The aetiology of sporadic Alzheimer's disease is complex. The well-established risk factors include ageing, gender, and some genetic and environmental factors. No single cause have been identified that can be considered to be responsible for the disease, even though a combination of pathological events in genetically predisposed individuals may be considered to initiate and facilitate Alzheimer's disease pathology.

IS ALZHEIMER'S DISEASE AN IMMUNOLOGICAL DISORDER?

The idea that inflammation may contribute significantly to the pathogenesis of Alzheimer's disease has been supported as well as it has met resistance from both neuroscientists and immunologists. One of the greatest problems in evaluating the inflammatory parameters in Alzheimer's disease is related to the long progression of the disease. The possible contribution of inflammation in the pathogenesis of Alzheimer's disease is not stationary but varies with the progression of the disease, making the estimation of inflammation at any given moment difficult. The studies on brain tissue are made mostly in the final stages of the disease, and the analysis of blood and cerebrospinal fluid reflecting the events in the brain parenchyma are still quite scarce. The major objection has been related to the fact that Alzheimer's disease pathology lacks evidence for a classical immune-mediated response.

Some studies have reported a few T-cells in Alzheimer's diseased brains (McGeer *et al.*, 1989b; Rogers *et al.*, 1988), but numbers of inflammatory cells have generally been insignificant and results have not been convincing. Moreover, expression of molecules required for the recruitment of leucocytes from the blood, such as vascular adhesion molecule 1 and endothelial selectin, has not been shown in endothelial cells of brain capillaries in Alzheimer's diseased brains (Eikelenboom and Veerhuis, 1996; Eikelenboom *et al.*, 1998). Recently, however, many immunohistochemical, biochemical and molecular studies have indicated that inflammation is associated with Alzheimer's disease pathology, whereas the inflammation has been shown to be virtually nonexistent in brain tissue from normal aged individuals (McGeer and McGeer, 1999; Rogers *et al.*, 1996).

Various elements of the immune system, including features associated with both the innate and adaptive immune mechanisms, are associated with neuritic plaques and tangles. It is evident that a complex network of glial cells, cytokines, complement activation, growth factors, and oxidative stress is involved in Alzheimer's disease pathogenesis. Due to the highly interactive nature of these inflammatory subsystems, it is not plausible that any single pathway is more important than another in Alzheimer's disease pathophysiology. How, and to what extent, these inflammatory mechanisms contribute to cell death and evolution of other lesions in the Alzheimer's diseased brain remains to be resolved.

Table XV-6.1 lists the inflammatory mediators and proteases that have been found in association with amyloid plaques.

The complex inflammatory mechanisms may (1) modify the secretion and processing of the β-amyloid precursor protein (βPP); (2) modify the deposition or fibrillization of Aβ protein, a constant feature of Alzheimer's disease; (3) cause cell damage by the activation of the classic complement pathway, or by the release of potentially toxic products such as proteases, nitric oxide and free radicals; or (4) induce an abortive regenerative response in Alzheimer's diseased brains.

That the inflammatory response contributes to several crucial events in the pathogenetic cascade of Alzheimer's disease has been supported by various studies. Recent epidemiological data suggest that chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs) reduces the risk of Alzheimer's disease (McGeer and McGeer, 1998; Rich *et al.*, 1995). The regional variability in the upregulation of inflammatory mechanisms is in concordance with the regional variability of Alzheimer's disease lesions. This is demonstrated clearly by the differences between cerebral and cerebellar pathology in Alzheimer's diseased brains (Brachova *et al.*, 1993; Kida *et al.*, 1995; Lue and Rogers, 1992). Whereas diffuse Aβ deposits are found in abundance in the cerebellum, neuritic plaques are virtually absent. On the other hand, the numbers of activated microglia and acute-phase proteins are lower in the cerebellum than in the cerebral cortical areas. Furthermore, most of the inflammatory mechanisms that seem to operate in the Alzheimer's diseased brain are cytotoxic in the periphery (Akiyama *et al.*, 2000). There are no reasons to think that the brain would be resistant to these toxic influences. Moreover, non-demented patients displaying some Alzheimer's disease pathology show only modest inflammatory reaction in their brains as compared with extensive neuroinflammation in demented patients with extensive Alzheimer's disease pathology (Hull *et al.*, 1995; Lue *et al.*, 1996). Cathepsins (B, D, E, H, L, S)
Cystatins (A, C)
Thrombin
Tissue plasminogen activator
Integrins
ICAM-1

support for the notion that chronic inflammation contributes to the pathology of Alzheimer's disease comes from animal studies. In rats, chronic lipopolysaccharide (LPS) infusion into the fourth ventricle leads to spatial memory impairment and hippocampal pyramidal cell loss (Hauss-Wegrzyniak *et al.*, 1998), enlargement of the lateral ventricles and decrease of the hippocampal volume and the temporal lobe structures (Hauss-Wegrzyniak *et al.*, 2000), and a decrease of choline acetyltransferase activity within the basal forebrain region (Wenk *et al.*, 2000).

