported a sensitivity ranging from 65% to 96%, a specificity from 46% to 89% and an efficiency from 64% to 88%. Dawson *et al.* (1985) also investigated SCOR as a diagnostic marker and reported a sensitivity of 85%, a specificity of 75% and an efficiency of 80%. In an attempt to improve discrimination among different diagnoses, some authors have used multi-component recording to measure the orienting response (OR). In particular, the finger pulse amplitude response (FPAR) has often been used in association with the SCOR, as it represents the OR of an autonomic system component which is physiologically and biochemically independent of the EDA system (Bernstein *et al.*, 1981; Fowles, 1986). The use of multi-component recording to measure OR might also foster understanding of the pathophysiological mechanisms of abnormal OR in psychiatric disorders. Empirical findings suggest that when OR is jointly indexed by both SCOR and FPAR, subjects with depression can be differentiated much better from subjects with schizophrenia (Bernstein *et al.*, 1988): in fact, while the latter exhibit reduced responding across all OR components, suggesting a central OR deficit related to attentional dysfunction, the former showed a high rate of non-responding only in the electrodermal component, interpreted by Bernstein *et al.* (1988) as related to a peripheral deficit involving the EDA system. More recently the authors confirmed previous findings (Bernstein *et al.*, 1995) and proposed that a reduction in cholinergically mediated activity, rather than a central deficit of OR, may be implicated in autonomic findings in depression. The hypothesis is based on the fact that, besides FPAR, other aspects of the OR component have been found unimpaired in depressives (e.g. pupillary dilatation response or P300), while other cholinergically mediated systems appear dysfunctional (e.g. salivation reduction, reduced blood flow response in the forearm during mental tasks, reduced variability of the respiratory sinus arrhythmia in the resting ECG). The hypothesis remains difficult to reconcile with evidence for a functional excess of central cholinergic activity in depression. It should be mentioned, however, that measuring SCOR and FPAR in concert, Levinson (1991) failed to differentiate subjects with schizophrenia from those with depression, while Schnur *et al.* (1999) could not differentiate patients with schizophrenia from those with mania.

The possibility that different pathophysiological mechanisms underlie EDA reduction in subjects with schizophrenia and those with mood disorders is also suggested by the findings of Katsanis and co-workers, showing that in subjects with mood disorders, in contrast with what is observed in those with schizophrenia, there is no relationship between season of birth and EDA reduction (Katsanis *et al.*, 1992). Similarly, Bernstein *et al.* (1988) pointed out that in schizophrenics the frequency of electrodermal responding varies with the task relevance of the stimulus, while in depression no relationship is observed, suggesting that SCOR deficit is centrally determined in schizophrenia but not in depression, where a peripheric cholinergic defect might be implicated.

Bilateral recordings of EDA in subjects with mood disorders have shown higher activity from the left than from the right hand (Gruzelier and Venables, 1974; Myslobosky and Horesh, 1978; Schneider, 1983). The asymmetry pattern has been interpreted as the result of either a hypoactivation or a hyperactivation of the right hemisphere in depressive disorders. Conflicting interpretations originate from the difficulty of disentangling the relative activating or inhibitory contribution of each hemisphere to EDA from either hand. Lenhart and Katkin (1986) recorded, in adjunct to bilateral EDA, conjugate lateral eye movements in a group of college students with subsyndromal depression. They confirmed the previously reported pattern of EDA asymmetry (L > R) and found a bias toward left-tending conjugate lateral eye movements. Findings were interpreted as reflecting right-hemisphere hyperexcitability in affective illness.

The EDA asymmetry pattern L > R was also found in high-risk subjects, the offspring of parents with bipolar affective disorders (Zahn *et al.*, 1989). However, in the latter study it was limited to the recording task period and concomitant with high self-ratings of depressed mood, which led the authors to conclude that, rather than being a stable property of the nervous system, it should be considered as a state marker of depression. Several studies failed to find any asymmetry in bilateral EDA recordings of patients with affective disorders (Iacono and Tuason, 1983; Storrie *et al.*, 1981; Toone *et al.*, 1981).

Cardiovascular Measures

Heart rate (HR), heart rate orienting responses (HRORs) and heart rate variability (HRV) have been the most frequently used indices. Systolic, diastolic and mean blood pressure, as well as forearm blood flow, have also been investigated in some studies.

The main findings in subjects with depression included an elevated resting heart rate and/or HRORs (Carney *et al.*, 1988; Dawson *et al.*, 1977, 1985; Lahmeyer and Bellur, 1987; Lehofer *et al.*, 1997) and a reduced HR variability (Carney *et al.*, 1995a; Dallack and Roose, 1990). Discrepant findings have also been reported (Jacobsen *et al.*, 1984; Lader and Wing, 1969; Yeragani *et al.*, 1991). Medication status, concomitant anxiety and failure to adequately match subjects for age and sex might account for the discrepancies.

Research on HRV has received particular attention, due to its medical implications: reduced HRV as a result of diminished cardiac vagal tone was shown to be a strong predictor of sudden death in subjects with myocardial infarction; subjects with depressive disorders have an increased incidence of mortality for cardiovascular diseases, and reduced HRV might represent a predisposing factor (for review see Dalack and Roose, 1990).

As a measure of HRV the respiratory sinus arrhythmia (RSA; the variation in heart rate associated with respiratory cycles) has been employed in some studies. It is used to assess cardiac parasympathetic tone. Spectral analysis of beat-to-beat variations in HR and blood pressure (BP) has also been applied to describe sympathetic and parasympathetic contributions to cardiovascular regulation (Malliani *et al.*, 1991; Tulen, 1993). Three spectral peaks are identified: a low-frequency peak (around 0.04 Hz), which for HR is associated with both sympathetic and parasympathetic activity, while for BP reflects variations in peripheral vasomotor activity; a mid-frequency peak (around 0.1 Hz), associated with the baroreflex response (and reflecting mainly sympathetic activity, although for HR the parasympathetic contribution cannot be excluded); and a high-frequency peak (around 0.20–0.35 Hz), which for HR reflects the RSA and therefore the parasympathetic tone, while for BP mainly results from mechanical effects of respiration.

Tulen *et al.* (1996) investigated autonomic regulation in 16 drug-free female depressed patients, divided into high and low on trait anxiety (HTA, LTA), during supine rest, orthostatic challenge, and post-orthostatic challenge supine rest. Spectral analysis of fluctuations in HR and BP was employed. They found that patients did not differ from controls during supine rest; during the orthostatic challenge they did not show the normal increase of BP mid-frequency band fluctuations, suggesting a reduced sympathetic activation, and exhibited a reduction of HR variations, pointing to a strong vagal inhibition. The latter effect was more marked in HTA patients; during the post-orthostatic supine rest patients showed a significant increase in HR variability, in the absence of clear changes in BP variability, suggesting a predominant cardiac vagal increase. The authors conclude that an impairment of orthostatic reflex in depressed patients is suggested, with a prevalence of parasympathetic over sympathetic dysfunction, especially in HTA patients.

Lehofer *et al.* (1997) studied both RSA and HR in 23 unmedicated and 23 medicated DSM-III depressed subjects, melancholic subtype, and 46 healthy comparison subjects. HR was higher in both medicated and unmedicated depressed subjects, while RSA was lower only in medicated patients versus comparison subjects. They concluded that there is no difference in vagal tone between unmedicated depressives and healthy controls, and therefore higher HR in unmedicated patients might be due to either an increased sympathetic tone or an increased 'autonomous' heart rate (which, together with the vagal and sympathetic activity, contributes to the heart frequency). It is independent of autonomic nervous system control, is about 100 beats per minute and is found in transplanted heart patients (Bernardi *et al.*, 1989). Moser *et al.* (1998) came to a similar conclusion measuring heart rate, RSA, pulsewave velocity (a measure of the sympathetic tone in the cardiovascular system) and BP in 26 patients suffering from major depression, melancholic type, who had been unmedicated for at least three months, and 26 comparison healthy subjects. Patients exhibited a higher HR, and no difference in cardiac vagal tone or sympathetic cardiovascular tone. Taken together, the results indicate that autonomous heart rate is higher in subjects with depression; whether this is due to a less well-trained heart resulting from reduced physical exercise or is a physiological state or trait marker of depression is left open by the authors.

Austen and Wilson (2001) measured RSA in unmedicated subjects with subsyndromal seasonal affective disorder (SAD) and healthy comparison subjects in both winter and non-winter periods. They found a significant group−season interaction due to significant higher RSA scores in winter only in subjects with SAD. For HR, SCL and diastolic blood pressure, instead, only an effect of the season was found: in both SAD and control subjects HR decreased while SCL and blood pressure increased during winter. According to the authors, increased RSA, due to an increased vagal tone, may parallel the sleep symptom observed in SAD (increased sleep), thus suggesting a similarity with the hibernation process and different underlying mechanisms with respect to non-seasonal depression. As also proposed by the authors, further research across a year-long period is needed to confirm and extend these observations across groups, and eventually confirm that SAD is a different disorder from non-seasonal depression.

Dysregulation of the autonomic nervous system has been considered a leading candidate mechanism for the association between depression and increased medical morbidity and mortality in patients with coronary heart disease (CHD) (Carney *et al.*, 1999). In a group of 50 depressed and 39 medically comparable CHD non-depressed subjects, Carney *et al.* (1999) found an elevated resting HR and an exaggerated HR response to orthostatic challenge in the former group. However, the mechanism underlying the observed autonomic dysfunction remains unclear: in fact, the two groups did not differ in resting or standing plasma levels of norepinephrine, excluding an increased sympathetic activity; at the same time, studies of HRV in depressed CHD patients have found no support for lower vagal tone in these subjects (Carney *et al.*, 1995b).

Eye Movements

Although included in the section on peripheral measures, the study of eye movements is not relevant to autonomic dysregulation. Eye movement investigations, in fact, provide important clues to central nervous system functioning. Increasingly sophisticated studies enable attempts to relate the results of electrophysiological recordings to the topology of brain function, as well as to brain imaging findings.

The majority of eye movement studies carried out in subjects with affective disorders have focused on the smooth pursuit eye movement system; a minority have investigated saccadic eye movements.

Smooth pursuit eye movements (SPEMs) occur when a moving object (target) is fixated and followed by the eyes. More often visual targets oscillating in a uniform sinusoidal or pendular manner have been used. Saccades are the brief rapid movements of the eyes aimed at bringing the eye focus from one point to another of the visual field.

SPEMs have been largely investigated in subjects with schizophrenia, in which their dysfunction is regarded as a promising biological marker of the disorder (Holzman, 1987; Holzman *et al.*, 1973, 1974; Iacono and Clementz, 1992). Several studies have also found SPEM abnormalities in subjects with affective disorders, calling into question the diagnostic specificity of SPEM dysfunction.

Studies contrasting subjects with affective disorders to healthy comparison groups have reported abnormal SPEMs in patients (Holzman, 1985; Iacono *et al.*, 1982; Klein *et al.*, 1976; Levin *et al.*, 1981; Salzman *et al.*, 1978; Shagass *et al.*, 1974). Several studies have reported no striking difference between subjects with mood disorders (both bipolar and unipolar) and those with schizophrenia on eye-tracking performance (Amador *et al.*, 1991; Friedman *et al.*, 1992; Iacono *et al.*, 1992; Küfferle *et al.*, 1990; Levin *et al.*, 1981; Lipton *et al.*, 1980; Sweeney *et al.*, 1999; Yee *et al.*, 1987), while others did find significant differences (Cegalis and Sweeney, 1981; Iacono and Koenig, 1983; Iacono *et al.*, 1982; Muir *et al.*, 1992). Heterogeneity in recording techniques, experimental paradigms, evaluated measures, patients' diagnosis or medication status may account for discrepancies.

Some studies used global performance measures (qualitative ratings of eye tracking or quantitative global evaluation, which assess the similarity between the target trace and the eye movement trace), while others used quantitative measures of SPEM-specific characteristics, such as gain (eye velocity/target velocity), anticipatory saccade (AS) rate (frequency of large saccades that take the eyes ahead of target), square wave jerk (SWJ) rate (frequency of pairs of small saccades, in opposite directions, separated by approximately 200 ms) or corrective catch-up saccade (CUS) rate (frequency of saccades occurring when a low pursuit gain causes the eyes to fall behind the target in order to quickly take the eyes to the target). ASs and SWJs are intrusive saccades, while CUSs are corrective saccades.

The increasing use of more sophisticated methods is relevant to the diagnostic issue: global measures might be less sensitive than specific quantitative measures. Patients in different diagnostic categories might have globally abnormal eye tracking; however, the specific pattern of abnormalities might help discriminating among them.

Friedman *et al.* (1995), in a study including 26 unmedicated schizophrenics, 14 unmedicated subjects with affective disorders (mostly unipolar), never treated with lithium, and 45 healthy subjects, used two global measures — qualitative rating and root mean square (RMS), which is a measure of the extent to which the eye position and target position differ over time — and six quantitative measures — CUS rate, CUS amplitude, gain, SWJ rate, AS number, and total time scored. They found that (1) RMS error and qualitative measures did not differentiate subjects with schizophrenia or affective disorders from healthy comparison groups, and (2) patients with affective disorders were not impaired on eye-tracking measures, whereas patients with schizophrenia were impaired in terms of gain, CUS rate and total time scored. They concluded that unmedicated subjects with affective disorders never exposed to lithium treatment perform an easy SPEM task as well as comparison subjects, that SPEM abnormalities are specific to schizophrenia and that specific quantitative ratings are more sensitive than global ones.

Friedman *et al.* (1992) reported that subjects with schizophrenia and those with affective disorders did not differ on SWJ and AS rate; the same group (Abel *et al.*, 1991) had previously found that CUS rate at the target velocity of 20°/s differentiated

the two diagnostic groups, being significantly higher in subjects with schizophrenia. Each diagnostic group showed a different abnormality pattern when compared with healthy subjects. Similar findings were reported by Flechtner *et al.* (1997), who studied 43 subjects with schizophrenia, 34 with major depression and 42 healthy comparison subjects, and found that the two patient groups did not differ on gain, intrusive saccades and AS, while CUS rate was significantly higher in subjects with schizophrenia than in those with depression.

Sweeney *et al.* (1999) have recently stressed the importance of studying eye tracking by using experimental paradigms providing assessment of the pursuit across different target velocities and evaluating other important SPEM components, such as pursuit initiation or performance in conditions of low stimulus position predictability. In a carefully designed study, they tested 32 subjects with schizophrenia (20 drug-naïve, 12 drug-free for 28 days), 35 with affective disorders (26 unipolar, 9 bipolar, all drug-free for 28 days) and 24 comparison healthy subjects. All patients were tested during acute episodes of illness. No abnormality showed a diagnostic specificity.

As mentioned above, several variables may affect eye movements. Substances with a depressant effect on the central nervous system (such as barbiturates, chloral hydrate, alcohol and benzodiazepines) may either superimpose nystagmus or increase saccadic events during pursuit or fixation, whereas neuroleptics, tricyclics and monoamine oxidase inhibitors do not seem to influence SPEMs (Holzman *et al.*, 1975, 1991; Levy *et al.*, 1984). In studies involving subjects with affective disorders, lithium treatment in particular has been regarded as an important confounding variable (Iacono *et al.*, 1982; Levy *et al.*, 1985). According to Corbett *et al.* (1989) the oculomotor effects of lithium include nystagmus, saccade pursuit, saccadic dysmetria and oculogyric crises. Holzman *et al.* (1991), in a study in which subjects with affective disorders were tested prior to starting lithium and then at weekly intervals after beginning treatment, reported that, in the context of clinical improvement, lithium administration degraded SPEMs and the nature of the degradation was idiosyncratic, involving different changes in different subjects and including gain decrements, increase in total number of saccades (but not AS) and fixation instability. Gooding *et al.* (1993), however, in a carefully designed study, found no lithium effect on SPEMs.

Eye-tracking abnormalities were also investigated in the offspring of probands with either unipolar or bipolar depression. In the unaffected offspring of subjects with bipolar disorder no impairment of eye tracking was found (Holzman *et al.*, 1984; Iacono *et al.*, 1992; Levy *et al.*, 1983), suggesting that the dysfunction represents a trait marker in schizophrenia and a state-related measure in mood disorders. Such a conclusion is not completely supported by a study carried out in the offspring of schizophrenic, unipolar depressed and bipolar probands from the New York High-Risk Project (Rosenberg *et al.*, 1997). In that study, in fact, a significant global performance deficit was demonstrated in the offspring of depressed probands and of schizophrenic probands, but not in those of bipolar patients. However, only the offspring of probands with schizophrenia had a higher mean frequency of anticipatory saccades. The authors suggested that the familial specificity of global eye-tracking deficit to schizophrenia might be limited with respect to unipolar major depression.

Visual fixation — that is, the ability to maintain gaze on a stationary target — has also been investigated in subjects with affective disorders. Amador *et al.* (1991, 1995) found fixation abnormalities in subjects with schizophrenia and their first-degree relatives, but not in those with depression. Gooding *et al.* (2000) did not find any fixation abnormality in either subjects with schizophrenia or those with bipolar I disorder. The latter study used a different recording technique (infrared scleral reflection instead of electro-oculogram recording) and added quantitative to qualitative evaluation.

Several studies showed no latency or accuracy abnormality of saccadic eye movements in subjects with bipolar affective disorders versus healthy comparison groups (Crawford *et al.*, 1995; Sereno and Holzman, 1995; Tien *et al.*, 1996). Some other studies, while confirming saccade accuracy, reported increased saccadic latency in bipolar versus healthy subjects (Park and Holzman, 1992; Yee *et al.*, 1987). An increased error rate on antisaccade tasks has also been reported in bipolar versus healthy comparison subjects (Sereno and Holzman, 1995; Tien *et al.*, 1996). Relatively few studies have investigated saccadic eye movements in depressed subjects. Fukushima *et al.* (1990) reported that medicated depressed patients had a normal saccade latency and were able to suppress reflexive saccades during an antisaccade task. Done and Frith (1989) found a normal saccade latency during a visually guided saccade task in a small group of drug-free depressed subjects, but a prolonged latency during a voluntary saccade task. Sweeney *et al.* (1998) administered a battery of oculomotor tasks (selected to assess the functional integrity of frontostriatal circuitry and of the cerebellar vermis) to 29 unmedicated inpatients with unipolar major depression and 19 comparison subjects. In the patient group, in comparison with healthy subjects, they found no abnormality of saccade latency, an impaired ability to suppress saccades to peripheral targets in the antisaccade task, more saccadic intrusions during fixation and a mild saccadic dysmetria during sensorially guided eye movements. Since lesions of the cerebellar vermis disrupt saccade accuracy but not necessarily latency or velocity, the impaired accuracy observed in depressed patients is compatible with a dysfunction of the cerebellar vermis. The remaining abnormalities are interpreted as the result of prefrontal dysfunction. The authors conclude that a functional disturbance of the dorsolateral prefrontal cortex may be common to both bipolar and unipolar patients, whereas the cerebellar vermis dysfunction seems characteristic of unipolar patients. It is worthy of notice that abnormalities of the cerebellar vermis have been reported by both structural and functional brain imaging studies in depressed patients (Dolan *et al.*, 1992; Shah *et al.*, 1992).

Bipolar patients receiving neuroleptic treatment were less accurate than neuroleptic-free patients on saccades directed towards remembered or predicted targets, which presumably require an internal representation of the stimulus (Crawford *et al.*, 1995).

CENTRAL PSYCHOPHYSIOLOGICAL INDICES IN RESEARCH ON MOOD DISORDERS

Central indices have been extensively used in the psychophysiological research on mood disorders. The huge literature on the EEG, ERPs and sleep parameters in affective disorders cannot be exhaustively reviewed for obvious space limitations. In the following section, the main results will be summarized and discussed in the light of their contribution to the generation of hypotheses on the pathophysiology of these disorders.

Quantitative Electroencephalogram (QEEG)

QEEG in Depressive Disorders

QEEG research in depressive disorders did not report consistent findings. Most replicated results include an increase of alpha (Brenner *et al.*, 1986; John *et al.*, 1988; Schaffer *et al.*, 1983; von Knorring, 1983) and/or beta (Flor-Henry *et al.*, 1979; John *et al.*, 1988; Knott and Lapierre, 1987a) activity in depressed patients, when compared with healthy subjects. Increased slow-wave activity, generally observed in subjects with dementia, has

been found in elderly depressed patients by some authors, though to a lesser degree than in dementia (Brenner *et al.*, 1986; Have *et al.*, 1991; Nystrom *et al.*, 1986). Studies investigating early- and late-onset depressed patients failed to find differences between the two groups, but reported a relationship between increased delta wave activity and poor performance on several neurocognitive tests in patients with late-onset depression (Dahabra *et al.*, 1998; Visser *et al.*, 1985).

Lateralized findings have also been inconsistent. An increase of beta activity, predominantly over the left side, was reported in depressed when compared to healthy subjects, suggesting left hemisphere overactivation (Flor-Henry and Koles, 1984; Kemali *et al.*, 1981; Matousek *et al.*, 1981). Some authors reported an increase of alpha activity and a polymodal distribution of the mean alpha amplitude over the right hemisphere in depressed compared to healthy subjects, suggesting a reduced activation and a disorganization of this hemisphere (von Knorring, 1983; von Knorring *et al.*, 1983).

An asymmetric increase of the alpha activity over the left frontal regions was reported by some studies in currently or previously depressed patients (Baehr *et al.*, 1998; Gotlib *et al.*, 1998; Henriques and Davidson, 1990, 1991) and in subclinically depressed students (Davidson *et al.*, 1987; Schaffer *et al.*, 1983). Children of depressed mothers, who might be at risk for affective disorders, were shown to have greater alpha activity over the left than over the right frontal regions (Tomarken *et al.*, 1994). The increase of alpha was interpreted as a sign of decreased left frontal activation with a deficit in approach-related behaviours (Davidson, 1992). The opposite asymmetry pattern was observed for the parietal regions, with an increase of alpha power over the right-hemisphere leads, in currently or previously depressed subjects (Davidson *et al.*, 1987; Henriques and Davidson, 1990). The increase of alpha over the right parietal regions might be associated with cognitive deficits, suggesting right posterior dysfunction in depression (Davidson *et al.*, 1987; Tucker *et al.*, 1981). For the parietal asymmetry pattern, however, conflicting results were reported by some studies in either depressed students or subjects with major depression. Some of them failed to find any abnormality in parietal regions (Henriques and Davidson, 1991; Schaffer *et al.*, 1983), while others found a bilateral increase of alpha (Pollock and Schneider, 1989, 1990) or a right posterior alpha reduction (Pozzi *et al.*, 1995; Suzuki *et al.*, 1996). According to Bruder *et al.* (1997) the presence of anxiety in the clinical picture might influence the laterality pattern observed over the posterior regions. In fact, non-anxious depressed patients showed more alpha activity (less activation) over the right than over the left posterior leads, whereas anxious depressed patients showed the opposite pattern. Two studies reported a failure to suppress alpha activity over the right posterior regions in depressed subjects during the performance of a spatial task (Henriques and Davidson, 1997; Reid *et al.*, 1995), suggesting that a cognitive challenge might be necessary to disclose the right-hemisphere deficit in posterior regions. Suicidal ideation might also influence the posterior asymmetry pattern. In fact, preliminary findings suggest that adolescent depressed and non-depressed suicide attempters have more alpha activity over the left than the right frontal regions, but differ in the direction of the asymmetry over the posterior regions: a greater alpha activity over the left than the right posterior leads was related to suicidal intent, but not to depression severity (Graae *et al.*, 1996).

So far the topographic analysis of the brain electrical activity from multilead recordings by means of the identification of the brain electrical microstates (BEMs) has not received great attention in relation to mood disorders. BEMs are stable segments of scalp electric fields in the sub-second range, and reflect the coordinated activation of neuronal circuits involved in mentation (Koenig and Lehmann, 1996; Lehmann *et al.*, 1987). The main quantitative parameters of the BEMs include the duration, the spatial variance (i.e. spatial changes per time unit), the topographic characteristics of the field, as assessed by the locations of the positive and negative centroids (the centre of gravity of the positive and negative areas, respectively), and the field strength. With respect to healthy comparison subjects, depressive patients showed a reduced duration of the brain electrical microstate more represented in subjects' mentation and a larger spatial variance. However, the topographic characteristics of the identified microstates were similar in the two groups (Strik *et al.*, 1995). The findings were interpreted as the electrophysiological correlates of impaired attention and automatic processing in depressive patients.

QEEG in Bipolar Disorder

Only a few QEEG studies have been carried out in acute, drug-free subjects during a manic episode, probably because of the difficulty of obtaining cooperation from these patients. Flor-Henry and Koles (1984) found a decrease of alpha power in manic patients with respect to healthy subjects, suggesting an overarousal in the former group. Shagass *et al.* (1984) found that patients with mania have higher EEG frequencies and greater variability than those with depression, and interpreted the results as a sign of overarousal in mania. In bipolar subjects left hemisphere abnormalities have been reported, akin to those in schizophrenia (Davidson, 1987; Flor-Henry, 1987).

A study on the adult offspring of subjects with bipolar disorder, comparing the ill siblings (subjects who met the DSM-III criteria for bipolar disorder) with those who were well, showed a reduction of alpha activity in the ill group (Knott and Lapierre, 1987b). However, in the ill-sibling group, all subjects were asymptomatic at the moment of assessment, some were on maintenance treatment or had been treated with antidepressants and observed a very short wash-out period (72 hours) before assessment, leaving open the possibility that study findings were influenced by drug treatment.

QEEG and Treatment Responsiveness

A few investigations were aimed at assessing the usefulness of QEEG in the prediction of response to antidepressant drugs. Knott *et al.* (1985) with an open-label paradigm found a lower relative theta power in the baseline recording of depressed subjects with a favourable clinical response to imipramine, with respect to non-responders to the same drug. Cook *et al.* (1999) used a new measure, combining relative and absolute power, the cordance, in the theta band to investigate QEEG correlates of response to fluoxetine in unipolar depression, with a double-blind, placebo-controlled paradigm. Significantly more depressed subjects with high cordance in theta band were responders to fluoxetine in comparison to those with low cordance. Since previous studies showed that cordance correlates with brain metabolism (Leuchter *et al.*, 1999), the results were interpreted as suggesting that only depressed subjects with low baseline dysregulation respond to treatment.

Galderisi *et al.* (1996) used a test-dose procedure to study the QEEG changes associated with clinical response to moclobemide in unipolar depressed patients. A single dose of 200 mg moclobemide induced a transient increase of theta activity (observed up to the third hour after drug administration), a slight augmentation of alpha and a sustained increase of beta activity (observed up to the sixth hour after drug administration). Drug-induced increase of beta was found to correlate with the decrease of depression psychopathological ratings observed after 42 days of treatment.

In a group of drug-free, acute patients with mania, Small *et al.* (1999) reported more baseline fast theta activity (6–8 Hz) in non-responders to pharmacotherapy than in responders. After treatment, non-responders had more delta and theta over frontal and temporal regions, as well as more beta1 activity over left temporal leads.

Event-Related Potentials (ERPs)

ERPs in Depressive Affective Disorders

For nearly all ERP components discrepant findings were reported in depressed subjects (Bruder *et al.*, 1995, 1998; el Massioui and Lesevre, 1988; Kayser *et al.*, 2000; Ogura *et al.*, 1993; Pierson *et al.*, 1996; Zahn, 1986).

The contingent negative variation (CNV) is a slow negative potential occurring within the interval between a warning stimulus and an imperative signal which prompts the subject's response. The CNV has generators in the prefrontal cortex and shows a brainstem cholinergic modulation (Halgren, 1990). It is thought to be related to the orientation, expectation and preparation for the motor act (Wascher *et al.*, 1997).

The CNV was found to be reduced in depressed when compared with healthy subjects (Ashton *et al.*, 1988; Sartory, 1985; Shagass, 1983). However, other studies failed to find the CNV reduction (Elton, 1984; Knott and Lapierre, 1987a). A study subdividing depressed patients into two groups, one with retardation/blunted affect and the other with anxiety/impulsiveness, found a reduced CNV only in the former group versus healthy subjects (Pierson *et al.*, 1996). An augmented CNV amplitude was demonstrated in a subgroup of depressed patients with increased reactivity to apomorphine, underscoring the clinical-biological heterogeneity of depressive disorders (Timsit-Berthier, 1986). A reduction of the P1-N1 component amplitude was reported in depressed compared to healthy subjects (el Massioui and Lesevre, 1988; Pierson *et al.*, 1996), suggesting a disturbance in early sensory processing. The finding was not replicated by other studies (Bruder *et al.*, 1995; 1998).

For N2, an ERP component thought to index both automatic orienting and initial effortful stimulus evaluation (Bruder *et al.*, 1998), a reduced amplitude was observed in depressed versus healthy subjects, when using emotional faces; differences were maximal over right parietal regions, indicating a posterior right-hemisphere deficit (Deldin *et al.*, 2000).

Several studies examined the P3 component of the ERPs in depression. This component includes (1) the P3a subcomponent, with a centro-frontal amplitude maximum, which represents an orienting response, and (2) the P3b subcomponent, with a centro-parietal maximum, which is related to the categorization and completion of the task. The P3 amplitude was found to be reduced in depressed versus healthy subjects (Bruder *et al.*, 1998; Pfefferbaum *et al.*, 1984; Roth *et al.*, 1981; Thier *et al.*, 1986). However, according to some studies (Gangadhar *et al.*, 1993; Picton, 1992), the reduction was not seen during episode remission. Other studies reported a normal P3 amplitude in depressives (Bange and Bathien, 1998; Giedke *et al.*, 1980; Sara *et al.*, 1994). Depressed subjects with retardation/blunted affect presented a reduced P3a amplitude, while those with agitation/impulsiveness did not (Partiot *et al.*, 1993). Since P3a is related to the orienting, the authors interpreted the results as evidence of disturbed automatic processing in depression with retardation and blunted affect. In a subsequent study, in which a more complex task was used, a group of retarded/blunted depressives showed a reduction of both P3a and P3b amplitude with respect to anxious/impulsive patients and healthy subjects (Pierson *et al.*, 1996). Actually, in the anxious/impulsive group the P3b amplitude was even larger than in healthy subjects, suggesting that the combination of the two subgroups may cancel out differences between patients and comparison groups. Kayser *et al.* (2000) investigated the P3 during passive viewing of faces with negative and neutral emotional valence in depressed and healthy subjects. The P3b showed an amplitude reduction in depressed compared to healthy subjects. Furthermore, the P3b showed an amplitude enhancement over right posterior leads for negative as compared to neutral faces, only in healthy subjects. Depressed patients presented a similar effect for the P3a component. The authors hypothesized that an early stimulus categorization (indexed by the P3a) was followed by inhibition of further affective processing (indexed by the P3b) in depressed subjects. The study findings gave further support to the presence of a reduced activation of right posterior areas in depressed subjects.

Discrepant findings were reported for P3 latency increase (which might index cognitive deterioration) in depressed subjects (Blackwood *et al.*, 1987; Dahabra *et al.*, 1998; Pfefferbaum *et al.*, 1984; Roth *et al.*, 1991). Bruder (1995) criticized the use of very easy tasks in studies reporting negative results and demonstrated a longer P3 latency in depressed subjects, with respect to a comparison group, only for a right-hemisphere task (Bruder, 1995). In a previous study, comparing subgroups of depressed subjects, Bruder *et al.* (1991) reported an increase of P3 latency in subjects with typical as compared with those with atypical depression only during the performance of a right-hemisphere task. Thus, discrepancies concerning P3 latency might be related to the use of tasks of different complexity and to the heterogeneity of depressive disorders.

ERPs in Bipolar Disorder

A reduced sensory gating, as measured by the suppression of the amplitude of the auditory P50 in response to the second of paired stimuli, was observed in manic patients, akin to findings in schizophrenia. However, in mania the abnormality is limited to acute symptomatic phases, while in schizophrenia it is a trait characteristic (Franks *et al.*, 1983; Freedman *et al.*, 1987). A study found that although the abnormality was present in bipolar subjects with manic or depressive episodes as well as in schizophrenics, only in subjects with mania it was associated with increased plasma levels of the norepinephrine metabolite 3-methoxy-4-hydroxyphenylglycol (Baker *et al.*, 1990). Knott and Lapierre (1987b) reported an increased amplitude of the auditory P1 in the ill group compared with the well group in the adult offspring of bipolar subjects, suggesting an increased arousal in the ill group. The P200 component, thought to reflect the evaluation of stimuli physical characteristics and with generators in modality-specific cortical areas, was found to be reduced in bipolar I and schizophrenic patients with a negative family history compared to those with a positive family history for psychotic disorders (Tabarés-Seisdedos *et al.*, 2001). The two groups also differed in the presence of a larger right Sylvian fissure in patients with a negative family history. All patients were treated at the moment of testing.

Asymmetry indices might be useful in discriminating bipolar depressed from both unipolar depressed and healthy subjects (Bruder *et al.*, 1992). As a matter of fact, bipolar depressed subjects had a lower N1 amplitude for stimuli presented to the left than for those presented to the right visual hemifield. The same asymmetry was not found in either unipolar depressed or healthy subjects. In the same study, bipolar subjects were tested in a dot enumeration task and showed a reduced left visual field accuracy which was responsible for the absence of the visual field asymmetry found in both unipolar depressed and comparison subjects. The findings were interpreted as signs of reduced right-hemisphere arousal due to a dysfunction of the arousal/attentional system in the same hemisphere.

A few studies examined the P3 component in patients with mania. Salisbury *et al.* (1999) investigated P3 in treated patients with schizophrenia and bipolar disorder with psychotic features, and in healthy comparison subjects. They found a P3 amplitude reduction in both patient groups, with respect to healthy subjects. Maximum reduction of P3 amplitude was found over the left temporal lead in patients with schizophrenia and over the midline frontal lead in those with bipolar disorder. A study comparing

bipolar and healthy subjects reported an amplitude reduction over the frontal regions and a more posterior location of the P3 topography in the patient group, suggesting a reduced inhibitory frontal control in mania (Strik *et al.*, 1998). In line with a frontal deficit are recent findings of a functional imaging study showing a reduction of frontal activity in mania (Blumberg *et al.*, 2000).

ERPs and Treatment Responsiveness

The intensity dependence of the N1/P2 component of the auditory ERPs has been used to predict clinical response to treatment with lithium or antidepressants in subjects with mood disorders. The slope of the amplitude/stimulus intensity function (ASF) is an index of the amplitude changes due to increasing stimulus intensity: the steeper the slope, the greater the amplitude changes of the studied ERP components due to increasing stimulus intensity. The concept of intensity dependence has substituted that of augmenting/reducing introduced by Buchsbaum and Silverman (1968). Several authors reported that subjects showing a steeper pre-treatment ASF exhibited a favourable response to lithium treatment (Baron *et al.*, 1975; Buchsbaum *et al.*, 1971, 1979; Hegerl *et al.*, 1986, 1987; Nurnberger *et al.*, 1979). Hegerl and Juckel (1993) argued that the intensity dependence of the N1/P2 auditory ERP component is modulated by the serotonergic system: a strong intensity dependence of this component indicates a low central serotonergic activity. Among the findings supporting this hypothesis, the relationship between ASF slope and response to fluvoxamine is relevant to the present review. The effects of a fluvoxamine test dose on the ASF slope was related to clinical response to the same drug: patients with a flattening of the ASF slope induced by the fluvoxamine test dose were responders to the subsequent fluvoxamine therapy (Hegerl and Juckel, 1993). Subsequent research by Hegerl's group confirmed the role of serotonin in the modulation of ASF (Hegerl and Juckel, 1993; Juckel *et al.*, 1997, 1999). They showed that a strong pre-treatment ASF of the N1/P2 predicts a favourable clinical response to specific serotonin reuptake inhibitors (SSRI) in depressed patients (Gallinat *et al.*, 2000; Hegerl *et al.*, 2001).

A study showed an increase in the amplitude of the visual P3b and a significant decrease in its latency in depressed patients, after 6 weeks of treatment with moclobemide with respect to baseline (Galderisi *et al.*, 1996). The latency modification of the component was independent of changes in psychopathological scores.

Ancy *et al.* (1996) showed a larger baseline P300 amplitude in responders than in non-responders to ECT.

Sleep Studies

Sleep disturbances are common in affective disorders, with a prevalence of insomnia in the majority of subjects and hypersomnia in some subtypes of affective disorders (Armitage and Hoffmann, 1997; Reynolds and Kupfer, 1987; Riemann *et al.*, 2001). Insomnia represents a risk factor for depression (Ford and Kamerow, 1989; Livingston *et al.*, 1993; Schramm *et al.*, 1995) and increases the risk of suicide (Wingard and Berkman, 1983). Sleep deprivation may alleviate depressive symptoms (Wirz-Justice and Van der Hoofdakker, 1999; Wu and Bunney, 1990) and trigger mania in bipolar subjects (Wehr, 1991). In line with the latter observation, insomnia was shown to be a risk factor for mania (Barbini *et al.*, 1996). These data underscore the importance of sleep to mood disturbances.

Normal sleep includes alternating episodes of rapid eye movement (REM) sleep and non-REM (NREM) sleep. The latter includes four stages of progressively deeper sleep (stages 1–4). The deepest stages (3 and 4) represent the so-called slow-wave sleep (SWS). A sleep cycle of about 90 minutes includes both NREM and REM episodes. Within the cycle, SWS predominates during the first part of the night, while REM sleep predominates during the last part of the night.

An endogenous circadian clock, involved in biological circadian rhythms (such as body temperature and melatonin secretion) and thought to be located in the suprachiasmatic nucleus of the hypothalamus, regulates REM sleep and sleep spindles (12–15 Hz EEG oscillations with prevalent occurrence in stage 2 of the non-REM sleep). The circadian clock is entrained by time cues so that the sleep–wake cycle is synchronized to the day–night cycle and biological rhythms are synchronized with one another. A forced desynchronization in healthy subjects between the circadian internal clock and day–night cycle influences mood (Boivin *et al.*, 1997). There is also strong evidence that the balance between cholinergic and aminergic neurotransmitter systems regulates REM propensity. In particular, serotonergic tone regulates the level of activity of the cholinergic pontine neurons that stimulate REM sleep (Rye, 1997). Sleep spindles are associated with low levels of hyperpolarization of thalamocortical GABAergic neurons, while SWS is associated with high levels of hyperpolarization of the same neurons and a complete inhibition of the thalamic relay (McCormick and Bal, 1997; Steriade *et al.*, 1993). Homeostatic mechanisms (e.g. enhancement of the propensity to sleep by prolonged wakefulness) determine the amount of SWS and contribute to the regulation of sleep spindles and the progression from spindles to SWS (Borbely, 1998; Dijk and Czeisler, 1995).

Power spectral analysis of the sleep EEG demonstrated that SWS sleep is characterized by high amplitude delta, which is inversely related to beta activity (Merica and Fortune, 1997; Portas *et al.*, 1997). The increase of low-frequency (in the theta-alpha range) power during extended wakefulness might be associated with the homeostatic process of sleepiness promotion (Cajochen *et al.*, 1999). An association between beta frequency and cortisol secretion was demonstrated (Chapotot *et al.*, 1998), suggesting a relationship between arousal and HPA axis function. Beta activity during non-REM sleep was found to be inversely correlated with subjective sleep quality (Nofzinger *et al.*, 2000).

It has been recently hypothesized that non-REM sleep involves the deactivation of the ventromedial prefrontal cortex, mediating a dissociation of higher order cortex from sensory cortex, which might be essential in restorative sleep (Nofzinger *et al.*, 2000).

Sleep Disturbances in Unipolar Depression

Sleep alterations in depression include reduced sleep time and sleep fragmentation, reduced REM latency (<65 min), increased percentage of time spent in REM sleep in the first part of the night and increased REM density (i.e. density of rapid eye movements during REM sleep), and reduced SWS, particularly during the first sleep cycle (Benca *et al.*, 1992; Lauer *et al.*, 1991; Reynolds and Kupfer, 1987; see also Brunello *et al.*, 2000; Riemann *et al.*, 2001, for reviews).

Most of these sleep abnormalities, probably with the only exception of increased REM density, are not specific to depressive patients (Benca *et al.*, 1992; Lauer *et al.*, 1991; Reynolds and Kupfer, 1987), and are more prominent in older than in young depressed subjects (Riemann *et al.*, 2001). The relationships of sleep abnormalities with severity of depression, endogenous or psychotic features, and the course of the illness remain controversial (Buysse *et al.*, 1994; Frank *et al.*, 1992; Kerkhofs *et al.*, 1988; Hubain *et al.*, 1995, 1996; Kupfer *et al.*, 1984, 1990; Riemann and Berger, 1989; Rush *et al.*, 1986; Thase *et al.*, 1986, 1995). Patients with seasonal affective disorders, which often present daytime sleepiness and fatigue, do not show the same sleep abnormalities reported in those with non-seasonal major depression (Anderson *et al.*, 1994; Brunner *et al.*, 1996; Palchikov *et al.*, 1997; Partonen *et al.*, 1993). However, they might have a disturbance in

homeostatic processes as expressed by a lower increase of theta-alpha power during extended wakefulness, with respect to healthy controls (Cajochen *et al.*, 2000).

It is not clear whether some of the described sleep abnormalities might be present during phases of remission (Riemann and Berger, 1989; Rush *et al.*, 1986; Steiger *et al.*, 1989). Discrepancies in the findings might be related to the medication status of the subjects (REM sleep is likely to rebound at initial withdrawal from antidepressants) or to the definition of remission adopted by the different investigations. A reduced REM latency in remitted depressed subjects was found to be related to the risk of relapses (Buysse *et al.*, 1997; Giles *et al.*, 1987).