AMYLOID: A CENTRE OF INFLAMMATORY REACTION

The core protein of amyloid plaques is a 4–kDa peptide, Aβ, that is derived from a much larger precursor protein, βPP (Kang *et al.*, 1987). Several isoforms of βPP are generated by alternative splicing of mRNA transcribed from a single gene on chromosome 21 (Ashall and Goate, 1994). βPP is synthesized as an integral membrane molecule, whereas Aβ is secreted as a product of proteolytic cleavage of βPP (Selkoe, 1994).

Aβ accumulates in the neuropil either as diffuse protein aggregates (diffuse plaques) that contain non-fibrillar Aβ, or as fibrillary Aβ, a major constituent of neuritic plaques. The complex structure of neuritic plaques also includes abnormal neurites with paired helical filaments and activated glial cells (Wisniewski and Wegiel, 1995). It appears that the fibrillar but not the diffuse Aβ protein deposits are involved in neuronal degeneration. This is supported by the finding that microinjection of soluble Aβ into the brains of experimental animals does not induce neuronal degeneration (Winkler *et al.*, 1994). Furthermore, the presence of numerous diffuse plaques in brains from elderly non-demented individuals (Tagliavini *et al.*, 1988) and concomitant lack of neuritic pathology indicate that the mere presence of Aβ deposits seems insufficient to induce cytopathology. Many different laboratories have shown that aggregation or fibrillization of Aβ is necessary for neurotoxicity (Selkoe, 1994). Immunohistochemical studies have shown diffuse foci of Aβ without evidence of neuropil pathology (Tagliavini *et al.*, 1988), whereas in neuritic plaques the fibrillar Aβ peptide is associated with abnormal neurites, activated microglia and reactive astrocytes (Figure XV-6.1).

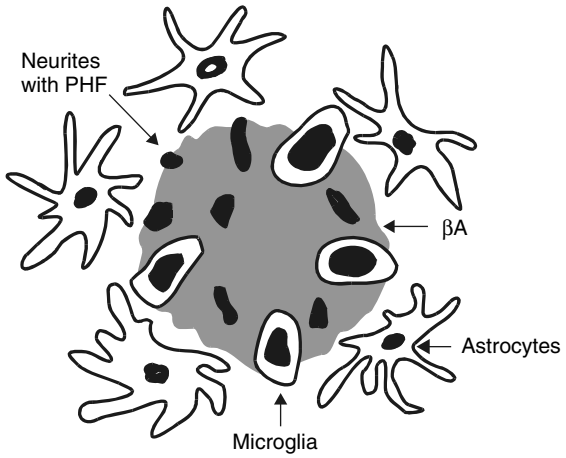

Figure XV-6.1 Schematic presentation of a neuritic plaque and location of glial cells in association with the plaque. Centrally located Aβ aggregates are surrounded by astrocytes. In the middle of the accumulated protein are seen microglial cells and neurites containing paired helical filaments (PHF) with hyperphosphorylated tau

Why does Aβ fibrillize or remain soluble? The stab-wound experiments and studies of transgenic mice show that neither overexpression of βPP alone, nor the presence of soluble Aβ protein, leads to amyloid formation (Fukuchi *et al.*, 1994; Sandhu *et al.*, 1991). Test-tube studies of synthetic Aβ peptides showed that fibril formation is influenced by Aβ peptide concentration, pH, length of Aβ peptide, and interaction with other proteins (Selkoe, 1994). Current data indicate that additional factors, such as some components of basement membrane or extracellular matrix, and Aβ carrier proteins, affect fibrillization of Aβ (Kisilevsky and Fraser, 1997). Amyloid component P or components of basement membrane and extracellular matrix may promote the initial steps in fibril formation (Leveugle and Fillit, 1994; Tennent *et al.*, 1995). The highly sulphated proteoglycans of extracellular matrix promote aggregation of Aβ peptide (Snow *et al.*, 1994), immobilize apolipoprotein E (apoE) in the amyloid aggregates (Ji *et al.*, 1993), and lead to aggregates of Aβ. The intermediating processes causing cell damage include neurotoxicity of fibrillar Aβ, oxidative injury and immune activation.