Cholinergic stimulation by arecoline administration was found to induce shorter latency REM episodes in remitted depressed subjects than in healthy comparison groups (Nurnberger *et al.*, 1989; Sitaram *et al.*, 1980). Relatives of depressed subjects without a personal lifetime history of affective disorders showed the same response to the cholinergic challenge (Krieg *et al.*, 2001; Schreiber *et al.*, 1992; Sitaram *et al.*, 1982); however, a study found that affectively ill relatives had shorter latency REM episodes than well relatives (Sitaram *et al.*, 1987), suggesting that the cholinergic hypersensitivity is both a trait and a state marker.

Increased REM density and reduced SWS were also reported in non-depressed subjects with a family history of affective disorders, suggesting that these abnormalities represent a vulnerability marker (Giles *et al.*, 1989; Krieg *et al.*, 2001; Lauer *et al.*, 1995).

Studies using power spectral analysis have reported that high pretreatment delta activity, irrespective of sleep stage, is associated with clinical responsiveness (Kupfer *et al.*, 1994). The decrease of slow-wave activity in the first with respect to the second non-REM episode was found to be related to poor clinical response to both pharmacotherapy and psychotherapy (Ehlers *et al.*, 1996; Thase *et al.*, 1998).

Buysse *et al.* (1997) found that the upper frequency part of the delta activity (2–3 Hz) is related to the acute depressed state, while the lower part (0.5–1 Hz) is related to the risk of recurrence.

A study has reported an increase of beta activity in non-REM sleep in depressed as compared with healthy subjects, which was related to increased relative glucose metabolism in ventromedial prefrontal cortex (Nofzinger *et al.*, 2000).

Period analysis of the EEG has also been used to study sleep dysregulation in depression, particularly disturbances of ultradian rhythms (90 minutes, which is approximately the period of a sleep cycle). The main findings include a lower interhemispheric coherence in the beta and theta frequency range and reduced intrahemispheric coherence between delta and beta bands (Armitage *et al.*, 1992, 1993, 1995). The same abnormalities were found in remitted, previously depressed, drug-free patients (Armitage *et al.*, 1993), as well as in healthy relatives of affective patients (Armitage *et al.*, 2000). The authors interpret the data as evidence of dysregulated ultradian rest–activity cycle as a vulnerability marker of depression (Armitage *et al.*, 2000).

Sleep Disturbances in Subjects with Bipolar Affective Disorders

Several studies comparing age-matched unipolar and bipolar depressed subjects did not find any difference in sleep abnormalities (Duncan *et al.*, 1979; Feinberg and Carrol, 1984; Kerkhofs *et al.*, 1988; Lauer *et al.*, 1992).

Sleep architecture in bipolar depressed subjects with hypersomnia was found to be normal (Thase *et al.*, 1989).

Manic patients have severe sleep disorders but are difficult to investigate and only a few studies were carried out. Some of them reported a normal sleep architecture, while others found reduced REM latency and increased REM density with respect to healthy comparison groups (Gann *et al.*, 1993; Goodwin and Jamison, 1990; Hudson *et al.*, 1988, 1992). Unlike depressed patients, manic patients do not show reduced SWS (Hudson *et al.*, 1988, 1992).

CONCLUSIONS

In conclusion, a great amount of work has been carried out, but few questions have been clearly addressed and answered. Several limitations in many of the reviewed studies have hampered the possibility of fully exploiting the potential of such valuable work; the most important among them are the lack of strong hypotheses, the poor characterization of populations under investigation and the application of experimental paradigms using tasks which are far too simple to disclose cognitive-emotional dysfunctions specific to these disorders.

Some efforts must be acknowledged, such as the identification of psychophysiological markers of vulnerability to mood disorders and predictors of illness course, response to treatment and outcome. Vulnerability markers have been identified by research on eye tracking, quantitative EEG asymmetry and sleep architecture, while ERP studies have found predictors of response to SSRI drugs and sleep studies have characterized predictors of both course and treatment responsiveness. The clinical relevance of these research findings urges further investigation to confirm and extend the available evidence.

Much work has also been devoted to the search for a diagnostic marker, but no conclusion can be drawn. EDA reduction, REM dysregulation and the reduction of SWS are examples of proposed diagnostic markers for affective disorders. However, their efficiency was not systematically assessed and, when evaluated, has not always appeared satisfactory; according to some data it might be improved by the combination of multiple indices. Attempts at using psychophysiological indices to validate clinical subtypes (e.g. unipolar/bipolar, typical/atypical, endogenous/non-endogenous) have not been systematic, preventing clear conclusions. The use of psychophysiological indices to identify more homogeneous phenotypes might be a promising alternative strategy, which has not been adequately explored so far.

A few studies (e.g. those investigating ERP asymmetry during emotional activation) have designed experimental paradigms using tasks aimed at disclosing specific cognitive-emotional dysfunctions of affective disorders, yielding consistent findings. A larger application of these experimental paradigms is highly advisable.

Findings provided by EEG asymmetry studies in depression deserve special attention for their internal consistency and coherence with both neuropsychological and brain imaging findings (Bench *et al.*, 1992; 1993; Delvenne *et al.*, 1990; Fox, 1994; Passero *et al.*, 1995; Schlegel *et al.*, 1989). Future EEG and ERP studies in mood disorders might take advantage from the application of advanced electrophysiological topographic and tomographic techniques, such as the brain electrical microstates and low resolution electromagnetic tomography (LORETA) (Pascual-Marqui *et al.*, 1994).

An important limitation of psychophysiological research in mood disorders has been the poor control of confounding variables, such as medication status, age, gender, handedness, state or trait anxiety. This limitation has plagued early investigations in this field, and, surprisingly, can still be found in more recent work, despite clear demonstrations of the strong influence that such confounders exert on psychophysiological indices.

A task of future research should be the disambiguation of important empirical findings, such as those concerning EDA asymmetry, interpreted as either a hypoactivation or a hyperactivation of the right hemisphere.

Further progress of the whole research field might be fostered by studies carried out in a more comprehensive perspective — that

is, combining, for example, clinical, psychophysiological, neuroendocrinological and brain imaging techniques.

The Neuropsychology of Mood Disorders: Affect, Cognition and Neural Circuitry

Aprajita Mohanty and Wendy Heller

Research in the past decade has greatly enhanced our understanding of the neural processes that implement cognitive, emotional and physiological functions in mood disorders. Abnormalities or disturbances in these functions have been shown to be associated with corresponding abnormalities in regional brain functions (Heller and Nitschke, 1998). This has led to increased research efforts focused on linking theories of cognitive neuropsychology to the anatomy and physiology of related brain function in mood disorders.

Despite extensive evidence indicating impairment of cognitive functioning in depression, this area is largely ignored, especially in diagnostic evaluation (Austin *et al.*, 1992). The current *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association, 1994) identifies cognitive factors (e.g. indecisiveness, difficulties in thought and concentration) as fundamental components of depressive episodes and dysthymia. Neuropsychological studies have identified a variety of other cognitive characteristics associated with depressed moods. For example, depression is associated with deficits in executive functioning (Channon and Green, 1999; Freidman, 1964; Goodwin, 1997; Raskin *et al.*, 1982; Silberman *et al.*, 1983), memory (Burt *et al.*, 1995), attention (Mialet *et al.*, 1996), and visuospatial processing (Asthana *et al.*, 1998). Depression-related cognitive deficits range in severity from mild subclinical impairments to pervasive global deficits, often referred to as pseudodementia (Abrams and Taylor, 1987; Golinkoff and Sweeny, 1989; Watts *et al.*, 1990). The term pseudodementia was coined to describe patients with affective disorders who display an unusually large number of cognitive deficits that are typically associated with organic brain disease (Kiloh, 1961). The conjunction of depression and cognitive impairments of various types poses a clinical diagnostic problem because it increases the likelihood of a variety of misdiagnoses, including degenerative dementia, stroke or learning disability (Marsden and Harrison, 1972).

Abnormal patterns of brain activity and function associated with depression have been demonstrated in research using a variety of techniques, such as neuropsychological testing (Miller *et al.*, 1995; Rubinow and Post, 1992; Silberman and Weingartner, 1986), lesion techniques (Lipsey *et al.*, 1983; Robinson and Price, 1982; Robinson *et al.*, 1984), electrophysiological techniques (Deldin *et al.*, 2000; Heller *et al.*, 1995; Henriques and Davidson, 1990), and haemodynamic techniques (Baxter *et al.*, 1989; Bench *et al.*, 1992, 1993; George *et al.*, 1994a). Parallel findings to those obtained in depressed populations have been described in normal individuals following induction of depressed mood (Davidson *et al.*, 1979, 1985) as well as individuals scoring high on measures of depressed affect (Tomarken *et al.*, 1992). Despite substantial evidence indicating that the same brain regions implicated as abnormal in depression are also fundamental for various aspects of cognitive processing, the implications of these neuropsychological findings for cognitive processing in depression have rarely been studied (Rubinow and Post, 1992).

In this chapter, we review the evidence and describe the nature of the cognitive characteristics that have been identified in depression. In addition, we provide a brief discussion of the neural mechanisms likely to be associated with these cognitive characteristics. Before discussing the nature of cognition in depression we review a number of important factors that are likely to impact cognitive function in depression. These factors can introduce important methodological confounds in studies examining the relationship between depression and cognitive impairment, thus weakening the conclusions drawn from the results of clinical neuropsychological studies (Murphy and Sahakian, 2001).

GENERAL COGNITIVE DEFICITS AND CHARACTERISTICS OF DEPRESSION

Cognitive deficits in depression are influenced by the clinical characteristics of the disorder, such as the presence of specific symptoms, depression subtype and symptom severity. For example, cognitive deficits in depression have been found to vary with the presence of psychotic symptoms.

Cognition and Psychosis

Studies show that depressed patients with psychotic features such as delusions and hallucinations have more structural brain abnormalities than normal controls (Lesser *et al.*, 1991), show neuropsychological performance comparable to that of patients with schizophrenia (Jeste *et al.*, 1996; Nelson *et al.*, 1998) and are more impaired than patients with non-psychotic depression and normal controls (Basso and Bornstein, 1999; Jeste *et al.*, 1996; Lesser *et al.*, 1991; Nelson *et al.*, 1998) on a broad range of neuropsychological measures such as attention, response inhibition, verbal declarative memory and visuospatial abilities. It is important to keep in mind that drug effects can be a possible confounding factor in these studies as the selected clinical groups differed in the types and dosages of psychotropic medications with which they were being treated. Studies have shown that some psychotropic medications can impair or, conversely, improve neuropsychological test performance (Spohn and Strauss, 1989). Furthermore, individuals with psychotic depression may have more severe depressive symptoms, more frequent recurrence of depressive episodes and longer episodes, poorer response to pharmacotherapy, more hyperactive hypothalamus–pituitary–adrenal (HPA) activity (Coryell *et al.*,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

1996) and more structural brain abnormalities such as cortical atrophy (Gewirtz *et al.*, 1994). To the degree that these factors have a detrimental influence on cognitive function, individuals with psychotic features will present with more deficits.

Cognition and Subtypes of Depression

Cognitive deficits have also been found to vary with subtypes of depression. For example, Austin *et al.* (1999) reported that although depressed individuals were impaired on most mnemonic tasks, on simple reaction time and on Trails B of the Trail Making Test, melancholic patients defined by narrower criterion were additionally impaired on the Wisconsin Card Sorting Task (WCST) and on digit symbol substitution. In contrast, the cognitive performance of the more narrowly defined non-melancholic patients was largely unimpaired. Silberman *et al.* (1985) reported that patients exhibiting an abnormal dexamethasone suppression test (DST) response, usually seen in endogenous depression, showed more cognitive impairment than those with less evidence of physiological dysfunction. Using the Newcastle scale to define subjects with endogenous and non-endogenous depression, Cornell *et al.* (1984) reported impairment of complex reaction time only in subjects with endogenous depression.

Cognition and Severity of Depression

The relationship between depression subtype and cognitive deficits is confounded by depression severity, which can also affect cognitive functioning. For example, while Austin *et al.* (1992, 1999) reported frontal deficits only in individuals narrowly diagnosed with endogenous or melancholic depression, the differences disappeared after controlling for depression severity (Austin *et al.*, 1999). Individuals with melancholia showed poorer performance on cognitive tasks in the morning, when mood is reported to be more depressed, compared to evening — whereas controls displayed the opposite pattern (Moffoot *et al.*, 1994). The impact of severity has also been studied by correlating scores on clinical scales such as the Hamilton Depression Scale (Hamilton, 1960) with cognitive performance scores (for review, see Austin *et al.*, 2001). Using this method, studies have shown that severely depressed patients, especially those with significant psychomotor impairment, are more cognitively impaired (Austin *et al.*, 1992; Tarbuck and Paykel, 1995). Thus, depression severity appears to contribute to the neuropsychological deficits seen in individuals with depression. However, this does not imply that cognitive deficits occur only in acute stages; some research has shown that cognitive deficits might persist even after symptom remission (Trichard *et al.*, 1995).

Cognition and Treatment of Depression

Individuals with depression generally receive a combination of medications — including mood stabilizers, antidepressants, neuroleptics and benzodiazepines — which could have an impairing effect on neuropsychological performance. It is possible that differences observed between patients and controls, or patients in different stages of bipolar illness, are confounded by different medication regimens (Murphy and Sahakian, 2001). There is some evidence to suggest that different antidepressants may exert different effects on cognitive functioning. For example, amitriptyline, mianserin and trazodone have been reported to have adverse effects on a range of cognitive processes, including memory. The detrimental impact of these drugs was found to be more marked immediately following administration, and the effects wore off with time (Thompson, 1991). Studies have also shown that compared to depressed patients not treated with ECT, patients treated with ECT showed explicit memory deficits (Squire *et al.*, 1984). In general, however, prolonged antidepressant treatments appear to be associated with improved cognitive function as depressive symptoms remit (Frith *et al.*, 1983).

Cognition and Motivation

Some studies have argued that cognitive deficits in depression reflect motivational impairments (Hockey, 1986). In support of this notion, depressed patients show deficits in effortful as compared to automatic cognitive tasks, including problem solving, explicit memory, general learning and reading (for review, see Hartlage *et al.*, 1993; see also Klein and Seligman, 1976; Klein *et al.*, 1976; Price *et al.*, 1978). For example, depression has been found to be associated with impaired performance on verbal recall but unimpaired performance on verbal recognition (Roy-Byrne *et al.*, 1986) and with impaired explicit memory performance but intact implicit memory performance (Danion *et al.*, 1995; Ilsley *et al.*, 1995).

Several hypotheses have been proposed to explain the impairment of controlled operations in depression. These include lack of availability of cognitive resources due to decreased arousal (Gjerde, 1983), inadequate allocation of available resources due to an emphasis on irrelevant thoughts (Ellis and Ashbrook, 1988) or self-focused worries (Ingram, 1990), lack of initiative in the use of strategies required for information processing (Hertel and Hardin, 1990), or activation of automatic processes in depression (such as depressive ideation and depressive biases) which interfere with controlled processes (Mialet *et al.*, 1996).

Some researchers have suggested that abnormal responsivity to negative feedback, a commonly reported phenomenon in depression, may contribute to poor performance on some cognitive tasks. They (e.g. Elliott *et al.*, 1996) have argued that deficits in executive functions in depression are mediated by a highly specific form of motivational deficit involving the response of patients to perceived failure. Using conditional probability analyses, their study demonstrated that failure on one item of a test dramatically increased the chance of failure on the subsequent item in patients with depression. On both the Tower of London test and matching to sample tests, both of which provide feedback on performance, depressed patients showed a significant tendency to respond incorrectly after negative feedback. According to Elliott *et al.* (1996) the over-sensitivity to negative feedback is a highly specific form of motivational impairment that interacts with and exacerbates the neuropsychological deficits seen in depression. This impairment in the ability to alter behaviour in response to feedback could also account for the higher rates of perseverative errors seen in the performance of depressed individuals on executive functioning tasks (Channon, 1996).

Although motivational factors are likely to play a role in most aspects of performance, current perspectives do not support the notion that deficits in motivation alone can account for the patterns of cognitive deficit in depression (Heller and Nitschke, 1998; Hertel and Rude, 1991; Richards and Ruff, 1989). Heller and Nitschke (1998) argued that most of the data can be accounted for by impairments in functions of the prefrontal cortex (to be reviewed in more detail in subsequent sections of this chapter).

Cognition and Anxiety

A great deal of research has suggested that depression and anxiety are accompanied by distinct physiological, cognitive and emotional characteristics that appear to reflect the activity and function of different brain regions (Heller and Nitschke, 1997, 1998; Heller *et al.*, 1995; see also Chapter XIX-8). An important implication of these findings would be that a number of neuropsychological and neurophysiological studies may have been compromised by a failure to account for the substantial comorbidity of depression

and anxiety (Keller *et al.*, 2000). In light of these findings, it is important to consider the comorbidity of anxiety and depression in studies of cognition as disparate patterns of activation in anxiety and depression may differentially affect cognitive functioning.

From this review it is evident that differences observed between patients and controls, or between patients in different stages of depression, may be confounded by different factors such as clinical features of depression, medication regimens and comorbidity of depression with anxiety. Although these methodological problems bring unavoidable complications into investigations of disordered mood and cognition, it is important to adopt measures that control for potential confounds (Murphy and Sahakian, 2001). These measures include careful choice of controls, matching patients and controls on age and premorbid intelligence, and matching patients on measures of phase of illness, severity of depression, treatment regimen, comorbid conditions, etc.

NEUROPSYCHOLOGICAL FUNCTIONING IN DEPRESSION

Executive Functioning

Executive functions are known to rely on anterior regions of the brain (Banich, 1997; Heller and Nitschke, 1997) and include judgement, planning, abstract thinking, metacognition (i.e. 'thinking about thinking'), cognitive flexibility (i.e. flexibility in strategy use), verbal fluency, initiative, and the ability to generate alternate strategies and to direct behaviour in a goal-directed manner. Examples might include the ability to shift response set and modify strategies in task performance (Cicerone *et al.*, 1983), the evaluation of a situation and the use of cues and extra information in the environment to guide behaviour (Alivisatos and Milner, 1989), and the ability to monitor behaviour or performance accurately (Luria, 1966).

Miyake *et al.* (2000) argued that executive functions involve three important target functions — shifting, updating and inhibition — which are clearly distinguishable but are also moderately correlated constructs. Shifting involves shifting back and forth between multiple tasks, operations or mental sets (Monsell, 1996), updating requires monitoring and coding incoming information for relevance to the task at hand and revising the items held in working memory by replacing old, irrelevant information with new, relevant information (Morris and Jones, 1990), and inhibition involves the ability to deliberately inhibit dominant, automatic or prepotent responses when necessary (Miyake *et al.*, 2000). Furthermore, these executive functions were seen to contribute differentially to performance on specific tasks. More specifically, WCST performance was related most to shifting, Tower of Hanoi to inhibition, random number generation to inhibition and updating, and operation span to updating.

Individuals with depression display deficient performance on a number of set-shifting tasks such as the WCST and 'Go–No Go' tasks (Jones *et al.*, 1988). Deficits on the WCST were correlated with the severity of depression and were less severe than those demonstrated by patients with schizophrenia (Merriam *et al.*, 1999). However, another study showed that both schizophrenic and depressed individuals showed very little difference in their deficient performance on frontal lobe tasks like WCST, the Trail Making Test, and a verbal fluency test (Franke *et al.*, 1993). Channon (1996) reported that dysphoric subjects were poorer than controls in sorting to correct categories and had higher rates of both perseverative and non-perseverative errors on the WCST. The dysphoric subjects also had greater difficulties in shifting sets correctly. Unipolar depressed patients have been seen to show deficits on other attentional set-shifting tasks such as intradimensional/extradimensional (ID/ED) set shift (Purcell *et al.*, 1997). Thus, the majority of evidence points towards deficits on set-shifting tasks in depression.

A number of studies have also shown that depression is associated with impairment in working memory (Elliott *et al.*, 1996). Working memory is conceptualized as a limited capacity mental workspace involving holding task-relevant information online as well as simultaneous manipulation and updating of its contents by executive processes. Thus, working memory is presumed to be supported by an attentional control system, or 'central executive', probably localized to dorsolateral prefrontal cortex (Nitschke *et al.*, 2000; Pelosi *et al.*, 2000). Measuring event-related potentials (ERPs) as a neurophysiological correlate of working memory impairment, Pelosi *et al.* (2000) reported that individuals with depression showed deficits on a working memory task that were accompanied by ERP abnormalities consistent with dysfunction of a central executive system.

Individuals with depression also show impaired performance on tasks that test inhibitory aspects of executive functioning such as the Tower of London planning test (Elliott *et al.*, 1996, 1997). Similar results have been reported for the Stroop colour-word test (Degl'Innocenti *et al.*, 1998; Trichard *et al.*, 1995). In summary, findings from a wide variety of neuropsychological tasks indicate that depression is associated with deficits on important executive functions including set shifting, inhibition and updating.

Researchers have also investigated whether executive functioning deficits are a persistent feature of depression. A residual deficit in executive function appears to be seen in some patients with a history of depression. Paradiso *et al.* (1997) reported neurocognitive impairment in individuals after recovery from unipolar depression which was most noticeable on set-shifting tasks and was not related to medication status. Beats *et al.* (1996) also showed that deficits such as slowed simple and choice reaction times, perseveration on the set-shifting task and impaired verbal fluency did not fully remit upon recovery. Similarly, Trichard *et al.* (1995) in a study of executive functioning in middle-aged individuals with severe depression reported improved performance on the verbal fluency task but not the Stroop task upon recovery. Currently, it appears that residual deficits in mnemonic and executive functions persist in some patients with a history of depression. However, the relationship of these deficits to epidemiological variables such as age, treatment, duration and chronicity of illness, and number of episodes remains to be more clearly determined (Austin *et al.*, 2001).

Neural Correlates of Executive Function

The cognitive findings described above showing deficits in multiple domains of executive function are consistent with evidence from a variety of neuropsychological techniques indicating abnormal function of anterior brain regions in depression. Studies have identified abnormal patterns of asymmetric brain activity as well as abnormal levels of brain activity in a number of regions in prefrontal cortex, including dorsolateral, medial, orbitofrontal and anterior cingulate regions.

Abnormal patterns of asymmetric activity in anterior brain regions are demonstrated by lesion studies showing that left hemisphere strokes are significantly associated with the development of symptoms of depression (Lipsey *et al.*, 1983; Robinson *et al.*, 1983). Furthermore, significant correlations have been reported between the severity of depression and proximity of the lesion to the anterior pole of the left hemisphere (Lipsey *et al.*, 1983; Robinson and Price, 1982; Robinson *et al.*, 1984, 1985). The finding of asymmetric activity in anterior brain regions in depression has been substantiated by psychophysiological studies. In studies of EEG alpha, depression has been associated with less left than right anterior activity (Henriques and Davidson, 1990, 1991;

Schaffer *et al.*, 1983). Similarly, evidence from a variety of resting and cognitive activation paradigms has shown that depression is associated with altered regional cerebral blood flow (rCBF) and metabolism in prefrontal cortex, anterior cingulate gyrus and basal ganglia (for review, see Videbech, 2000). Consistent with EEG findings, positron emission tomography (PET) studies have reported a decrease in regional rCBF in the left dorsolateral prefrontal cortex in depression (Baxter *et al.*, 1989; Bench *et al.*, 1992, 1993; George *et al.*, 1993, 1994a; Martinot *et al.*, 1990).

In addition, specific changes in the medial prefrontal cortex have been associated with cognitive impairment in depression. The medial prefrontal region is characterized by reciprocal connections with other higher order association areas, mainly dorsolateral and caudal orbitomedial prefrontal cortex as well as anterior cingulate cortex (Kendell and Gourlay, 1970). In a study comparing patterns of rCBF in depressed patients with cognitive impairment to those of equally depressed patients without cognitive impairment, Dolan *et al.* (1992) reported decreased rCBF in the medial prefrontal brain region in the depressed cognitively impaired group. Similarly, significant decreases in rCBF in medial frontal gyrus were reported in patients with depression-related cognitive impairment (Bench *et al.*, 1992) and there was a significant correlation between a measure of global cognitive function and rCBF decreases in medial prefrontal cortex in patients meeting criteria for primary depression (Bench *et al.*, 1993).

Dolan *et al.* (1994) conducted a principal component analysis on two subtests discriminating most between depressed patients, non-patients and patients with cognitive impairment, which resulted in a two-factor solution (memory and attention) accounting for 50% of the variance in test scores. Increasing neuropsychological impairment on both factors was associated with decreased rCBF in the medial prefrontal and the frontal polar cortex. These findings were interpreted by Dolan and colleagues to indicate that the medial prefrontal cortex could mediate psychological components such as executive functions that are common to both attention and memory. In addition, each factor showed unique patterns of correlations with posterior brain regions. The memory factor was associated with rCBF in the retrosplenial precuneus and posterior cingulate cortices, regions implicated in auditory and verbal long-term memory (Grasby *et al.*, 1993). The attention factor was associated with rCBF in the posterior brain region extending from inferior post-central gyrus to the inferior parietal lobule.

Contrary to findings of decreased activity in particular brain regions, some studies have shown increased rCBF in areas of left prefrontal cortex, including ventrolateral prefrontal cortex, frontal polar cortex, medial orbital cortex, and the pregenual portion of the anterior cingulate gyrus as well as the left amygdala in individuals with familial pure depressive disease (FPDD), defined as primary major depression in an individual with a first-degree relative with primary depression. In light of these conflicting findings, Drevets and Raichle (1995) propose that the findings of decreased frontal flow and metabolism can be attributed to confounds introduced by medication effects and decreased frontal lobe size, as reported in post-mortem and MRI studies (Bowen *et al.*, 1989; Coffey *et al.*, 1993). They suggest using methods that correct PET measurements for volumetric differences. While these cautions are appropriate, a resolution of these inconsistencies awaits further research.

Drevets and Raichle (1998) also argue that different brain regions are involved in emotional versus cognitive conditions, and that there is a reciprocal relationship between them (Drevets and Raichle, 1998). Across a number of PET studies, they observed that regions implicated in emotional processing, such as the orbitofrontal cortex (OFC), ventral prefrontal cortex and amygdala show increased activity during emotional states but decreased activity during performance of cognitive tasks. Conversely, a complementary set of regions including dorsal anterior cingulate and dorsolateral prefrontal cortex show increased activity during attentionally demanding cognitive tasks, but decreased activity during experimentally induced and pathological emotional states such as depression. Drevets and Raichle (1998) hypothesize that suppression of neural activity in certain cognitive processing regions during intense emotional states could be a possible mechanism by which severe depression may interfere with cognitive performance.

An alternative to this cognition–emotion reciprocity position is the idea that tasks typically classified as 'cognitive' and 'emotional' may rely, at least in part, on common, overlapping neural systems due to their common, overlapping behavioural functions (Compton *et al.*, submitted; Heller and Nitschke, 1997; Miller, 1996; Nitschke *et al.*, 2000). We have argued that, because of the overlap in 'cognitive' and 'emotional' functions implemented by many brain regions, patterns of brain activity associated with changes in emotional state provide an important means for exploring the cognitive characteristics of emotional disorders (Heller and Nitschke, 1997; Miller, 1996; Nitschke *et al.*, 2000).

Earlier, we reviewed evidence examining the impact of abnormal response to feedback on cognitive functioning in depression. Some researchers have argued that cognitive deficits in depression are related to dysregulation of the neurobiological reinforcement and reward systems (Beats *et al.*, 1996; Elliott *et al.*, 1996, 1997). Using PET, Elliott *et al.* (1998) showed that behavioural response to feedback in depression is associated with attenuated activation in medial caudate and orbitofrontal cortex, regions that are implicated in reward mechanisms (Schultz *et al.*, 1992).

In summary, studies show that executive functioning deficits in depression are associated with abnormal patterns of brain activation in prefrontal brain regions. In future research, it will be important to examine more precisely how emotion modulates cognition and vice versa in depression. Further investigation into reciprocal brain mechanisms as well as integrated brain mechanisms for emotion and cognition could have important implications for cognitive deficits in depression. Another potentially important line of research appears to be that of the role of brain systems that regulate reinforcement and reward in depression.

Memory

Evidence from a large number of studies indicates that individuals with depression perform comparatively poorly on memory tasks. A meta-analytic study (Burt *et al.*, 1995) synthesizing 147 recall and recognition studies in clinically depressed and non-depressed samples revealed a significant, stable association between depression and memory impairment. Furthermore, the study showed that memory impairment in depression is linked to particular aspects of memory as well as particular subtypes of depression. Specifically, depression is associated with deficits on explicit, but not implicit, memory tasks. It is also associated with a tendency to remember negative material better than positive material.

Depression has been associated with impaired performance on tests of short-term memory, verbal and visual recognition memory, spatial working memory, and immediate or delayed recall (Cutting, 1979; Massman *et al.*, 1992; Richards and Ruff, 1989). Two main theoretical frameworks have been proposed to explain memory deficits in depression. According to one model, they can be attributed to impairment in effortful processing related to reduced attentional resources (Ellis and Ashbrook, 1988). Support for this model comes from studies that show that depressed individuals are more likely to show deficits on effortful or controlled tasks than on recognition tasks or tests of implicit memory (Denny and Hunt, 1992; Hertel and Hardin, 1990; Ilsley *et al.*, 1995; Hertel and Milan, 1994; Roy-Byrne *et al.*, 1986).

In contrast, Hertel (1994) proposed that attentional resources are intact in depression, but what is missing is the initiative to control

them. This model is strongly supported by studies that show that use of attentional control strategies such as focusing attention on the task and monitoring relevance of the past (Hertel, 1994) can result in improvement of memory deficits in depression. Similarly, a study conducted by Weingartner *et al.* (1981) reported that depressed individuals failed to use encoding operations that are useful in reorganizing input to facilitate later recall. This is consistent with findings that depressed patients perform more poorly than normal controls on memory tasks involving intentional coding strategies than on tasks in which memory is encoded incidentally (Hartlage *et al.*, 1993).

A phenomenon that is commonly demonstrated in memory studies in depression is that of mood congruency, that is, enhanced encoding and/or retrieval of negatively valenced material while the individual is in the corresponding mood state. The biasing effect of mood on recall of autobiographical memories has been demonstrated in studies of clinically depressed individuals (Clark and Teasdale, 1982, Gilligan and Bower, 1984; Williams and Scott, 1988). For example, Lloyd and Lishman (1975) reported that the speed of retrieval of unpleasant memories in depressed individuals correlated positively with severity of depression. Similarly, Williams (1992) showed that depressed individuals demonstrate a biased pattern of recall with fewer memories of positive experiences.

However, biased recall of negative memories could be attributed to depressed patients actually having more depressing experiences or, conversely, being more likely to interpret neutral experiences in a negative way. Some studies have tried to resolve this ambiguity by using mood induction techniques and randomly assigning normal individuals to 'happy' and 'sad' conditions with the aim of controlling the number of depressing experiences across groups. Results from these studies show that when mood is 'sad', people tend to recall more negative personal memories and fewer positive personal memories, whereas the trend is reversed when mood is more positive (Teasdale and Fogarty, 1979; Teasdale *et al.*, 1980). A similar experiment was conducted on individuals with clinical depression characterized by diurnal mood swings. Results showed that when patients were more depressed, negative memories were more probable and positive memories were less probable, whereas the pattern was reversed for patients in a more positive mood (Clark and Teasdale, 1982).

Similar to findings on autobiographical memory, the biased recall of mood congruent information in depression has also been demonstrated for explicit memory tasks, which are tasks that require conscious recollection of facts or episodes. Studies with normal individuals with varying levels of depression (Gotlib and McCann, 1984) as well as clinically depressed individuals (Bradley and Mathews, 1983; Dunbar and Lishman, 1984) provide evidence for increased recall of negative material and/or decreased recall of positive materials. Depressed mood has been shown to be associated with higher recall for negative content than positive content in incidental free-recall paradigms (Gotlib *et al.*, 2000). The memory bias for negative material appears to be specific to depression-relevant stimuli (Gotlib *et al.*, 2000). For example, Watkins *et al.* (1992) found that depressed individuals exhibited a bias for depression-relevant but not threat-related words. Although there is substantial evidence indicative of memory bias related to explicit memory in depression, there is little evidence supporting this bias on implicit memory tasks (Gotlib *et al.*, 2000; for review see Roediger and McDermott, 1992).

Some researchers hypothesize that the enhanced recall of negative memories and material in depressed mood may provide a cognitive mechanism for the maintenance of depression (Teasdale, 1983), and cognitive theories of depression (Beck, 1967) assert that negatively biased information processing may constitute a vulnerability factor for the onset and/or maintenance of depression. Gotlib and Krasnoperova (1998) reviewed research focusing on information-processing paradigms to examine depression-associated biases in attention to, and memory for, negative information. They concluded that there is strong evidence that depression is associated with concurrent information-processing biases and that some aspects of cognitive functioning, particularly those involving memory processes, may represent a vulnerability factor for depression. Thus, the research on memory biases in depression has potential clinical implications as these maladaptive biases may represent an enduring cognitive characteristic that can be measured and utilized as an indicator of vulnerability for depression (Dalgleish and Watts, 1990).

Neural Correlates of Memory

The cognitive findings described in the previous section are consistent with the neuropsychological data suggesting deficits in a variety of executive functions associated with prefrontal cortex, as reviewed above. Impairment in the strategic use of information, inappropriate deployment of attentional resources, and inadequate maintenance and updating of online material could account for many of the observed memory deficits (for review, see Heller and Nitschke, 1997). A recent study by Herrmann *et al.* (2001) also emphasized the importance of prefrontally mediated executive control strategies in efficient episodic memory retrieval. Additional support comes from an electrophysiological study conducted by Etienne *et al.* (1999), which reported that participants higher in depression did not initiate frontal lobe functions in anticipation of the task that would later improve their memory performance. However, when asked to attend to stimuli, high-depressed individuals showed an association between better memory performance and increased frontal activity. Thus, deficits could be attributed to a lack of initiative in the use of frontally-mediated strategies that are required for memory processing.

The extensive literature on cognitive biases in depression is also highly relevant to the relationship between anterior brain asymmetry and emotional valence (Heller and Nitschke, 1997). There is considerable evidence from a variety of research paradigms that anterior brain asymmetries are associated with valence (for review, see Heller, 1990) with relatively more right than left anterior activity associated with unpleasant affect and sad mood states. This model of asymmetric brain activity would lead us to predict an increased bias towards negatively valenced material and a bias in the opposite direction for positively valenced material, a pattern that is commonly seen in depression.

Besides the anterior brain regions, posterior brain regions have also been implicated in memory deficits in depression. Beats *et al.* (1996) argue that the profile of memory deficits seen in depression can best be characterized by temporal lobe dysfunction in addition to frontostriatal dysfunction. Austin *et al.* (1992) reported that depression-related clinical variables were significantly associated with tests of temporal lobe function such as pattern recognition, spatial span and delayed match to sample task (DMST). A study by Sweeney *et al.* (2000) showed that deficits in bipolar and nonbipolar depressed patients were restricted to episodic memory, suggestive of a more selective dysfunction in mesial temporal lobe function during episodes of depression. It is also possible that these memory deficits are a function of poor visuospatial spatial functioning rather than memory *per se*. Visuospatial functions, implemented in the posterior brain regions, are commonly impaired in depression and could lead to poor encoding resulting in impairment in memory retrieval.

Researchers have also hypothesized that hippocampal dysfunction may contribute to the verbal declarative memory deficits observed in depression. Depressed individuals have smaller left hippocampal volume (Bremner *et al.*, 2000; Mervaala *et al.*, 2000)

and exhibit reduced grey matter density in the left temporal cortex, including the hippocampus (Shah *et al.*, 1998). Additionally, neuropsychological impairment in depressed individuals has been shown to be associated with smaller left hippocampal volume (Shah *et al.*, 1998; von Gunten *et al.*, 2000). Individuals with a history of major depressive episodes but who are currently in remission show significantly smaller left and right hippocampal volumes with no difference in total cerebral volumes (Sheline *et al.*, 1996). It has been hypothesized that hippocampal volume loss in depression is due to neuronal cell death in the hippocampus resulting from adverse effects of stress hormones (Bemelmans *et al.*, 1996). Brown *et al.* (1999) reviewed studies to examine the hypothesis that hypercortisolaemia leads to hippocampal dysfunction and found cognitive impairment consistent with hippocampal dysfunction in depression, bipolar disorder, Cushing's disease, and in those individuals receiving exogenous corticosteroids. It will also be important in future research to take into account the comorbidity of anxiety with depression, because hippocampal involvement has been reported in post-traumatic stress disorder (see Chapter XIX-8).

Attention

Impaired attention has been considered one of the cardinal features of clinical depression. Decreased concentration is an important criterion for the diagnosis of depression in DSM-IV (American Psychiatric Association, 1994). In a thorough review of the attention literature in depression, Mialet *et al.* (1996) reported that impairment was consistently observed on tasks such as simple and choice reaction time tasks (Cornell *et al.*, 1984), the Digit Symbol Subtest (Austin *et al.*, 1992), the Continuous Performance Task (Cornblatt *et al.*, 1989) and sustained attention tasks (Mialet *et al.*, 1996).

Despite the claim that attentional biases are more common in anxious individuals and memory biases more common in depressed individuals (Dalgleish and Watts, 1990; Mathews and MacLeod, 1994), a number of studies have reported an attentional bias for negatively valenced stimuli in depression. Studies have shown that both depressed non-patients and clinically depressed patients took longer to name the colours of tachistoscopically presented depression-relevant words than neutral words (Gotlib and Cane, 1987; Gotlib and McCann, 1984). Furthermore, this bias was not evident after symptomatic recovery. Depressed individuals were also slower on a reaction time task when the distractor words were negative than when they were positive or neutral (Ingram *et al.*, 1994; McCabe and Gotlib, 1993). Similarly, studies have shown that on an emotional dot probe task depressed individuals were faster to detect a dot that replaced negative stimuli (e.g. words and emotion faces) than a dot that replaced positive stimuli (Krasnoperova *et al.*, 1998; Mathews *et al.*, 1996). However, a number of studies failed to find the association between depression and attentional bias to negative stimuli (Clark *et al.*, 1983; Mogg *et al.*, 1993, 2000). Due to substantial comorbidity between depression and anxiety, the possibility that attentional biases observed are not due to depression but to accompanying anxiety cannot be ruled out.

ERP studies have also demonstrated deficits in attentional processing in depression. For example, N2b, an ERP measure of selective attention, was enhanced in non-patients with dysthymia and anhedonia (Fernandes *et al.*, 1999; Giese-Davis *et al.*, 1993) and in patients with major depression (Keller *et al.*, 1999). Due to substantial comorbidity of anxiety and depression, Mohanty *et al.* (2000) used self-report scales that have been shown to distinguish between anxiety, depression and negative affect (Nitschke *et al.*, 2001) to determine which among these is related to the attentional deficit measured by N2b enhancement. The results indicate that it is negative affect, not something specific to depression or anxiety, that carries the N2b enhancement.

Two main hypotheses have been proposed to explain attention disturbances in depression; the resource allocation hypothesis, discussed in detail in earlier sections, and the distractor inhibition hypothesis (Ellis, 1991; Ellis and Ashbrook, 1988; Hertel and Rude, 1991). According to the distractor inhibition hypothesis, depressed individuals show an impaired ability to suppress external and internal distractors, resulting in inappropriate allocation of resources. The increased interference seen on attentional tasks requiring distractor inhibition such as the colour-word Stroop task (Raskin *et al.*, 1982; Trichard *et al.*, 1995) led Lemelin *et al.* (1997) to hypothesize that there is a difficulty in inhibiting distractors in depression. Support was provided for this hypothesis by a study using a negative priming paradigm which demonstrated that depressed patients had reduced ability to inhibit features of a distractor (MacQueen *et al.*, 2000).

Neural Correlates of Attention

An area that has been strongly implicated in both attentional and emotional processing is the anterior cingulate cortex. Bush *et al.* (2000) conducted a meta-analysis of activations and deactivations in the anterior cingulate during cognitive and emotional studies. They reported that the dorsal portion of the anterior cingulate was activated by Stroop and Stroop-like divided attention tasks as well as by complex response selection tasks. This area was deactivated (reduced blood flow or MR signal) by emotional tasks. The rostral ventral portion of the anterior cingulate was activated by tasks that relate to emotional content or symptom provocation (e.g. anxiety and induced sadness in depressed subjects) whereas this region was deactivated by cognitively challenging tasks. The reciprocal suppression of the so-called cognitive subdivision during intense emotional states such as severe depression (Bench *et al.*, 1992; Mayberg, 1997) or film-induced negative emotion could have important implications for attentional deficits in depression. Studies have shown that the cingulate gyrus is important in directed attention and in choosing the appropriate response in the presence of distractions or competing responses (Bench *et al.*, 1993; George *et al.*, 1994b). In a study designed to investigate the neural regions that could be involved in an attentional task in depression and normal controls, George *et al.* (1997) used a Stroop interference task and a modified Stroop interference task consisting of sad words. Results showed that control subjects activated the left anterior cingulate gyrus during a response interference task, whereas depressed individuals failed to show a corresponding increase in activity in this area. Instead, depressed individuals showed increased activation in the dorsolateral prefrontal cortex and visual cortex.