GLIAL CELLS

One of the major differences between diffuse and neuritic plaques is the presence of glial cells. Microglia and astrocytes are associated with neuritic plaques but are lacking from most diffuse plaques.

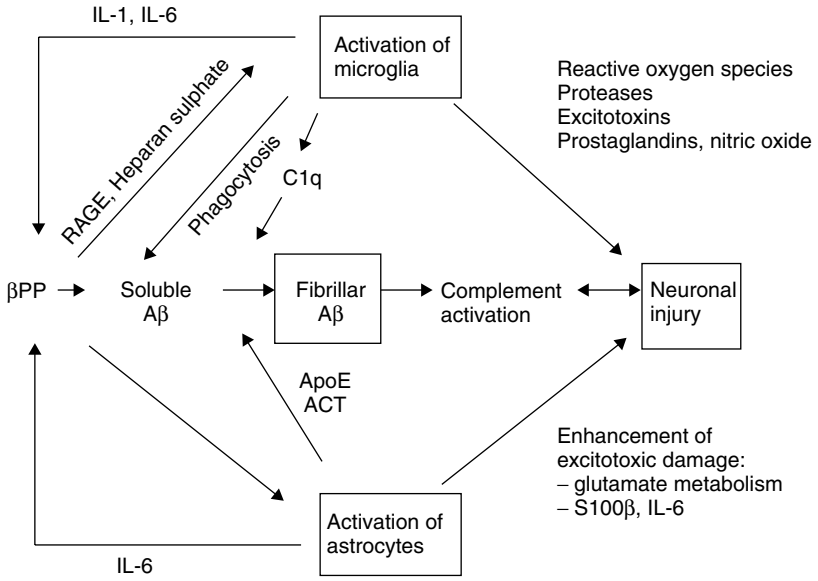

Figure XV-6.2 Activated glial cells produce substances that contribute to the production and fibrillization of Aβ and neuronal injury in the pathogenesis of Alzheimer's disease

The expression of microglial activation markers, such as class II major histocompatibility antigens, Fc-receptors, receptors belonging to the leucocyte adhesion family (β-2 integrins), and the vitronectin receptors, has been shown to be enhanced in Alzheimer's diseased brains (Akiyama *et al.*, 1991; Eikelenboom *et al.*, 1998; McGeer *et al.*, 1994; Overmyer *et al.*, 1999a). Moreover, microglia associated with neuritic plaques show intensive staining for many interleukins, such as interleukin 1 alpha (IL-1α), interleukin 1 beta (IL-1β), interleukin 6 (IL-6) and tumour necrosis factor (TNF) (Eikelenboom *et al.*, 1994; McGeer and McGeer, 1999). Immunohistochemical studies have shown that a number of complement factors of the classical complement pathway and their inhibitors are localized in both diffuse and/or neuritic plaques in the neocortex and cerebellum in patients with Alzheimer's disease and Down's syndrome (Eikelenboom and Stam, 1982; Kalaria, 1993; McGeer *et al.*, 1994). While many acute-phase proteins (α1-antitrypsin, α1-antichymotrypsin (ACT), α2-macroglobulin C-reactive protein (CRP), amyloid P component) are found in neuritic plaques, only some of them (amyloid P component and ACT) are also present in diffuse plaques (Eikelenboom *et al.*, 1994; Kalaria, 1993). A variety of cell-adhesion molecules (integrins, intercellular adhesion molecule 1 (ICAM-1), vitronectin) are also found in association with neuritic plaques (Eikelenboom *et al.*, 1998).

Glial Activation in the Alzheimer's Diseased Brain

Present data suggest that a low-grade chronic inflammatory response is operating in Alzheimer's disease. Activated microglia seem to be the main immunocompetent cells contributing to the response. The signals leading to the microglial activation in the Alzheimer's diseased brain are not clear. Recent studies have shown that residues 13–16, the HHQK domain of the Aβ protein, bind to microglial cells (Giulian *et al.*, 1998), and the interaction between Aβ protein and microglia has been shown to be mediated by microglia-associated heparan sulphate. Other studies have shown that Aβ binds to microglia via the receptor for advanced glycated end-products (RAGE) (Yan *et al.*, 1996) or the scavenger receptor (El Khoury *et al.*, 1996). More recent data also imply CD40–CD40L interaction in microglial activation (Tan *et al.*, 1999). The interaction between Aβ protein and microglia may be essential for neurotoxicity.