Mayberg (1997) postulated that the dorsal anterior cingulate (in conjunction with the dorsolateral prefrontal cortex) modulates the cognitive and psychomotor aspects of depression while the ventral anterior cingulate appears to modulate the vegetative, autonomic and affective aspects of depression, via the modulation of subgenual prefrontal cortex. Mayberg *et al.* (1999) reported increases in limbic–paralimbic blood flow (subgenual cingulate, anterior insula) and decreases in neocortical regions (right dorsolateral prefrontal, inferior parietal) during depression. After recovery, the reverse pattern, with limbic metabolic decreases and neocortical increases, was seen. A significant correlation between subgenus cingulate and right dorsolateral prefrontal activity was also demonstrated in both conditions. According to Mayberg and colleagues, the reciprocal regional relationship between ventral limbic and dorsal cortical compartments suggests that the negative influence of depressed mood on attention can be attributed to abnormal functional connections between these regions rather than concurrent changes in both sites independently.

Visuospatial Functioning

Depressed individuals have been shown to display deficits on tasks associated with cognitive functions implemented by right posterior regions of the brain (Heller and Nitschke, 1997). Individuals with depression show impaired performance on right hemisphere tasks such as judgement of line orientation, three-dimensional constructional praxis, spatial association learning, and subtests of the WAIS-R performance scale (Flor-Henry, 1976; Asthana *et al.*, 1998; Silberman and Weingarter, 1986). Furthermore, severity of depression has been found to correlate with performance on tests of visuospatial function such as spatial span, pattern recognition and delayed matching to sample (Elliott *et al.*, 1996).

NEUROPSYCHOLOGICAL FUNCTIONING IN MANIA

In contrast to the extensive literature describing the cognitive characteristics of depression, only a few studies have focused on the nature of cognitive impairment accompanying mania. According to Murphy *et al.* (2001) possible explanations for the scarcity of research in this area include practical problems in using standardized neuropsychological assessment procedures in mania, as well as the nature of a manic episode, which may prevent individuals from serving as reliable participants. In general, findings from a variety of studies show that mania is associated with impaired performance on neuropsychological tasks of attention (Bulbena and Berrios, 1993; Taylor and Abrams, 1986), memory, including pattern and spatial recognition memory as well as delayed visual recognition (Bulbena and Berrios, 1993; Bunney and Hartman, 1965; Henry *et al.*, 1971; Johnson and Magaro, 1987; Murphy *et al.*, 1999; Taylor and Abrams, 1986), and visuospatial functioning (Bulbena and Berrios, 1993; Taylor and Abrams, 1986). Some researchers attribute memory deficits in mania to altered patterns of verbal associations (Henry *et al.*, 1971), loosening of associations, and overinclusiveness, which results in an impaired ability to filter environmental stimuli (Andreason and Powers, 1974).

Another major area of functioning that is affected in mania is executive functioning. Individuals with mania exhibit disruptions in social behaviour and decision making similar to those observed in individuals with frontal cortical lesions (Bechara *et al.*, 1994). Mania is associated with deficits on executive functioning tasks such as attentional set-shifting tasks (Clark *et al.*, 2000; Morice, 1990), planning ability (Murphy *et al.*, 1999) and decision making (Clark *et al.*, 2000; Murphy *et al.*, 2001). Ferrier *et al.* (1999) also reported residual impairment in executive function in individuals with euthymic bipolar disorder after controlling for age, premorbid intelligence and depression symptoms.

Depression and mania are associated with distinct physiological, emotional and cognitive characteristics that seem to reflect the activity and function of different brain regions. Gainotti (1972) reported dramatic differences between patients with right brain damage, who exhibited cheerful and euphoric emotions (the 'indifference reaction'), and patients with left brain damage, who exhibited distressed and tearful emotions (the 'catastrophic reaction'). Similarly, another lesion study showed that mania was associated with damage to areas of the right hemisphere that are connected with the limbic system whereas depression was associated with damage to anterior cortical and subcortical regions of the left hemisphere (Robinson *et al.*, 1988). These findings suggest that brain mechanisms implemented in the right hemisphere are associated with negative affect while those associated with positive affect are implemented in the left hemisphere (Shackman, 2000). This is based on the assumption that focal brain lesions act as deactivating forces in the region in which they are located (Heller, 1990). Conversely, in normal individuals, one would expect that negative affect would be associated with increased activity in the right hemisphere while positive affect would be associated with increased activity in the left hemisphere.

Studies examining physiological activity during different emotions have shown that individuals who show greater left anterior activity report increased positive affect, engage in more approach behaviours, and respond more intensely to positive than negative stimuli, whereas individuals who show increased right hemisphere activity report more negative affect, engage in more avoidance behaviours, and respond more to negative than positive stimuli (for review, see Davidson, 1995). Consistent with these findings, the prefrontal cortex has been found to be differentially involved in negative and positive emotions, with increased left anterior activation during positive affect and increased right-sided activation during negative affect (Davidson, 1992, 1998; Davidson *et al.*, 1990).

Some studies comparing the performance of individuals on a range of neuropsychological tests report no differences between mania and depression (Bulbena and Berrios, 1993; Goldberg *et al.*, 1993). These findings have led to the hypothesis that similar neuropsychological processes are involved in mania and depression despite different clinical presentations (Murphy and Sahakian, 2001). However, differences in cognitive functioning between mania and depression emerged on a shifting task using affective stimuli (Murphy *et al.*, 1999). Individuals with mania were impaired in their ability to inhibit behavioural responses and focus attention, while depressed individuals were impaired in their ability to shift the focus of their attention. Furthermore, individuals with mania tended to show a bias towards positive stimuli while depressed individuals displayed a bias towards negative stimuli. These findings are in line with the prediction that different patterns of lateralized prefrontal activity would cause differences in cognitive performance, at least for affective stimuli, between mania and depression (Murphy *et al.*, 1999). Differences in performance were also seen on a recognition memory task, with a more conservative response bias associated with depression and a more liberal response bias associated with mania (Corwin *et al.*, 1990). Thus, cognitive performance in depression and mania seems to be influenced by the affective nature of the task as well as affective responses to task stimuli.

CONCLUSION

We have reviewed extensive evidence from a variety of sources suggesting that depression is associated with biases or deficits in cognitive functioning. Areas of cognitive functioning that are impaired in depression include executive functioning, attention, working memory, memory, particularly explicit memory, and visuospatial functioning. Further research aimed at the identification of moderator variables such as depression severity, psychosis, patient status and medication status is required to clarify the extent and nature of the relationship between depression and the aforementioned cognitive deficits.

Evidence from a variety of techniques such as neuropsychological testing, as well as lesion, electrophysiological and haemodynamic measurement, has implicated the role of different brain regions in cognitive functioning in depression. In general, cognitive deficits are associated with abnormal patterns of activity in anterior brain regions, particularly dorsolateral prefrontal, medial prefrontal, orbitofrontal and anterior cingulate cortex. Additionally, memory, attentional and visuospatial deficits appear to be related to abnormal activity in posterior brain regions, including the temporal lobe, and limbic structures such as the hippocampus.

Despite extensive evidence indicating of cognitive functioning deficits in depression, researchers examining the neuropsychology of depression have focused largely on the relationship of regional

brain activity to emotion and not cognition (Heller and Nitschke, 1997). For a better understanding of cognitive neuropsychological disturbances in depression it is important to develop a comprehensive theoretical formulation elucidating the relationship between various brain regions and cognition. Examples of theoretical formulations relating regional brain activity and cognition in emotional disorders include Heller (1990, 1993), Davidson (1998), Drevets and Raichle (1998) and Mayberg (1997). For better characterization of cognitive deficits in depression it is also important to examine how emotion modulates cognition and vice versa. More specifically, studies designed to investigate reciprocal brain mechanisms as well as integrated brain mechanisms for emotion and cognition have important implications for cognitive deficits in depression. Insights into these issues could also benefit research on the cognitive correlates of mania. For example, earlier studies using affectively neutral stimuli have yielded findings suggesting similarities in cognitive dysfunction for mania and depression. However, recent studies utilizing experimental designs that require both cognitive and emotional processing have indicated biases in information processing and abnormal responses to feedback that appear to be consistent with distinct patterns of regional brain activity in mania and depression.

The association between neuropsychological impairment and depression has a number of clinical and research implications. According to Austin *et al.* (2001), both affective disturbance and cognitive impairment need to be considered as equally important manifestations of depressive disorder. They propose that cognitive testing can be used as a helpful adjunct in clinical evaluation of patients both at initial episode and following recovery. Cognitive testing in depression has potential as an evaluative tool because performance on cognitive tests has been shown to be sensitive to a variety of depression-related clinical variables such as severity (Moffoot *et al.*, 1994), presence of psychosis (Basso and Bornstein, 1999) and depression subtype (Silberman *et al.*, 1985). Despite evidence supporting sensitivity of cognitive measures to depression, it is still debatable whether cognitive deficits such as memory impairment are specific to depression or a reflection of a more general form of psychopathology (Burt *et al.*, 1995). Thus, an important diagnostic issue for clinicians is to determine whether findings of impaired memory in depression are specific to depression and distinctive enough to be used for purposes such as differentiating between depression and dementia (Burt *et al.*, 1995).

An area of research that has immense clinical utility involves the role of cognitive biases and deficits in the onset, course and maintenance of depression. For example, cognitive precursors such as information-processing biases may taint perceptions of previously depressed individuals and predispose them to the mood disturbance (Mathews and MacLeod, 1994). According to another cognitive perspective, known as the diathesis-stress model of cognitive vulnerability (Beck *et al.*, 1979), depression-relevant experiences trigger latent negative thoughts, leading to an increased risk of depression. Mineka and Gilboa (1998) argue that cognitive biases may play a threefold role, in which they mediate the course of emotional disorders, predict vulnerability to relapse, and contribute to the onset of depression.

In conclusion, an understanding of the neuropsychological concomitants of depression has the potential not only to enhance basic scientific knowledge of the disorder but also has important implications for intervention. Since researchers have proposed that cognitive characteristics such as executive functioning deficits, memory biases and attentional deficits play an important role in increasing risk for, as well as the maintenance of, depression (Mineka and Gilboa, 1998), treatment strategies aimed at improving neurocognitive functioning in these domains may prove to be beneficial in depression. Support for such strategies comes from treatment of schizophrenia and organic brain syndromes where neurocognitive rehabilitation programmes focusing on cognitive flexibility, working memory and planning ability have been shown to be effective (Delahunty and Morice, 1996; Garety *et al.*, 2000; Moore *et al.*, 2001; Morice and Delahunty, 1993). Similarly, research on patterns of abnormal brain activity in depression may contribute to an understanding of the mechanisms underlying pharmacological and psychological treatment in depression. For example, Mayberg *et al.* (1999) has suggested that the neural pathology associated with depression can be addressed via a top-down (psychotherapeutic) or bottom-up (pharmacological) intervention strategy, based on a model of reciprocal relationships between limbic and prefrontal cortical regions. Bench *et al.* (1995) reported that recovery from depression was associated with increases in rCBF in the same areas in which focal decreases in rCBF were described in the depressed state. Another example comes from the field of transcranial magnetic stimulation (TMS), a method that allows non-invasive stimulation of regions of the cerebral cortex. Using this method, researchers have demonstrated that left dorsolateral prefrontal cortex TMS resulted in significant decreases on measures of depression (Pascual-Leone *et al.*, 1996). Future research might capitalize on these findings by using cognitive and emotional activation paradigms to activate regions of the brain such as the left dorsolateral prefrontal cortex, and examining the effect of these manipulations on both depressed mood and cognitive deficits in depression.

Functional Neuroscience of Mood Disorders

Michel Le Moal and Willy Mayo

INTRODUCTION

The evolution of criteria, symptoms and models for diagnosing mood disorders, as reflected in classical twentieth-century textbooks, has been a long process, if we consider Kraepelin's (1921) phenomenological characterizations to constitute a historical landmark. This is especially true for classification and the progressive importance of biological theories. A depressive state is considered to result from either endogenous determinants or a reaction to environmental or life events and a failure to adapt. The evolution from the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) (American Psychiatric Association, 1952) to the fourth edition (DSM-IV) (American Psychiatric Association, 1994) illustrates, through the push for more reliable and valid diagnoses and for a change to a categorical system (notably for research), profound changes due largely to the new pharmacological thought and its aminergic theories and derivatives. However, it remains clear that the parallel neurobiological investigation on mood has not played a pivotal role, and that pathophysiological mechanisms have still not been identified, at least in a specific manner, in relation to the categories proposed by the last DSM (Boland and Keller, 1999). Moreover, the relation between the genetic aspects of susceptibility to mood disorders (mainly bipolar) and possible defects at the neuronal levels have not yet been demonstrated. These problems are now at the forefront of psychiatric research. Thanks to advances in statistical analysis combined with powerful new biotechnology methods, hypotheses can now be explored more rapidly. Replicated linkage has, at present, proposed susceptibility loci on chromosomes X, 18 and 21, but a single locus genetic model is in no way responsible for unipolar, bipolar and recurrent disorders (for review, see Sanders *et al.*, 1999), leading to multifactorial vulnerabilities, including environmental factors as well as many genes. Finally, promising data from brain-imaging techniques have opened a new era to help identify circuitries involved in the physiopathology and proposed new neuroanatomies of mood disorders (Manji *et al.*, 2001). However, these investigations raise methodological problems.

NEUROSCIENCE OF MOOD DISORDERS: THEORETICAL AND METHODOLOGICAL CONSIDERATIONS

Difficulties for an Experimental Psychopathology of Mood Disorders

Basic and experimental neurosciences and clinical neuropsychiatry have joined forces over the past decade to promote the biological foundations of mental illness. The task is so difficult that it can be considered, together with the mind–consciousness problem, as the last frontier in biomedical research and the definitive inclusion of psychiatry in medical sciences. In spite of significant advances that have transformed the clinical perspectives in neurology and related disorders (obsessive–compulsive disorders and Tourette's syndrome are good examples), the growing tendency to 'neurologize' classic psychiatric syndromes, such as the various forms of schizophrenia, has not yet led to universal consensus regarding the aetiology and pathophysiology of such major mental illnesses.

From a neurobiological standpoint, and in the perspective of the neuroanatomical bases of the syndromes, three main general questions remain to be solved. First, when considering a given syndrome or disorder, or a specific mental disease, the symptoms that define the disease still have to be related to a given (or a set of related) 'normal' integrated functions. In other words, a continuum from physiology to pathology and vice versa is expected and, if so, then these functional dimensions should correlate with anatomical loci. The neurobiological interpretations of the symptoms have to be placed within the framework of the structure–function paradigm (Pearlson, 1999), in which modern neurosciences and neuropsychology have made enormous progress, even regarding mental functions and higher cognitive processes. The neuropsychological paradigm first applied to the neurology of cortical functions is now open to psychiatric symptoms. For instance, the disinhibition syndrome characteristic of acute mania will be referred to a similar syndrome sometimes seen after frontal brain injury, and mania will be attributed to a dysfunction of this region.

Second, by the same token, using working hypotheses inspired by experimental medicine, and considering that the concept of experimental psychopathology results directly from the structure–function paradigm, the neurobiologist could create appropriate animal models of the given illness by manipulating either the function or the underlying structure. In this context, the interpretation of experimental conditions is limited by the fact that most of the major human mental disorders do not exist *per se* in animals. Moreover, two other problems render experimental psychopathology difficult: on the one hand, manipulation of the model to obtain all the basic symptoms or dimensions that could characterize the illness or syndrome is theoretically impossible because they are known mainly by subjective report, and on the other hand, these basic symptoms may also be found in other heterogeneous disorders, because of the difficulty of defining mental illness, as reflected by ever changing concepts in psychiatry, or due to the clinical reality of considerable comorbidities. For instance, many depressed patients display anxiety symptoms, while anxiety and depression are also considered separately in DSM-IV.

Third, the pharmacological paradigm is not totally satisfying. It is based on a well-known working hypothesis: (1) the active drug acts on neuronal systems that are defective and part of the pathophysiology of the disease; (2) it is of major interest to discover the site of action of therapeutic drugs, and these sites or structures have generally been characterized as being the specific

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

neurotransmitter systems; and (3) the more a given drug acts on many transmitter systems, the better is its therapeutic efficacy. However, the transmitter systems cannot be considered as the anatomical locus of the mental functions whose defects are reflected in the symptoms; in other words, it is difficult to imagine that the serotoninergic neurons are the anatomical substrates of symptoms characteristic of mood disorders. Of course, it is possible that the primary defect has taken place at this level, but that the symptoms result from the dysfunction of the region modulated by these neurons whose cell bodies are located in the reticular formation and related structures (Le Moal, 1995; Le Moal and Simon, 1991).

From the Physiology of Emotion to the Pathophysiology of Mood

Mood disorders have — as a trivial definition — a disturbance of mood as the predominant feature (DSM-IV). The term 'mood' refers to something based on an empirical consensus but nevertheless represents a construct with multiple facets that needs to be clarified according to its roots (old English *mod*, meaning mind, soul, courage, or German *mut*, meaning mental disposition, spirit, courage, or an Indo-European prefix, *me-*, adding the sense of strong activity, energy), leading to the general definition of a particular state of mind or feeling, humour, temper or spirit. According to common sense, mood is a mixture of feeling, humour and state of mind, i.e. a state of emotional tone and cognition. The construct emotion is not considered in the DSM-IV or in classical psychiatric dictionaries as concerns its generally understood meaning (strong feelings aroused to the point of awareness, complex reactions with both physical and mental manifestations, whatever the specific labels used, e.g. fear, anger, love, hate). Conversely, the neurobiologist deals with emotion and the construct affect but not mood. After two decades in which studies on emotion were not a central theme in neurosciences — a topic blunted largely by a hard-line, reductionistic, new-wave computational cognition that neglected feelings and emotions as important aspects of everyday life — a huge amount of knowledge has now been accumulated (LeDoux, 2000), and publications have acknowledged the neurobiology of emotion, or affective neuroscience, as a major discipline (Damasio, 1994; Damasio, 2000; Lane and Nadel, 2000; LeDoux, 1996; Pankseep, 1998; Rolls, 2001). Classically, specialists attempt to identify genetically dictated emotional operating systems considered to exist in both animal and human brains, and to evaluate how emotional feelings are generated. The vast difference in cognitive abilities among species contrasts with the homology in mammals concerning ancient subcortical evolutionarily derived systems. The problem is to appraise whether these data have something to do with mood, and whether they represent the neurophysiological foundations of mood disorders. As stated by Pankseep (1998; p. 5), 'Clinical psychology and psychiatry attempt to deal at a practical level with the underlying disturbances in brain mechanisms, but neither possesses an adequate neuroconceptual foundation for the sources of emotionality upon which systematic understanding can be constructed.' It is a challenge for this decade to relate modern cognitive neuropsychology to a new 'neuropsychology of emotion' (Lane and Nadel, 2000) and a neuropsychology of mood disorders.

NEUROSCIENCE AND NEUROENDOCRINOLOGY OF EMOTIONS

Anatomical Networks

Early in the twentieth century, neurophysiologists and clinicists suggested that emotions originated from (or were processed) at a subcortical level (Dupré-Devaux, 1901; Nothnagel, 1889) and that this subcortical 'emotional' level would be under the control of the cortex (Cannon, 1929). During the same period, Bard (1928) demonstrated in animals the critical role of a subcortical structure, namely the hypothalamus. These data were confirmed in humans through the observations of Foerster and Gagel (1933), indicating that lesions located in the hypothalamus could induce profound emotional disturbances. However, the first description of a network devoted to the processing of emotions was due to Papez (1937). For Papez, the 'stream of feeling' flows through interconnected medial structures. External inputs through primary sensory cortices reach the hippocampus, and via the mammillary bodies this information arrives at the hypothalamus. For Papez, the hypothalamus still represents the core structure of the emotional circuitry; its role is to associate an emotional value with the sensory afferents and to induce the associated motor response. From mammillary bodies, information can also reach the cingulate gyrus, and through the retrosplenial cortex it induces a feedback on the hippocampal formation. Interestingly, a direct route has also been described from the thalamic nuclei to the hypothalamus, possibly explaining the relatively quick and direct processing of some emotional information (Figure XVIII-8.1).

A few years later, Yakovlev (1948) suggested that emotional and motivational expressions are controlled by a 'middle layer' of the brain composed of partially myelinated long neurons located in the limbic thalamus, basal ganglia and hippocampal and olfactory structures. Yakovlev also dissociated a mediodorsal pathway from a basolateral pathway. The mediodorsal pathway centred on the hippocampus is similar to the circuit of Papez and seems to be involved mainly in memory functions (Livingston and Escobar, 1971). The basolateral pathway, more involved in mood regulation, involves the amygdala and its connections with the hypothalamus, dorsomedial thalamus and orbitofrontal cortex. The functional anatomy of emotional processes proposed by Papez and Yakovlev was reanalysed by McLean (1949) as the concept of the limbic system (referring to the *grand lobe limbique* initially identified by Broca in 1878). This limbic system concept is still in debate (Kötter and Meyer, 1992; LeDoux, 1991), but the recurrent problem in the search for neural substrates of emotions again lies in the definition of the word and the construct of emotion itself (Lewis and Haviland, 1992). Currently, only the circuits involved in the detection and response to danger seem to be well defined. The core structure is the amygdala: the lateral part receives cortical sensory or hippocampal inputs, and the central part controls fear responses by way of projections to the brainstem areas. The crucial role of the amygdala was evidenced by numerous studies in animals (Gloor, 1960; Kaada, 1951) and, more recently, by the experiments of LeDoux (for review, see LeDoux, 2000). These experiments also emphasize the previously suggested dual networks of Papez, i.e. a direct thalamolimbic pathway and a classical thalamocorticolimbic pathway (Figure XVIII-8.1b).

The Monoaminergic Hypothesis

Among the neurotransmitter circuits of the brain studied for their possible roles in mood disorders, monoaminergic systems have been implicated repeatedly since the 1960s. In 1965, the hypothesis of a deficit in monoamines — mainly noradrenaline — was proposed for the first time (Bunney and Davis, 1965; Schildkraut, 1965). This hypothesis was supported by evidence of low urinary levels of 3-methoxy-4-hydroxyphenylglycol (MHPG), the principal metabolite of noradrenaline, in depressed patients (mainly in bipolar depression) compared with control subjects (Maas *et al.*, 1972), and by the fact that antidepressant drugs (tricyclics and monoamine oxidase inhibitors) are known to increase noradrenergic transmission. As well as the depressive phase of bipolar disorders,

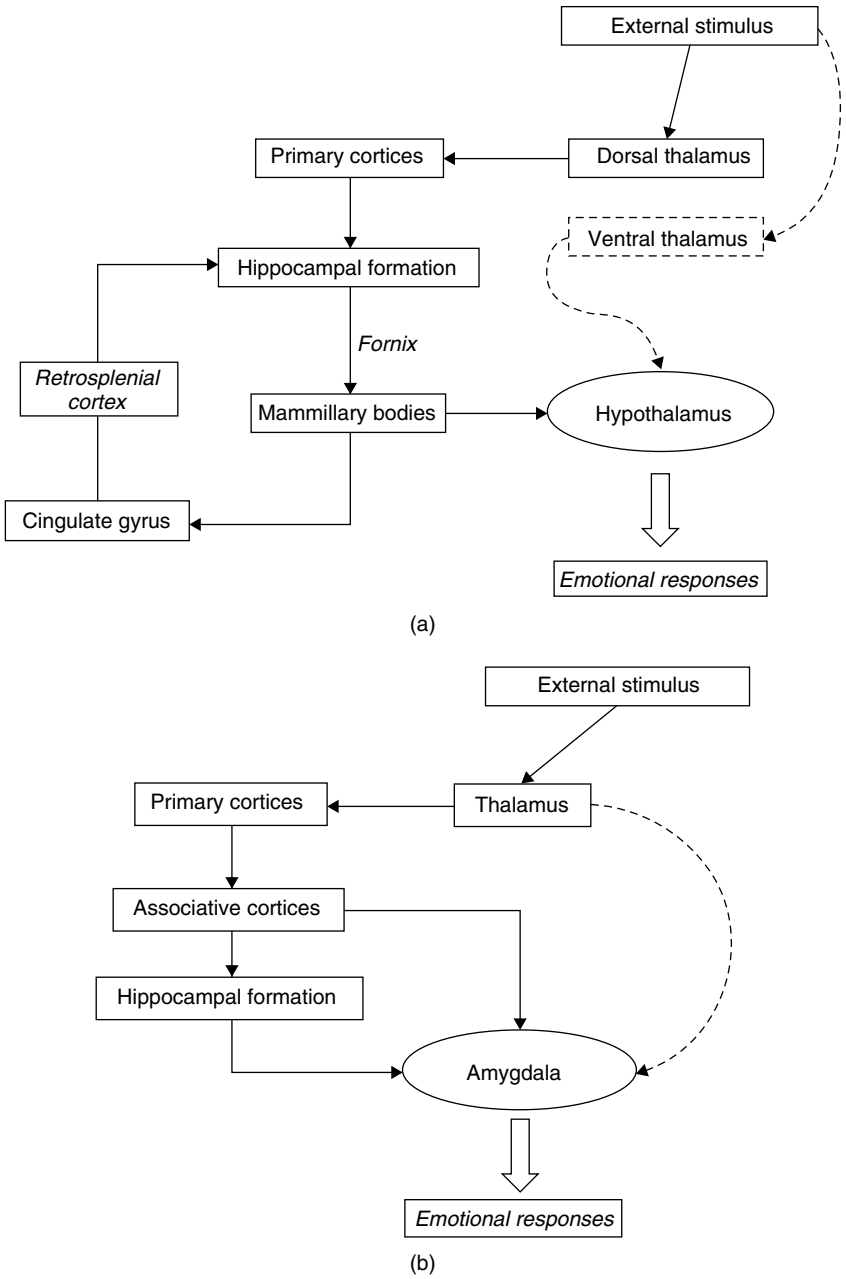

Figure XVIII-8.1 Models of anatomical networks integrating cortical and subcortical structures that could associate emotional values with sensorial afferents. (a) the model of Papez; (b) the model of LeDoux

the noradrenaline hypothesis was proposed to explain the manic phase of the illness in terms of increased noradrenaline activity (Schildkraut, 1965), and was supported more recently by Maj *et al.* (1984) and Swann *et al.* (1987). Further evidence came from the use of α-methylparatyrosine (AMPT), a competitive inhibitor of the rate-limiting enzyme for the synthesis of noradrenaline that reinstalls depressive symptoms in patients previously treated with noradrenaline uptake inhibitors (Miller *et al.*, 1996). Interestingly, AMPT has a far less significant effect in normal subjects, and is ineffective in patients treated with selective serotonin reuptake inhibitors (SSRIs) (Delgado *et al.*, 1993), indicating that noradrenaline alterations alone are not sufficient to induce depression. α2-Adrenergic and β-adrenergic receptors seem to be implicated in the pathophysiology of depression. Indeed, an increase of α2 receptors has been described both peripherally (platelets) and centrally (Garcia-Sevilla *et al.*, 1987; Meana *et al.*, 1992), indicating increased sensitivity of these receptors, inducing a decrease of the activity of noradrenergic neurons. β-Adrenergic receptors have also been implicated in depression, but there are many discrepancies in the reports available.

A serotonin (5-hydroxytryptamine, 5-HT) hypothesis for depression was also proposed to explain the pathophysiology of the disease as well as the mechanisms of antidepressants. This hypothesis is supported by various observations. Concerning precursor availability, there are data indicating that plasma concentrations of L-tryptophan are lower in some depressive subjects compared with

Table XVIII-8.1 Relationships between the HPA axis, neurotransmitter systems and some trophic factors on the hippocampal formation integrity in depression, antidepressant treatments and stress. The data refer to a cellular hypothesis of depression in which neural plasticity plays a crucial role. Neuronal atrophy or death in the hippocampal formation and prefrontal cortex contribute to the pathophysiology of mood disorders. The stress factor and life events may contribute to differential individual vulnerabilities to subsequent stressors and to depressive trends. It is possible that antidepressant treatments could oppose these adverse cellular effects, resulting in loss of neuronal plasticity by increasing either neurogenesis or cell survival. The molecular mechanisms underlying these effects include the role of cAMP signal transduction cascade and neurotrophic factors (after Duman and Charney, 1999)

normal subjects (Meltzer and Lowy, 1987). These lower levels of the precursor could lead to decreased serotonin synthesis in the central nervous system (CNS), and experimental reductions of plasma L-tryptophan can induce some symptoms of depression (Delgado *et al.*, 1989) or reverse the action of SSRIs (but not noradrenergic antidepressants) (Delgado *et al.*, 1999). Concerning the evaluation of metabolites, there are no clear data linking the cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA) and the depressive symptoms, except for impulsive suicidal behaviour (Asberg *et al.*, 1976; Roy *et al.*, 1989). A decrease in the binding of the serotonin transporter (SERT) in platelets of depressed subjects compared with normal subjects was reported frequently (Ellis and Salmond, 1994), and this decrease was also observed in the occipital cortex of depressed subjects (Perry *et al.*, 1983). A decrease in SERT binding has been described in suicide victims in the frontal cortex (Stanley *et al.*, 1982) and in the ventrolateral prefrontal cortex (Arango *et al.*, 1995). Concerning the possible alteration of serotonin receptors in depression, the complexity of these receptors must be taken into account (there are at least seven receptor families with multiple members in each family) (Saxena, 1995). Nevertheless, most research has focused on 5-HT_{2A} and more recently on 5-HT_{1A} receptors. 5-HT_{1A} receptors are found mainly in the CNS, whereas 5-HT_{2A} receptors are found in various central and peripheral tissues. Many studies report an increase in the binding of 5-HT_{2A} receptors in platelets of depressed subjects compared with normal subjects, and treatment of depressed patients with antidepressants downregulates 5-HT_{2A} receptors in platelets (Biegon *et al.*, 1990; Cowen *et al.*, 1987). The 5-HT_{1A} receptor, which controls the rate of firing of 5-HT neurons, exhibits a reduced binding in the frontal cortex of depressed medicated subjects compared with controls, suggesting a downregulation effect of antidepressants (Yates *et al.*, 1990). Altogether, these studies evidence the implication of noradrenaline and 5-HT systems in the pathophysiology of depression and an alteration of their functioning with compounds having antidepressant properties.

The pathogenesis of mood disorders cannot be explained only in terms of altered noradrenaline and/or 5-HT neurotransmission. Indeed, an involvement of dopamine was suggested several years ago (Serra *et al.*, 1979). Subsequent animal and clinical studies have suggested that drugs that increase dopamine levels (amphetamine, cocaine) induce mood elation, while drugs that decrease dopamine levels (reserpine) and dopamine receptor blockers (neuroleptics) can depress mood and induce dysphoria, respectively (for review, see Willner, 1995). Chronic antidepressant treatments increase the sensitivity to dopamine receptor stimulations, possibly trough an increase of D2/D3 receptor function and a decrease in D1 receptor number and activity (D'Aquila *et al.*, 2000). Interestingly, these changes occur mainly in the mesolimbic dopaminergic system. This system is crucial for reward-related behaviour and incentive motivation (Le Moal, 1995), which are altered in depression. In this circuit, the modulation of the dopaminergic transmission in the nucleus accumbens may represent 'a common final pathway responsible for at least part of the spectrum of behavioural actions of antidepressant drugs' (Willner, 1995); interestingly, recent imaging studies report significant modifications of the volume of this nucleus in mood disorders (see Anatomical considerations following postmortem studies below).

It remains to be determined whether the aminergic changes are a primary cause, a consequence, or only a part of a complex chain of pathophysiological events. Answering this question would help us to understand the real place of antidepressants as therapeutic agents. These agents will be taken into account when neuroplastic changes due to therapeutics are considered (see Table XVIII-8.1).

The Hypothalamic-pituitary-adrenal Axis, Stress, and the Neurotrophic Hypothesis

Patients suffering from depression exhibit some symptoms that indicate a deregulation of the main neuroendocrinological system implicated in the stress response, the hypothalamic-pituitary-adrenal (HPA) axis, notably hypercortisolaemia and the absence of suppression in the dexamethasone suppression test. Corticotropin-releasing factor (CRF) is a peptide involved in the regulation of the HPA axis, and its physiology is affected in depression. In depressed patients, there is an increase of CRF concentrations in the CSF (Nemeroff *et al.*, 1984), and these concentrations can be normalized by various antidepressant treatments (De Bellis *et al.*, 1993; Nemeroff *et al.*, 1991). Thus, an alteration of HPA axis regulation in depression could magnify some deleterious effects of stress (Figure XVIII-8.2).

It is well known that stress can induce neuronal atrophy in some limbic structures, particularly the hippocampus (Sapolsky *et al.*, 1990), and a reduced hippocampal volume has been described in depressed patients (Sheline *et al.*, 1996). Furthermore, it is now established that stress and the associated glucocorticoid release decreases neurogenesis in the hippocampus (Gould *et al.*, 1997; Tanapat *et al.*, 2001). Conversely, antidepressant treatments increase hippocampal neurogenesis (cell proliferation

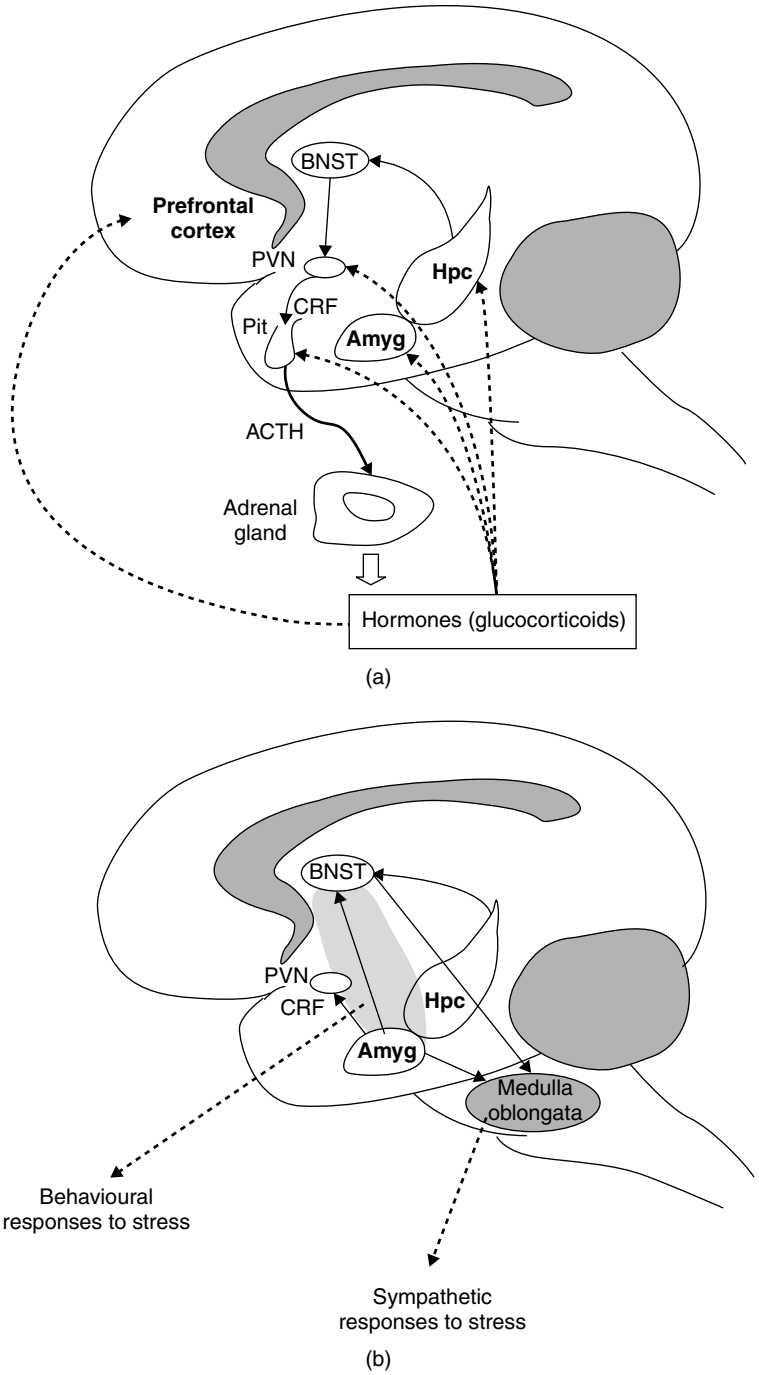

Figure XIII-8.2 The brain stress systems. (a) HPA axis stress system: Stressful stimuli increase CRF, which in turn stimulates adrenocorticotropic hormone (ACTH) release from the pituitary, which results in enhanced release of glucocorticoids from the adrenal gland. High levels of glucocorticoids, through negative feedback, decrease CRF synthesis at the level of the paraventricular nucleus (PVN) but activate CRF activity at the level of the central nucleus of the amygdala. (b) Extrahypothalamic stress system: Stressful stimuli also activate CRF systems in the basal forebrain, notably the bed nucleus of the stria terminalis and the central nucleus of the amygdala, to help mediate behavioural responses to stressors and to mediate sympathetic activation associated with stressors Amyg, amygdala; BNST, bed nucleus of the stria terminalis; Hpc, hippocampus; Pit, pituitary gland Redrawn from Koob and Le Moal (2001)

and cell survival) (Malberg *et al.*, 2000). The mechanisms underlying such actions of antidepressants are still unknown. Antidepressants may normalize the HPA axis activity, which may lead to an upregulation of brain-derived neurotrophic factor (BDNF), reported to be increased in the hippocampus of subjects treated with antidepressants (Nibuya *et al.*, 1995), possibly by an activation of the cyclic adenosine monophosphate (cAMP)–cyclic adenosine monophosphate response element binding protein (CREB) cascade. BDNF is known to enhance the growth and survival of 5-HT cells (Mamounas *et al.*, 1995), and to increase synaptic strength in the hippocampus (Kang and Schuman, 1995), and it is downregulated in the latter by stress (Smith *et al.*, 1995). In some animal models of

depression, BDNF seems to have antidepressant-like effects (Siuciak *et al.*, 1996). Imaging methods have shown smaller pituitary volumes in bipolar but not unipolar disorders, suggesting a dysfunction in the HPA axis (Sassi *et al.*, 2001).

According to the neurotrophic hypothesis, depression may result from damage of hippocampal neurons, possibly stress-induced and amplified by the hypercorticosterolaemia of depressed patients (Table XVIII-8.1). Some antidepressant treatments could enhance the expression of neurotrophic factors (BDNF), thus stimulating hippocampal neurons. Nevertheless, this hypothesis only seems to be related to depression associated with stress, and additional studies are required to understand better the link between the neuroprotective role of antidepressants and the compensation of hippocampal atrophy.

MORPHOLOGICAL STUDIES IN A NEUROPSYCHOLOGICAL CONTEXT

Anatomical Considerations Following Post-Mortem Studies

Post-mortem studies may provide evidence for the hypothesis that structural-morphological changes are responsible for the chronic functional disorders (for review, see Baumann and Bogerts, 2001). In contrast to schizophrenia and other major psychoses, little has been done to investigate the neurohistological correlates of mood disorders. Studies resulting from subjects who committed suicide frequently suffer from the lack of robust amnestic and retrospective diagnosis that establishes firmly the existence of a chronic monopolar or bipolar disorder. Future studies should use well-characterized brain specimens, well-constructed experimental designs, and well-controlled confounds (for review, see Lewis, 2002). However, investigations suggest structural disturbances in the parahippocampal cortical regions with malformations in the entorhinal lamination (Bernstein *et al.*, 1998), reduction in size (Altshuler *et al.*, 1990), and alterations in the temporal lobe. The prefrontal regions have also been investigated, and a decrease in laminar thickness was found without a change in laminar density (Goodwin, 1997; Rajkowska, 1997), while layer-specific reduction of interneurons was noticed in the anterior cingular cortex (Vincent *et al.*, 1997). No firm data or significant investigations can be reported concerning the cytoarchitecture of monoaminergic neurons, although some studies favour a role for indolaminergic neurons with a reduced neuron number in the ventral subnuclei of the dorsal raphe nucleus in major depression without a clear generalization for bipolar disorder (Baumann and Bogerts, 2001).

Volume measures have been undertaken for large regions, such as the telencephalic basal ganglia and limbic regions (Baumann *et al.*, 1999b; Baumann *et al.*, 1999c), but possible post-mortem artefacts (autolysis, medication, age, gender) have to be excluded. Results suggest that predominantly limbic-affiliated basal ganglia are involved in the pathology of mood disorders, irrespective of the diagnosis of polarity: there are reduced volumes in the right putamen, right and left pallidum (external part), and, in the most affected patients, the left nucleus accumbens. Moreover, the data suggest a trend towards reduction of the left amygdala in current major depression but not in bipolar disorder. These studies do not evidence changes in the volume of the hippocampus, stria terminalis, temporal horn or thalamus. In major depression, the right hypothalamus was smaller.

In parallel, brainstem structures have been explored, in particular for a possible pathomorphology of the aminergic nuclei. In the locus coeruleus, the main source of forebrain noradrenergic innervation, the total number of neurons was higher bilaterally in bipolar disorder (Baumann *et al.*, 1999c), in particular in the rostral two-thirds and in the dorsal part. This finding is considered to be consistent with others (for review, see Baumann and Bogerts, 2001). Fewer tyrosine hydroxylase-immunoreactive neurons were found in a depressed non-suicide group compared with depressed suicide and control groups (Baumann *et al.*, 1999a). The cytoarchitecture of the dorsal raphe has also been investigated, and the ventral part shows fewer neurons, especially of the ovoid and round types, in patients with unipolar or bipolar mood disorders; a compensatory adaptive process is noticed in the form of increased nucleolar size. Such structural changes may contribute to an impaired serotoninergic innervation of brain regions supposed to be involved in the pathophysiology of mood disorders (Arango *et al.*, 1990; Baumann and Bogerts, 2001).