Microglial activation may contribute to Alzheimer's disease pathogenesis and cell death in many ways (Figure XV-6.2). Activated microglia secrete proinflammatory cytokines, such as IL-1 and IL-6, and some growth factors, which have been shown to stimulate βPP mRNA and induce increased production and altered processing of βPP in neuronal or endothelial cell cultures (Del Bo *et al.*, 1995; Forloni *et al.*, 1992; Ohyagi and Tabira, 1993; Vasilakos *et al.*, 1994). In turn, Aβ stimulates glial cells in culture to produce cytokines such as IL-1, TNF-α and basic fibroblast growth factor (BFGF) (Araujo and Cotman, 1992; Meda *et al.*, 1995), and thus enhances the vicious circle. Many studies have shown that Aβ stimulates microglia via the same signalling pathways that are employed by classical immune stimuli (McDonald *et al.*, 1997; McDonald *et al.*, 1998). *In vitro* studies suggest that Aβ by itself is a weak activator of microglia, whereas Aβ in association with augmenting proinflammatory signals stimulates a robust microglial response (Araujo and Cotman, 1992; Yates *et al.*, 2000). While LPS or interferon gamma (IFN-γ) have not been detected in Alzheimer's diseased brain, macrophage colony-stimulating factor (M-CSF) is elevated in cerebrospinal fluid of Alzheimer's disease patients (Du *et al.*, 1997). The important role of M-CSF is supported further by the finding that stimulation of RAGE receptor induces M-CSF (Yan *et al.*, 1997), whereas RAGE receptor is suggested to be a ligand for Aβ. The expression of the receptor of M-CSF (M-CSFR) is increased on plaque-associated microglia (Akiyama *et al.*, 1994), and M-CSF has been shown to augment microglial activation by Aβ (Murphy *et al.*, 1998). Increased expression of M-CSFR has also been shown after mechanical brain injury or ischaemia (Raivich *et al.*, 1998; Wang *et al.*, 1999). Investigators have also reported expression of M-CSFR in AβPPV717F mice that show extensive microglial activation (Murphy *et al.*, 2000). The latter data suggest that M-CSF and M-CSFR have pathophysiological relevance in Alzheimer's disease.

A possible role of microglia in the plaque evolution could be direct synthesis of βPP and Aβ by the cells. Electron-microscopical studies have indicated that newly formed amyloid fibrils appear in the deep cytoplasmic membrane infoldings and channels of

microglia (Wegiel and Wisniewski, 1990; Wisniewski *et al.*, 1989; Wisniewski *et al.*, 1990). Furthermore, there are data indicating that microglia may be involved in conversion of non-fibrillar Aβ into insoluble fibrils (Shirahama *et al.*, 1990; Wisniewski *et al.*, 1989). Many studies have also shown that microglia phagocytose exogenous fibrillar Aβ (Shaffer *et al.*, 1995; DeWitt *et al.*, 1998).

In addition, there are many indirect mechanisms through which microglial activation in the Alzheimer's diseased brain might be harmful. Activated microglia secrete a variety of other neurotoxic factors, such as eicosanoids, free radicals and nitric oxide, as well as proteases, protease inhibitors and excitotoxins (Cotter *et al.*, 1999; Eikelenboom *et al.*, 1994; Espey *et al.*, 1997; Lipton and Gendelman, 1995; Giulian *et al.*, 1995; McGeer and McGeer, 1989b). *In vitro* experiments demonstrate that activation of microglia by Aβ leads to the production of reactive nitrogen intermediates and neuronal cell injury (Meda *et al.*, 1995; Goodwin *et al.*, 1995; Li *et al.*, 1996). Investigators have shown that a neurotoxic amine secreted by plaque-associated activated microglia destroys hippocampal pyramidal cells (Giulian *et al.*, 1995). Moreover, activated microglia secrete glutamate (Piani *et al.*, 1992), which may influence synapses and dendrites without killing the entire neuron.

Whereas the microglia are located in the plaques in the midst of the Aβ protein, surrounding the protein aggregates are numerous reactive astrocytes displaying fibrous processes and increased immunoreactivity for glial fibrillary acidic protein (GFAP) (Mandybar and Chuirazzi, 1990; Pike *et al.*, 1995; Overmyer *et al.*, 1999a). The extent of GFAP correlates with both the density of neocortical neurofibrillary tangles (Harpin *et al.*, 1990; Overmyer *et al.*, 1999b) and the number of neuritic plaques (Overmyer *et al.*, 1999b).