Structural Imaging

Structural imaging for evaluating morphology changes includes computed tomography (CT) and magnetic resonance imaging (MRI). These studies are just beginning to guide proposals for functional and structural models. Most of the studies reveal significant prevalence of hyperdensities in deep and periventricular white matter, which have also been found in the thalamus, basal ganglia, putamen and globus pallidus, especially in elderly subjects during their first experience of unipolar depression (Chimowitz *et al.*, 1992; Drevets *et al.*, 1999; Krishnan *et al.*, 1988; Soares and Mann, 1997), in the course of late-life unipolar depression (Lidaka *et al.*, 1996). One group of subjects, who experienced their first major depressive episode later in life and exhibited cerebrovascular defects as an aetiological factor, had left frontal lobe and striatum hyperdensities (Greenwald *et al.*, 1996; Greenwald *et al.*, 1998). These anatomical characteristics do not seem to be found in bipolar disorder. In parallel, neuromorphometric explorations report regional volumetric reductions in the temporal and frontal cortices. There are some data on volumetric reduction of the hippocampus and amygdala in unipolar depression (Botteron and Figiel, 1997; Duman and Charney, 1999; Pearlson *et al.*, 1997; Sheline *et al.*, 1996), and the same type of information was found for the prefrontal cortex (Drevets *et al.*, 1997a). Observations are contradictory for the basal ganglia.

The safer conclusion deduced from structural neuroimaging is that some structural changes can be observed in unipolar depression, essentially in late-onset cases, while in other pathological situations, and in young or adult subjects or bipolar episodes, brain morphology seems to be relatively preserved (Soares and Mann, 1997). The regions targetted were those shown to participate in emotional processing (thalamus, basal ganglia, frontal lobe, hippocampus, amygdala), with the exception of the hypothalamus, brainstem nuclei and regions related to neuroendocrine-autonomic systems less tractable to neuroimaging approaches.

Functional Imaging

Functional imaging is open to new concepts closer to behavioural physiology, revealing physiological correlates of depressive states but also of asymptomatic situations. As discussed previously, the theoretical assumption is that mood disorders correspond in terms of symptoms to the disruption of emotional processes normally depressed or regulated in normal subjects, and reflect the passage from homeostatic regulation to allostasis and pathology (Koob and Le Moal, 2001). Again, such a hypothesis includes the fact that hyperemotional situations experienced by normal subjects (fear, anxiety, sadness) are correlated with metabolic and blood flow–haemodynamic changes that might be related functionally to pathophysiological changes thought to take place in mood disorders (Banki *et al.*, 1992). It is becoming possible to quantify neuroreceptor binding and neurochemical abnormalities, and such an approach aims to provide neuroimaging bases for research concerning vulnerability. In practice, as regards mood disorders, the

literature is composed essentially of glucose metabolism and blood-flow studies. The elevation or decrease of the latter may reflect an increase or inhibition of neurotransmitter functioning, regardless of the cause, and comparison with normal-state or healthy subjects aims to provide evidence on correlative changes due to depressive symptomatology (affective, cognitive, behavioural).

Reviews of more than 30 studies confirm that deficits are present when these parameters are examined regionally (Soares and Mann, 1997). A decrease in the cerebral frontal cortex was observed and confirmed with a variety of methodologies, as well as abnormalities in the basal ganglia and thalamic and cerebellar areas, in both unipolar and bipolar patients. This seems to correlate with the severity of the illness, especially for the frontal cortex. Data concerning the temporal lobe and other limbic regions, such as the hippocampus and amygdala, are more conflicting, at least for bipolar patients.

Integration of Different Approaches

Integration of data from functional and structural imaging is not easy. With respect to the main structural characteristics, the following points can be observed: (1) increased incidence of white-matter lesions in bipolar subjects and hyperdensities in unipolar major depressions; (2) smaller basal ganglia in unipolar patients and smaller cerebellum in unipolar and bipolar patients; and (3) conflicting findings for smaller frontal lobe in unipolar patients. The complex symptomatology and the various syndromes that characterize mood disorders suggest the existence of an extensive network and subtle imbalances and dynamics between regions as well as between neurotransmitters due to various causes, such as genetic-developmental, environmental and vascular ageing, and these aetiologies penetrate the circuits in different loci (Figure XVIII-8.3). Moreover, a dysfunction at one level of the circuit results in dysfunction in other areas. These modular systems could also be involved in other pathologies or comorbidities, such as Tourette's syndrome or obsessive–compulsive disorders.

The prefrontal cortex, the most consistently identified functional neuroimaging finding, represents a set of regions and plays a role in cognitive processes, working memory, planning, control and inhibition, attentional set shifting, motivation and mood regulation (George, 1994; Weinberger, 1993). Its dysfunction, lesion or atrophy seems consistent with a role in the pathophysiology of mood disorders. It is proposed that depressed mood and psychomotor retardation are related to changes in the dorsolateral part but also in the anterior cingulate due to its extensive connections with the limbic regions: suicide is related to the ventral prefrontal and anxiety to the posterior cingulate. Such phrenological approaches are still working hypotheses.

However, contradictions do exist, especially when neuropsychological data are confronted with possible underlying neurostructural abnormalities. Rubinsztein *et al.* (2001), departing from the observations that decision-making and task-related activation are associated with activation in the ventral prefrontal cortex and the anterior cingulated gyrus, investigated these regions in manic, unipolar depressive, and control subjects. They showed that during appropriate tasks, activation was increased in the left dorsal anterior cingulate, but decreased in the right frontal polar region, in the manic patients compared with the control patients. Moreover, less activation was noticed in the inferior frontal gyrus. Depressed patients did not show significant task-related differences in activation compared with control subjects. These patterns point to abnormal responses in specific frontal regions in manic patients and are consistent with neuropsychological observations in patients with lesions in the ventromedial prefrontal cortex. However, in a parallel study, another group did not reach the same conclusions (Clark *et al.*, 2001). In this context, the authors wanted to describe the neuropsychological profile of severe acute mania using a range of tasks selected primarily for the detection of localized neural disruption within the prefrontal cortex. They showed that manic patients did not resemble patients with ventromedial prefrontal cortex damage, and concluded that this region is not implicated as a locus of pathology in mania.

Coupled with the cortical regions, functional abnormalities are noticed in the basal ganglia in unipolar and even bipolar depression.

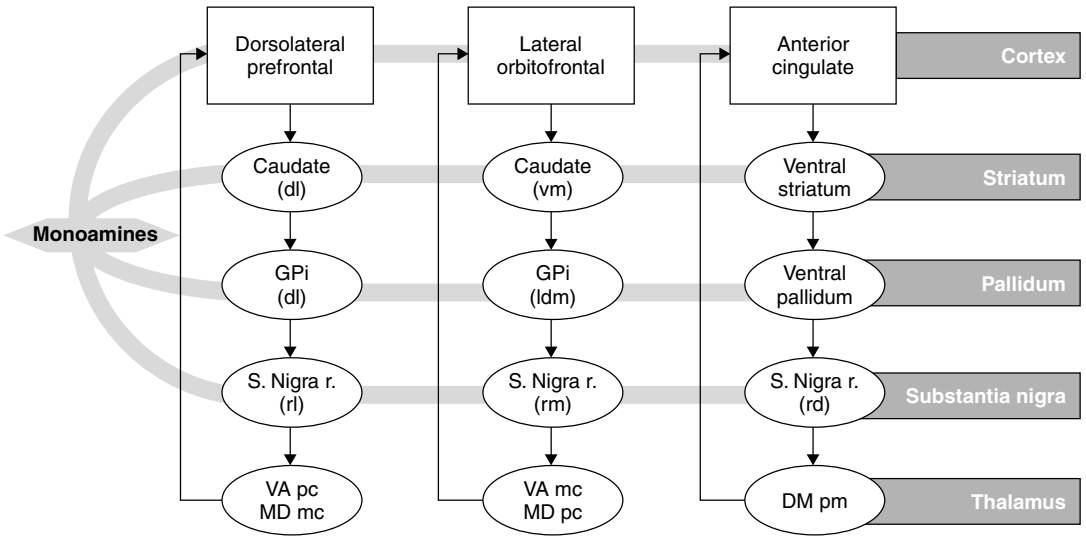

Figure XVIII-8.3 Modular organization of thalamocorticostriatal circuits. Note that each circuit engages specific regions at five levels of integration of the forebrain, and that the monoamines regulate the functioning of each circuit and allow each element to function in relation to the others. Interestingly, monoamines modulate numerous structures included in classical emotional anatomical networks. dl, dorsolateral; DM, dorsomedial; GPi, internal segment of globus pallidus; ldm, lateral dorsomedial; MD mc, medialis dorsalis pars magnocellularis; MD pc, medialis dorsalis pars parvocellularis; pm, posteromedial; rd, rostrodorsal; rl, rostrolateral; rm, rostromedial; S. Nigra r, substantia nigra pars reticulata; VA mc, ventralis anterior pars magnocellularis; VA pc, ventral anterior pars compacta; vl, ventrolateral; vm, ventromedial Redrawn from Alexander *et al.* (1986) and Le Moal (1995)

Atrophies have been noted in the caudate and putamen. Specific neurological diseases of these areas are associated with prefrontal mood changes. Moreover, the caudate and putamen have major connections with the medial temporal structures, hippocampus and amygdala, which in turn have relations with the frontal cortex. The metabolic rate in the amygdala region predicts severity of depression in depressed patients (Abercrombie *et al.*, 1996); in this circuit, potential white-matter abnormalities may contribute to the pathogenesis. An increasingly well-documented role of the amygdala-hippocampal complex has been described in dementia subsequent to recurrent stress, HPA feedback inhibition and neuronal destructions (McEwen and Sapolsky, 1995) (see Figure XVIII-8.2). This process may occur in depression characterized by HPA axis overactivity, and indeed hippocampal atrophy seems to exist in depression, although this is disputed in the literature (Pearlson *et al.*, 1997; Sheline *et al.*, 1996). The cerebellum and brainstem structures are connected with the limbic regions, and structural abnormalities have been described. In total, many studies are in agreement regarding a frontotemporal-basal ganglia circuitry in primary depression. In general, data also imply connected circuitries in major unipolar depression: a limbic (amygdala)-thalamo-(mediodorsal)-corticofrontal circuit and a limbic-striatal-pallidal-thalamic circuit (Cummings, 1993; George *et al.*, 1993a; Grodd *et al.*, 1995; Guze and Gitlin, 1994; Gyulai *et al.*, 1997; Schneider *et al.*, 1995). Cellular physiologists propose the existence of excitatory projections and subsequent increase of synaptic transmission from the limbic and frontal regions. These converging data, mainly from functional imaging techniques, remain to be interpreted in the course of major depression. Indeed, these imaging abnormalities may reflect neuromodulator dysfunction, and/or real concomitants of one or some of the symptoms of a general emotional state and/or a general pathophysiological trait and a vulnerability to depression, and/or a neuroplasticity and circuit reorganization (see Table XVIII-8.1).

Again, the main problem that confronts these neuroanatomical findings is the correspondence between what is known from behavioural physiology and neuropsychology on the one hand and symptoms on the other hand, i.e. neural and biological substrates or correlates of the various emotions and mood disorders expressed by the symptom that characterizes the different forms of depression.

Regarding the prefrontal cortex, interesting data are provided by imaging changes (increase or decrease in the imaging aspect) according to the mental state, cognitive operations, positive or negative emotions and, even more interestingly, when cognition and emotion interact in the same region. These functional correlations facilitate interpretations of the pathological changes from the symptom point of view. In view of these neuropsychological dysfunctions, reduced blood flow in the dorsomedial frontal cortex may be related to the classic impaired attentional and memory processing observed in major depression, while slowing of cognitive processes is confined to reduced dorsolateral functioning (Dolan *et al.*, 1994), regions where increased blood flow was observed in normal subjects who increased their mental activity. Moreover, the orbital subregion is assumed to play a role in modulating psychological perseveration and emotional states, and increased blood flow is observed in ventrolateral, pregenual anterior cingulate and orbital subregions during emotional processing and obsessive–compulsive states and during experimentally induced anxiety. These regions also constitute part of the circuitries described for obsessive–compulsive disorders, due to their connections with the amygdala, accumbens and hypothalamus, and decreased blood flow appears in the course of active pharmacological treatments. It has been shown that these orbital cortical regions are activated during depression in order to modulate — or inhibit — emotional responses, or to break perseverative problems and negative thoughts (Drevets and Botteron, 1997). Finally, some authors described increased functional imaging correlates with severity of symptoms (Abercrombie *et al.*, 1996; Drevets *et al.*, 1997b; Drevets and Raichle, 1992). Regional glucose metabolism in the right amygdala was shown to predict the severity of predispositional negative affect in depressed patients (Abercrombie *et al.*, 1996).

HYPOTHESIS AND CONCLUSION

Research into the pathophysiological bases of mood disorders is progressing at each level of organization under investigation (Manji *et al.*, 2001): (1) the genetic-molecular level (transcription factors, mRNA stabilization, nuclear import/export) and the subsequent gene expression-transcriptome processes; (2) the cellular level with signal transduction and modulation processes (cytoskeletal events, G-proteins, protein kinase C (PKC) and other substrates); (3) the system levels, neuronal circuits, and circadian and neurovegetative regulations (neuroplasticity processes); and (4) the cognitive-affective interactions. However, from molecular genetics (Craddock and Jones, 2001) to structural and functional defects, very little is known that might suggest a possible lead or causality between these levels.

A functional neuroanatomy of mood disorders (Soares and Mann, 1997) has emerged recently, and data obtained from morphological and imaging techniques are confronted and interpreted on the grounds of affective neuroscience. A frontolimbic-basal ganglia circuitry has been proposed, but such a structural approach needs to be refined. The regions involved account for two of the main groups of symptoms on the cognitive side (Austin *et al.*, 2001) and on the affective side, both interacting in everyday life (Buck, 1999; Cacioppo and Gardner, 1999; van Weelden, 1997). In summary, the prefrontal cortex is believed to play a role in volition, control and inhibition, working memory, and perhaps motivation and mood regulation. Dysfunction of the dorsolateral part orients the pathology to psychomotor slowing and depressed mood. Anxiety seems to be related to the posterior cingulate and also the amygdala. It is clear that the hierarchical position of these cortical regions results in dysfunction in the other areas. Defects in another group of regions seem to be present in unipolar and — in some studies — bipolar mood disorders, and are translated into psychomotor and cognitive symptoms. Both the putamen and caudate have many relations with the amygdala and hippocampus, suggesting possible trouble in affective, cognitive and inhibition abilities, the appearance of anxiety thus rendering comorbidities plausible. The amygdala-hippocampal complex may be subjected to structural abnormalities, in which overactivity of the HPA axis might have a role (McEwen and Sapolsky, 1995). Many studies have noted lateralization of functional or structural abnormalities; these data are very important (the classic interhemispheric differentiation of mood disorders after stroke) and need more clarification. Needless to say, autonomic, motivational and hormonal symptoms might be caused by sympathetic hormonal peripheral systems.

Neuropathological and imaging techniques have provided data that strengthen working hypotheses for future investigations. Again, as in pathologies such as anxiety, obsessive–compulsive disorders (Baxter *et al.*, 1992), Tourette's syndrome (George *et al.*, 1993b; Lombroso and Leckman, 1999), and drug dependence (Koob and Le Moal, 1997; Koob and Le Moal, 2001), a network including the prefrontal cortex, basal ganglia and limbic regions, including the anterior cingulate cortex (Bush *et al.*, 2000), is undoubtedly implicated (Figure XVIII-8.4).

Neuroimaging (structural and functional) abnormalities observed *in vivo* suggest neurohistological alterations linking macro- and micropathology: the basal ganglia are smaller, and structural changes are observed in noradrenergic and serotonergic nuclei (Baumann and Bogerts, 2001). However, clear distinctions between

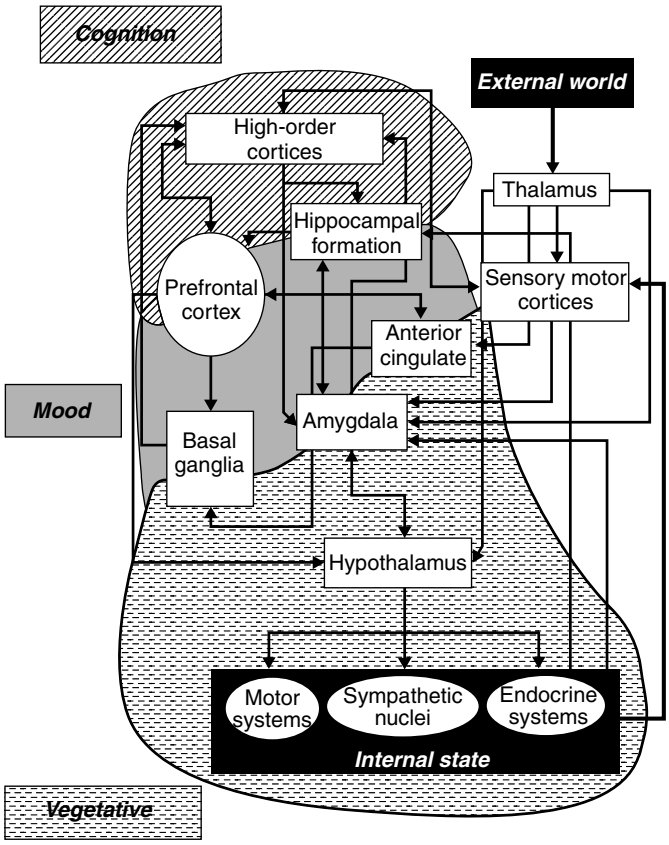

Figure XVIII-8.4 Neuroanatomical model of the central processing of emotions. Parts of these circuits are related mainly (but not exclusively) to cognitive, mood or vegetative processing and are modulated by monoamines (cf. Figure XVIII-8.3). The different circuits presented here are involved in the dialogue between the external and the internal world. External input, such as sensory information, via a classical thalamic relay, could be processed by the cortex or directly by the amygdala. The amygdala can also be influenced by the internal state (mainly by way of hormonal signalling) and, in turn, through the hypothalamus, which modulates this internal state. The evaluation of the nature of information is mainly via the prefrontal cortex, while comparison between this information and previous personal experiences involves the hippocampal formation. The prefrontal cortex and hippocampus are interconnected closely with the amygdala, and these three structures emerge as a possible mood-processing network integrating cognitive and vegetative inputs in order to make sense of the dialogue between the external and internal worlds

unipolar and bipolar syndromes, between the variety of syndromes and collateral symptoms, between acute and chronic defects, between early and late onset, and between the various aetiologies are needed for future investigations. Hemispheric lateralization dysfunction in the limbic system has been observed and merits confirmation. Besides the variety of technical manifestations and the problem of comorbidity (Nathan and Langenbucher, 1999), refinements of the techniques and methodologies will allow a more precise dissection of the circuitries, substructures or functional modules involved, such as the frontal cortex (Schoenbaum and Setlow, 2001), amygdala (Davis, 1998) or basal ganglia (Le Moal, 1995) in both acute and chronic depression.

There is still a gap between the enormous advances that have been made in past decades in affective neurosciences and a neuroscientifically based physiopathology of mood disorders, in particular in terms of structure–function relationships. It is possible that different circuitries are recruited for different emotional expression of feelings in normal subjects. For instance, experiments in humans support the hypothesis of a left hemisphere specialization for positive emotional expression and a right hemisphere specialization for expression of a negative emotion (Lee *et al.*, 1993). Moreover, there may be relationships between emotional and pre-existing personality traits, especially the harm avoidance dimension, which covaries with mood and anxiety (Svrakic *et al.*, 1992). During the past few years, progress has been made concerning (1) the neurofunctional and neuroadaptive changes, considered longitudinally, in the course of the illness, before and during mood disorders, and also in the recovery phases, in parallel with symptom evaluation; and (2) the neurofunctional changes due to pharmacotherapeutic agents or to behavioural-cognitive therapies, from disorder to recovery. Although differences in overall efficacy among groups receiving lithium, imipramine or paroxetin were not statistically significant, these drugs may affect the brain in different ways, the same being true for the mechanisms of mood stabilizers, which also have underappreciated neuroprotective effects (Manji *et al.*, 2001).

Further knowledge concerning the neurobiology and neuroanatomy of mood disorders will benefit from intense collaborative efforts in imaging techniques, neuropharmacology, physiological approaches and behavioural neurosciences.

Brain Imaging in Mood Disorders

Klaus P. Ebmeier and Dina Kronhaus

INTRODUCTION

Depression, as the reversible psychiatric condition par excellence, is clearly an ideal object for functional neuroimaging studies. In theory, patients return to their initial (healthy) brain state so that any image changes observed during an affective episode should mark the brain structures and circuits involved in the expression of symptoms and signs. Authors have imaged patients when ill and after recovery and used a number of strategies to exploit short-term fluctuations of symptoms. Such fluctuations occur naturally, as in the typical diurnal variations of mood (Moffoot *et al.*, 1994b), or they can be provoked by interventions, such as mood induction (Baker *et al.*, 1997), sleep deprivation (Ebert *et al.*, 1994a) or tryptophan depletion (Smith *et al.*, 1999b). If, on the other hand, anatomical changes did exist in depression, they would be predicted in cases of treatment resistance (Shah *et al.*, 1998), in secondary or late-onset depression (Ebmeier *et al.*, 1998), or possibly a priori in certain patients with a genetic predisposition for the illness (Drevets *et al.*, 1998).

Anatomical systems involved are likely to be medial limbic, with the anterior cingulate cortex and orbitofrontal cortex playing a prominent role (Ebert and Ebmeier, 1996). There is also the well-rehearsed hypothesis of hypercortisolaemia, which occurs frequently in depression and, at least in animal models, leads to hippocampal damage. Hippocampal damage, in turn, would release the pituitary secretion of adrenocorticotropic hormone (ACTH) from hippocampal suppression and result in a positive feedback loop (Sapolsky *et al.*, 1986). This mechanism may not be specific to depression (Welberg *et al.*, 2001), as some authors have also used it to explain cognitive impairment or dementia (Hibberd *et al.*, 2000) and the sequelae of severe psychological trauma (Bremner *et al.*, 1995).

Neuropsychological tasks have been employed in imaging studies to activate brain systems thought to be implicated in depression, in particular using 'frontal' (e.g. word-generation) or 'temporal' (memory) tasks. In such experiments, limited task performance may be responsible for group differences. Attempts to control for such performance differences include pacing tasks at a speed that all patients can manage, and post-hoc correlation of brain activity with task performance, e.g. by using analysis of covariance. A further complication of functional imaging protocols is that it is now very difficult to recruit untreated patients in a psychiatric setting. Primary-care physicians have usually already treated their patients with a standard antidepressant (e.g. a selective serotonin reuptake inhibitor, SSRI) by the time of referral. The cost and effort required to recruit patients at the primary-care level is usually seen as prohibitive. For this reason, many studies contain samples of medicated patients and have to be interpreted with caution. It also cannot be excluded that changes in brain activity or even brain anatomy may be caused by medication (DelBello *et al.*, 1999).

Medication is, of course, a particular problem for receptor ligand studies. Based on effective pharmacological treatment, there are a variety of hypotheses, particularly involving the serotonergic and noradrenergic transmitter systems, which are theoretically amenable to *in vivo* testing with neuroimaging (Delgado *et al.*, 1990). Not only the availability of untreated patients but also the availability of receptor ligands has limited such research. The latter may be partially responsible for the dearth of noradrenaline ligand studies. Not all ligands are suitable; their use may be limited by their specificity for the receptor concerned, their affinity (i.e. the likelihood to be displaced by endogenous ligand) and their nondisplaceable (non-specific) binding fraction. In spite of these limitations, first results are now emerging that test some of the extant pharmacological hypotheses in depression.

Rather than giving a balanced review of all studies carried out in the field, we will focus on certain themes and future prospects that appear to be emerging. Our selection will no doubt be idiosyncratic, but we hope that we have captured the important paradigms and paths of current research. In order to limit the size of the chapter, we will focus on key publications of the last 5 years (at the time of writing), as earlier literature has been summarized well in a number of other reviews (Davidson *et al.*, 1999; Drevets, 1998; Kennedy *et al.*, 1997; Norris *et al.*, 1997; Stoll *et al.*, 2000; Videbech, 1997; Videbech, 2000). Rather than systematically dividing the imaging literature by image modality or diagnosis, we will attempt to present a logical narrative, proceeding from simple (e.g. neurochemical) hypotheses, such as the dopamine theory of psychomotor retardation in depression, to more complex models. Hypotheses that are, in a sense, post-hoc, i.e. exploit the natural history of depressive symptoms and their treatment, will be followed by experimental approaches, which imply complex neuronal systems and attempt to activate selectively such systems that are thought to be implicated in the expression of depressive symptoms. Mania is a rare condition that is very difficult to study with neuroimaging techniques, and reports are rare (Al-Moussawi *et al.*, 1996). This illness will, therefore, not be discussed, except when included in studies of bipolar depressed patients.

PHARMACOLOGY

Dopamine and Motor Function

Although dopamine is not thought to be involved primarily in the treatment and the experience of symptoms of depression, it may play an important role in the brain reward systems and in movement control. It has been implicated in retarded depression, both by the reduction of the dopamine metabolite homovanillic acid in cerebrospinal fluid (Jimerson, 1987) and by increased D2 receptor binding, particularly in psychomotor retarded patients (Ebmeier and

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Ebert, 1997). Increased postsynaptic receptor binding is interpreted mainly as evidence of reduced dopaminergic activity with resulting receptor supersensitivity or, alternatively, reduced displacement of the radioligand by endogenous dopamine (Shah *et al.*, 1997). Sleep deprivation, which may have an amphetamine-like effect, is associated with displacement of such ligands from their binding sites in the neostriatum (Ebert and Berger, 1998). Whether reduced availability of dopamine is ubiquitous in depression is, however, doubtful. At least one single photon emission computed tomography (SPECT) study (Klimke *et al.*, 1999) ($n = 15$) found a reduction in ligand binding to D2 receptors that normalized on clinical recovery and predicted response to SSRIs. Paillere-Martinot *et al.* (2001) reported a reduction in left caudate 18F-dihydroxyphenylalanine (DOPA) positron emission tomography (PET) only in blunted and retarded, but not in impulsive and anxious, depression. Examining presynaptic loci, 15 drug-naive patients with major depression showed significant increases in SPECT striatal dopamine transporter (DAT) binding capacity (Laasonen-Balk *et al.*, 1999). This may be interpreted similarly to the findings in D2 receptors, as a correlate of reduced availability of dopamine (see above). This effect, however, was not reported in 31 drug-naive children. Serotonin transporter (SERT) binding (see below) but not DAT binding in the hypothalamus and midbrain was increased (Dahlstrom *et al.*, 2000). Interestingly, during acute cocaine abstinence ($n = 28$), associated with depressive symptoms and a 20% increase in striatal DAT binding capacity measured by SPECT, there was a negative correlation of tracer binding with Hamilton depression scores (Malison *et al.*, 1998a), suggesting an adaptive response. Basal ganglia involvement in depression is demonstrated not only by abnormal dopamine ligand studies but also by imaging studies examining brain activation and blood flow. Hickie *et al.* (1999) reported a correlation between (delayed) reaction time and (reduced) left neostriatal activation from simple to choice reaction time tasks in psychomotor retarded patients. Finally, basal ganglia pathology may predispose to late-onset or secondary depression, as suggested by magnetic resonance imaging (MRI) lesion studies (Lauterbach *et al.*, 1997) and MRI studies of iron deposition (Steffens *et al.*, 1998).

Noradrenaline

Although noradrenaline has been implicated in depression for many years (Zis and Goodwin, 1982), there have been relatively few neuroimaging studies. After driving the noradrenergic system with clonidine, an $\alpha 2$ agonist, a study in six depressed and six healthy women found an increase in right prefrontal perfusion only in the depressed group, suggesting either presynaptic subsensitivity or a local supersensitivity of postsynaptic alpha2 receptors (Fu *et al.*, 2001). This may not be a specific finding, as Moffoot reported similar results for patients with Korsakoff psychosis (Moffoot *et al.*, 1994a).

Serotonin

Serotonergic Activation, Treatment Effects and Response

In accordance with the theoretical and practical importance of SSRIs in the treatment of depression, a number of studies have examined the effects of SSRIs on brain function, both explicitly and by comparing patients when they are ill and recovered. Mayberg *et al.* (1997) examined 18 hospitalized patients with unipolar depression and reported that rostral (anterior) cingulate (Brodman's area 24a,b) metabolism predicted response (hypermetabolism) and lack of response (hypometabolism) to fluoxetine. In a repeat measures study (Brody *et al.*, 1999), 16 depressed outpatients were imaged with 18F-fluorodeoxyglucose (FDG)–PET before and after treatment with paroxetine. SSRI responders showed a reduction in ventral prefrontal perfusion, but (left) ventral anterior cingulate reduction before treatment predicted a better response. These findings could be in contradiction to the data of Mayberg *et al.* (1997). However, patients in that study were more clinically unwell, different SSRIs were used, and the target areas do not seem to be congruent.

In reversal of SSRI treatment, depletion of serotonin by a low-tryptophan amino acid drink can lead to a temporary lowering of mood in recovered depressed patients. Smith *et al.* (1999b) found that 'increasing levels of depression after tryptophan depletion were associated with diminished neural activity in ventral anterior cingulate, orbitofrontal cortex and caudate nucleus regions' during paced verbal fluency performance. In addition, depressive relapse attenuated cognitive task-related activation in the anterior cingulate. This study illustrates potential complications in design arising when behavioural conditions are mixed with pharmacological interventions in neuroimaging: although not obvious in this study, the pharmacological interventions may affect task performance as well as mood. The separation of drug and clinical effects, and the statistical definition of the interaction between the two, are, up to a point, arbitrary. The same group also confirmed the specific hypothesis that mood deterioration induced by low-tryptophan drink would increase activity in the projection from the habenula to the raphe, structures that are part of the feedback loop controlling the release of 5-hydroxytryptamine (5-HT) throughout the brain (Morris *et al.*, 1999). A reliable differential effect of the indirect serotonin agonist fenfluramine on brain perfusion in healthy volunteers and depressed patients has not been established. A study of 13 depressed and 18 healthy women showed identical effects in both diagnostic groups after intravenous infusion (Meyer *et al.*, 1998).

Serotonin Transporter

After an initial rush of interest in the association of certain SERT alleles with depression, a number of imaging studies have used SERT ligands with patients (Battersby *et al.*, 2001). Such studies are understandably difficult to conduct, as medicated patients cannot be used. Unipolar depressed patients exhibited a characteristic reduction of 18% in SERT in the brainstem, where the highest concentrations of receptors can be found, compared with healthy volunteers (Malison *et al.*, 1998b). Patients with seasonal affective disorder showed reduced SERT binding capacity in the thalamus and hypothalamus but not in the midbrain or pons (Willeit *et al.*, 2000). This effect, however, was reversed in the hypothalamus and midbrain, where increased SERT binding correlated with concurrent depression in a group of drug-naive children ($n = 41$). Increased binding could be attributed to a reduction of serotonin within the synaptic cleft (thus allowing increased tracer binding), with developmental differences accounting for contradictory results for transporter binding in adults and children (Dahlstrom *et al.*, 2000).

5-HT2 Receptor

Post-mortem studies have suggested that a history of depression and, in particular, suicidal behaviour is associated with an increase in 5-HT2 receptors (Mann *et al.*, 1999). In contrast, a study of six drug-free, depressed patients examined with 18F-altanserin PET reported reduced binding in the right posterolateral orbitofrontal cortex and anterior insula with trends on the left side (Biver *et al.*, 1997). This apparent contradiction may be explained by receptor downregulation due to medication: eight of ten depressed patients who improved with desipramine showed a decrease in 18F-setoperone binding to the 5-HT2 receptor in many cortical areas

(Yatham *et al.*, 1999). Further, an 18F-setoperone study before and after 6 weeks of paroxetine medication in 19 depressed patients suggested a reduced binding capacity after treatment, which was found mainly in patients younger than 30 years of age. A study of 14, better controlled, drug- and self-harm-free (>6 months) depressed patients showed no abnormalities in prefrontal 18F-setoperone binding (Meyer *et al.*, 1999). Similarly, 11 elderly depressed patients did not show an *in vivo* reduction of 18F-altanserin binding capacity (Meltzer *et al.*, 1999).

5-HT1a Receptor

Rueter *et al.* (1998) have argued that antidepressant effects are due to a desensitization of 5-HT1a somatodendritic autoreceptors in the rat. This is responsible for the return to normal firing rate levels in the dorsal raphe nucleus. A single study has confirmed the hypothesized reduction in 5-HT1a binding capacity in depressed patients (Lesch *et al.*, 1990) using the PET ligand 11C-WAY-100635. Twelve primarily depressed patients with a family history of the illness showed reductions in binding capacity in the brainstem raphe, medial temporal cortex and possibly other cortical areas. This effect was greatest in bipolar patients and patients with a family history of bipolar illness (Drevets *et al.*, 1999).

'NATURAL EXPERIMENTS': CLINICAL PROFILES, TREATMENT RESPONSE AND TREATMENT RESISTANCE

What can neuroimaging studies tell us about depression that clinical description could not? Comparison of pretreatment and post-treatment neural activity is the most obvious way to associate *in vivo* neurobiological markers with depressive symptoms, cognitive ability or deficits. There is also mounting evidence for a correspondence between pretreatment metabolism in specific areas and treatment outcome. Characteristic changes in perfusion may help to classify patients with similar neuropathology. Changes in functional circuitry may emerge as predictors of treatment response and residual dysfunction whenever remission is not synonymous with recovery. Because substantial placebo or spontaneous remission effects contribute to the drug treatment of depression, it is unclear whether changes in cortical dynamics upon recovery are associated with the nature or the extent of drug-induced changes (Andrews, 2001).

Neuroanatomical and functional deficits may already be identifiable as vulnerability factors in patients' families. They may, at the other extreme, be the correlate of lingering abnormalities, such as perturbed cortical dynamics and impaired cognitive performance that are present beyond remission (Abas *et al.*, 1990). Persistent abnormalities can be a consequence of several factors. First, chronic administration of antidepressant, anticonvulsant or antipsychotic medication may contribute to the enduring brain changes (DelBello *et al.*, 1999). Second, impaired function during (or between) clinical episodes may compromise a system that is already fragile or affected in some way, and thus cause enduring damage (Sapolsky *et al.*, 1986). Finally, since affective disorders are often characterized by recurrent episodes over time, the normal process of ageing may be a confounder or may interact with the illness process (Kapur *et al.*, 1994). The interpretation of treatment progress in depression is also not straightforward. Change in behaviour, cognition or motor activity may not necessarily imply an associated modification in functional circuitry with return to normal activity (Goodwin *et al.*, 1993). Psychopharmacological agents target one or more neurotransmitter systems. Nonetheless, if the activity of one of the widely projecting neurotransmitter systems (dopamine, noradrenaline, 5-HT) increases, then global cortical dynamics will also be affected. Functional connectivity changes in mood disorders will be associated with abnormalities at rest (baseline) or, more likely, an abnormal pattern of recruitment during cognitive or motor activity. Where structural abnormalities have been reported in unipolar and bipolar depression, it is not unreasonable to assume that baseline and task-associated functional connectivity changes may occur. Brain imaging provides an assessment tool for the course of both illness-induced changes and active mechanism of recovery or compensation. In accordance with Alexander's (Alexander *et al.*, 1986) and Swerdlow and Koob's (1987) theories of functional cortico-subcortical loops, cortical areas (such as the frontal, temporal and parietal cortices), subcortical areas (such as the basal ganglia and thalamus), and most of all areas related to the limbic system (such as the anterior cingulate, hippocampus and amygdala) will be affected.

In order to better understand blood-flow abnormalities in affective disorders and consequent remission effected by different forms of treatment, findings can be separated into a number of distinct categories: pretreatment perfusion, post-treatment perfusion, activity in responders and non-responders, and the comparison of either or both with control subjects. Some studies do not include healthy volunteers; therefore, it is impossible to tell whether remission is associated with normalization of perfusion. The use of diverse methodologies in clinical studies makes the comparison between their findings difficult. The neuroanatomical maps or delineation of specific brain regions (Brodman's areas) used to localize activation may not be identical throughout the literature. Despite anatomical proximity, these areas may have very different connectivity patterns. For example, the medial or orbital frontal networks receive input from very different areas of the cortex (Barbas *et al.*, 1999; Bhashghaei and Barbas, 2001). Methodological constraints on studies in a clinical setting include great variations in the size of samples, which are often small and occasionally non-uniform in terms of age, medication and clinical history. Medication can influence outcomes in both neuropsychological and imaging studies, although the duration of medication effects is not known (Elliott *et al.*, 1998). An agreed standard for response to medication lies around 6 weeks, but it may take longer to establish remission. Therefore, brain imaging carried out at a later stage (Pizzagalli *et al.*, 2001) may be recording the long-term behavioural gain of therapeutic intervention, rather than incidental drug effects.

An alternative to measuring regional metabolic changes is to examine functional connectivity. Mallet *et al.* (1998) found decreased interhemispheric connectivity along with reduced connectivity within the right hemisphere (in a cortical–subcortical as well as anterior–posterior orientation) in schizophrenia, obsessive–compulsive disorder and unipolar depression. In depressed subjects, these deficits were mostly resolved on remission. A distinct 'melancholic pattern' was noted, with decreased correlation between the orbitofrontal cortex and the dorsolateral prefrontal cortex compared with controls and non-melancholic depressed subjects (Mallet *et al.*, 1998).

TREATMENT METHODS

Sleep Deprivation

Up to 60% of patients can improve after a night of total sleep deprivation (TSD) (Ebert and Berger, 1998). In contrast to the delayed cumulative effects of antidepressant medication, TSD has an immediate effect that does not appear to extend beyond the next full night's sleep (Ebert and Berger, 1998). The experimental advantage of TSD is that patients do not have to be medicated to show a short-term clinical improvement. The effects of TSD have been explained by increased dopamine release in the basal ganglia, which results in increased displacement of the D2/D4 receptor radio ligand 123I-iodobenzamide (IBZM) by endogenous dopamine, i.e. reduced

ligand binding (Ebert *et al.*, 1994b). However, an allele of the D4 dopamine receptor, which has been suggested previously to increase susceptibility to this treatment, was not linked to treatment response in 124 bipolar patients (Serretti *et al.*, 1999). A growing body of evidence is documenting hyperperfusion in the medial prefrontal cortex as a state or trait related change (Ebert and Berger, 1998; Ebert *et al.*, 1996). Allied with limbic hyperperfusion, a number of studies describe dorsolateral prefrontal cortex hypoperfusion in depression and during mood induction in normal volunteers (Mayberg *et al.*, 1999). The early sleep-deprivation literature reported increased perfusion in the orbitofrontal cortex that was found in the right anterior cingulate and bilateral orbitofrontal cortex and basal cingulate. Increased right hippocampal pretreatment flow was associated with greater treatment response (Ebert *et al.*, 1994a). Similar findings, indicating the association between successful drug treatment and pretreatment limbic hyperperfusion, have since been reported by a number of groups. Comparing glucose metabolism in hospitalized unipolar patients, Mayberg *et al.* (1997) reported hyperperfusion in the rostral anterior cingulate (Brodman's area 24a/b) to be indicative of a favourable treatment outcome. Although subsequent non-responders were reported to be marginally more impaired than responders on neuropsychological performance, no other correlation between perfusion and clinical ratings was found. Hypoperfusion in responders was greater than in non-responders in the dorsolateral prefrontal cortex (Brodman's area 45/46), anterior insula and inferior parietal cortex (Brodman's area 40). Pretreatment premotor cortex activation, on the other hand, was greater in responders.

The prognostic capacity of anterior cingulate activity with reference to the extent of treatment response can also be measured with electroencephalography (EEG) (Smith *et al.*, 1999a). Higher θ (6.5–8 Hz) activity in the rostral cingulate was associated with a greater response after 4–6 months of treatment with nortriptyline. A greater degree of response was associated with increased pretreatment θ activity in the medial frontal cortex (Brodman's area 24, 32), consistent with previous functional imaging reports (Mayberg *et al.*, 1997).