Aβ has been shown to induce stellate cell morphology and proliferation of astrocytes *in vitro* (Araujo and Cotman, 1992; Hu *et al.*, 1998; Kerokoski *et al.*, 2001; Singh *et al.*, 1994), although the mechanisms of this proliferative effect of A$\beta(1-42)$ are unknown. Aβ also stimulates the production of cytokines or nitric oxide in astrocyte cell cultures (Araujo and Cotman, 1992; Hu *et al.*, 1998; Pike *et al.*, 1994). The positioning of astrocytes in the surrounding of the protein aggregates is such that they may create a barrier that prevents Aβ phagocytosis. Moreover, astrocytes secrete proteoglycans that greatly inhibit the microglial attack (DeWitt *et al.*, 1998). On the other hand, reactive astrocytes secrete acute-phase proteins, which may contribute to Aβ fibrillogenesis (Koo *et al.*, 1991). For example, α1-ACT has been shown to enhance fibril formation of Aβ (Fraser *et al.*, 1993; Ma *et al.*, 1999).

Astrocytes are involved in supportive functions of the brain. They maintain ionic homeostasis, remove neurotransmitters such as glutamate thus preventing excitotoxicity, release growth factors, and participate in inflammatory responses. Another mechanism by which astrocytes may contribute to Alzheimer's disease pathogenesis is disruption of homeostatic and neurotrophic functions. Cytokines may stimulate production of prostaglandins (Parpura-Gill *et al.*, 1997; Katsuura *et al.*, 1989), which can elevate the extracellular concentration of glutamate by inducing its release from astrocytes (Bezzi *et al.*, 1998) or inhibiting its reuptake by astrocytes (Rothstein *et al.*, 1993). These changes will augment the excitotoxic damage.

Many protease inhibitors have potential neurite growth-promoting activity, and they may be released from astrocytes in response to neuronal degeneration (Kalaria, 1993). Investigators have demonstrated signs of a regenerative process in Alzheimer's diseased brains that may involve a complex network of proteases, cytokines, growth-promoting factors, protease inhibitors, integrins and adhesion molecules (Eikelenboom *et al.*, 1994). The relationship between apoE and Aβ has been studied widely since the apoE ε4 allele was shown to be the most important risk factor for the development of Alzheimer's disease (Corder *et al.*, 1993; Saunders *et al.*, 1993). ApoE is involved in transport and cellular uptake of lipid complexes via the low-density lipoprotein receptor (LDL-R) and the low-density lipoprotein receptor-related related protein (LRP) receptor (Mahley, 1988). Both of these receptors are expressed in human brain (Rebeck *et al.*, 1993; Rebeck *et al.*, 1995). ApoE binds to Aβ (Strittmatter *et al.*, 1993), and is colocalized with Aβ in plaques (Namba *et al.*, 1991). It has been suggested that LRP-mediated uptake of apoE/Aβ complexes may be a mechanism of Aβ clearance from the neuropil (Rebeck *et al.*, 1993; Rebeck *et al.*, 1995), and the risk associated with the ApoE genotype would then be related to the clearance of the Aβ from the neuropil. This is also supported by the high load of Aβ in the brain tissue of individuals carrying one or two copies of the apoE ε4 allele (Alafuzoff *et al.*, 1999).

Another important acute-phase protein implicated in the clearance of Aβ is α2-macroglobulin (α2-MG). This binds to a variety of other proteases, including ACT, forming a complex that is removed by endocytosis via α2-MG receptor (α2-MACR)/LRP (Borth, 1992). Moreover, the same endocytic pathway may operate in the clearance of many other inflammatory proteins, such as apoE, APP, IL-1β, and even Aβ itself (Borth, 1992; Narita *et al.*, 1997), and thus attenuate Aβ fibril formation and inflammation in the Alzheimer's diseased brain.

In cerebrospinal fluid, soluble Aβ forms complexes with apoE and apolipoprotein J (apoJ) (Ghiso *et al.*, 1993). Binding of Aβ with carriers or chaperon proteins, including transthyretin (Schwarzman *et al.*, 1994) and apolipoproteins E, J and A1 (Ghiso *et al.*, 1993; Koudinow *et al.*, 1994; Strittmatter *et al.*, 1993; Zlokovic *et al.*, 1994), is now considered a physiological mechanism in mediating solubility, transport and clearance of Aβ.

INTERLEUKIN 1 AND 6 AND BRAIN ACUTE-PHASE RESPONSE

In 1991, Vandenabeele and Fiers suggested that amyloidogenesis in the Alzheimic diseased brain could be due to an IL-1/IL-6-mediated acute-phase response. Since then, the role of proinflammatory cytokines IL-1α, IL-1β and IL-6 in the Alzheimer's disease pathogenesis have been studied extensively. Overexpression of these molecules has been shown consistently in the Alzheimer's diseased brain (Cacabelos *et al.*, 1994; Griffin *et al.*, 1998; Strauss *et al.*, 1992; Wood *et al.*, 1993).

Griffin *et al.* (1998) and Sheng *et al.* (1996) have promoted a hypothesis whereby microglia-associated IL-1 overexpression has a role in the pathogenic cascade in Alzheimer's disease. IL-1 overexpression seems to occur early in the plaque formation (Griffin *et al.*, 1989). IL-1 promotes synthesis and processing of βPP (Goldgaber *et al.*, 1989; Buxbaum *et al.*, 1992), astrocyte activation (Griffin *et al.*, 1989), and formation of dystrophic neurites and neuritic plaques (Mrak *et al.*, 1995). IL-1 can activate astrocytes to produce acute-phase proteins and other cytokines, such as S100β, IL-6 and interleukin 8 (IL-8) (Das and Potter, 1995; Sheng *et al.*, 1996). Elevation of protein and mRNA levels of S100β (Marshak *et al.*, 1992) in the Alzheimer's diseased brain is of particular interest, since the neurite-promoting actions of this cytokine may be a driving force in the development of dystrophic neurites (Mrak *et al.*, 1996). Animal studies have, on the other hand, implicated IL-1 in memory deficits and reduced long-term potentiation in ageing rat hippocampus (Lynch, 1998), and in hippocampal cell damage (Araujo, 1992). IL-1 also increases acetylcholinesterase activity and may thus exacerbate cholinergic dysfunction in Alzheimer's disease (Li *et al.*, 2000).

IL-6 is expressed in the nervous system during development and affects cell growth and differentiation (Satoh *et al.*, 1988; Nakashima *et al.*, 1999). Normal adult central nervous system (CNS) contains barely detectable levels of IL-6, but the expression of IL-6 is elevated strongly under pathological conditions (Frei *et al.*, 1989; Vallieres and Rivest, 1997). Receptors for IL-6 have been detected on neurons (Marz *et al.*, 1996), and many studies

have indicated that IL-6 has an important role in neuronal survival and function (Campbell, 1998; Gadient and Otten, 1997). On the other hand, chronically elevated levels of IL-6 may be destructive, as shown in the experiments with transgenic mice overexpressing IL-6 (Heyser *et al.*, 1997). These mice exhibited age-related neuropathology and deficits in avoidance learning. Upregulation of IL-6 in the Alzheimer's diseased brain seems to be an early phenomenon, as immunohistochemical studies have shown colocalization of IL-6 with diffuse plaques before development of neuritic pathology (Hull *et al.*, 1996). IL-6 may modulate βPP metabolism (Ringheim *et al.*, 1998), influence neuronal functions via induction of ERK1/ERK2 and STAT3 activation (Schuman *et al.*, 1999), and increase synthesis of plaque-associated acute-phase proteins, such as α2-MG (Ganter *et al.*, 1991; Strauss *et al.*, 1992).

Glial activation and overexpression of both IL-1 and IL-6 may be a driving force for the amyloid-associated acute-phase response. A variety of acute-phase reactants, including the pentraxins serum amyloid protein (SAP) and CRP and the protease inhibitors α1-ACT, α1-antitrypsin and α2-macroglobulin, have been shown in association with amyloid deposits. The role of these molecules in fibrillization and clearance of Aβ has already been discussed. The other interesting aspect of brain acute-phase response is that βPP has a number of properties in common with acute-phase proteins. IL-1 increases synthesis of βPP (Goldgaber *et al.*, 1989), and its expression is upregulated after tissue damage (Banati *et al.*, 1994). βPP may enhance neuroinflammation by inducing IL-1 and nitric oxide synthase (Berger and Harmon, 1997). On the other hand, βPP has neurotrophic and neuroprotective effects after transient ischaemia or excitotoxic injury (Masliah *et al.*, 1997; Smith-Swintosky *et al.*, 1994).