Pretreatment metabolism in the medial prefrontal cortex (Brodman's area 32), ventral anterior cingulate (Brodman's area 24) and posterior subcallosal gyrus (Brodman's area 25) was found to be higher in responders to TSD than in non-responders and healthy volunteers (Wu *et al.*, 1999). Normalization upon recovery was noted with decreased flow in the medial prefrontal cortex (Brodman's area 32) and the frontal pole (Brodman's area 10). All depressed subjects had a lower striatal (putamen) metabolic rate than controls, which persisted after treatment and, by contrast, decreased in normal volunteers. Frontal and occipital cortex metabolism was also higher in both groups before treatment. The activity in the right lateral prefrontal cortex (Brodman's area 46) and higher superior temporal cortex and right insula increased in responders. Perfusion was decreased in the lateral prefrontal cortex of controls. Moreover, in comparison with control subjects, the neuropsychological performance of all depressed patients deteriorated markedly after a night of TSD. Normal subjects performing a verbal learning task following 35 hours of sleep deprivation exhibited a pattern of increased activation in the prefrontal and parietal cortices, whereas activity in their temporal lobe was decreased (Drummond *et al.*, 2000). Decline in subjects' performance of a free recall task was correlated positively with activation of their parietal lobe. Bilateral prefrontal cortex activation, which was related closely to personal perception of fatigue, was interpreted as a competitive mechanism associated with the homeostatic urge for sleep. Compensation for decreased temporal lobe activity appears to be achieved by increased perfusion in the bilateral parietal lobes in verbal tasks, which are not associated with this area in the control condition. Just as TSD created characteristic changes in blood flow during the verbal learning challenge, elevated pretreatment regional cerebral blood flow (rCBF) in the right orbitofrontal cortex and basal cingulate of patients was normalized in responders to partial sleep deprivation (in the latter part of the night). Post-treatment left inferior temporal flow was correlated with treatment response (Volk *et al.*, 1997).

In summary, these studies appear to suggest that elevated metabolism and blood flow in the prefrontal or medial prefrontal cortex areas is an adaptive marker aiding response to different forms of therapeutic intervention, especially sleep deprivation. Depressed patients may share an abnormal functional network (decreased flow in subcortical structures) (Wu *et al.*, 1999) or persistent abnormalities throughout the temporal cortex (where structural changes have also been reported) (Shah *et al.*, 1998; Sheline *et al.*, 1998; Sheline *et al.*, 1999) that may accommodate behavioural changes by compensating for hypoperfusion elsewhere. In certain patients, this mechanism may later cease to be effective.

Sleep disturbance during rapid eye movement (REM) and non-rapid eye movement (NREM) sleep are well documented in patients suffering from affective disorders (Kupfer and Reynolds, 1992). Ho *et al.* (1996) studied the δ stage of slow-wave (high-amplitude) sleep of NREM sleep with FDG–PET in depression and found that metabolism was elevated in the occipital and parietal cortices to a greater degree than elsewhere. Limbic structures, such as the posterior cingulate, amygdala and hippocampus, were more active in depressed patients; however, metabolism in midline structures and the neostriatum (including the medial prefrontal cortex, medial thalamus, anterior cingulate, bilateral caudate, putamen and the head of the caudate) was reduced compared with controls. In conjunction with an EEG investigation, Nofzinger *et al.* (2000) studied the link between β EEG frequency (characterized by higher frequency and lower amplitude) and glucose metabolism in different areas of the cortex, defined on the basis of findings from control data. β-Wave frequency had been coupled previously with secretion of cortisol (Chapotot *et al.*, 1998) and, in this study, was present for longer in depressed subjects and was associated negatively with subjective sleep quality. No hypofrontality was found in this study; however, orbitofrontal cortex (including Brodman's areas 11, 25, 32) metabolism was higher in depressed patients than in controls, which may be indicative of dysfunctional arousal. Finally, the contrast between waking and REM sleep revealed that, unlike controls, depressed subjects failed to recruit anterior paralimbic areas (right parahippocampal gyrus, right insula and anterior cingulate). Instead, temporal-limbic areas (amygdala, subiculum, inferior temporal cortex, sensorimotor cortex) were activated (Nofzinger *et al.*, 1999).

Light Therapy

In patients suffering from seasonal affective disorder, light therapy produced dissimilar blood-flow changes in responders and non-responders. Responders expressed a globally increased activity, measured with hexamethyl-propyleneamine-oxim (HMPAO)–SPECT, relative to the cerebellum mainly in the frontal and cingulate cortices along with the thalamus (Vasile *et al.*, 1997).

Pharmacotherapy

Ogura *et al.* (1998) found in an HMPAO–SPECT study of patients with major depression that the severity of depression was correlated negatively with perfusion in the left superior frontal, right lateral temporal and right parietal cortex. After treatment with tricyclic antidepressants (clomipramine and amoxapine), remitted patients' perfusion did not differ significantly from that of controls.

Brody *et al.* (1999) reported that a better response to the serotonin reuptake inhibitor paroxetine was associated with lower pretreatment glucose uptake in the left ventral anterior cingulate. In

responders, values returned to normal in the ventrolateral prefrontal cortex and orbitofrontal cortex, but not in the dorsolateral prefrontal cortex or inferior frontal gyrus. Hamilton depression score changes were correlated with changes in glucose metabolism in some areas (ventrolateral prefrontal cortex and inferior frontal gyrus). Remission was associated with increased baseline perfusion in the left premotor and supplementary motor areas, along with decreased left ventral anterior cingulate metabolism (Brody *et al.*, 1999). These findings do not fit the Mayberg *et al.* (1997) study, but patients in Brody's study were more depressed and the researchers identified an area that lies ventral to Mayberg's 'rostral cingulate'.

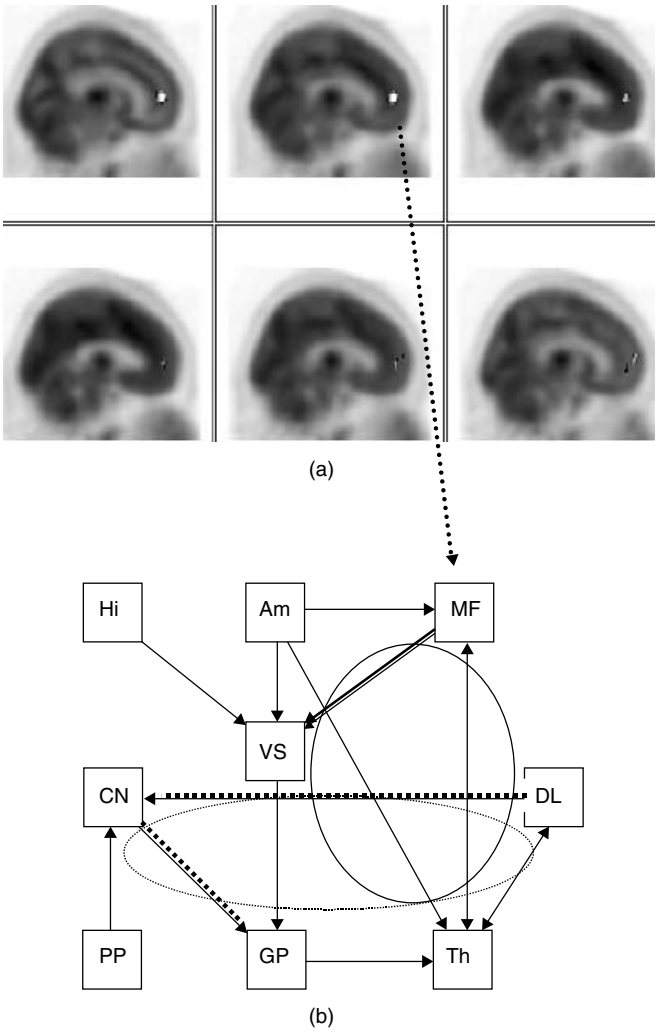

Figure XVIII-9.1 Effect of one session of TMS (5–20 Hz at 80% motor threshold over the left dorsolateral prefrontal cortex) on rCBF during a word-generation task. (a) Statistical parametric map of areas with $P < 0.01$ for effect size (z) and contiguous area (k), using Statistical Parametric Mapping, version 1996. (b) Neuroanatomical projections. Am, amygdala; CN, caudate nucleus; DL, dorsolateral prefrontal cortex; GP, globus pallidus; Hi, hippocampus; MF, medial orbitofrontal cortex; PP, posterior parietal cortex; Th, thalamus; VS, ventral striatum; Dotted ellipse, dorsolateral prefrontal loop; continuous ellipse, limbic loop; dotted arrow DL to CN, increase in regression coefficient c with significance levels in left dorsolateral loop ($c = 2.45$, $P < 0.05$); dotted arrow CN to GP, increase in regression coefficient c with significance levels in left dorsolateral loop ($c = 2.15$, $P = 0.05$); continuous arrow MF to VS, bilateral limbic loop (left: $c = 2.51$, $P < 0.05$; right: $c = 2.89$, $P < 0.05$) (See Colour Plate XVIII-9.1)

Physical Therapies

Electroconvulsive treatment (ECT) is by itself anticonvulsant, which suggests a reduction in cortical activity after a course of treatments (Ketter *et al.*, 1999; Post *et al.*, 2000). Using glucose uptake as a measure of cortical activity 5 days after a course of bilateral ECT in ten patients, Nobler *et al.* (2001) were able to support this hypothesis. Yatham *et al.* (2000) had previously failed to detect a significant change in five patients 1 week after a course of ECT. This is likely to be an effect of insufficient power.

Transcranial magnetic stimulation (TMS) has been used extensively to investigate cortical function in healthy volunteers and psychiatric patients (George *et al.*, 1998). A number of the simple hypotheses underlying the use of TMS in the treatment of psychiatric illness are based on the assumption that low-frequency TMS suppresses cortical activity (quenching) while high-frequency stimulation increases cortical excitability. Speer *et al.* (2000) were able to support this notion using 1- and 20-Hz stimulation over the left dorsolateral prefrontal cortex in a cross-over study of ten depressed patients. They found rCBF increases under the stimulation site and in associated paralimbic structures after 20-Hz stimulation and decreases in more restricted frontal, temporal and subcortical structures after 1-Hz stimulation. Similarly, Zheng (2000) found increases in cerebral perfusion in areas remote from the stimulation site after stimulation over the left dorsolateral prefrontal cortex.

In a parallel design study comparing 5, 10 and 20 Hz applied over the left dorsolateral prefrontal cortex in depressed patients, we found localized increases in the anterior cingulate after the first day's treatment, in combination with increased functional connectivity in the ipsilateral dorsolateral prefrontal loop and bilateral in the cingulate (limbic) loop (Figure XVIII-9.1).

In summary, recent studies have suggested an association between anatomical and functional changes in different prefrontal areas and their associated structures on one hand and disordered cognition and affect on the other. Such changes have been documented extensively in cingulate activity following successful treatment (e.g. Ebert *et al.*, 1996; Mayberg *et al.*, 1999; Volk *et al.*, 1997). Cingulate pretreatment perfusion differentiates between responders and non-responders (Mayberg *et al.*, 1997; Wu *et al.*, 1999). Furthermore, abnormalities in glial density (Drevets, 1999) and even changes in neuronal size (Rajkowska *et al.*, 1999) were found in the prefrontal cortex of unipolar patients (as discussed below). Finally, the cingulate is activated differentially in cognitive tasks (e.g. Stroop) involving attention or motivation (Whalen *et al.*, 1998), possibly denoting subregions that can be involved in specific tasks, promising a more differentiated understanding of the cognitive and emotional aspects of depression.

EFFECTS OF AGE, CHRONICITY AND TREATMENT RESISTANCE: IRREVERSIBLE AND REVERSIBLE CHANGES

Depression has been perceived as a transitory state where, on remission, brain function and altered or compromised cognition return to normal. This is no longer considered to be accurate in every case. Neuropsychological studies have discovered persistent abnormalities in cognitive performance, pertaining to the duration and severity of the illness (Abas *et al.*, 1990; Shah *et al.*, 1998). A number of imaging studies have also found potentially enduring deficits (e.g. Abas *et al.*, 1990; Shah *et al.*, 1998; Sheline *et al.*, 1999). Shah *et al.* (1998), in addition to a mere group difference, described a correlation between abnormal verbal memory and left medial temporal lobe grey matter deficits in the impaired group. Just as for certain unipolar depressed patients, structural abnormalities in bipolar depression include white-matter lesions, decreased cerebellar size, and sulcal as well as ventricular enlargement (see

Stoll *et al.*, 2000 for review). Structural MRI in 24 hospitalized bipolar patients (Strakowski *et al.*, 1999) revealed an increase in amygdala size with a similar trend in the globus pallidus, thalamus and striatum. These changes did not appear to correlate with other clinical measures, such as illness duration, medication, substance abuse, or the presence of previous episodes, although antipsychotic use would be a likely candidate.

Pathological studies have shown an excess of atheromatous disease in elderly depressed patients (Thomas *et al.*, 2001). In fact, some authors used the term 'MRI-defined vascular depression' (Krishnan *et al.*, 1997) to describe a group of elderly depressed patients with mainly later age of onset, nonpsychotic subtype, functional disability, anhedonia and a relative absence of family history (Krishnan *et al.*, 1997). Although these patients did not have a significantly worse prognosis than nonvascular depressives, a subgroup with late onset of the illness did (Krishnan *et al.*, 1998). In a large epidemiological study of cardiovascular health, small vascular lesions of the basal ganglia but not severity of white-matter lesions were associated with increased reporting of depressive symptoms as measured by the Centre for Epidemiological Studies Depression Scale (Steffens *et al.*, 1999). In a subsample, however, the MRI vascular changes in basal ganglia and non-basal ganglia structures appeared to exert their effects on depressive symptoms via the functional consequences of vascular disease, such as physical disability and cognitive impairment (Sato *et al.*, 1999). On the other hand, a case–control study of 96 elderly patients with late- and early-onset depression found the former to be associated with more white-matter hyperintensities, enlarged ventricles and hypertension (Lavretsky *et al.*, 1998).

MRI white-matter hyperintensities thus appear to be a hallmark of late-onset depression. Hyperintensities are also associated with treatment resistance (Lavretsky *et al.*, 1999; Simpson *et al.*, 1998) and future residual dysfunction, as well as cognitive decline (Hickie *et al.*, 1997; Jenkins *et al.*, 1998; Kramer-Ginsberg *et al.*, 1999) White-matter lesions seem to go with medical comorbidity, relatively independently of whole-brain and frontal atrophy, which are also more common in late-life depression (Kumar *et al.*, 2000). In particular, frontal lobe atrophy is correlated with severity of depression (Kumar *et al.*, 1998). A recent Newcastle study found that frontal white-matter changes were also more common in depressed patients with dementia. Finally, white-matter changes and frontal atrophy may be more common in depressed elderly patients with delusions (Kim *et al.*, 1999; O'Brien *et al.*, 1997a).

A combined MRI and SPECT study conducted in Edinburgh suggested greater temporal perfusion abnormalities in late- than early-onset depression and an association between cognitive deterioration and deep white-matter changes (Ebmeier *et al.*, 1997b; Ebmeier *et al.*, 1998). Similar (left medial) temporal lobe changes were reported in late-onset depression (Greenwald *et al.*, 1997), suggesting a possible link between late-onset depression and Alzheimer's disease. A large study comparing 61 depressed patients with 77 demented patients suggests, however, that temporal lobe volumetry can distinguish clearly been these two groups (O'Brien *et al.*, 1997b). Similar results were obtained using hippocampal width alone (Ebmeier *et al.*, 1997b).

Research in younger but also elderly depressed patients suggests that there may be a subgroup with long-lasting or treatment-resistant illness who show (medial) temporal lobe structural and functional changes (Shah and Ebmeier, 1998; Sheline *et al.*, 1999; Vakili *et al.*, 2000). Although there is little corroborating clinical evidence, some authors have argued that hypercortisolaemia associated with clinical depression may be responsible for the hippocampal damage observed in elderly patients. Contrary to this assumption, there is some limited evidence that temporal lobe changes are more common in late onset, i.e. shorter-lasting, depression (Ebmeier *et al.*, 1998; Lavretsky *et al.*, 1998).

Age Effects

As in younger patients, in elderly patients variation of depressive symptoms is associated with changes of brain activity in (medial) prefrontal structures. This can be shown in sleep-deprivation studies (Smith *et al.*, 1999a), in follow-up studies of depressed patients (Halloran *et al.*, 1999), in cross-sectional studies of clinical correlates in elderly depression (Awata *et al.*, 1998; Ebmeier *et al.*, 1997b) and even Alzheimer's disease (Hirono *et al.*, 1998).

Depression in children and adolescents has been attracting researchers' attention in recent years. Although the prevalence of affective disorders in childhood is now accepted to be on a par with the adult form of the illness, the contribution of the child's environment, along with cognitive and neuroanatomical developmental factors, is unclear. Data on functional brain activity in early-onset depression are consistent with findings in adults reporting left anterolateral hypoperfusion. Nonetheless, it is not certain whether the association between haemodynamic response and neural activity are analogous across the lifespan (Davidson and Slagter, 2000). Decreased frontal volume and increased choline-to-creatinine ratios in the anterior medial frontal lobe have been reported in depressed children and adolescents (reviewed in Steingard, 2000). Bipolar, just as schizophrenic, adolescents ($n = 35$) were reported to have reduced intracranial volume with enlarged ventricles and increased frontal and temporal sulci (Friedman *et al.*, 1999).

Treatment Resistance

Shah *et al.* (1998) demonstrated in 20 young patients with treatment-resistant unipolar depression, all of whom had been ill for more than 2 years, that temporal lobe structures, including the hippocampus, were reduced in grey matter density. The reduction in left medial temporal lobe grey matter density was correlated with poor performance in an auditory verbal memory task. Mervaala *et al.* (2000) examined 34 drug-resistant patients with major depression and were able to replicate findings of reduction in volume of left hippocampus. In addition, the choline/creatinine ratio in mesial temporal lobe was raised, suggesting membrane breakdown. Sheline *et al.* (1999) imaged 24 women with recurrent major depression and found that bilateral hippocampi were reduced in volume in proportion to illness duration and after controlling for age effects. Interestingly, patients also performed poorly in a verbal memory task, which may be a correlate of hippocampal reductions. Vakili *et al.* (2000) measured hippocampal volumes in 38 patients with primary depression. Although as a group patients had normal-sized hippocampi, treatment response to 20 mg fluoxetine for 8 weeks was associated with a relatively larger right hippocampus in women. Somewhat at variance with these results, a study focusing on temporal lobe epilepsy patients reported amygdala enlargement to be associated with dysthymia and depressive symptoms (Tebartz van Elst *et al.*, 1999; Tebartz van Elst *et al.*, 2000). The discrepancy may be explained by different pathology underlying mood changes in epilepsy, by divergent changes in amygdala and hippocampus, or by a different timepoint in the natural history of depression. Ketter *et al.* (2001) examined 43 treatment-resistant bipolar patients and found a contrast between cortical and subcortical glucose metabolism (18FDG–PET). Normalized effects indicating increased metabolism were reported in subcortical areas (ventral striatum and right amygdala) as well as in the posterior cortex, thalamus and cerebellum. Depressed bipolar patients also showed an absolute prefrontal, temporal and anterior paralimbic hypometabolism. Elevated metabolism in posterior cortical areas (including posterior thalamus and cerebellum) persisted beyond remission (i.e. in euthymic patients), indicating a trait marker

unique to bipolar patients. Cognitive task activation (in this case, an auditory task) may be recruiting qualitatively different circuits in patients and controls, a concern shared by all studies employing neuropsychological activation paradigms (Ketter *et al.*, 2001).

Cellular Changes

Both neuronal and glial volume changes have been reported. The latter can be a consequence of a number of factors. As a result of the chronic use of antipsychotic medication, increased volume of glial cells was noted in the prefrontal cortex of rhesus monkeys (Selemon *et al.*, 1999). Reports of laminar as well as regionally specific patterns of glial but also neuronal reduction, where neurons decreased both in size (dorsolateral prefrontal cortex) and density (orbitofrontal cortex), was observed in the prefrontal cortex of unipolar patients (Rajkowska *et al.*, 1999). By contrast, post-mortem studies in both unipolar and bipolar patients with a family history of depression have not revealed any differences in the neuronal population, while glial density was decreased; glial volume of schizophrenic patients was unchanged (Drevets *et al.*, 1997; Ongur *et al.*, 1998). Finally, age-associated glial changes in primate grey matter reached statistical significance only in the cingulate (Sloane *et al.*, 2000). It is apparent that some association between changes in glial density and pathological or restorative processes has been established in patients suffering from affective disorders. Nonetheless, it is still unclear whether these changes are adaptive, compensatory or incidental. Further, the functional effect of such changes is still undetermined.

The association between neuronal activity and the metabolic processes measured by various functional brain-imaging modalities (haemodynamic response in functional magnetic resonance imaging (fMRI), glucose utilization in FDG–PET, and so forth), is not without question. Furthermore, it is apparent that astrocytes as well as neurons may contribute to the signal changes observed in FDG–PET (Magistretti and Pellerin, 1996; Magistretti and Pellerin, 1999). In the presence of glial reduction in anterolimbic structures reported by a number of groups (Drevets *et al.*, 1998; Rajkowska *et al.*, 1999), it is unknown whether, and to what extent, glucose utilization and its associated PET signal are altered as a result.

Lithium and valproate have been suggested to have neurotrophic and neuroprotective effects. An increase of 3% in the cortical grey matter volume of bipolar patients after 4 weeks of lithium administration is attributed to neurotrophic factors rather than to cell swelling (Moore *et al.*, 2000). Mood stabilizers could be involved in the regulation of gene expression by increasing levels of mRNA for PEBP2β (polyomavirus enhancer-binding protein 2 beta subunit), which controls coding for the neuroprotective protein BCL2 (B cell lymphoma protein 2) in the frontal cortex. Increased neuronal survival and increased regeneration are all effected by BCL2 upregulation, protecting against excitotoxic damage (Chen *et al.*, 1999; Chen and Chuang, 1999). It is unclear whether recent post-mortem findings of increased neuronal numbers throughout the hypothalamus and the dorsal raphe could be related to chronic use of medication (Rajkowska *et al.*, 1999).

Small structures such as the brainstem raphe nuclei are imaged with difficulty. It is, therefore, fortuitous that ultrasound sonography can be applied using a preauricular acoustic bone window to image the mesencephalic brainstem with structures such as the red nucleus and the rostral pontine brainstem. Becker *et al.* (1995) examined 40 unipolar, 40 bipolar depressive and 40 schizophrenic inpatients, as well as 40 healthy volunteers. Reduced midline echogenicity relative to the red nucleus, which can be interpreted as structural disruption of the raphe nuclei, was found only in the unipolar depressed patients.

EXPERIMENTAL APPROACHES TO DEPRESSION: COMPLEX MODELS

Cognitive performance in depression and its relationship with the disturbance of emotion or mood have been examined in a number of contexts. Along with an investigation of cognitive impairment in subjects suffering from affective disorders, there is a large body of literature reporting different procedures of precipitating depressed or dysphoric mood in healthy subjects (mood induction). A number of conceptual questions are inherent in this literature. Above all, it is unclear to what extent sad mood is analogous with clinical depression. The transient time course of the neuropsychological impairment brought about by mood induction is usually far shorter than the experience of clinical depression. Similarly, induced mood may be of a different quality from morbid depression, although biological symptoms, such as depressive retardation, can be observed after experimental mood induction (Ebert *et al.*, 1996). The absence of biological markers often associated with depression (such as hypercortisolaemia), along with structural and functional differences, hinder direct comparison. In this sense, even if the neural systems recruited in healthy controls during mood induction are analogous to the neuroanatomical circuit activated in depressed patients at rest, the dynamics of the circuit may be different in the two conditions due to selective dysfunction in specific components or the connectivity between these. It is even possible that some of the differences between patients and controls can be explained by simple mechanisms, e.g. that depressed patients are slower to recruit the appropriate neuronal systems or their components.

Since neuropsychological studies are described in detail in Chapter XVIII-7 and XIX-8 of this book, we will focus on neuronal systems implicated by clinical and mood-induction paradigms. We will try to integrate structural and functional findings reported earlier in the chapter in an attempt to assemble some of the complex interactions between specific structures and the systems they comprise in the manifestation of affective illness.

Neuropsychological studies suggest that cognitive deficits may be the consequence of competition between cognitive and affective functional resources. If this holds true, such that neural pathways identified in the induction paradigm are analogous to those affected in the specific mood disorder they are trying to emulate, then transient sadness or elation in normal volunteers can provide a useful insight into the neural correlate of cognitive performance in mood disorders. However, covariation between the degree of depression, impaired task performance and (in-)activity of relevant functional circuits does not necessarily imply a causal relationship between the three. Thus, apparently similar short-term deficits of neuronal activity observed both in clinical depression and after mood induction could be grounded in dissimilar processes. In the long term, these may be of no consequence for healthy volunteers, but they could result in the significant deficits noted in patients with recurrent and severe depression (Shah *et al.*, 1998).

The following section includes studies emphasizing perfusion changes associated with emotional states. Most studies report impaired cognitive performance as a consequence of transient mood change, although their methods may differ greatly. Anatomical structures that are classically grouped under the definition of 'limbic lobe' are involved in circuits responsible for both cognitive function and the generation of affect. These include the cingulate cortex, hippocampus, amygdala and thalamus, as well as other prefrontal and subcortical structures. Both mood-induction and clinical studies report altered dynamics in the limbic and prefrontal circuits, comprising activation or deactivation under specific conditions, compensatory effects, and the interplay between different regions (e.g. cortical and subcortical, limbic and dorsolateral prefrontal cortex, etc). The role of the cingulate has been emphasized by authors such

as MacLean (1985). He saw the phylogenetic emergence of the cingulate cortex as fundamental to the development of maternal care in mammals. There is therefore a convergence of paradigms (Stevens and Price, 2000) between psychodynamic speculation about attachment and loss (Bowlby, 1969) and the understanding of limbic brain function in depression (Ebert *et al.*, 1996).

Such theories are now amenable to empirical testing. Lorberbaum *et al.* (1999) employed fMRI in four recently confined mothers listening to recordings of infants' cries and white noise as a control condition. Increased brain activity could be demonstrated in the anterior cingulate and right medial prefrontal cortex. These regional activations are probably not very specific, as similar areas are activated during pain and are thought to be related to affective and attentional concomitants of pain sensation (Peyron *et al.*, 2000; Schnitzler and Ploner, 2000). However, with careful experimental procedures, hypotheses about the specific role of the medial prefrontal cortex in emotion are testable, in principle.

Supporting the imaging studies in humans, there is also an animal model of congenitally helpless rats with reductions in brain activity in the dorsal frontal, medial orbital and anterior cingulate cortex, combined with increases in the subgenual cingulate (Shumake *et al.*, 2000).

Mood Induction and Neuropsychological Paradigms

Neuropsychological studies use cognitive tasks in order to recruit associated functional circuits through their component structures. Specific functional vulnerability can be described by either impaired performance of a particular task or impaired activation of characteristic circuits or their constituents. Neuropsychological tasks have been designed to probe activity in brain regions associated with them. Frontal areas are activated by tasks such as the Wisconsin card sorting test (WCST) or the Tower of London (TOL) task, both of which involve the application and manipulation of rules, adaptive skills and flexibility necessary for set shifting. Tasks that involve memory are expected to be particularly sensitive to structural and/or functional discontinuity in (mesial) temporal structures, such as the hippocampus. Finally, the involvement of subcortical structures in the experience of clinical and experimental mood is expressed by both perseverative responses (the inability to change strategies) and psychomotor slowing, experienced predominantly by melancholic patients (Austin *et al.*, 1999; Austin *et al.*, 2001). It appears that similar limbic-subcortical circuits are involved in different experimental mood-induction procedures; however, different substructures may be affected, possibly due to inconsistent methodology of experimental paradigms and the different affects involved.

Studies: Mood Induction

Baker *et al.* (1997) induced sad and elated mood in controls and examined brain activity following performance of a verbal fluency task. They reported anatomical dissociation between mood and cognitive function. Both mood states curtailed the activity normally associated with the verbal fluency task throughout the left prefrontal, premotor and cingulate cortex, as well as the thalamus. Reduced activation in the rostral medial orbitofrontal cortex and anterior cingulate was associated uniquely with sad mood.

Mayberg *et al.* (1999) proposed a simplified model of brain responses. They hypothesized a general increase in limbic-paralimbic perfusion coupled with a decrease in neocortical perfusion to accompany induction of sadness in healthy volunteers, while reciprocal changes were predicted during the resolution of dysphoric symptoms in depressed patients. These authors also observed an inverse correlation between right dorsolateral prefrontal and subgenual cingulate perfusion, supporting this notion. These finding can be interpreted as corollary evidence for the inverse relationship between depressed mood and attention.

Beauregard *et al.* (1998) studied patients' and controls' ($n = 7$) responses to mood induction. Transient sadness (triggered by film clips with emotional content) produced activation in the medial and inferior prefrontal, middle temporal cortex, cerebellum and caudate. Significantly greater activation in the left medial prefrontal cortex (Brodman's area 8) and right cingulate gyrus (Brodman's area 32) was observed in depressed patients, suggesting that these two structures may have a role in pathological sadness.

Elliott *et al.* (1997) postulated a catastrophic reaction to failure as a specific neuropsychological mechanism underlying poor performance in depression. They examined performance feedback responses in six patients and controls. Depressed patients did not share the expected activation in the medial caudate and ventromedial orbitofrontal cortex found in controls. Patients' brains were, therefore, insensitive to changes in both task and feedback conditions, consistent with the a priori hypothesis.

Schneider *et al.* (1996) found activation in a network related to performance feedback during the attempt at solving unsolvable anagrams; perfusion increased in healthy subjects ($n = 12$) in the mammillary bodies and the amygdala, and decreased in hippocampus. Solvable tasks were associated with increased perfusion in the latter. Increased frontal and temporal perfusion was associated with both conditions.

The Stroop interference task has been typically associated with activation of the cingulate gyrus (Pardo *et al.*, 1990). A different activation pattern was observed in depressed patients ($n = 11$), who failed to activate the left cingulate in comparison with control subjects. Reduced perfusion in patients' right cingulate was balanced by stronger activation of the left dorsolateral prefrontal cortex and the visual cortex (George *et al.*, 1997). A variant of the Stroop interference task (the emotional counting Stroop paradigm) showed a unique activation of the rostral anterior cingulate using fMRI in normal volunteers (Whalen *et al.*, 1998). Comparing perfusion between trials containing affective (such as murder) and neutral words, associated negative content with increased perfusion in the anterior cingulate without a change in reaction time. Performance of this form of the Stroop task compared with fixation *per se* was associated with overall decreased perfusion. These findings may suggest an association between pathological anxiety and an inability to reduce cingulate activation during task compared with fixation.

Correlation between higher global perfusion and increased cognitive demands was associated with task switching. The superior parietal cortex was reported to have a specific role in task switching, although this effect may be task specific (Kimberg *et al.*, 2000). Illness severity in this subtype correlates with increased perfusion in frontolimbic structures parahippocampal gyrus and cingulate (Ebmeier *et al.*, 1997a).

Induction of depressed and elated mood can, at times, be associated with overlapping or diverging neural circuitry. Dissociable recruitment of subcortical and cortical structures in healthy subjects ($n = 16$) during experience of both positive and negative affect was associated with specific changes in subcortical structures (especially the amygdala) but not frontotemporal structures (Schneider *et al.*, 1995). Both happy and sad mood correlated with increased blood oxygen level-dependent (BOLD) fMRI response in the left amygdala of healthy subjects ($n = 12$) (Schneider *et al.*, 1997). De Raedt *et al.* (1997) used a modified Velten procedure to induce mood both 'within and out of the realm of attention'. The latter involved a combination of dichotic listening and subliminal stimulation. Right lateral reduction in thalamic perfusion was found during both conditions compared with responses to neutral stimuli. Increased hippocampal perfusion was limited to subliminal stimulation conditions.

Divergent circuits were found in the evaluation of negative versus positive affective content. While the former was associated with increased perfusion in the right frontal gyrus and thalamus, the latter produced activation of the bilateral insula and the right inferior frontal gyrus. Neither showed associated changes in amygdala perfusion (Teasdale *et al.*, 1999). In a different study, subcortical limbic structures (amygdala, associative cortex, primary visual cortex, cerebellum) were activated through evaluation of unpleasant stimuli, while pleasant stimuli activated cortical structures (medial prefrontal cortex, dorsolateral prefrontal cortex, and the right orbitofrontal cortex, Paradiso *et al.*, 1999). Spatiotemporal differences in activation of the neuroanatomical correlate of positive and negative affect, expressed through characteristic activation of either orbitofrontal cortex or prefrontal cortex, were shown in healthy volunteers ($n = 10$). Recruitment of the medial prefrontal network in the context of negative affective content was established faster than the activation of the lateral prefrontal circuit, which was associated with positive affect (Northoff *et al.*, 2000). Finally, retrieval of episodic memories with affective content was associated with activation of anterior temporal lobe and left amygdala (Dolan *et al.*, 2000), a pattern mirrored by McGaugh and Cahill (1997) and Hamann and Adolphs (1999) in encoding of similar memories.

Hypofrontality along with specific prefrontal deficits have been reported extensively in the literature. Both depressed ($n = 6$) and control subjects performing the TOL task exhibited a pattern of deactivating the medial prefrontal cortex, superior temporal gyrus and posterior cingulate. For control subjects, increased difficulty was associated with a linear augmentation in the recruitment of the appropriate functional circuitry. By contrast, depressed patients presented with decreased activity in the rostral prefrontal cortex, caudate nucleus and anterior cingulate, without the expected compensation by the dorsolateral prefrontal cortex (Elliott *et al.*, 1997). Parietal cortex activation did not reach threshold in this experiment. Neural dissociation between cognitive and affective activation denoted specific activity-related changes in the medial frontal cortex. A reduction from baseline activity in the medial prefrontal cortex was linked to cognitive activation. Practice was associated with decreased perfusion in the medial prefrontal cortex, while performance anxiety was linked to increased perfusion in the same region. In a different experiment, elevated perfusion in the medial prefrontal cortex was reported during the anticipation of painful stimuli, and was correlated negatively with anxiety rating (i.e. increased anxiety produced a smaller reduction from baseline). Corresponding changes in flow were noted in the hypothalamus and midbrain. Thus, a decrease from baseline activity in the prefrontal cortex is thought to be a consequence of recruiting the network related to attention (Simpson *et al.*, 2001a; Simpson *et al.*, 2001b).

Systems

We conclude the chapter by discussing the neuronal circuits or systems putatively linked with affective illness. To the best of our current knowledge, there is no clear or direct correspondence between neurobiological factors and their effect on emotional experience or expression. Structural changes in areas such as the hippocampus, prefrontal cortex, cingulate or amygdala are perfect candidates for theories of dysfunctional loci. However, as we have indicated throughout this chapter, neurobiological abnormalities are not entirely predictive of functional deficits. Furthermore, dysfunction in affective disorders may involve long-term mechanisms of compensation and deterioration over time, which may not be explicit in present theories of unipolar and bipolar depression.

The limbic system is, of course, a natural candidate for many neuroimaging investigations. The evolutionary angle described earlier in this chapter (Bowlby, 1969; MacLean, 1985) places structures associated closely with environmental feedback, particularly in a social context, at the locus of a system associated with integrating internal and external states. For example, specific behaviours or neuropsychological tasks yield an associated activation in structures such as the cingulate gyrus (maternal separation cry, Stroop), amygdala (fear), hippocampus (autobiographical memories) and dorsolateral prefrontal cortex (TOL task), to name but a few. It is important to note that in brain regions not classically associated with the limbic system (and thus not salient in many investigations), such as the parietal cortex, reports of functional abnormalities are increasing (Davidson *et al.*, 1999; Drummond *et al.*, 2000; Ho *et al.*, 1996; Mayberg, 1997) Since regions of functional interest are often defined a priori in neuroimaging studies, a bias towards the well-documented structural and functional changes in limbic regions may be perpetuated.

Behavioural response to long-term stress in a social context seems to be adaptive, in the sense that initial alarm and resistance will ultimately lead to exhaustion and acceptance (Selye, 1936). Similarly, rank theories in mood disorders postulate acknowledgement of subordinate status and a 'yielding' motor response in the presence of higher rank (Stevens and Price, 2000). The limbic system is therefore assumed to unite behaviour and neuroanatomy, where conflict between external and internal input can be resolved, a role associated particularly with the cingulate. The impact on both psychomotor and prefrontal-cognitive associated capacity is inherent in these theories.

Expanding Papez's early theories of limbic circuit connectivity and function, current neuroimaging tools are instrumental in facilitating both understanding and advancement of functional circuitry in depression and mania. Careful attention to experimental design (such as activation under different experimental conditions), as well as the development of new chemical tracers and more powerful imaging technology, will contribute towards a better appreciation of the various phases associated with affective disorders. We are nearing a qualitative coupling between systems with either function or dysfunction. This is achieved by direct and indirect comparison between patients and healthy control subjects performing tasks under similar conditions. Nonetheless, quantitative knowledge regarding activity in distinct systems is, for now, sketchy.

Common to both prefrontal and limbic structures is the overlap between sensory and affective processes (LeDoux, 1996), where a visceral system provides feedback through endocrine and other neurobiological mechanisms. It is possible that inhibition by the prefrontal cortex may be involved in feedback control (not only the classically inhibitory orbitofrontal cortex but also the lateral prefrontal cortex, both denoting different strategies of associative learning) (Roberts and Wallis, 2000). Consequently, activity, or lack thereof, in frontal regions may lead to limbic hyperperfusion via nonlinear excitatory or inhibitory operational modes.

Hypofrontality has been reported extensively in different contexts. Thus, the interaction between cognitive and affective circuits with the frontal cortex has been described by neuroanatomical (Barbas *et al.*, 1999; Price *et al.*, 1996), neuropsychological and neuroimaging studies (Mayberg *et al.*, 1997; Rogers *et al.*, 1998). These circuits appear to have functional as well as structural regional specificity, whereby connectivity to other (remote) regions throughout the cortex and the subcortex are clearly defined.

The limbic system has been separated into affective and cognitive components, supported by neuroanatomical studies in humans and primates (e.g. Devinsky *et al.*, 1995; Mayberg *et al.*, 1999; Mega *et al.*, 1997; Price, 1999a). The integration of viscerosensory and affective information, yielding endocrine and motor changes (Price, 1999b) contributes to an extended network, which cannot be explicable by lesion studies alone (Frith and Dolan, 1998).

A number of compensatory mechanisms can be deduced from the extensive neuroimaging literature in the field. The amygdala and orbitofrontal cortex appear to activate in synergy, where the orbitofrontal cortex is activated more strongly in response to amygdala dysfunction (Drevets, 1999). In healthy subjects, compensatory strategies require greater activity in the prefrontal and parietal cortices to balance for decreased temporal lobe perfusion and associated performance deficits after a night of TSD (Drummond *et al.*, 2000). By contrast, Elliott *et al.* (1997) showed that depressed patients lacked an adaptive capacity, which was expressed by their inability to recruit prefrontal as well as subcortical structures during performance of the TOL task. Further, correspondence between hyperperfusion in the cognitive and affective divisions of the cingulate reported by Mayberg *et al.* (1999) could arguably have a compensatory role in depression and recovery.

Therefore, a hyperactive limbic (or 'ventral'; see Mayberg *et al.*, 1999) system was noted by a number of groups, where increased perfusion can imply higher probability for response to treatment (Mayberg *et al.*, 1997; Wu *et al.*, 1999) or, alternatively, increased likelihood of more severe illness (Austin *et al.*, 1992). In the long term, connections to temporal (amygdala, hippocampus), parietal, prefrontal and subcortical structures will help us understand the extent to which an extended network can compensate for limbic hyperperfusion.

Blood flow and glucose metabolism in subcortical structures, the dorsolateral prefrontal cortex and the cingulate have been linked extensively with affective disorders through neurological and movement disorders, lesion studies, functional activation and imaging at rest (Cummings, 1993; Mega and Cummings, 1994, Soares and Mann, 1997). Furthermore, basal ganglia and frontal lesions carry a higher probability for cognitive impairment (Rogers *et al.*, 1998; Videbech, 1997). It is apparent that subcortical involvement can be associated with increased pathophysiology (e.g. psychomotor retardation), recurrent episodes and cognitive decline (Hickie *et al.*, 1997; Hickie *et al.*, 1999; Simpson *et al.*, 1998). The anterior cingulate may play a cardinal role in this context, due to its widespread connections and functional association with the prefrontal cortex (Ebert *et al.*, 1996; Koski and Paus, 2000). This is, at present, not clearly specified, ranging from theories of a 'somatic marker' (Damasio, 1994), motivation, attention and error detection (Carter *et al.*, 1999) due to its specificity in the integration of cognition and affect. It is confounded by the structural changes in specific subgroups of unipolar and bipolar patients (Drevets *et al.*, 1997). Finally, since hippocampal volume reduction is associated with the severity of depressive illness (Sheline *et al.*, 1999) and, by association (Drummond *et al.*, 2000), transient hypoactivity in the temporal cortex, its function may be balanced by prefrontal and parietal regions.

It would be interesting to probe such functional correspondences between two or more structures in a clinical context.

To conclude, a unified theory of affective disorders is developing through the application of different imaging methods and consideration of both animal and human neuroanatomical data. Future studies will no doubt consider a larger, distributed functional network, coupled with better understanding of the long-term effects of clinical deterioration, medication and the ageing process. What emerges, is a functional interplay of brain modules that are associated with specific mood states, attention, non-specific emotional factors, and certain aspects of the neuropsychological tasks used. We now have the tools to test relevant hypotheses in the living brain. The groundwork will have to be done with fMRI and possibly TMS in healthy volunteers, although in the last analysis, studies in sufficiently large, homogeneous and representative groups of patients will be necessary. The understanding that has come from studies so far is that dimensions of mood are indeed interlinked closely with cognitive categories, and that experimental studies may necessitate our rethinking of clinical and psychological constructs.