COMPLEMENT ATTACK IN THE ALZHEIMER'S DISEASED BRAIN

The complement system seems to be involved intrinsically in cerebral amyloidosis, and increasing evidence links complement activation in the progression of pathology in Alzheimer's diseased brains (see Akiyama *et al.*, 2000). Some studies suggest that complement production in the Alzheimer's diseased brain may be as great as that in the liver, the primary source of complement in the periphery (Yasojima *et al.*, 1999). Complement pathways may contribute to Alzheimer's disease pathology indirectly, via interactions with Aβ, or directly, causing neuronal damage.

The pattern of complement fragments in Alzheimer's diseased brains indicates activation of the classical complement pathway (Kalaria, 1993; McGeer *et al.*, 1994). Lack of immunoglobulins in neuritic plaques indicates that instead of immune complex-mediated complement activation, antibody-independent mechanisms are operative in Aβ plaques. The classical complement pathway consists of tens of components that are activated sequentially in an amplifying cascade (Akiyama *et al.*, 2000). The cascade is activated when C1q binds to activating molecules, such as antibodies, CRP, SAP and DNA. Unless inhibited, the reaction leads to formation of C5b-9, the membrane attack complex (MAC), which assembles on a cell membrane creating a transmembrane channel, which permits the diffusion of ions and small molecules across the membrane. This may lead to disruption of calcium homeostasis, and ultimately result in cell lysis. Many studies have consistently shown that fibrillar Aβ (Jiang *et al.*, 1994; Rogers *et al.*, 1992; Webster *et al.*, 1997b), and also tau-containing neurofibrillary tangles (McGeer *et al.*, 1989a; Rogers *et al.*, 1996), can directly activate the classical complement pathway and lead to formation of MAC *in vitro*. A direct linkage between Aβ and complement activation was first established by Rogers *et al.* (1992), who showed that Aβ could activate the classical complement pathway in an antibody-independent manner. Other studies have showed that C1 activation is dependent on aggregation of Aβ (Jiang *et al.*, 1994; Webster *et al.*, 1997a). An amino acid sequence on the human C1q A-chain within the collagen-like domain of C1q (residues 14–26) contains five cationic side chains that bind in a charge-based fashion to anionic side chains in the N-terminus of human Aβ (Jiang *et al.*, 1994). C1 activation by Aβ corresponds to that by other non-immune activators, such as CRP, RNA and DNA, that contain a high density of negative charges, thus providing the possibility of multivalent binding (Cooper, 1985). One requirement for C1 activation by Aβ is that the peptide is in a beta-pleated sheet, multimeric form (Webster *et al.*, 1997a). Inhibition studies have implicated Aβ residues 1–11 in C1q binding (Webster *et al.*, 1997b), and at least two negatively charged residues, Asp 7 and Glu 11, as critical for the C1 activation (Velazquez *et al.*, 1997). The latter leads to generation of C3 and C4 fragments. Recent studies have also shown that Aβ forms covalent ester-linked complexes with C3 activation fragments. After incubation of fibrillar Aβ with a complement source, the C5a activation fragment is generated, which mediates formation of the proinflammatory C5b-9 membrane attack complex (Bradt *et al.*, 1998; Webster *et al.*, 1997c). In addition to the classical pathway, fibrillar Aβ can directly activate the alternative complement pathway in serum, as well as in mixtures of purified proteins of the alternative pathway (Bradt *et al.*, 1998). The activation of complement pathways by fibrillar Aβ appears to be a specific process, as other peptides of similar size and charge, such as fibrillar amylin, lack the ability to activate complement pathways (Bradt *et al.*, 1998).

Immunohistochemical data indicate that complement activation occurs *in vivo* in Alzheimer's diseased brains. Levels of mRNA of complement proteins are upregulated in Alzheimer's diseased brains (Shen *et al.*, 1997). Many complement proteins, including C1q, C4, C3, C5, C6, C7, C8, C9, activation fragments of C3 and C4, and MAC colocalize with Aβ deposits and neurofibrillary tangles (Alafuzoff *et al.*, 1987; Eikelenboom and Stam, 1982; McGeer *et al.*, 1989a; Rogers *et al.*, 1992). The covalently bound C3b molecules in neuritic plaques may remain bound and provide a nidus for chronic complement activation (Bradt *et al.*, 1998). Many studies have shown that MAC is fixed in membranes of dystrophic neurites (Itagaki *et al.*, 1994; Webster *et al.*, 1997c), which show signs of cells under complement attack: blebbing and endocytosis of their membrane at the site of fixed complement (Webster *et al.*, 1994). C5b-9 complexes may not be directly cytotoxic for neurons, since they bear CD59 (Morgan and Gasque, 1996), but they may alter functional properties of the neurons over time. The upregulation of complement defence proteins, including C4 binding protein, vitronectin and clusterin (apoJ), gives further support for the hypothesis that complement activation is a pathophysiologically relevant process in the Alzheimer's diseased brain and contributes to neurodegeneration. ApoJ is expressed by several cell types, and in neurons apoJ mRNA is induced in response to excitotoxins (Morgan *et al.*, 1999). In the Alzheimer's diseased brain, apoJ is expressed particularly in dystrophic neurons.