Molecular Genetics in Mood Disorders

D. Souery, S. Linotte and J. Mendlewicz

INTRODUCTION

Despite intensive search for biological underpinnings, the aetiology of major mood disorders remains unknown. More work on the neurobiology of these disorders is clearly indicated. Twin and family studies have consistently demonstrated a genetic component to the disorders. Decades of research into the genetic aetiology of mood disorders provide evidence in favour of a complex mode of inheritance unlikely to be determined by single gene dysfunction, and apparently non-Mendelian patterns of inheritance. Part of the complexity of the genetic variance lies in the heterogeneity of the disorders — the depressive patient, for example, can be characterized by a variety of different symptoms and identifying features that may represent different subtypes. Different genetic mechanisms may be involved: epistasis, locus heterogeneity, allelic heterogeneity, dynamic mutations, imprinting and mitochondrial gene mutation (these issues are reviewed in Chapter XII). In terms of phenotype, there are also a variety of non-genetic factors that lessen our ability to detect genes in mental disorders: phenocopies, clinical heterogeneity, assessment bias, population stratification and lack of appropriate control groups.

Of the genetic mechanisms listed above, it is possible that more than one may be involved in the transmission of psychiatric disorders. In complex disorders the correspondence between gene and phenotype is not necessarily direct: a given genotype may give rise to a variety of phenotypes according to other genes present and environmental factors, or different genotypes may give rise to the same phenotype. Despite these complex characteristics, family- and population-based studies have provided substantial evidence that genetic factors contribute to the expression of the disorders. Recent molecular genetic approaches indicate that several chromosomal regions may be involved in the aetiology of mood disorders.

The initial molecular genetic studies of Bipolar disorder (BPAD), considered as the core phenotype of mood disorders, involved the parametric linkage studies of large families. Linkage examines the cosegregation of a genetic marker and disease in affected individuals within families; that is, the non-random sharing of marker alleles between affected members of each family (Smeraldi and Macciardi, 1995). Two genetic loci are linked if they are located closely together on a chromosome. In linkage analysis, the frequency of meiotic recombinations as an expression of the distance between marker locus and the gene under investigation is used for gene mapping (see Chapter XII). Given the difficulties inherent in detecting genes of small to modest effect using the linkage approach, the candidate gene association method offers an alternative strategy of studying genetic factors involved in complex diseases in which the mode of transmission is not known. Association between diseases and marker may be found if the gene itself, or a locus in linkage disequilibrium with the marker, is involved in the pathophysiology of the disease (Hodge, 1994). Thus, an association may imply a direct effect of the gene tested, or the effect of another gene close to the marker examined. The candidate gene approach is a useful method to investigate association between markers and disease. A candidate gene refers to a region of the chromosome which is potentially implicated in the aetiology of the disorder concerned. The possibility of false-positive results must be taken into account, as a very large number of candidate genes now exist. The probability that each of these genes is involved in the aetiology of the disorder is relatively low.

The candidate gene approach can be extended to phenotypes not directly linked to the diagnoses of mood disorders. The therapeutic effect of psychotropic drugs may be considered to investigate genetic polymorphisms (psychopharmacogenetics). In recent years, research in psychopharmacogenetics has focused on evaluating functional polymorphisms both in genes coding for drug-metabolizing enzymes and in genes coding for other enzymes or receptors involved in the mechanism of action of psychoactive drugs. In this context, the use of new technologies is rapidly evolving. Gene expression patterns in response to drug treatments can be investigated by new techniques such as DNA microarrays. Microarrays are powerful tools for investigating the mechanism of drug action by measuring changes in mRNA levels in brain tissues before and after exposure to treatment (Debouck and Goodfellow, 1999).

This chapter reviews the current methodologies and study tools used to search for molecular genetic factors in mood disorders and the chromosomal regions of interest already investigated for bipolar (BPAD) and unipolar (UPAD) mood disorders.

CANDIDATE CHROMOSOMAL REGIONS AND CANDIDATE GENES

Chromosome X

A systematic review of the literature on linkage studies in BPAD (Turecki *et al.*, 1996) indicated that the proportion of positive DNA findings is higher for X markers compared to other chromosomal regions. Mendlewicz *et al.* (1987) first reported possible genetic linkage between BPAD and coagulation Factor IX (F9) located at Xq27 in 11 pedigrees. The same genetic marker was also tested in a French pedigree where linkage was confirmed (Lucotte *et al.*, 1992). Linkage with DNA markers on the X chromosome has been excluded, however, in other pedigrees (Berrettini *et al.*, 1990; Bredbacka *et al.*, 1993; Gejman *et al.*, 1990). A study published in 1987 by Baron *et al.* (1987) demonstrated positive linkage for glucose 6 phosphate dehydrogenase (G6PD), but later results from the same author did not support this finding (Baron *et al.*, 1993), although G6PD was slightly positive for linkage in one family. In a more recent study (De Bruyn *et al.*, 1994), several DNA markers in the Xq27–28 region were tested in nine bipolar families.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Results suggestive of linkage were found in four bipolar I (BPI) families with the markers F9, F8 and DXS52. Pekkarinen *et al.* (1995) evaluated 27 polymorphic markers on the X chromosome (Xq25–28 region) in one large Finnish family, and found the highest lod scores when using a narrower phenotype definition (BPI and BPII only). Linkage was found between a marker located on Xq26 (AFM205wd2) and BPAD. This marker is located about 7 cM centromeric to the F9 locus. The initial genome screen for BPAD in the NIMH genetics initiative of 97 pedigrees also revealed positive though small lod scores on the X chromosome (Xp22 and Xq26–28) (Stine *et al.*, 1997). All these results are extremely suggestive of X linkage and in particular, the Xq26–28 region should be considered a strong candidate for genetic studies in BPAD.

The associations between BPAD and polymorphic DNA markers in the pseudoautosomal region of the X chromosome have also been investigated. Yoneda *et al.* (1992) reported an association between the A4 allele of the marker DXYS20 in this chromosomal region in Japanese BPAD patients. This has not been replicated in European populations, however (Nöthen *et al.*, 1993; Parsian and Todd, 1994).

The MAOA and MAOB genes which code for the enzymes that degrade biogenic amines, including neurotransmitters implicated in the pathophysiology of mood disorders, such as norepinephrine, dopamine and serotonin, are both located on the X chromosome and tightly linked to each other (Xp11.12–Xp11.4). Lim *et al.* (1994a, 1995) reported a weak but significant association for three different polymorphisms of MAOA, yet not for MAOB, in a sample of 57 BPAD patients compared to population controls not assessed for psychiatric status. A weak association was found for MAOA and bipolar disorder by Kawada *et al.* (1995), but different alleles were more frequent in the patient population compared to the previous report. A series of negative reports followed, leaving the question open as to the usefulness of the MAO genes in psychiatric genetics research (Craddock *et al.*, 1995a; Muramatsu *et al.*, 1997; Nöthen *et al.*, 1995).

Chromosome 18

Berrettini *et al.* (1994) first reported linkage of BPAD to chromosome 18 DNA markers in a systematic genome survey of 22 families including 156 subjects with bipolar disorder. Although the overall lod score for the pedigree series was negative, results of two-point linkage analysis in individual families indicated possible linkage with some marker loci in the 18p11 region. Non-parametric analysis (affected pedigree member and affected sib-pair analysis) of this sample confirmed the observation of linkage (Gershon *et al.*, 1996). These results suggested the existence of a susceptibility gene in the pericentromic region that can not be fully evaluated by classic linkage analysis. These results may be of interest because genes coding for the alpha unit of a GTP binding protein involved in neurotransmission, a corticotrophin receptor gene, and RED-1 containing triplet repeats have been mapped to this region. Stine *et al.* (1996) studied 28 nuclear families for markers on chromosome 18 and also found evidence for linkage and allele sharing between sib-pairs at 18p11.22–p11.21. This study replicated the findings of Berrettini and colleagues, yet also demonstrated evidence for linkage and parent-of-origin effect in a region located on the long arm of chromosome 18, a sex-averaged distance 30 cM away. An excess of paternally but not maternally transmitted alleles from the D18S41 was observed.

In a study of five rigorously defined, high-density German families, no robust evidence for linkage for the pericentromeric region could be found, although one family showed slightly elevated lod scores under a recessive mode of inheritance for D18S40 (Maier *et al.*, 1995). Linkage to the pericentromeric region of chromosome 18 was excluded in three large Old Order Amish families (Pauls *et al.*, 1995), and in two large Belgian pedigrees (De Bruyn *et al.*, 1996). In the Belgian pedigrees, while negative lod scores were found for a marker located in the pericentromeric region, linkage and segregation analysis in one family suggested that the 18q region of the chromosome (18q21.33–q23) might contain a susceptibility locus for BPAD (De Bruyn *et al.*, 1996). Freimer *et al.* (1996), using both linkage and association strategies, reported evidence of linkage with markers in this region (18q22) in a Costa Rican pedigree with a common founder. A subsequent study further supported the interest of the 18q23 region, showing linkage among six pedigrees (Coon *et al.*, 1996). An additional study of 173 affected subjects using the multilocus affected pedigree member method demonstrated a susceptibility gene in the pericentromeric region, and multilocus analysis by the affected sib-pair method also showed evidence for linkage (Berrettini *et al.*, 1997). Yet despite slight allele sharing with two markers on chromosome 18 (D18S40 on 18p and D18S70 on 18q) in the NIMH genetics initiative BPAD pedigrees, linkage to chromosome 18 was not confirmed in this large genome scan (Detera-Wadleigh *et al.*, 1997). Furthermore, Knowles *et al.* (1998) found no evidence for significant linkage between bipolar disorder and chromosome 18 pericentromeric markers in another large sample (1013 genotyped individuals) using ten highly polymorphic markers.

Chromosome 5

Preliminary linkage data including three DNA markers on this chromosome (D5S39, D5S43 and D5S62) suggested linkage with BPAD (Coon *et al.*, 1993). Two of these markers, D5S62 and D5S43, are located on the distal region of the long arm of chromosome 5 (5q35-qter). This region contains candidate genes for mood disorders such as the alpha-1 protein subunit of the GABA A receptor (GABRA1) and the 5-HT1A receptor (5-HTR1A). These two markers, however, had exclusion lod scores in a previous study of 14 families (Detera-Wadleigh *et al.*, 1992). Similarly, strongly negative lod scores were found in a linkage study covering the 5-HTR1A locus in five pedigrees (Curtis *et al.*, 1993). The dopamine transporter gene (DAT1) is located in a different region of chromosome 5 (5p15.3). This marker has been investigated in association studies with BPAD yet no association has been found (Gomez-Casero *et al.*, 1996; Manki *et al.*, 1996; Souery *et al.*, 1996a). Kelsoe *et al.* (1996) reported possible linkage, however, between a locus near the dopamine transporter (DAT) and BPAD, under a dominant transmission model giving a modest lod score of 2.38. Replication of this finding was shown in another linkage analysis subsequently (Waldman *et al.*, 1997).

Chromosome 11

Chromosome 11 has been thoroughly investigated in mood disorders because of the presence of candidate genes involved in catecholamine neurotransmission such as tyrosine hydroxylase (TH, 11p15), tyrosinase (11q14-21), dopamine receptor D2 (DRD2, 11q22-23), dopamine receptor D4 (DRD4, 11p15.5) and tryptophan hydroxylase (TPH, 11p15). Overall, results of linkage studies indicate that the TH gene does not contribute a major gene effect to BPAD (Souery *et al.*, 1996b). A possible role for the TH gene was also examined in BPAD association studies, all on moderate to small sample sizes. Meta-analysis of the results (Furlong *et al.*, 1999) does not support the TH gene having a major role in the aetiology of BPAD, while data suggest that this candidate gene should be examined in larger samples of UPAD for which this marker may confer susceptibility to the disease.

Linkage to the dopamine 2 receptor (DRD2) has been excluded in a number of studies (Byerley *et al.*, 1990; Ewald *et al.*, 1994;

Holmes *et al.*, 1991; Kelsoe *et al.*, 1993; Nanko *et al.*, 1994). Most association studies have similarly showed no association between the gene for this receptor and BP (Craddock *et al.*, 1995b; Manki *et al.*, 1996; Souery *et al.*, 1996a).

Linkage to the DRD4 receptor gene has not been definitively excluded (Nanko *et al.*, 1994; Sidenberg *et al.*, 1994), and a few association studies have found positive results. For unipolar patients alone, an excess of short exon III repeats (2–4 repeats) has been found to be significantly more frequent than in controls (Manki *et al.*, 1996). The 7 repeat allele was associated with bipolar disorder, and an excess of allele 3 among controls in another study, yet negative results were then found in a larger sample by the same group (Lim *et al.*, 1994b). Serretti *et al.* (1998) recently reported an excess of allele 7 among mood disorder patients with delusional features, suggesting its importance in psychoses, not necessarily mood disorders.

Serotonin Markers and Mood Disorders

Dysfunction of the serotonergic system has long been suspected in major depression and related disorders. Depression can be treated successfully with selective drugs which target serotonin receptors. The serotonin transporter may also be involved in susceptibility to mood disorders and in the response to treatment with these drugs. Allelic association has been suggested between the serotonin transporter gene (located on chromosome 17q11.1–12) and UPAD (Ogilvie *et al.*, 1996). The presence of one allele of this gene was significantly associated with a risk of UPAD. This study also included a group of BPAD patients although no associations were found with this marker in this patient group compared to normal controls. This preliminary finding may add to our understanding of the possibility of polygenic inheritance in mood disorders. These findings were replicated in two different samples, again showing an association between this marker and UPAD (major depression with melancholia) (Gutierrez *et al.*, 1998a) and no association with a group of BPAD patients (Gutierrez *et al.*, 1998b). A higher frequency of the 12-repeat allele of the variable number tandem repeat (VNTR) polymorphism has been associated with mood disorders in a number of studies (Battersby *et al.*, 1996; Collier *et al.*, 1996; Rees *et al.*, 1997), with results being the most significant for bipolar subjects. The 9 repeat allele has been shown to be significantly associated with unipolar depression, on the other hand (Battersby *et al.*, 1996; Ogilvie *et al.*, 1996).

A linkage study with the functional variant of the serotonin transporter gene in families with BPAD could not exclude linkage (Ewald *et al.*, 1998b). More interestingly, a polymorphism within the promoter region of the serotonin transporter gene has been associated with treatment response to fluvoxamine, a typical serotonin reuptake inhibitor (SSRI) in major depression with psychotic features (Smeraldi *et al.*, 1998). This promising preliminary finding requires to be confirmed. The tryptophan hydroxylase (TPH) gene, which codes for the rate-limiting enzyme of serotonin metabolism, is also an important candidate gene for mood disorders and suicidal behaviour. Bellivier *et al.*, (1998b) reported a significant association between genotypes at this marker and BPAD; no association was found with suicidal behaviour. In a previous study in depressed patients suicidal behaviour has been associated with one variant of this gene (Mann *et al.*, 1997).

Chromosome 4

Possible candidate genes on chromosome 4 include the dopamine receptor D5 (DRD5) and the alpha adrenergic 2C receptor (ADRA2C) genes. Using both linkage and sib-pair methods to evaluate six families, positive results have been found for the loci for DRD5 and ADRA2C (Byerley *et al.*, 1994), although this was not fully replicated in a later study with a larger sample size (Blackwood *et al.*, 1996). Linkage was found between a locus on chromosome 4p (D4S394, 4p16) and BPAD in the latter study, yielding a robust two-point lod score of 4.1 under a model that allowed for heterogeneity. Although the region of 4p16 contains the genes for both DRD5 and ADRA2C, specific markers for these genes were not significant for linkage in this study. Although linkage was not found in the NIMH initiative for any region on chromosome 4, modest elevation of allele frequencies was found for markers on both arms of the chromosome, D4S2397 and D4S391 on 4p and DS1647 4q (Detera-Waldeigh *et al.*, 1997).

Other possible candidate genes mapped to chromosome 4 include those coding for protein subunits of the heteromeric GABA A receptor: the alpha 2 protein subunit (GABRA2) and the beta 1 subunit (GABRB1), located at 4p13–12. This region was excluded for linkage in a large family in the Blackwood *et al.* (1996) study, but perhaps could be examined more fully.

Chromosome 21

Straub *et al.* (1994) detected linkage with the locus for liver-type phosphofructokinase enzyme (PFLK) on chromosome 21 (21q22.3) in one large, multigenerational bipolar family. Initial results from 47 families assessed in this genome survey did not support linkage with this marker, however. Follow-up linkage analysis of an extended sample of 57 families on the 373 most informative individuals, using markers less than 2 cM apart, found evidence of linkage (lod score 3.35) at marker D21S1260, which is 5 cM proximal to PFKL (Aita *et al.*, 1998). Linkage between bipolar disorder and the PFLK region has also been confirmed in other studies (Ewald *et al.*, 1996, Smyth *et al.*, 1997), although negative results have also been reported (Byerley *et al.*, 1995; Vallada *et al.*, 1996). Further confirmation of linkage to this region with a large sample size, and a later report of excess allele sharing of a cluster of markers within a 9 cM interval on 21q (D21S1254, D21S65, D21S1440 and D21S1254), were found in the NIMH Genetics Initiative bipolar pedigrees (Detera-Waldeigh *et al.*, 1996, 1997). Linkage to a larger region proximal to the gene for PFKL, 21q21–22, has also been reported by a number of groups (Kwok *et al.*, 1999, LaBuda *et al.*, 1996). Taken together, these results indicate that the region of interest on 21q remains large, although no discrete locus or obvious candidate gene has been identified as of yet.

Chromosome 12

Darier's disease (keratosis follicularis), a rare autosomal dominant skin disorder associated with increased prevalence of epilepsy and mental retardation, whose gene has been mapped to chromosome 12q23–24.1 was found to cosegregate with bipolar disorder in one pedigree (Craddock *et al.*, 1994). The Darier's disease region has been investigated in several family studies in BPAD, suggesting a possible linkage (Barden *et al.*, 1996; Craddock *et al.*, 1994; Dawson *et al.*, 1995; Ewald *et al.*, 1998a). Two of these studies have been able to report significant lod scores greater than 3 (Barden *et al.*, 1996; Ewald *et al.*, 1998). To further test the hypothesis that genes containing expanded trinucleotide repeats may contribute to the genetic aetiology of BPAD, loci within this region containing CAG/CTG repeat expansions have also been investigated, but no association was found with BPAD (Franks *et al.*, 1999).

ANTICIPATION AND EXPANDED TRINUCLEOTIDE REPEAT SEQUENCES

Anticipation implies that a disease occurs at a progressively earlier age of onset and with increased severity in successive generations.

This may explain deviations from Mendelian inheritance observed in some inherited diseases. This phenomenon has been observed in several neurological diseases, including myotonic dystrophy, fragile X syndrome, Huntington's disease and spinobulbar muscle atrophy (Paulson and Fischbeck, 1996; Trottier *et al.*, 1995). Anticipation has been found to correlate with a new class of mutations, expanded trinucleotide repeat sequences. An expanded repeat sequence is unstable and may increase in size across generations, leading to an increased disease severity of the disorder. CAG repeats are detected by the repeat expansion detection (RED) method. Such unstable mutations could also be an alternative explanation in addition to environmental factors for discordance between monozygotic twins for mood disorders, where the repeat amplification might be different during mitosis in each of the two twins. A shortcoming of anticipation studies involves ascertainment bias. Earlier age of onset and/or increased severity in successive generations may be related to increased sensitivity to diagnosis in offspring of affected parents. It may appear that parents have a later age of onset compared to children, but perhaps parents with an earlier age of onset were not able to reproduce at all. Social and environmental factors in the younger generation may favour earlier detection, and expression of the disease is not necessarily related to observed repeats. Cohort effects can be controlled for in statistical analyses, however, such as examining age at onset in an entire generation compared to the difference observed between probands and parents.

Most unstable nucleotide repeat diseases showing anticipation also demonstrate imprinting, or parent-of-origin effect. Mood disorders have not yet unequivocally shown such an effect, although this does not necessarily exclude the possibility that anticipation occurs.

Evidence for anticipation has been observed in BPAD (Grigoroiu-Serbanescu *et al.*, 1997; McInnis *et al.*, 1993; Nylander *et al.*, 1994; Ohara *et al.*, 1998) and in UPAD (Engström *et al.*, 1995). Correlation between anticipation observed at the phenotypic level with the number of dynamic mutations may be the only way to confirm the implication of this phenomenon in mood disorders. One study highlighted an association between the number of CAG trinucleotide repeats and severity of BPAD illness in Swedish and Belgian patients (Lindblad *et al.*, 1995). This study, replicated subsequently in a different sample (O'Donovan *et al.*, 1995; Oruc *et al.*, 1997), showed for the first time in a major psychiatric disorder that the length of CAG repeats were significantly higher in BPAD compared to normal controls. These molecular genetic findings may indicate a genetic basis for anticipation in BPAD. However, no correlation has been found between CAG/CTG repeats and phenotypic measures of severity in a sample of 133 unrelated BPAD patients (Craddock *et al.*, 1997) and in several independent studies (Guy *et al.*, 1999; Li *et al.*, 1998; Vincent *et al.*, 1996; Zander *et al.*, 1998). This hypothesis has recently been tested in a sample of two-generation pairs with BPAD. Globally, no significant differences were found in the mean number of CAG repeats between parent and offspring generations. A significant increase in CAG repeats between parents and offspring was observed, however, when the phenotype increased in severity, i.e. changed from major depression, single episode or unipolar recurrent depression to BPAD (Mendlewicz *et al.*, 1997). A significant increase in CAG repeat length between generations was also found in female offspring with maternal inheritance, but not in male offspring. This is the first evidence of genetic anticipation in BPAD families and should be followed by the identification of loci within the genome containing triplet repeats. CTG18.1 on chromosome 18q21.1 and ERDA1 on chromosome 17q21.3 are two repeat loci recently identified (Lindblad *et al.*, 1998) which can be investigated in such study. In this study, several hundreds of candidate loci containing repeats were screened in a set of BPAD patients but expanded alleles at ERDA1 and CTG18.1 loci were found to be associated with BPAD phenotype. The authors observed that in a Swedish sample, including both unrelated and familial cases, 89% of expanded RED products correlate with expansions at these two loci and that expansion at the CTG18.1 locus was associated to the phenotype. Using the same method in a Belgian sample, Verheyen *et al.* (1999) demonstrated that 86% of the RED expansions could be accounted for by ERDA1 and CTG18.1 repeats. Expanded alleles at ERDA1 were found to be more frequent in bipolar patients. Eight CAG/CTG triplet repeats located in the 18q21.33–q23 region, identified as a candidate region in bipolar families, have been investigated in bipolar disorder by Goossens *et al.* (2000), but no expansion has been found in the bipolar family and the case-control sample investigated.

CONCLUSIONS

The physical mapping of the human genome provides an immense factory providing thousands of genes which will accelerate the identification of genes responsible for mood disorders and will contribute to significant advances in the awareness of diagnosis (diagnostic process and early recognition), pathophysiology, epidemiology and treatment issues. During the past two decades, the search for genes for mood disorders has mainly contributed to better understand and confirm the genetic complexities inherent in these disorders. The large amount of results available and the difficulty of digesting them corroborate this observation. The major contribution of these findings should be integrated in the context of the worldwide efforts to identify the thousands of genes of the human genome. The majority of these genes will be identified within the next few years. Several consistent hypotheses are currently being tested and will, hopefully, speed up the process of narrowing the important regions when the complete genome map becomes available. The most promising chromosomal regions have been localized on chromosomes 4, 5, 11, 12, 18, 21 and X. A number of candidate genes have also been investigated, some of which are directly linked to neurobiological hypotheses of the aetiology of mood disorders. In parallel, specific hypotheses have been implicated, such as anticipation and dynamic mutations. Further research should concentrate on these hypotheses and confirm positive findings through interdisciplinary and multicentre projects.

Neonatal Developmental Neuroplasticity: A Critical Contribution from Environment

Robert M. Post

INTRODUCTION

Hubel and Wiesel won the Nobel Prize for medicine with their elegant dissection of the impact of visual deprivation on the biochemistry, physiology and microstructure of the ocular dominance columns in the visual cortex (Hubel and Wiesel, 1979). They elucidated a gradient of progressively more profound and irreversible effects in the normal development of visual pathways and processing as a function of depriving environmental input by reducing visual input in one eye to virtually zero by suturing it shut. Not only was there dysfunction and atrophy of the ocular dominance columns related to the deprived eye, but a compensatory increase in those columns synaptically related to the eye that continued to have normal visual stimulation (Wiesel and Hubel, 1965; Hubel and Wiesel, 1979, 1998).

Similar, and perhaps even more complex, interactions appear to be occurring in diencephalic, paralimbic and cortical circuits involved in mediating the normal processes of maternal infant nurturing and bonding. The lack of normal developmental trajectories in this domain have been repeatedly linked to vulnerability to depression in adults later in life (Emde *et al.*, 1965; Powell *et al.*, 1967; Brown *et al.*, 1973a, b; Breier *et al.*, 1988). Thus, the neuropsychobiology of such early environmental insults is of particular interest to the topic of this chapter, and re-emphasizes a role for environmental contingencies as well as genetic inheritance in vulnerability to affective illness.

Depression Recurrence

The work of Kendler and associates provides a particularly cogent set of examples of both gene and environmental effects. As illustrated in Figure XVIII-11.1, a variety of early environmental losses or adversities are risk factors for subsequent depressions (Kendler *et al.*, 1993). In addition, concurrent stresses and losses interact with these earlier vulnerabilities in the precipitation of affective episodes. Moreover, minor or neurotic depressions are precursors to more major depressions, and major depressions are a key risk factor for subsequent major depressive recurrences, all within the background of genetic vulnerability to the recurrent affective disorders. Whether such dual contributions would meet the more formal criteria enunciated earlier by Boomstra and Martin for gene–environment interactions remains to be delineated, and in this chapter we will use the term interactions loosely only to imply that effects of both inherited and environmental domains can be discernible.

Suicidality in Bipolar Illness

A similar interactive schema is evident in the risk factors for suicidality in patients with bipolar disorder (Leverich *et al.*, 2002a, b). A family history of severe suicides attempted or completed, as well as a family history of substance abuse, interacts with a variety of environmental experiential variables as precursors of suicide attempts (Figure XVIII-11.2). An increased incidence of suicide attempts is affected by genetics, course of illness variables, psychiatric Axis I and Axis II comorbidities, medical comorbidities, and a history of early extreme stressors and environmental adversities (physical or sexual abuse in childhood or adolescence), as well as more proximal stressors such as loss of significant others and lack of adequate access to mental and medical health care.

Thus, paradigms in unipolar depression and in suicidality in patients with bipolar illness both indicate powerful interactions of genetic and environmental variables. On the experiential side, both paradigms suggest components of episode sensitization and stress sensitization.

Episode Sensitization

Perhaps the best clinical evidence for the occurrence of episode sensitization is the study of Kessing *et al.* (1998) of more than 20 000 patients hospitalized for depression or mania. These investigators found that for both unipolar and bipolar patients, the best predictor of incidence and time to relapse was the number of prior episodes, supporting the hypothesis that episodes beget episodes. However, one has to caution that it is possible that those patients who are most vulnerable to recurrence were preselected and one may have a poor prognosis subgroup in those who have the most prior episodes and subsequent recurrences. Kessing and associates present statistical reasons to suggest that this is not the case (Kessing, 1998; Kessing *et al.*, 1998), but such a proposition could only be resolved with a randomized prospective study of adequate versus inadequate long-term prophylaxis to see whether the intervening occurrence of episodes did change the future course; this study is not really possible given the ethical constraints against inadequate prophylaxis.

The studies of Brown and colleagues (Harris *et al.*, 1986, 1987; Bifulco *et al.*, 1987) are among the most elegant in demonstrating the interaction of proximal and distal stressors in the occurrence of depression. Brown and colleagues found that a variety of risk factors in single mothers appeared to be associated with the occurrence of depression upon the occurrence of a proximal stressor. One of these factors, again related to loss of a significant other (in this case loss of one's mother in childhood), could act as a predictor of subsequent depression. This occurred with a variety of other modulating variables including lack of a confidant, having more than four children at home to care for, and lack of employment. The study of Breier *et al.* (1988) is particularly revealing in terms of the potential lasting effects of early

parental loss. These investigators found that loss of a parent in childhood increased the incidence of adult depression only if the surviving parent failed to adequately substitute for the loss of the other. These data are particularly important, indicating that a variety of factors can be involved within any given risk factor as to whether or not it becomes a crucial determinant of increasing the risk of episode recurrence or of a suicidal act. The studies of Brown and colleagues in unipolar depression (Harris *et al.*, 1986, 1987; Bifulco *et al.*, 1987) and of Leverich and colleagues for suicidality in bipolar depressed patients (Leverich *et al.*, 2002a, b) re-emphasize this point, that lack of a confidant may be a particularly important mediating factor. Given a variety of stressors, the lack of availability of others to share perspectives, give their insights, and provide psychological and physical support, appears to be critically important.

Stress Sensitization

A variety of empirical investigations in affective illness suggest stress sensitization. The first (noted above) suggests that several types of early-life stressors are pertinent to later affective illness onset. In addition, numerous studies document that proximal stressors or psychosocial precipitants are more obvious in initial episodes of affective disorder than in later ones in which the episodes often occur more autonomously (reviewed in Post, 1992). Although the literature is not completely in agreement in this regard (Hammen and Gitlin, 1997), the majority of studies do suggest that early compared with later episodes are more likely to be associated with stressors. These observations thus validate Kraepelin (1921) and others' original view that:

> we must regard all alleged injuries as possibly sparks for the discharge of individual attacks, but that the real cause of the malady must be sought in *permanent internal changes*, what at least very often, perhaps always, are innate.
> in spite of the removal of the discharging cause, the attack follows its independent development. But, finally, the appearance of wholly similar attacks on wholly dissimilar occasions or quite without external occasion shows that even there where there has been external influence, it must not be regarded as a necessary presupposition for the appearance of the attack.
> Unfortunately the powerlessness of our efforts to cure must only too often convince us that the attacks of manic-depressive insanity may be to an astonishing degree *independent of external influences*. (Kraepelin, 1921, pp. 180–1)

Stress sensitization may not be unique to unipolar and bipolar disorders; evidence is emerging that it plays a role in the occurrence of the full-blown post-traumatic stress disorder (PTSD) syndrome. Several investigators have indicated that in patient populations who did develop PTSD after a given stressor compared with those who did not, there is a greater history of prior early stressors (Bremner *et al.*, 1993; Yehuda *et al.*, 1995; Breslau *et al.*, 1999). Together, these data in affective illness and in PTSD suggest that early stressors provide an area of vulnerability upon which the more proximal stressors act and interact. Should this prove to be true, the neurobiological and neuropsychological mechanisms that could underlie these types of stress sensitization phenomena deserve exploration.

EARLY MATERNAL SEPARATION

Maternal separation and parental neglect have long been recognized as potential risk factors for depression. Spitz and others studied anaclitic depression (Emde *et al.*, 1965; Harmon *et al.*, 1982), and Harlow and associates described some of the catastrophic and lasting consequences of social and environmental deprivation (Harlow *et al.*, 1965; Suomi *et al.*, 1970; Young *et al.*, 1973). Kuhn and Schanberg were among the first to demonstrate the physiological potency of even transient aberrations in the normal maternal–infant relationship (Kuhn *et al.*, 1978). They observed that the failure to show normal trajectories of growth and development in neonatal rat pups separated from their mothers could be ameliorated by the appropriate amount of touch and licking substitution (Pauk *et al.*, 1986). Separated animals did not show a failure to secrete adequate levels of growth hormone, but that growth hormone could not activate the critical enzyme for neural development, ornithine decarboxylase (Kuhn *et al.*, 1978). If neonatal rat pups were stroked lightly with a toothbrush on the ventral surface of their abdomens, they showed normal growth and normal amounts of ornithine decarboxylase activity induced by growth hormone (Pauk *et al.*, 1986). The ethological background of this interaction was determined to involve the fact that the neonate rodent has a neurogenic bladder and urinates only when the mother licks the ventral surface of the abdomen. This urine is then further licked by the mother to enhance the neonatal maternal bond at the level of smell and taste, as well as sound and touch.

Based on these preclinical observations, Kuhn and Shanberg moved to the neonatal nursery and demonstrated that properly handled premature infants grew better than those who were less handled in their incubators (Field *et al.*, 1986). At the same time, Levine and colleagues (Stanton *et al.*, 1988; Levine *et al.*, 1991) were demonstrating the consequences of single brief periods (24 hours) of maternal deprivation in neonatal rat pups, which were long-lasting alterations in behaviour and endocrinology. Some of the fundamental neurobiological mechanisms in those alterations have begun to be revealed; these animals remain hypercortisolaemic and anxious in open field tests and show a variety of changes in acute signal transduction chemicals and neurotrophic factors (Suchecki *et al.*, 1993; Rots *et al.*, 1996; Smith *et al.*, 1997; Zhang *et al.*, 1998, 2002).

For example, in rat pups separated for one day on day 11 of their life and then sacrificed on day 12, there was an increased induction of mRNA for nerve growth factor (NGF) and c-jun (Zhang *et al.*, 1998) and a decrease in hippocampal brain-derived neurotropic factor (BDNF), calcium-calmodulin kinase II (CaMKII), and nitric oxide synthase (NOS) (Zhang *et al.*, 2002; Xing *et al.*, 1998) (Figure XVIII-11.3a). In common with these changes is an approximate doubling in the rate of apoptosis observed throughout the brain, which correlates with the degree of increase in growth hormone in white matter areas of brain (Zhang *et al.*, 2002), raising the question of why increases in growth hormone might be associated with increases in cell death measured by the apoptag technique. It appears that the high-affinity receptor for NGF, the Trk-A receptor, is not adequately developed at this neonatal age and the low affinity p75 growth factor receptor predominates. When activated, the p75 receptor mediates an increase in apoptosis (Barrett, 2000). Zhang and associates (Zhang *et al.*, 2002) have observed that apoptosis occurs in both neuronal and glial cells.

Although these acute observations remain to be followed longitudinally, and the long-term consequences on brain microstructure and behaviour remain to be elucidated, they do provide another plausible mechanism (in addition to genetic deficits and other prenatal alterations) for the reported deficits in neurons or glia in selected areas of the brain in patients with schizophrenic, unipolar and bipolar affective disorders (Selemon *et al.*, 1995, 1998; Drevets *et al.*, 1998; Ongur *et al.*, 1998; Rajkowska *et al.*, 1999; Knable, 1999). In addition, they provide another plausible mechanism for the near uniform reports that patients with schizophrenia

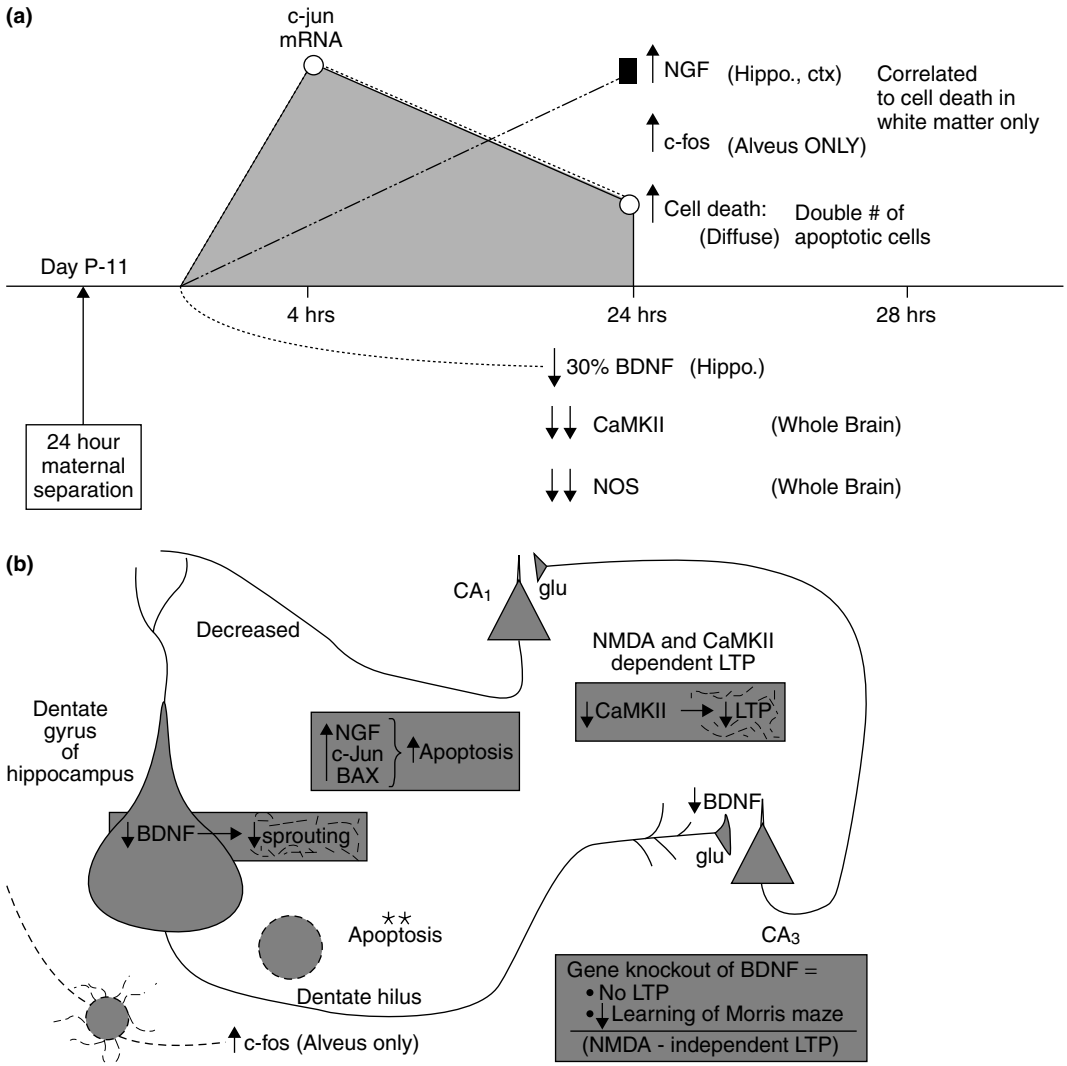

Figure XVIII-11.3 (a) Effects of maternal separation in neonatal rat pups on neurotrophins, transcription factors and gene expression (compiled using data from Zhang *et al.*, 1998, 2002). NGF, nerve growth factor; Hippo., hippocampus; ctx, cortex; BDNF, brain-derived neurotrophic factor; CaMKII, calcium-calmodulin kinase II; NOS, nitric oxide synthase. (b) Potential hippocampal effects of neonatal maternal separation. BDNF, brain-derived neurotrophic factor; NGF, nerve growth factor; NMDA, *N*-methyl-D-aspartate; glu, glutamate; CaMKII, calcium-calmodulin kinase II; LTP, long-term potentiation

often have significantly smaller brain sizes than comparative control populations (Lawrie and Abukmeil, 1998). Although it is not clear what factors mediate such processes, the potential impact of environmental deprivation should now be added to those of genetic determinants so beautifully demonstrated in the twin studies of Weinberger and colleagues (Suddath *et al.*, 1990; Berman *et al.*, 1992; Weinberger *et al.*, 1992; Torrey *et al.*, 1995), who found that in identical twins discordant for schizophrenia, the ill twin almost always had increased ventricle size. Ventricular size was highly correlated within twin pairs, showing the effect of genetics, but additional environmental vulnerabilities appeared to be at work in increasing the risk for becoming ill in those who had another factor associated with the larger ventricular size (Suddath *et al.*, 1990).

The maternal-separation-induced decrements in hippocampal BDNF are equally interesting in relation to a number of reports of smaller hippocampal size in patients with either affective disorders (Sheline *et al.*, 1996; Bremner *et al.*, 2000) or PTSD (Bremner *et al.*, 1995, 1997; Gurvits *et al.*, 1996; Stein *et al.*, 1997), although there are notable exceptions in this regard (Hauser *et al.*, 2000; Vakili *et al.*, 2000). Could a sufficiently consistent or recurrent stress-induced decrement in BDNF early in life be associated with the relatively small hippocampal size (Figure XVIII-11.3b)? Moreover, even if the size of the hippocampus were normal, recent evidence suggests that BDNF is important to the development of normal learning and memory, as reflected in a variety of behavioural tests, and for the normal development of long-term potentiation (LTP) in the hippocampus (Korte *et al.*, 1996, 1998), the best studied model of learning and memory (Malenka and Nicoll, 1999). Similarly, animals deficient in CaMKII have impaired LTP (Silva *et al.*, 1992).

One can only wonder whether the acute decrements in these two substances (CaMKII and BDNF) after maternal separation stress could occur at a critical developmental juncture and result in sustained deficits (Figure XVIII-11.3b). Recent data of Xing and colleagues show that CaMKII amRNA is significantly decreased

in the prefrontal cortex of patients with bipolar illness compared with normal controls (Xing *et al.*, 2002). Could such a defect in this and related signal transduction systems necessary for adequate learning and memory be a factor in the many different types of evidence of frontal dysfunction in patients with bipolar illness? The fact that CaMKII is decreased in the prefrontal cortices of patients with bipolar illness, and that it can be acutely decreased in rat pups undergoing a single day of maternal deprivation stress, at least opens the possibility of both genetic and environmental influences on such a critical intracellular transduction system.

Increases and decreases in intracellular calcium are crucial to reading the input on a single neuron and translating it into synaptic and neuronal output. On the synaptic level, increases or decreases in intracellular calcium can be associated with LTP or long-term depression (LTD), respectively (Malenka *et al.*, 1989; Bolshakov and Siegelbaum, 1994), and at a cellular level can be associated with neurotrophic, apoptotic and excitotoxic effects. Thus, neural excitability as well as neural life and death are intimately related to reading intracellular calcium signals. Could a 30% deficit of CaMKII in prefrontal cortex (Xing *et al.*, 2002), one of the most critical kinases involved in calcium homeostasis based on either genetic and/or environmental determinants, account for some of the dysregulations in cognition and affect in patients with bipolar illness?

REPEATED MATERNAL DEPRIVATION: BRIEF SEPARATIONS VERSUS LONGER SEPARATIONS

The work of Plotsky and Meaney reveals a number of striking principles about the quality, quantity, timing and duration of stressors as crucial variables in determining the eventual neurobiological and behavioural outcomes. Repeated maternal deprivation stress lasting 15 minutes produces animals that are relatively hypocorticosteronaemic and are protected against age-related memory defects as adults in association with lesser degrees of hippocampal atrophy. In contrast, animals subjected to repeated maternal deprivation stress of 3 hours' duration remain anxious in the open field and are hypercorticosteronaemic throughout their lives (Plotsky and Meaney, 1993). In addition, they are more prone to alcohol- and cocaine-self-administration than their litter mate non-separated controls. Strikingly, all of these alterations are reversible with treatment with serotonin-selective reuptake inhibitors (SSRIs), although if the SSRI is discontinued, the full syndrome returns (Huot *et al.*, 2001; Meaney *et al.*, 2002).

Many of these behavioural and biochemical changes mirror those induced in the model of Barden and associates (Pepin *et al.*, 1992; Beaulieu *et al.*, 1994) in which transgenic mice were developed to have a deficient number of type II glucocorticoid receptors (Figure XVIII-11.4). These animals are hypercortisolaemic and anxious in a variety of open field tests and also normalize much of their behaviour and biochemistry with antidepressant treatment. These convergent data of a transgenic model and an environmentally-induced model emphasize not only the potential for each to affect a relatively similar behavioural syndrome, but also suggest the strong potential for genetic and environmental interactions.

Thus, one could conceptualize that an animal with a genetically low level of glucocorticoid receptors that are subthreshold for inducing hypercortisolaemia and anxious behaviours might, under the proper provocation stress, exceed that threshold and manifest new behavioural and biochemical pathologies. It is interesting that this anxious, hypercortisolaemic syndrome is driven by glucocorticoid receptor deficiencies in one instance, and by glucocorticoid excess with subsequent compensatory receptor downregulation in the other, again suggesting the possibility of multiple pathophysiological routes to similar behavioural and biochemical pathologies. An example of such common phenotypic manifestations arising from very different transmitter and receptor alterations is clearly evident in the case of diabetes mellitus, wherein one can develop the illness because of either a deficiency in the hormone insulin, or because of a variety of defects in the insulin receptor activation

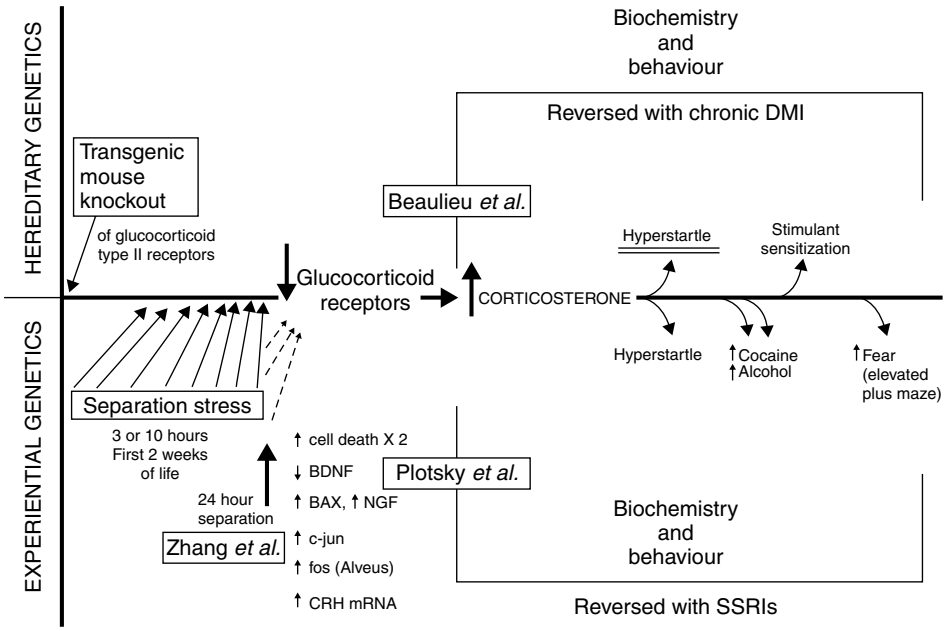

Figure XVIII-11.4 Convergent genetic and environmental models of depression. Either heredity or experiential genetics may lead to compounding behavioural and biochemical end-points similar to those seen in depression and reversible by antidepressants. DMI, desipramine; BDNF, brain-derived neurotrophic factor; NGF, nerve growth factor; CRH, corticotropin-releasing hormone; SSRIs, serotonin-selective reuptake inhibitors

and its associated downstream effects (insulin resistance) despite normal to high levels of circulating insulin.

In addition to this type of mechanistic heterogeneity, the work of Plotsky and Meaney has further elucidated mechanisms of individual differences in response to maternal deprivation stress. They noted that the potential mechanism of protection against age-related memory decline in the 15-minute separated animals was that their mothers engaged in increased licking behaviour upon return of the rat pup to the litter (Liu *et al.*, 1997). Conversely, in the 3-hour deprivation experience, the mother apparently fails to recognize the previously separated neonate as her own and continues to run about the cage in a somewhat frantic and agitated manner, sometimes virtually trampling her offspring. If the mother is given a substitute litter during the time that the 3-hour deprived rat pup is removed, her behaviour remains normal upon its return, and the 3-hour separated animal does not show the typical neurobehavioural effects of repeated 3-hour separations (Anisman *et al.*, 1998). These data, again, point to crucial interactions of parent and child in the evolution of pathological behavioural and biochemical syndromes. If the brief separation is accompanied by increased licking behaviour, animals show long-term benefit. Furthermore, if the 3-hour separated animal is spared some of the traumatic effects that occur as a sequel, it is spared the long-term adverse consequences. These effects are also dependent on the time-course of neural development because animals that are separated as adolescents instead of neonates tend to show the opposite long-term behavioural and biochemical outcomes.

Given the potential potent and long-lasting effects of degree of maternal licking behaviour upon reunion, Meaney and colleagues sought to ascertain whether normal variations in maternal licking behaviour were associated with individual variability in corticosterone levels and anxiety behaviours. Indeed, they found that low-licking mothers tended to have highly anxious, highly corticosteronaemic offspring. Conversely, mothers with naturally high levels of the licking behaviour tended to have low anxious, low corticosteronaemic offspring (Liu *et al.*, 1997).

These familial traits could thus have a hereditary genetic or experientially mediated impact on gene expression. In a series of studies, these investigators elegantly demonstrated that the latter was the case. In cross-fostering studies, offspring of low-licking mothers were reared by high-licking mothers and, in fact, manifested the biobehavioural signature typical of high-licking offspring, i.e. low levels of corticosterone and low levels of anxiety. Conversely, when offspring from a naturally high-licking mother were cross-fostered by a low-licking one, high levels of corticosterone and high levels of anxiety behaviour were evident (Francis *et al.*, 1999)

Most strikingly, the signature of the second generation followed not the familial pattern, but that induced by the cross-fostering. That is, animals destined to be hypercorticosteronaemic and anxious who were cross-fostered by a high-licking mother had the opposite behavioural signature themselves as adults, and when they later had their offspring, they continued to manifest low corticosterone and anxiety. Thus, a multi-generational change in the biobehavioural signature was induced, based only on a single change in maternal rearing behaviour in one generation (Francis *et al.*, 1999). These data must give one pause about the interpretation of hypothetically hereditary genetic traits which, without the appropriate controls, may on closer examination (such as this one) turn out to depend on familial- and experience-based alterations in gene expression.

Biochemistry of Longer Separations

The neurobiological mechanisms mediating high corticosterone and high anxiety behaviours in the 3-hour separated animals are beginning to be revealed, including distinct changes in the expression of corticotropin-releasing hormone (CRH) in the amygdala and hypothalamus, and a variety of other changes in neuroendocrine and peptide set-points that are permanently altered by repeated maternal deprivation (Plotsky and Meaney, 1993). Other neurobiological changes include a decrease in tone of the inhibitory GABA/benzodiazepine system and increased corticotropin-releasing factor (CRF) and noradrenaline (NA) (Ladd *et al.*, 2000). What is clear from these studies is that some of these stress-related changes in neurobiology can be manifest over the entire life span of the organism. This appears to result from altered levels of gene transcription in critical developmental pathways which, with the proper timing, duration, quality and severity, may change neurobiological set-points in responsivity in an enduring fashion.

Thus, these data provide a plausible set of mechanisms for explaining how early environmental adversity could impart long-lasting effects on biochemistry as well as neuropsychological approaches to self, others, and the environment in parentally neglected and/or traumatized individuals. They also provide a multitude of potential compensatory mechanisms that could alter or even completely reverse this neurobehavioural signature. In the case of the briefly separated rat pup, increased evoked maternal behaviour results in long-lasting stress immunization and less decline in hippocampal function in old age (Plotsky and Meaney, 1993). It is also possible that individual differences in endogenous compensatory mechanisms could similarly play a role as to whether or not a stressor was sufficient to induce the neurochemical change.

Pathological versus Adaptive Changes in Gene Expression

The kindling model clearly elucidates the induction of endogenous compensatory mechanisms at the level of gene expression (Figure XVIII-11.5). Amygdala-kindled seizures evoke a series of alterations that appear related to the primary pathological process of kindling progression and maintenance of the pathological kindled 'memory trace'. At the same time, each seizure evokes a transient increase in a variety of endogenous anticonvulsant factors (Post and Weiss, 1992), including an increase in benzodiazepine and $GABA_A$ receptors as well as increases in neuropeptides that are potentially anticonvulsant by themselves such as thyrotropin-releasing hormone (TRH), cholecystokinin (CCK), neuropeptide Y (NPY) as well as the proconvulsant CRF.

The importance of these adaptations is indicated by the 'time-off from last seizure' effect (Weiss *et al.*, 1995; Post and Weiss, 1996). If an anticonvulsant (such as carbamazepine or diazepam) is given the day after an amygdala-kindled seizure, the drugs are highly effective in their acute anticonvulsant properties. However, if sufficient time from the last seizure is allowed to elapse (without intervening seizures being given) then the same doses of drug are no longer effective, apparently because the seizure-induced endogenous anticonvulsant mechanisms have dissipated over this period. An interval of four days or greater is necessary for carbamazepine to lose its effectiveness, and ten days for diazepam. Levels of TRH and TRH mRNA increase in the hippocampus for approximately four days after amygdala-kindled or electroconvulsive seizures, and benzodiazepine and $GABA_A$ receptor increases slightly longer.

That these data could reflect physiologically relevant endogenous anticonvulsant mechanisms is suggested by two sets of observations (in addition to the increases lasting about the appropriate length of time necessary to observe the 'time-off' effect). Wan *et al.* (1998) found that intra-hippocampal injections of TRH are indeed anticonvulsant against amygdala-kindled seizures. Moreover, in animals that have become tolerant to the anticonvulsant effects of carbamazepine or diazepam, even a full-blown seizure is insufficient to induce the increases in TRH mRNA, suggesting that loss of this and other related compensatory anticonvulsant adaptations could be

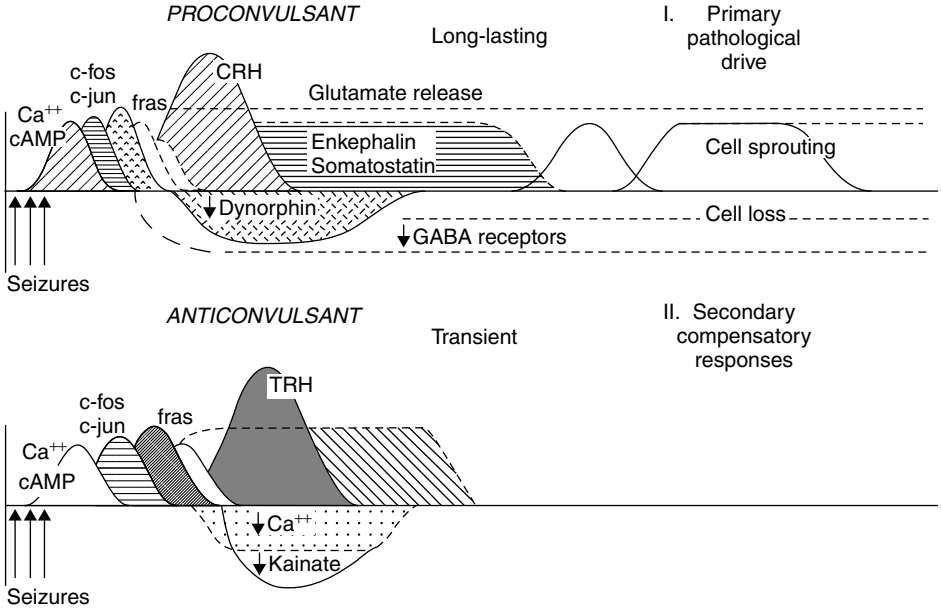

Figure XVIII-11.5 Schematic illustration of potential genomic, neurotransmitter and peptidergic alterations that follow repeated kindled seizures. Putative mechanisms related to the primary pathological drive (i.e. kindled seizure evolution) are illustrated on top and those thought to be related to the secondary compensatory responses (i.e. anticonvulsant effects) are shown on the bottom. The horizontal line represents time. Sequential transient increases in second messengers and immediate early genes (IEGs) are followed by longer lasting alterations in peptides, neurotransmitters and receptors or their mRNAs, as illustrated above the line, whereas decreases are shown below the line. Given the potential unfolding of these competing mechanisms in the evolution of seizure disorders, the question arises regarding whether parallel opposing processes also occur in the course of affective illness or other psychiatric disorders. Endogenous adaptive changes (bottom) may be exploited in the design of the new treatment strategies

linked to a loss of efficacy in instances of tolerance development as well (Figure XVIII-11.6) (Weiss *et al.*, 1995).

The idea that TRH represents an entire class of endogenous compensatory anticonvulsant mechanisms led us to follow up on the earlier observations of Prange and associates (1972) of the acute antidepressant effects of parenteral TRH. Given the evidence for TRH hypersecretion in some depressed patients based on increased levels in the spinal fluid or a blunting of the TSH response to TRH (Loosen and Prange, 1982; Banki *et al.*, 1988), we wondered whether this heightened TRH activity in depression could also represent a depression-induced endogenous antidepressant adaptation.

We thus administered 500 μg of TRH intrathecally in the context of a routine lumbar puncture (LP) in patients with refractory affective disorders and saw substantial antidepressant and antianxiety effects compared with a sham control injection (Marangell *et al.*, 1997). These data are consistent with the notion that increases in TRH observed in some depressed patients are endogenous antidepressant adaptations that, if sufficient, might normally lead to the spontaneous termination of a depressive episode. Although this proposition remains to be definitively tested and demonstrated, the data are not inconsistent with such a viewpoint.

The suggestion that changes in stress or depressive-episode-induced alterations in gene expression may either be part of a primary pathological process or a compensatory adaptation could help account for the inherent intermittency or cyclicity of the recurrent affective disorders (Figure XVIII-11.7) (Post and Weiss, 1996). One could postulate that during periods of relative wellness, the compensatory adaptions (as augmented [or not] by exogenous medications) would be sufficient to counter the underlying pathological processes.

Pathological alteration in gene expression might be driven by either those mediated by the hereditary genetic background or by experientially induced alterations. Similarly, the degree or set-point of the endogenous antidepressant mechanisms could also be determined by either genetic or environmental processes or their interaction (Figure XVIII-11.8). Thus, a predominance of depressive biological processes rather than those pushing to euthymia could be based on relatively low levels of a given compensatory neurochemical element, predisposing to, but not sufficient to result in, depressions. These could be further lowered and eroded by single or repeated episodes of extreme environmental adversity, such that they fail to exceed the threshold for adequate endogenous mechanisms maintaining euthymia.

Such a balance of pathological versus adaptive factors could also take place at the level of reaction to more proximal stressors that could influence the onset of a given affective episode. If appropriate medical and social supports are available, a stressor may not have the same pathological potency. This is most readily elucidated in the learned helplessness model, wherein the animal that receives the stressful tail shock and is able to terminate it by pressing a lever does not show helpless behaviour or the associated biochemical alterations. In contrast, the yoked control animal that receives exactly the same timing, magnitude and duration of the tail shock stress, but does not have the mechanism available for turning it off (ability to act/cope), develops the helpless neurobehavioural syndrome (Seligman and Maier, 1967; Seligman *et al.*, 1980). Thus, resistance to stress-induced behavioural changes could be built in at the level of either decreased pathological neurochemical response or increased compensatory adaptations, each mediated on either a genetic or environmental basis (or their interaction) (Figures XVIII-11.4 and XVIII-11.8). Both of these pathological or adaptive mechanisms could be enhanced or minimized with the appropriate targetted medication, or other somatic or psychotherapeutic treatment interventions.

Such a 'push–pull' model is reminiscent of the emerging perspective on the development of a variety of malignancies. In

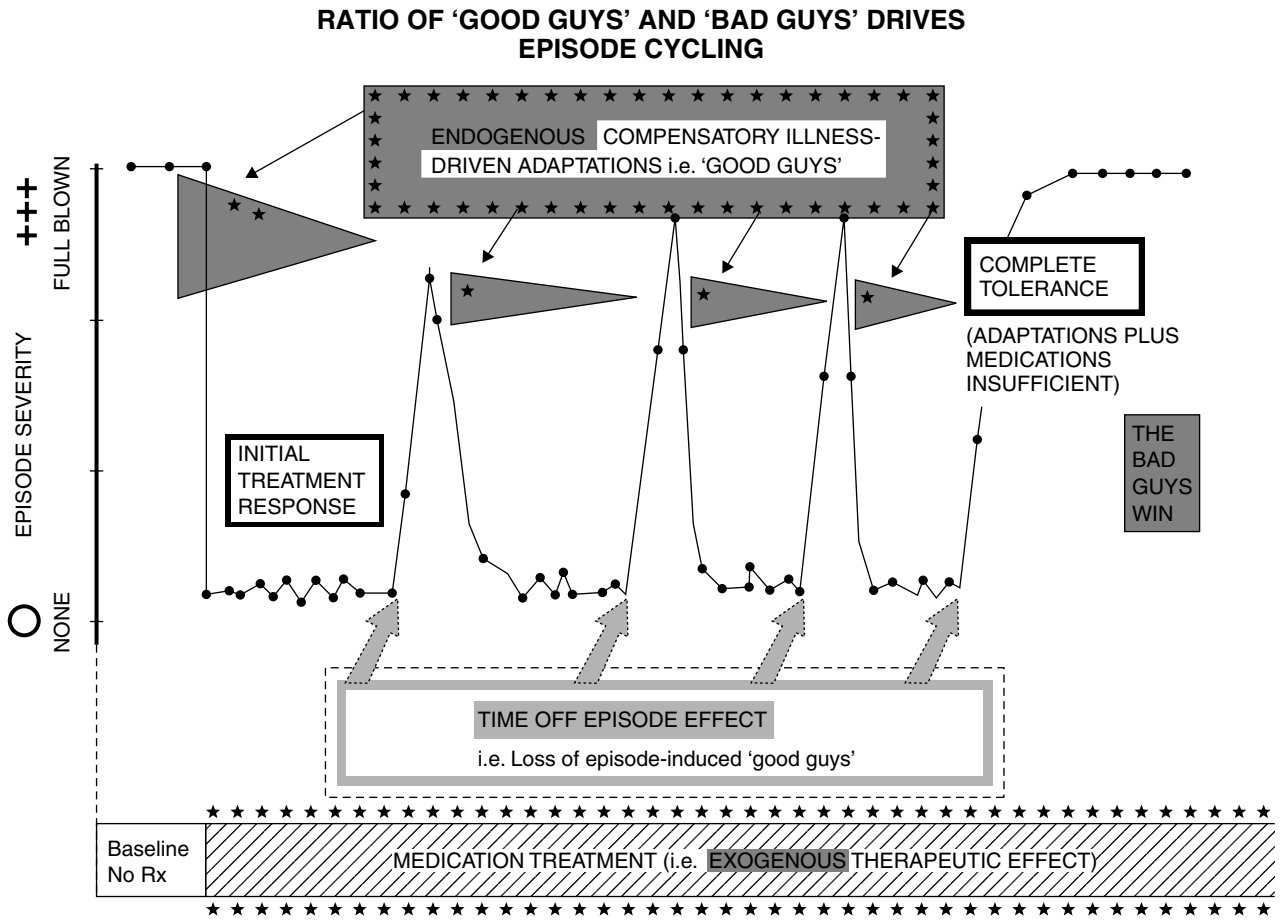

Figure XVIII-11.6 Hypothetical schema of the role of endogenous regulatory factors in the generation and progression of illness cyclicity. After an illness episode, adaptive compensatory mechanisms are induced (i.e. 'good guys'; shaded triangle with two stars), which together with drug treatment suppress the illness (initial treatment response; box). The 'good guys' dissipate with time (i.e. the 'time-off seizure' effect), and episodes of illness re-emerge. Although this re-elicits illness-related compensatory mechanisms, the concurrent drug treatment prevents some of the illness-induced adaptive responses from occurring (smaller triangles with one star). As tolerance proceeds (associated with the loss of adaptive mechanisms) faster illness re-emergence occurs. Thus, the drug is becoming less effective in the face of less robust compensatory mechanisms. The primary pathology is progressively re-emerging, driven by both additional stimulations and episodes (i.e. the kindled memory trace, or the 'bad guys') along with a loss of illness-induced adaptations. Because this cyclic process is presumably driven by the ratio of the 'bad versus good guys' at the level of changes in gene expression, we postulate that such fluctuations in the 'battle of the oncogenes' arising out of illness and treatment-related variables could account for individual patterns in illness cyclicity

the case of colon cancer, a sequence of five to more than a dozen changes in gene expression are required for the full-blown metastatic lesion (Gryfe *et al.*, 1997). These involve both increases in cellular activating, replicating and survival factors, as well as losses of neuroprotective and apoptotic (cell death) factors on the basis of multiple somatic mutations (Figure XVIII-11.9). With enough of this combination of enhanced mechanisms for cell replication and loss of compensatory tumour suppressor and cell death factors, the tumour can progress from a benign hyperplastic lesion to that of an adenoma, full-blown carcinoma, and finally, one with full metastatic malignancy. In the case of a malignancy, these positive and negative effects on gene expression enhancing cell replication and survival occur via the mechanism of somatic mutations, either genetically predisposed from the onset or arising spontaneously.

In a parallel fashion, at the level of experientially induced changes in gene expression interacting with hereditary genetic vulnerabilities, we could envision a similar cumulative progression to full-blown affective illness associated with increased likelihood of suicide attempts, treatment resistance and, ultimately, treatment refractoriness. As with the accumulating somatic mutations in the evolution of a cancer, in affective illness these might involve both increases in virulence of pathological mechanisms and, at the same time, a sequence of losing adaptive and protective mechanisms. This loss of protective factors could arise at the level of endogenous compensatory mechanisms (such as those represented by TRH), or those exogenously provided (such as those represented by some types of medications as well as social and psychotherapeutic support). Just as the animal that learns it is able to terminate the tail shock by pressing a lever does not develop the learned helplessness syndrome, if one approaches severe stressors and losses as adversities to which one can adapt (by virtue of positive distal factors derived from an optimal upbringing or by virtue of proximal factors such as new therapeutic insights), significant degrees of affective dysregulation may not occur (Figure XVIII-11.2 and Figure XVIII-11.8).

Such modulatory influences could, hypothetically, occur with appropriate psychotherapeutic intervention in a dynamic and supportive fashion, or with specific cognitive-behavioural interventions tuned to just these sets of issues and proactive problem solving toward them. However, if one has lost a parent early in life, one

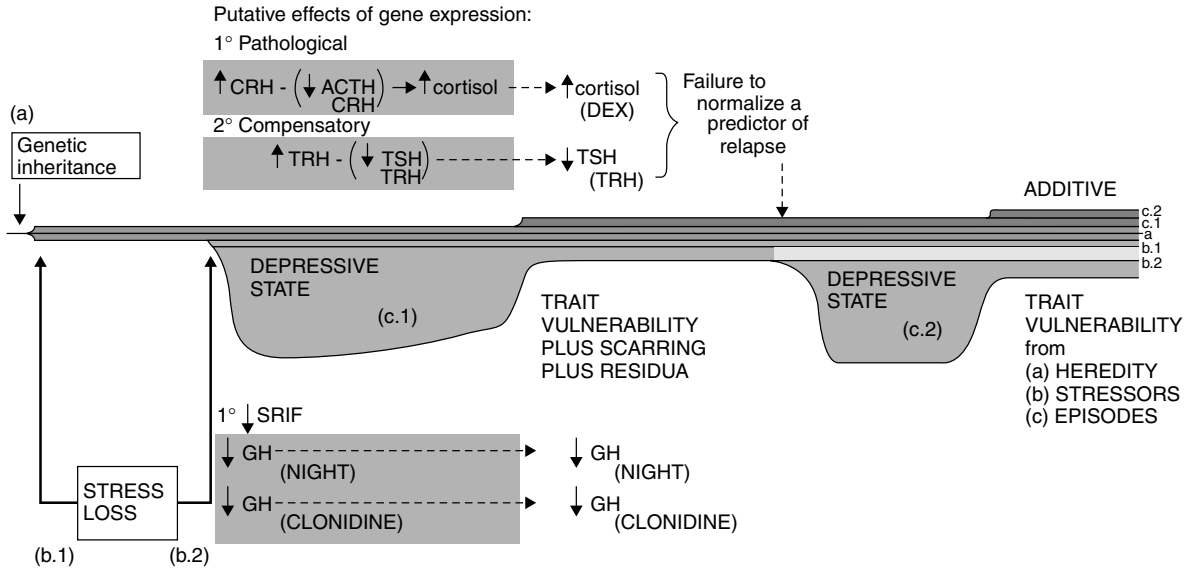

Figure XVIII-11.7 Accumulating experiential genetic vulnerability in recurrent affective illness. Schematic of how initial stressors may leave behind trait vulnerabilities (at the level of alterations in gene expression). With appropriate reactivation by stress of relevant neurobiological systems, the threshold for neuropeptide and hormonal changes associated with a depressive episode may be exceeded. These episode-related alterations may be normalized with the termination of episode but in some instances may persist and add further trait vulnerabilities toward recurrence (c) in addition to the genetic (a) and stressor (b) changes. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropin-releasing hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid stimulating hormone; DEX, dexamethasone; GH, growth hormone; SRIF, somatostatin

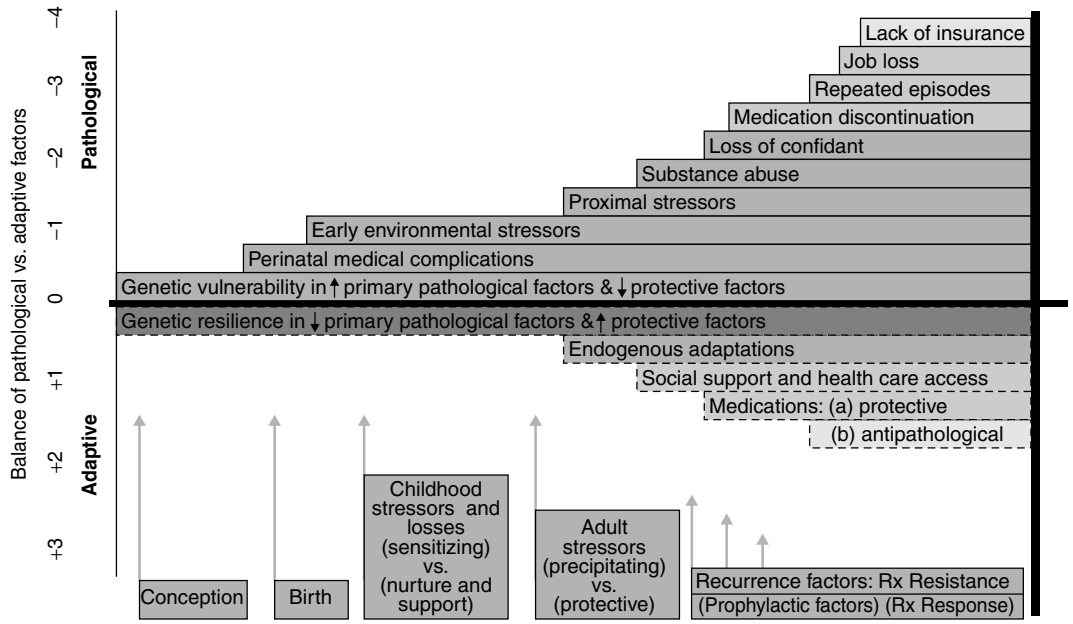

Figure XVIII-11.8 Ratio of pathological versus adaptive factors in determining illness episodes and well intervals

might have the dual liability of the loss itself and the associated failure to have the adaptive developmental benefits of that positive parental experience (in the absence of another stepping in to fill the role). If, in addition, one also loses more proximal social supports through lack of a confidant or inadequate access to health care resources, even malleable problems may appear unsolvable, particularly in the context of an inherent or experientially based set of depressive cognitions.

BRAIN MICROSTRUCTURE CHANGES: ENVIRONMENTAL AND PHARMACOLOGICAL INFLUENCES

A variety of micro- and macrostructural alterations have been described in unipolar and bipolar disorder (Figure XVIII-11.10), including altered cellular arrangements in frontal cortex and decreased glia in the subgenual part of the anterior cingulate gyrus

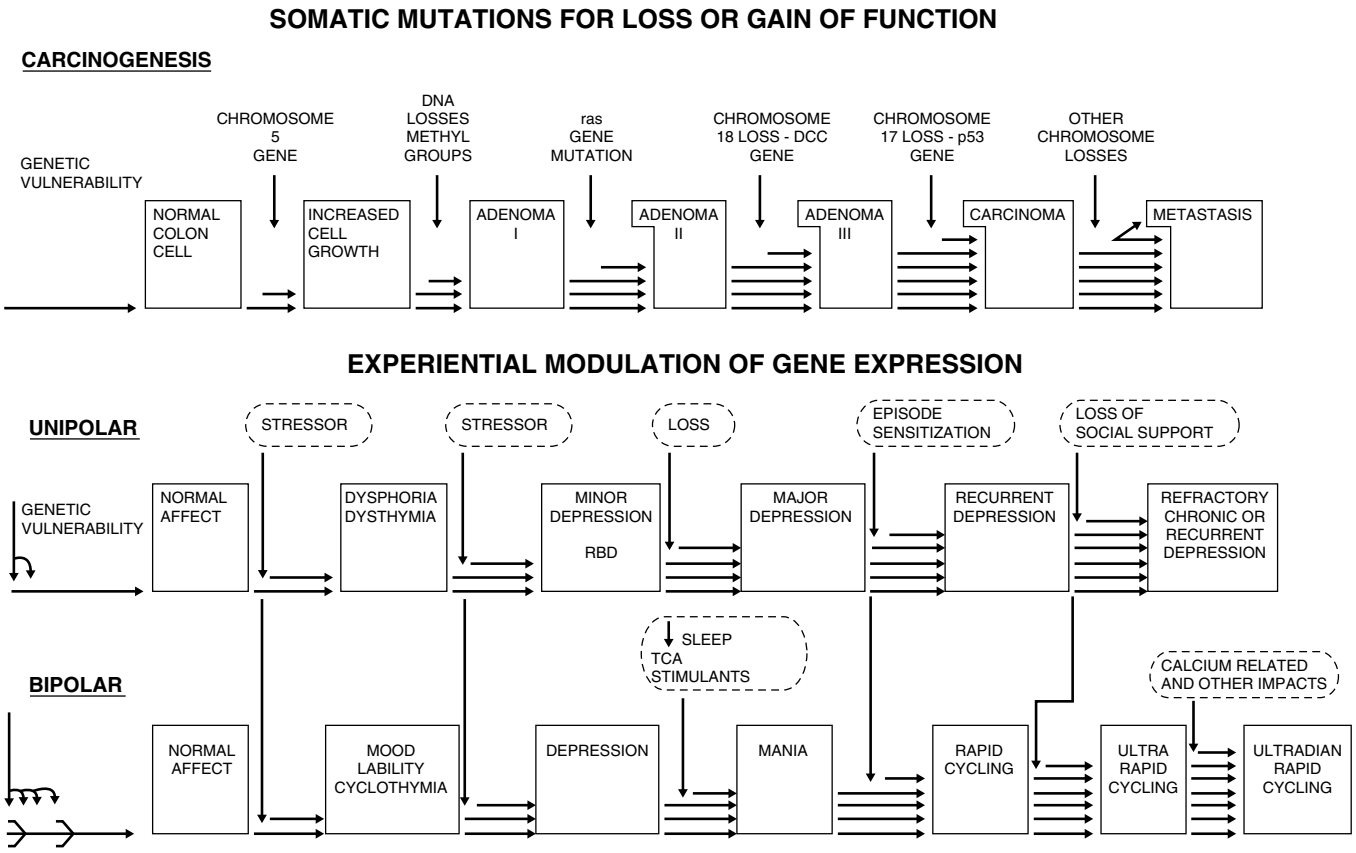

Figure XVIII-11.9 Similarities between somatic mutations in gene expression underlying carcinogenesis and experiential modulation of gene expression observed in unipolar or bipolar affective disorder. RBD, recurrent brief depression; TCA, tricyclic antidepressant

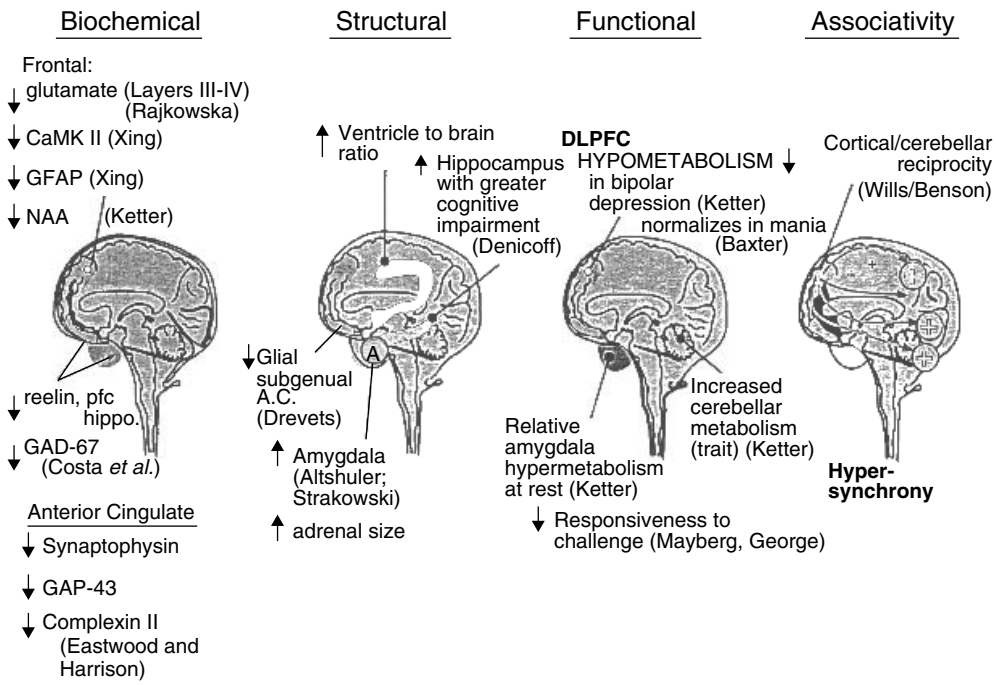

Figure XVIII-11.10 Biochemical, structural, and functional abnormalities in bipolar illness. CaMKII, calcium-calmodulin kinase II; GFAP, glial fibrillary acidic protein; NAA, *N*-acetylaspartate; pfc, prefrontal cortex; hippo., hippocampus; GAD-67, glutamic acid decarboxylase-67; GAP-43, growth associated protein-43; A.C., anterior cortex

(Drevets *et al.*, 1998; Rajkowska, 2000). Alterations in hippocampal size have been reported, as have increases in the size of the amygdala in two studies (Altshuler *et al.*, 1998; Strakowski *et al.*, 1999), but not in all cases (Pearlson *et al.*, 1997). We allude to these structural changes not because they have been definitively demonstrated, but only because they are likely to be contributing factors to the cascade of psychological and neurobiological processes that could be part of the mechanisms involved in illness vulnerability and progression. They may also be markers of high genetic vulnerability (the findings of Drevets *et al.* (1998) were limited to those patients with positive familial histories for affective disorder) or environmental impacts (not unlike the observations of Hubel and Weisel noted previously).

It may be particularly important to conceptualize even these structural alterations as potentially plastic and remediable rather than permanent and immutable. We know that environmental contingencies can be arranged to enhance cell survival, neurogenesis and the increased ratio of progenitor cells converting to neurons as opposed to glia. The latter finding is demonstrated in the studies of Kempermann *et al.* (1998) in which rearing in an enriched environment led to the increase of neural to glial ratio. Similarly, environmental adversity has been shown to decrease the rate of neurogenesis (Gould and Tanapat, 1999), which is estimated to occur in the adult rodent hippocampus at the rate of some 9000 cells per day (Cameron and McKay, 2001). Just as this neurogenesis appears bidirectionally malleable by environmental experiential mechanisms, it also appears to be alterable by pharmacology.

It is perhaps not a coincidence that the antidepressants as a class appear to induce stress counter-regulatory mechanisms at the level of gene expression for neurotrophic factors such as BDNF and neurotrophin-3 (NT3). The studies of Smith and associates at the NIMH (Smith *et al.*, 1995a, b) and those of Duman and colleagues (Nibuya *et al.*, 1995; Duman *et al.*, 1997; Duman, 1998) have revealed that antidepressants exert opposite effects to those of stress on these neurotrophic factors. Moreover, if an animal is stressed while on chronic antidepressant treatment, some of the stress-induced alterations are partially ameliorated or blocked altogether. There appears to be substantial blockade of stress-induced decreases in hippocampal BDNF when animals are co-treated with antidepressants and, concomitantly, a less robust increase in NT3 in the locus coeruleus occurs during antidepressant co-treatment compared with that during the stressor alone.

These data raise a variety of possibilities about the long-term effects of antidepressants in pharmacoprophylaxis of recurrent unipolar depression. Long-term effective prophylaxis could have multiple benefits for the individual with recurrent depression. The relative decrease in depressive episodes that occurs with a phenomenal level of statistical significance ($p < 10^{-34}$; Davis *et al.*, 1993) could spare the patient from considerable morbidity, and potential mortality from the illness by suicide. In addition, if the episode sensitization model proves valid, such pharmacoprophylaxis could alter the long-term course of the illness in a more favourable direction. To the extent that these agents exert some clinically relevant anti-stress effects at the level of gene expression on neurotrophic factors such as BDNF, antidepressants could help to lessen the impact of stressors, either as precipitating events for a depressive episode or on the microstructure of the brain as affected by the ratio of apoptotic to neurotrophic factors.

POTENTIAL NEUROTROPHIC AND NEUROPROTECTIVE EFFECTS OF LITHIUM CARBONATE

The mechanisms of action of lithium carbonate in recurrent affective disorders remain uncertain, although a host of candidate mechanisms have been postulated, as reviewed elsewhere (Post *et al.*, 2000). The latest findings on the mechanisms of lithium are of particular interest in relation to this chapter (Table XVIII-11.1). Lithium appears to exert neuroprotective effects in both a variety of *in vitro* cell culture model systems and *in vivo* in several models. Chuang and colleagues have shown that treatment with lithium reduces both the degree of neurological defect and the size of a brain infarct by approximately 50% in an animal receiving a middle cerebral artery ligation (Nonaka and Chuang, 1998). Similarly, they found that lithium reduced pathological effects of quinolinic acid injection into the striatum, a useful model for the striatal losses of Huntington's disease (Chuang *et al.*, 1999).

The groups headed by Manji and Chuang have demonstrated that lithium treatment is associated with the induction of neuroprotective factors such as Bcl2 and BDNF and decrements in cell death factors such as Bax and p53 (Chen and Chuang, 1999; Chen *et al.*, 1999; Manji *et al.*, 2000). That these alterations could be clinically relevant is revealed by several lines of evidence in addition to the *in vivo* models noted above. The changes in cell culture and in animals occur at clinically relevant concentrations of lithium, and preliminary evidence suggests that three weeks of treatment with lithium is able to increase *N*-acetylaspartate (NAA) in human brain as measured by magnetic resonance spectroscopy (Moore *et al.*, 2000a). Moreover, Moore *et al.* (2000b) demonstrated an increase in grey matter volume (using magnetic resonance imaging) in those exposed to lithium treatment compared with baseline. Thus, it remains possible that even on the level of synaptic and cellular structure of the brain, *endogenous* adaptations and *exogenous*

Table XVIII-11.1 Lithium: anti-apoptotic effects; neuroprotection; antisuicide effects (summary of data from Chuang and colleagues and Manji and colleagues)

In vitro	*In vitro* (rodent)	*In vitro* (Human)
Prevention of apoptosis in cultured neurons: Cerebellar granule cells Hippocampal (DG) cells Cortical cells	↑ Neurogenesis ↓ Size and neurological dysfunction of stroke (ligation MCA)	↓ Clinical suicide (UP & BP) ↓ Excess medical mortality (UP & BP)
Induction of cell survival factors: ↑ BCI-2; ↑ BDNF	↓ Lesion size model Huntington's chorea (Quinolinic acid in striatum)	↑ Neural integrity NAA (MRS) with 3 weeks of lithium
Inhibition of cell death factors: ↓ BAX; ↓ P53	↓ AIDS model apoptosis	↑ Neuronal volume Grey matter (MRI)

neurochemical alterations may be significant factors of short-term, if not long-term, therapeutic value.

Among the psychotropic agents used in the treatment of the recurrent affective disorders, the evidence is best for the antisuicide effect of lithium in those remaining on the drug long term (Muller-Oerlinghausen *et al.*, 1992a, b). Moreover, such long-term lithium treatment also appears to normalize the increased medical mortality that accompanies the recurrent affective disorders (Ahrens *et al.*, 1995). The data on the stroke and Huntington's disease models noted previously raise the question of whether some of lithium's effects on longevity in patients with affective illness could be mediated through cardiovascular and neuroprotective mechanisms in man similar to those demonstrated preclinically.

CONCLUSIONS

Given the multiplicity of postulated genetic and experientially driven changes in gene expression to which we have briefly alluded, one can envision the eventual use of gene therapy in reversing or ameliorating some of the key neurobiological alterations underlying vulnerability to recurrent affective disorders. However, already, currently available approaches include inhibiting or ameliorating adverse environmental experiential effects on gene expression through preventive measures and psychotherapeutic treatment, and enhancing compensatory mechanisms and minimizing primary pathological mechanisms through appropriate pharmacotherapy.

Thus, the conceptual overview espoused here is ripe for both further preclinical experimental testing and exploratory clinical therapeutic interventions. Given the virtually unlimited potential of the human brain for neuroplasticity, we look forward to increasingly effective therapeutics targetted to both pathological and adaptive processes, and ultimately, to the elucidation of the most opportune targets for gene therapy. Even when the era of gene therapy for psychiatric illness arrives, however, a role for interpersonal support and specific psychotherapeutic interventions attuned to the unique needs of patients with recurrent affective disorders will still be crucial to the successful acute treatment and long-term prevention of these otherwise recurrent disorders.

Female-Specific Mood Disorders

Meir Steiner, Edward Dunn, Leslie Born

The lifetime prevalence of mood disorders in women is approximately twice that of men. This higher incidence of depression in women is primarily seen from puberty on and is less marked in the years after menopause (Weissman and Olfson, 1995), with the exception of an additional perimenopausal blip (Kessler *et al.*, 1993). The underlying causality of this gender difference in mood-related disorders is not clear at this time. Since mood disorders occur in both men and women it is assumed that a unified basis for the development of these diseases exists. The principal constituent of this unified theory is believed to be related to genetic predisposition. Multiple environmental stressful events cause biochemical changes in a host of neuroendocrine systems and neuroanatomical areas. The genetic predisposition, which is multi-factorial, determines how stressful life events are interpreted and predicts the response, which can lead to the development of mood disorders (Heim and Nemeroff, 2001).

Notwithstanding, marked variations in the presentation of depression, comorbidity and treatment point to meaningful underlying sex differences. Women are about twice as likely as men to suffer from major depression or dysthymia (Kessler *et al.*, 1994; Weissman *et al.*, 1991). Women are prone to depressive episodes triggered by hormonal fluctuations related to reproductive events, such as during the premenstrual period, during pregnancy or the post-partum period, and around the menopause. Clinically, women present with a notably different depression symptom profile and more often develop a seasonal pattern to their depression (Ernst and Angst, 1992; Frank *et al.*, 1988; Leibenluft *et al.*, 1995; Moldin *et al.*, 1993; Whybrow, 1995). The burden of illness in women with chronic depression is profound (Kornstein *et al.*, 2000), while men may be more likely to 'forget' depressive episodes over time, a phenomenon which in turn may serve to protect them against recurrence (Ernst and Angst, 1992; Nolen-Hoeksema, 1987). Sex differences in the efficacy and tolerability of antidepressant medications is suggested by placebo-controlled and comparative studies (Kornstein, 1997, 2001; Kornstein and Wojcik, 2000). Moreover, there are marked differences between men and women in the pharmacokinetic and pharmacodynamic parameters of a number of psychotropic agents, including antidepressants (Kornstein and Wojcik, 2000; Yonkers *et al.*, 1992).

Collectively, the literature points to a higher prevalence of mood disorders in women related to an increased genetic predisposition, an increased vulnerability/exposure to stressful life events, modulation of the neuroendocrine system by fluctuating gonadal hormones, or a combination of any or all of these factors.

A biological susceptibility hypothesis has been previously proposed, to account for gender differences in the prevalence of mood disorders based on the idea that there is a disturbance in the interaction between the hypothalamic–pituitary–gonadal (HPG) axis and other neuromodulators in women (Dunn and Steiner, 2000; Meller *et al.*, 2001; Steiner and Dunn, 1996; Young *et al.*, 2000). According to this hypothesis, the neuroendocrine rhythmicity related to female reproduction is vulnerable to change and is sensitive to psychosocial, environmental and physiological factors. Thus, premenstrual dysphoric disorder (PMDD), depression with post-partum onset (PPD), and mood disorders associated with the perimenopause or with menopause may all be related to hormone-modulated changes in neurotransmitter function.

Control of mood and behaviour involves many different neurotransmitter systems, including glutamate, gamma aminobutyric acid (GABA), acetylcholine (ACh), serotonin (5-HT), dopamine (DA), noradrenalin (NA) and neuropeptides. Given the observation that prevalence and symptomatology of mood disorders is often different between males and females, it is presumed that gonadal steroid hormones are somehow involved. For example, declining levels of oestrogen in women have been associated with post-natal depression and postmenopausal depression, and the cyclical variations of oestrogens and progesterone are probably the trigger of premenstrual complaints in women with premenstrual syndrome (Fink *et al.*, 1996). The interaction between neurotransmitters and steroid hormones is extremely complex and delicately balanced. Each system appears to have a modulatory function on the other, and changes in one system may have dramatic effect on the other systems.

Glucocorticoid and gonadal steroid receptors are abundant in different areas of the brain. Gonadal steroid receptors are found in the amygdala, hippocampus, basal forebrain, cortex, cerebellum, locus ceruleus, midbrain raphe nuclei, pituitary gland and hypothalamus (Stomati *et al.*, 1998). Oestrogen receptors are also located in the preoptic area and amygdala (McEwen, 1988) and in the ventromedial nucleus and arcuate nucleus of the hypothalamus (Herbison *et al.*, 1995).

Activation of cholinergic, dopaminergic or adrenergic neurotransmitter systems can alter concentrations of cytosolic hypothalamic oestrogen receptors. Muscarinic agonists and antagonists can increase oestrogen-binding sites in the female rat hypothalamus (Lauber and Whalen, 1988). Oestrogen, progesterone and glucocorticoid receptors can also be activated by insulin-like growth factor 1 (IGF-1), epidermal growth factor (EGF), transforming growth factor alpha (TGF-alpha), cyclic AMP (cAMP), protein kinase activators and by various neurotransmitters (Culig *et al.*, 1995). Thus activation of neurotransmitter systems can have a direct modulatory effect on binding of gonadal hormones in the central nervous system (CNS).

Conversely, steroid hormones can modulate neuronal transmission by a variety of mechanisms. They may affect the synthesis and/or release of neurotransmitters, as well as the expression of receptors, membrane plasticity and permeability. It has been suggested that steroid hormone receptors function as general transcription factors to achieve integration of neural information in the CNS (Mani *et al.*, 1997; Stahl, 2001a). Steroids are believed to act primarily by classical genomic mechanisms through intracellular receptors to modulate transcription and protein synthesis. This

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

mechanism involves the binding of the steroid to a cytoplasmic or nuclear receptor. The hormone–receptor complex then binds to DNA to trigger RNA-dependent protein synthesis. The response time for this mechanism is on the order of several minutes, hours or days. It has also been shown that steroids can also produce rapid effects on electrical excitability and synaptic function through direct membrane mechanisms, such as ligand-gated ion channels, G-proteins and neurotransmitter transporters (Sumner and Fink, 1998; Wong *et al.*, 1996). These short-term (seconds to minutes) effects of steroids may occur through binding to the cell membrane, binding to membrane receptors, modulation of ion channels, direct activation of second messenger systems (Moss *et al.*, 1997) or activation of receptors by factors such as cytokines and dopamine (Brann *et al.*, 1995). Topical application of oestrogen or progesterone to nervous tissue has been shown to result in a rapid change in membrane potential, and sex steroids can affect membrane fluidity by modifying ion transport or receptor function (Maggi and Perez, 1985).

The role and potential relevance of oestrogen and other sex steroids to psychiatric disorders is the focus of current scientific attention. Oestrogen has been described as a 5-HT, NA, and ACh agonist, and it also modulates DA/D_2 receptors. Likewise, oestrogen may also alter the action of drugs that work on target neurotransmitters. The antidepressant properties of oestradiol have recently been demonstrated in a placebo-controlled trial of perimenopausal women with major depression (Soares *et al.*, 2001). Indeed, oestrogen is regarded by some as the 'new frontier' of potential therapeutic action in the treatment of women with mood disorders (Stahl, 2001b).

In this chapter, mood disorders across the reproductive life cycle in women will be briefly reviewed with particular attention to the impact of hormonal fluctuations during menarche, the premenstruum, pregnancy and post-partum, and the perimenopause.

MENARCHE AND MOOD DISORDERS IN ADOLESCENCE

Epidemiological studies consistently show that beginning at menarche, mood disorders are at least twice as common in women than in men. Why these gender differences exist and why they start at puberty is perhaps one of the most intriguing and least understood phenomena in clinical psychiatry (Lewinsohn *et al.*, 1998).

Prior to adolescence, the rates of depression are similar in girls and boys (or are slightly higher in boys), yet with the onset of puberty, the gender proportion of depression dramatically shifts to a 2 : 1 female to male ratio (Kessler and Walters, 1998; Lewinsohn *et al.*, 1998). In the US general population, the lifetime prevalence of major depression (MD) in adolescents and young adults (15–24 years of age) has been reported as 20.6% for females and 10.5% for males (Kessler and Walters, 1998). Lifetime rates of MD in early- as well as late-maturing girls were even higher (30% versus 22% and 34% versus 22%, respectively) when compared to 'on-time' girls.

There is conflicting opinion regarding the age at which gender differences in rates of MD emerge: researchers are divided between the 12–14 and the 15–19 year age brackets (Cohen *et al.*, 1993; Hankin *et al.*, 1998; Lewinsohn *et al.*, 1998).

An integrative theory of depression in adolescents has been introduced (Lewinsohn *et al.*, 1998), although a persuasive explanation of the sharp rise in the prevalence of depression in females after menarche has yet to be elucidated.

The onset of puberty is heralded by a growth spurt, which begins with rapid growth in height and weight typically between 7.5 and 11.5 years of age. Following this initial burst, physical growth continues at a slow pace for several years. The first sign of sexual maturation in girls is breast budding at about 10.5 years, followed by growth of pubic hair, which begins at about 11.5 years, growth of the uterus and vagina, and the enlargement of the labia and clitoris. Menstruation begins after these changes occur. Finally, axillary hair appears, hips broaden, and fat deposits increase. On average, these changes take 4–5 years; however, considerable variation exists in the sequence and tempo of these events.

In North America and Europe, the age of menarche has declined about 4 months per decade since 1850; in North America, menarche now occurs around 12.5 years of age on average (Tanner, 1968). This dramatic decline in the age at which girls reach puberty is one of the strongest examples of environmental factors that affect hormonal responses. The search to isolate the particular environmental factors involved in this acceleration, however, has been only marginally helpful. It has been suggested that urbanization has a major role in this change, as well as improvements in general health, nutrition and other sociocultural factors. But other environmental factors also seem to be implicated in the timing of menarche. Girls who are blind with some perception of light reach menarche earlier than normally sighted girls, and totally blind girls with no light perception reach puberty even earlier (Zacharias and Wurtman, 1964). Moreover, fewer girls start to menstruate during spring and summer time as compared to during seasons of reduced amounts of daylight (autumn and winter) (Bojlen and Bentzon, 1974).

The relationship between psychosocial development and physical maturation has been widely examined. Girls undergoing pubertal change are thought to experience greater distress and to be more vulnerable to stress than pre- or postpubertal girls (Caspi and Moffitt, 1991). Two parameters of pubertal change in particular have received much attention: pubertal status and pubertal timing. *Pubertal status* is defined as the current level of physical development of an adolescent relative to the overall process of pubertal change (a biological factor), usually denoted by a series of stages from prepubertal (stage I) to adult (stage V) according to Tanner (Tanner, 1962). *Pubertal timing*, on the other hand, is defined as the maturation of an adolescent relative to her peers (a psychosocial factor).

There appears to be a relatively sharp demarcated period in midpuberty when girls become more vulnerable to depression than boys. In a recent report on 1073 US children aged 9–13 years, the depression rates in girls rose significantly in mid-puberty, i.e., with the transition to Tanner stage III. In contrast, the prevalence of depression in boys *declines* from Tanner stage II (Angold *et al.*, 1998). Further, it has been determined that in girls, pubertal status (versus the age at puberty) better predicted the emergence of the sex ratio in depression rates. Thus, the onset of menarche may signal an increased but latent biological vulnerability to mood dysregulation in women (Nolen-Hoeksema and Girgus, 1994).

Although changes in affect, mood and behaviour are considered to be related to cyclic hormonal changes, studies of female adolescents and premenstrual syndrome (PMS) are inconclusive, with one study reporting no relationship between menstrual cycle phase and negative affect (Golub and Harrington, 1981) and others showing that PMS is associated with other distress factors in this age group (Freeman *et al.*, 1993; Raja *et al.*, 1992). Notwithstanding, relationships between changes in pubertal hormones and negative affect in female adolescents have been observed. For example, investigators have found that negative affect was significantly related to a rapid increase in oestradiol levels (Warren and Brooks-Gunn, 1989). Negative affect in healthy girls was also associated with higher levels of testosterone and cortisol, and lower levels of dehydroepiandrosterone sulphate (Susman *et al.*, 1991).

There is both direct and indirect — albeit limited — evidence of the involvement of the serotonergic system in the aetiology of depressive disorders in child and adolescent depression. In a comparative study of psychiatric inpatients and normal controls (aged 7–17 years), levels of whole-blood 5-HT were lowest inpatients with mood disorders (Hughes *et al.*, 1996). There is some indication of the responsiveness of children and adolescents with

MD to serotonergic but not noradrenergic agents; researchers have hypothesized that, in childhood, the serotonergic systems may mature at an earlier rate than the noradrenergic systems (Ryan and Varma, 1998). Gonadal hormones affect the production of 5-HT receptors at the transcriptional level, and the altered distribution or function of 5-HT receptor subtypes brought on by changes in the hormonal milieu at menarche may increase vulnerability to mood disorders.

It is nevertheless still unclear how the dramatic changes in the hormonal milieu associated with menarche and a host of psychosocial stressors combine to produce depressive symptoms. One possible unifying hypothesis suggests that disruption of biological rhythms, such as disturbed sleep patterns (Armitage *et al.*, 2001) or irregular menstrual cycles, together with psychosocial losses causing the disruption of social rhythms (also known as 'social zeitgebers') could trigger the onset of a major depressive episode in vulnerable individuals (Ehlers *et al.*, 1988). Another complementary theory emphasizes the neurobiology of stress and the dysregulation of affect during female biological transitions such as menarche, a transition which may be associated with changes in the reactivity of the stress system (Dorn and Chrousos, 1997). The newly fluctuating levels of gonadal hormones as well as gonadotropins, which mark the onset of menarche and the establishment of menstrual cycles, introduce a major change in the hormonal milieu to which the rest of the system has to adjust. This is the period during which the hypothalamic–pituitary–adrenal (HPA) axis has to mature and be sensitized to a variety of new feedback mechanisms. This is also the time during which the HPA axis may be more vulnerable to external psychosocial stressors, to sleep deprivation as well as to the influences of nicotine, alcohol and other drugs, resulting in a higher incidence of HPA axis dysregulation and mood instability.

Taken together, it is suggested that pubertal and other hormonal changes should be monitored prospectively along with individual, genetic, constitutional and psychological characteristics in our efforts to predict the development of negative affect during puberty (Steiner *et al.*, 2000).

PREMENSTRUAL DYSPHORIA

The inclusion of research diagnostic criteria for PMDD in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (DSM-IV) recognizes that some women in their reproductive years have extremely distressing emotional and behavioural symptoms premenstrually (American Psychiatric Association, 1994 pp. 717–18). Through the use of these criteria, PMDD can be differentiated from *premenstrual syndrome* (PMS) which has milder physical symptoms, i.e., breast tenderness, bloating, headache and minor mood changes (World Health Organization, 1996a). PMDD can also be differentiated from *premenstrual magnification* (concurrent diagnoses of PMS or PMDD *and* a major psychiatric or an unstable medical condition) and from *premenstrual exacerbation* of a current psychiatric disorder or medical condition (Steiner and Wilkins, 1996).

Epidemiological surveys have estimated that as many as 75% of women with regular menstrual cycles experience some symptoms of premenstrual syndrome (Johnson, 1987). PMDD, on the other hand, is much less common. It affects only 3–8% of women in this group (Angst *et al.*, 2001; Johnson *et al.*, 1988; Ramcharan *et al.*, 1992), but it is more severe and exerts a much greater psychological toll. These women report premenstrual symptoms that seriously interfere with their lifestyle and relationships (Freeman *et al.*, 1985; O'Brien *et al.*, 1995).

The aetiology of PMS and PMDD is still largely unknown. That PMS and PMDD are biological phenomena (as opposed to psychological or psychosocial events) is primarily underscored by recent, convincing evidence of the heritability of premenstrual symptoms (Kendler *et al.*, 1998) and the elimination of premenstrual complaints with suppression of ovarian activity (Schmidt *et al.*, 1998) or surgical menopause (Casson *et al.*, 1990). In women with PMDD, the ovarian axis is apparently functioning normally with normal oestrogen and progesterone levels (Schmidt *et al.*, 1998). The current consensus seems to be that normal ovarian function rather than simple hormone imbalance is the cyclic trigger for biochemical events within the central nervous system and other target tissues which unleash premenstrual symptoms in vulnerable women (Roca *et al.*, 1996). This viewpoint is attractive in that it encourages investigation of the neuroendocrine-modulated central neurotransmitters and the role of the HPG axis in PMDD.

There is increasing attention to the metabolite of progesterone, allopregnanolone, in the manifestation of premenstrual symptomatology. Current evidence suggests that progesterone and progestogens are not likely to be effective in the treatment of premenstrual syndromes (Wyatt *et al.*, 2001). Allopregnanolone, on the other hand, is thought to modulate GABA receptor functioning and produce an anxiolytic effect (Rapkin *et al.*, 1997); quantitative differences in progesterone and allopregnanolone levels between PMS subjects and controls have been examined. The findings to date, however, are contradictory (Bicikova *et al.*, 1998; Girdler *et al.*, 2001; Monteleone *et al.*, 2000; Rapkin *et al.*, 1997; Schmidt *et al.*, 1994; Wang *et al.*, 1996). A recent study using an animal model, though, is more promising. In a progesterone-withdrawal paradigm designed to mimic PMS and post-partum depression in female rats, Smith and colleagues have found that decreased levels of allopregnanolone lead to increased production of the $\alpha 4$ subunit of the $GABA_A$ receptor. This changes the sensitivity of the $GABA_A$ receptor to endogenous ligands, resulting in symptoms associated with PMS (Smith *et al.*, 1998).

The role of the female sex hormones in premenstrual symptomatology has been considered of central importance. Notwithstanding, attention by some has shifted from a focus on oestrogen and progesterone to the role of androgens in premenstrual dysphoria.

Early investigations of androgens have suggested that women with PMS or PMDD have elevated levels of serum testosterone in the luteal phase compared with controls (but still within the normal range), which may contribute primarily to the symptom of irritability (Dunn *et al.*, 2001; Eriksson *et al.*, 1992). This hypothesis of increased androgenicity is backed by both animal and human studies of androgens and irritability and/or aggression. Androgens promote sexual drive in humans, and also have been tentatively linked with mood (e.g. depression and premenstrual irritability) and impulsive behaviour (e.g. compulsions and binge eating). Enhanced serotonin availability (e.g. with the use of selective serotonin reuptake inhibitors; SSRIs), on the other hand, is associated with reduction in irritability, depression and impulsive behaviour, as well as reduced libido. An inverse relationship between serotonin and androgens, and their effects on human behaviour has been proposed; the behavioural effects of androgens may be therefore partly mediated by a reduction in serotonin activity (Eriksson *et al.*, 2000).

Reduction of premenstrual dysphoria with androgen antagonists in women with PMS who showed higher mean levels of total testosterone in the late luteal phase also lends support to the idea of increased androgenicity (Burnet *et al.*, 1991; Rowe and Sasse, 1986). Others, however, have not observed differences in plasma testosterone in comparisons of women with or without PMS (Dougherty *et al.*, 1997), and one study has reported significantly *lower* total and free testosterone plasma levels in a sample of 10 women with PMS (Bloch *et al.*, 1998). Further comparative studies of women with PMS and PMDD are therefore required.

An alternative strategy to measuring various hormone plasma levels in an attempt to discern the aetiology of PMDD has been to search for endocrine abnormalities that have been repeatedly

associated with various other forms of psychopathology. The main advantage of this approach is its potential to help further our understanding of PMDD as well as its relation to other psychiatric disorders. The current literature suggests that thyroid dysfunction may be found in a small group of women with premenstrual symptoms but that PMDD should not be viewed as a masked form of hypothyroidism (Korzekwa *et al.*, 1996; Schmidt *et al.*, 1993).

Of the neurotransmitters studied to date, increasing evidence suggests that 5-HT may be important in the pathogenesis of PMDD (Steiner *et al.*, 1997; Rapkin, 1992). PMDD shares many features of other mood and anxiety disorders linked to serotonergic dysfunction. In addition, reduction in brain 5-HT neurotransmission is thought to lead to poor impulse control, depressed mood, irritability and increased carbohydrate craving — all mood and behavioural symptoms associated with PMDD.

The serotonergic system is in close reciprocal relationship with gonadal hormones. In the hypothalamus, oestrogen induces a diurnal fluctuation in 5-HT (Cohen and Wise, 1988), whereas progesterone increases the turnover rate of 5-HT (Ladisich, 1977).

More recently, several studies concluded that 5-HT *function* may also be altered in women with PMDD. Some studies used models of neuronal function (such as whole-blood 5-HT levels, platelet uptake of 5-HT, and platelet tritiated imipramine binding) and found altered 5-HT function during all phases of the menstrual cycle (Ashby *et al.*, 1988; Bixo *et al.*, 2001; Rapkin, 1992; Steege *et al.*, 1992). Other studies that used challenge tests (with L-tryptophan, fenfluramine, buspirone, *m*-chlorophenylpiperazine) suggested abnormal serotonin function in symptomatic women but differed in their findings as to whether the response to 5-HT is blunted or heightened (Bancroft and Cook 1995; Bancroft *et al.*, 1991; FitzGerald *et al.*, 1997; Rasgon *et al.*, 2001; Su *et al.*, 1997; Steiner *et al.*, 1999). Acute tryptophan depletion (suppressing brain 5-HT synthesis) was significantly associated with exacerbation of premenstrual symptoms, in particular irritability (Menkes *et al.*, 1994). Additional evidence suggesting the involvement (although not necessarily aetiological) of the serotonergic system has emerged from treatment studies: drugs facilitating serotonergic transmission, such as SSRIs, are very effective in reducing premenstrual symptoms. These studies imply, at least in part, a possible change in 5-HT transporter/receptor sensitivity in women with premenstrual dysphoria (Steiner and Born, 2000).

The current consensus is that women with premenstrual dysphoria may be behaviourally or biochemically sub- or supersensitive to biological challenges of the serotonergic system. It is not yet clear whether these women present with a trait or state marker (alternatively, both conditions could be possible) of premenstrual syndromes.

The reciprocal relationship between the serotonergic system and the gonadal hormones has been identified as the most plausible target for interventions. This notion has recently gained further support in a very elegant study showing that an SSRI (fluoxetine) reduces sex-steroid-related aggression in female rats in a paradigm which is proposed as an animal model of premenstrual dysphoria/irritability (Ho *et al.*, 2001). Thus, beyond the conservative treatment options such as lifestyle and stress management, and the more extreme interventions that eliminate ovulation altogether, the SSRIs are emerging as the most effective treatment option for this population (Steiner and Born, 2000).

POST-PARTUM DEPRESSION

The specific link and the uniqueness of psychiatric disorders precipitated or triggered by pregnancy or childbirth have recently been acknowledged by the American Psychiatric Association (1994, pp. 386–7). Based primarily on the work of the Task Force on DSM-IV (Purnine and Frank, 1996) the manual now has a course-specific designation 'post-partum onset', which can be applied to both psychotic and non-psychotic post-partum mental disorders. Thus, major depressive disorders, bipolar disorders (manic and depressed), schizoaffective disorders, and psychotic disorders (not otherwise specified) will have the qualifier 'with post-partum onset'.

Post-partum 'blues' is considered the most mild of the post-partum mood disturbances; its prevalence has been reported to be 26–85%, depending on the diagnostic criteria used (Stein *et al.*, 1981). The symptoms of this syndrome typically begin within the first week following childbirth, peak on the fifth day and resolve by the twelfth day post-partum. Symptoms include dysphoria, mood lability, crying, anxiety, insomnia, poor appetite and irritability. The mood disturbance characterizing post-partum blues is considered transient and insufficient in and of itself to cause serious impairment of a woman's functioning (O'Hara *et al.*, 1991). In some women, however, the disturbance may persist beyond the initial post-partum period, leading to more serious PPD (Cox *et al.*, 1993).

Epidemiological studies of the nature, prevalence and course of an episode of major PPD have found that 10–15% of women exhibit depressive symptoms in the first weeks following delivery (Carothers and Murray, 1990; Pop *et al.*, 1993), and that the great majority of these depressive episodes resolve spontaneously within three to six months (Cooper and Murray, 1995; Cox *et al.*, 1993). The symptom profile of PPD resembles that of a major depressive episode experienced at other times in life, but it is unique in its timing and in that it always involves at least the mother–baby dyad and in most cases an entire family unit.

Post-partum psychosis is much more rare and more severe than either depression or the blues. It has a prevalence of approximately 1 in 500–1000 births, and a rapid onset within the first few days to two weeks post-partum (Brockington *et al.*, 1982). Post-partum psychosis, believed to be in most cases an episodic presentation of a manic-depressive illness, severely impairs the affected woman's ability to function. In the most extreme cases, the risks of suicide or infanticide are high (Millis and Kornblith, 1992), requiring admission to a psychiatric hospital (Kendell *et al.*, 1987).

Pregnancy and childbirth have an enormous combined psychological, physiologic and endocrine effect on a woman's body and mind. Since the changes in mood coincide with these profound changes in hormones and other humoral agents related to pregnancy and childbirth, a causal link has been supposed probable (Steiner, 1998). In the animal kingdom, maternal behaviour is mediated by hormonal and neurochemical changes associated with reproduction (Rosenblatt *et al.*, 1988). In animals, it has been suggested that the various neuromodulators be divided into groups which define their proposed role in maternal response: primers — most important during late pregnancy (e.g. steroid hormones and prolactin); triggers — released during parturition (e.g. oxytocin); and modifiers — of oxytocin release (e.g. beta-endorphins, other neurotransmitters) (Keverne and Kendrick, 1994). There is, of course, considerable scope for interactions between these changes and varying repertoires of maternal behaviour across different species (Fleming and Corter, 1988) and the relevance to human behaviour is as yet unclear.

The peak in mood disturbance during the blues at around the fifth day post-partum coincides with extreme hormonal fluctuations that are a natural consequence of parturition. These hormones act within the central nervous system at a variety of limbic sites known to be involved in emotional responses, arousal and reinforcement. Only a handful of studies have attempted to measure these changes, especially in gonadal hormones and prolactin. To date, most of the results do not seem to correlate strongly with changes in mood and are inconsistent. Serum allopregnanolone levels were shown to be lower in women experiencing post-partum blues (Nappi *et al.*, 2001), whereas serum testosterone levels have been

weakly correlated with depression and anger in the first post-partum days (Hohlagschwandter *et al.*, 2001). A rapid fall in progesterone showed a weak but significant relationship to the development of the blues in one study (Harris *et al.*, 1994) but not in another (Heidrich *et al.*, 1994).

Similarly, increased plasma cortisol levels correlated with the blues and with PPD in one study (Okano and Nomura, 1992) but not in others (O'Hara *et al.*, 1991; Smith *et al.*, 1990). Preliminary results suggest that natural-killer-cell activity is lower in post-partum dysphorics and that this decrease is related to higher levels of cortisol (Pedersen *et al.*, 1993a). In contrast, negative or false-positive results with the dexamethasone suppression test do not correlate with mood changes, indicating that the HPA axis is physiologically hyperactive post-partum ('ceiling effect') and measurements along this axis as an indicator for depression in this population are probably invalid (O'Hara *et al.*, 1991; Smith *et al.*, 1990; Steiner *et al.*, 1986). The HPA, rather than the HPG, axis may in fact play a unique role in human maternal behaviour. Euthymic new mothers with positive maternal attitudes and high levels of cortisol post-partum exhibit the highest level of post-partum maternal approach behaviour (Fleming *et al.*, 1987). None of the other hormones measured (oestradiol, progesterone, testosterone and thyroid indices) were correlated with any of the maternal behaviours measured (Fleming *et al.*, 1987, 1995). These results suggest that cortisol does not induce maternal behaviour directly but it probably facilitates maternal attitudes, which may then be expressed as emotions and/or behaviour.

Thyroid dysfunction has been implicated in mood disorders and it has been suggested that transient thyroid dysfunction following childbirth is associated with PPD (Pederson *et al.*, 1993b). In some women, pregnancy and the post-partum period are associated with pathological changes in thyroid function. A review of the literature in this area clearly indicates the possibility that a subgroup of women with PPD have a basis for the depressed mood in thyroid disorder. More specifically, in some women depressive symptoms are associated with positive thyroid antibody status during the post-partum period (Harris *et al.*, 1992). It is believed that 1% of all post-partum women will show a mood disorder associated with transient thyroid dysfunction, and treatment of the thyroid condition must be part of the management.

The direct and/or indirect effect of the rate of the post-partum withdrawal of some of the other major hormones and neuromodulators involved is nevertheless still intriguing. It has been suggested that women who experience a more rapid beta-endorphin withdrawal are more prone to mood changes (Smith *et al.*, 1990). A sharp fall in circulating oestrogen concentrations after delivery has been associated with acute onset of post-partum psychosis (Wieck *et al.*, 1991). These changes are believed to be the triggers to a cascade of changes at central and peripheral monoamine centres. Very preliminary data suggest an increased sensitivity of dopamine receptors in acute post-partum psychosis (Wieck *et al.*, 1991) and an abnormality in alpha$_2$ adrenoceptor sensitivity associated with the blues (Best *et al.*, 1988). Changes in sensitivities of serotonergic receptors have been documented in PPD (Hannah *et al.*, 1992), but not in women with the blues (Katona *et al.*, 1985).

More recently it has been hypothesized that PPD may be caused by transient hypothalamic corticotropin-releasing hormone (CRH) suppression (Magiakou *et al.*, 1996). The HPA axis is progressively hyperactive throughout pregnancy, with increasing levels of circulating CRH of placental origin and decreasing levels of CRH-binding protein. Both these phenomena, together with the elevated levels of oestradiol of pregnancy, which also stimulate the HPA axis, particularly during the third trimester, contribute to the elevated levels of CRH, ACTH and cortisol (Cizza *et al.*, 1997). After parturition the source of placental CRH is removed, and together with the post-partum oestrogen withdrawal, which is further prolonged by breastfeeding (Kim *et al.*, 2000), may lead to a prolonged state of HPA axis hypoactivity. Indeed, it has been demonstrated that in a subgroup of women with PPD, the suppression of the HPA axis was more severe and lasted longer than that of women who had no post-partum mood instability (Magiakou *et al.*, 1996).

CRH has been associated with the neurobiology of stress and depression (Chrousos and Gold, 1992). PPD also appears to be a state of central CRH dysregulation. With the additional established evidence of direct oestrogenic regulation of the CRH gene expression (Vamvakopoulos and Chrousos, 1993) it is therefore not surprising that oestrogen has been proposed as a treatment for PPD (Ahokas *et al.*, 2001; Gregoire *et al.*, 1996; Sichel *et al.*, 1995). In the only double-blind, placebo-controlled study published to date, a 3-month course of 200 μg per day of 17ß-oestradiol significantly improved the clinical symptoms of severely depressed women post-partum (Gregoire *et al.*, 1996). Unfortunately further research on the role of oestrogen therapy for PPD has not yet emerged. Similarly, progesterone has been widely used for the treatment of post-natal depression but without controlled trials (O'Brien and Pitt, 1994).

The role of hormone replacement therapy is of interest beyond the realm of the post-partum period and, as discussed in the next section, is of major relevance during the perimenopausal and menopausal years and beyond.

The reciprocal relationship between the serotonergic system and gonadal hormones has not as yet been studied during pregnancy or in post-partum women. However, preliminary results from studies in post-partum rats indicate that 5-HT receptor changes in the limbic area are negatively correlated with progesterone levels (Glaser *et al.*, 1990). It is argued that post-partum withdrawal of gonadal hormones may cause changes along the serotonergic cascade, which may lead to a mood disorder in vulnerable or genetically predisposed women. (It should therefore be possible to treat the disturbance by 'adjusting' the levels of the hormone (the trigger) (Henderson *et al.*, 1991) or by reversing the sensitivity (predisposition). Results from some preliminary studies on preventative interventions with lithium prophylaxis (Cohen *et al.*, 1995; Stewart *et al.*, 1991) and with SSRIs (Appleby *et al.*, 1997; Stowe *et al.*, 1995) are very encouraging. Since mood disorders associated with childbearing have different times of onset in different women and are heterogenous in their presentation, concomitant measurements of the changes over time in gonadal hormones and the biochemical changes in the monoamine system are crucial.

Further evidence of a biological component of post-partum mood disorders comes from family and family history studies. It has been suggested that women with a history of post-partum depression are differentially sensitized to mood-destabilizing effects of gonadal steroids (Bloch *et al.*, 2000). A study of women with post-partum mood disturbances and their first-degree relatives found that at least one family member met criteria for a past or present psychiatric disorder in 71% of the cases for which the information was available. Positive histories for MD and alcoholism were found in 48% and 30% of these families, respectively (Steiner and Tam, 1999). Further analysis of these data revealed an interesting gender distribution of psychiatric disorders in the first-degree relatives of the post-partum women. A female : male ratio greater than 2 : 1 was found in relatives with a past or present diagnosis of MD; in the case of alcoholism, a male : female ratio of 4 : 1 was evident. This lifetime prevalence of mood-related disorders in the first-degree relatives of women presenting with post-partum mood disorders is much higher than in the population at large and may indicate potential genetic or familial components of the disorders.

Despite the fact that most animals share the same physiological events at parturition, the differences in behavioural response between humans (as well as other primates) and non-primate mammals are remarkable. The differences between primates and non-primates are mainly in the organization of social structures, the

complex influences of the family unit, and the constant exposure of all members of a group to the young. It is therefore easy to assume that, in humans, even thinking about children may be sufficient to stimulate maternal responsiveness. The psychosocial literature to date has advanced several psychological and social stress factors as potential aetiological theories of primary non-psychotic PPD. These factors include lack of social support, negative life events, occupational instability, lack of prior experience with children, unplanned pregnancy and antenatal 'pessimism', dissatisfaction with the marital relationship (or being unmarried), and a poor relationship between the affected woman and her own mother (Murray *et al.*, 1995; Paykel *et al.*, 1980).

In summarizing these studies, no unifying conclusion can be reached, and it is impossible at this stage to translate any of these results into predictive, diagnostic, therapeutic, prognostic or preventative applications. It seems more likely that an intrinsic abnormal reaction to some of the hormonal changes, rather than the changes themselves, is responsible for the disorder. If the psychobiological factors (or their interactions) responsible for the emotional disorders associated with childbearing could be elucidated, our understanding of the aetiology not only of PPD but also of a wider range of psychiatric disorders might be enhanced.

PERIMENOPAUSE, MENOPAUSE AND BEYOND

The transition into menopause is a major hormonal event and is associated in many women with both physical and psychosocial symptoms. The term perimenopause describes the period immediately before the menopause — from the time when the hormonal and clinical features of approaching menopause commence until the end of the first year after menopause (World Health Organization, 1996b).

The physiological hallmark of the transition into menopause is gradual oestrogen depletion. In the 1960s and 1970s 'depletion' was equated with 'deficiency' and menopause, representing a state of oestrogen deficiency, was therefore considered a medical disorder warranting treatment. A famous quotation from that era highlights this approach: 'It sometimes seems as if the only thing worse than being subjected to the raging hormonal influences of the female cycle is to have those influences subside' (Parlee, 1976). The notion of universal hormone replacement for *all* menopausal women was so rampant that the WHO convened a special session and eventually came out with a consensus statement to counter the above, which read: 'Menopause is part of the normal aging process which in itself does not require therapeutic intervention. The health status of women during this period is not recognized as being a simple endocrine-deficiency state which could or should be corrected by attempting to create for each woman a premenopausal normal environment' (WHO, 1981).

Changes most commonly associated with oestrogen depletion (and/or unpredictable fluctuations) include vasomotor symptoms such as hot flushes and night sweats (Freedman, 2000; Guthrie *et al.*, 1996), urogenital dryness/atrophy causing dyspareunia as well as an increased risk over time of osteoporosis and cardiovascular disease (Mitchell and Woods, 1996). The relationship between the perimenopause/menopause and mood disorders is less well understood. Epidemiological data indicates that the majority of postmenopausal women do not experience prominent symptoms of depression, but a higher than expected prevalence of depressive-like symptoms has been observed in peri- and postmenopausal women attending gynaecological clinics (Avis and McKinlay, 1991; Schmidt and Rubinow, 1991).

It is unclear as to whether there is decline in new-onset episodes of major depression in females of this age group, as suggested by the Epidemiologic Catchment Area study, a finding not supported by data from the National Comorbidity Survey. The role of sociocultural factors and demographic differences have been the focus of much study but the results are controversial (Anderson *et al.*, 1987; Hay *et al.*, 1994).

Some cross-cultural differences are nevertheless noteworthy: Japanese women experience very few physical as well as emotional symptoms around menopause. It has been proposed that these findings are indicative not only of cultural and demographic differences but also reflect the influence of biological, genetic and nutritional/dietary factors (Lock, 1994; Nagata *et al.*, 1998).

The most prevalent mood symptoms during the perimenopause include irritability, tearfulness, anxiety, depressed/labile mood, lack of motivation/energy, poor concentration and interrupted sleep. These symptoms have been linked to predictable fluctuations in oestradiol, especially abrupt withdrawal from very high erratic levels, rather than to times when levels are slowly and gradually declining (Prior, 1998).

Several lines of evidence point to the link between oestrogen depletion/deficiency and mood disorders in vulnerable or predisposed women. Oestrogen has direct effects on the CNS in areas which are not strictly relevant to reproduction. For example, oestrogen regulates synaptogenesis, has a general trophic effect on cholinergic neurons and stimulates a significant increase in 5-HT_{2A} binding sites in areas which are involved in regulating both mood and cognition. It is therefore not surprising that oestrogen has been shown to improve psychological functioning and well-being in nondepressed postmenopausal women (Ditkoff *et al.*, 1991; Palinkas and Barret-Connor, 1992) and that oestrogen replacement therapy (ERT) has a positive effect on mood states (Zweifel and O'Brien, 1997). The ability of oestrogen to act as a 5-HT agonist/modulator is of particular significance. Oestrogen not only increases the number of 5-HT_{2A} receptor binding sites but also increases 5-HT synthesis, uptake and 3H-imipramine binding; it decreases 5-HT_1 receptor binding sites and 5-HT transporter mRNA and increases the prolactin response to 5-HT agonists — all in line with antidepressant-like action (Biegon and McEwen, 1982; Fink *et al.*, 1996; Halbreich *et al.*, 1995; Pecins-Thompson *et al.*, 1998; van Amelsvoort *et al.*, 2001). The clinical relevance of these effects to the pathophysiology of women-specific mood and anxiety disorders remains to be determined.

The strongest evidence to date for oestrogen's ability to improve mood and cognitive functioning comes from studies in young surgically menopausal women treated with ERT (Sherwin, 1988; Sherwin and Suranyi-Cadotte, 1990). It is encouraging to note that several very preliminary studies seem to indicate the beneficial effects of combining ERT with SSRIs in the treatment of postmenopausal depressed women (Schneider *et al.*, 1997). Preliminary evidence also indicates the efficacy of transdermal 17ß-oestradiol alone in the treatment of perimenopausal women with major and minor depression (Schmidt *et al.*, 2000; Soares *et al.*, 2001).