In addition to complement-mediated cell damage, plaque-associated complement activation products, such as C5a, provide chemotactic and activating signals to microglia and astrocytes. Glial cells express complement receptors, including C1qR, CR1, CR3, CR4, C3aR and C5aR (Gasque *et al.*, 1997; Lacy *et al.*, 1995; Webster *et al.*, 2000a). Activation of complement and resulting chemotactic signals may be one explanation for the presence of reactive astrocytes and activated microglia in the close proximity of amyloid plaques. Interestingly, C1q inhibits Aβ uptake by cultured microglia (Webster *et al.*, 2000b), and may thus influence the clearance of extracellular Aβ.

The proteins of the complement pathways may also contribute to amyloid formation in Alzheimer's diseased brains. Aβ/C1q binding may also enhance fibrillization of Aβ (Webster *et al.*, 1995). C1q is a hexamer that contains six identical subunits and C1q A-chains.

Thus, C1q may nucleate and stabilize the formation of Aβ fibrils by binding multiple Aβ molecules in its beta-pleated configuration. Furthermore, many studies have shown that apoJ binds Aβ and may be an important carrier of Aβ in blood (Matsubara *et al.*, 1996; Shayo *et al.*, 1997). There is evidence that apoJ facilitates Aβ transport across the blood–brain barrier (Zlokovic *et al.*, 1994; Shayo *et al.*, 1997). Some studies have also indicated that binding of apoJ to Aβ may decrease the formation of oligomeric Aβ (Choi-Miura and Oda, 1996; Matsubara *et al.*, 1996).

Complement involvement in the brain is not dependent on disruption of the blood–brain barrier, since neurons, astrocytes, microglia and oligodendrocytes synthesize most of the proteins of the complement system (Morgan and Gasque, 1996). *In situ* hybridization studies indicate that neurons can express virtually all proteins of the classical complement pathway (Shen *et al.*, 1997), and expression of complement mRNA increases after brain injury (Pasinetti *et al.*, 1992). Many studies have shown upregulation of C1qB and C4 in neurons in Alzheimer's diseased brains (Akiyama *et al.*, 2000).

Neurons also express receptors for complement molecules such as C3a and C5a (Davoust *et al.*, 1999; Nataf *et al.*, 1999), but the functional significance remains to be determined. Moreover, activated microglia and astrocytes secrete cytokines such as IL-1, IL-6 and TNF-α, which can stimulate secretion of C1s and C1r, and cultures of Alzheimer's disease microglia constitutively secrete C1q (Akiyama *et al.*, 2000).

IMMUNOGENETICS IN ALZHEIMER'S DISEASE

Previous studies have suggested that the presence of HLA-A2 antigen increases the risk of Alzheimer's disease. Payami *et al.* (1991) reported that the combined odds ratio from 12 different studies was 1.35, which was statistically significant but did not imply a strong association. However, two different studies suggested that HLA-A2 might be an important risk factor, particularly in men with early-onset Alzheimer's disease (Payami *et al.*, 1991; Small and Matsuyama, 1986). On the other hand, more recent studies have suggested that the presence of HLA-DR4 antigen seems to protect against the development of Alzheimer's disease (Curran *et al.*, 1997). However, this effect was not found in patients carrying the apoE4 allele.

Because α1-ACT has been indicated in the pathogenesis of Alzheimer's disease, the ACT gene is considered to be a candidate gene involved in Alzheimer's disease. One study reported that homozygotes for the ACT*A allele had a 1.5-fold increased risk of Alzheimer's disease as compared with other subjects (Kamboh *et al.*, 1995), but this could not be confirmed in another study (Haines *et al.*, 1996). However, recent studies showed that the concomitant presence of the ACT T,T and IL-1beta T,T genotypes increased the risk of Alzheimer's disease (odds ratio 5.6) and decreased the age at onset of the disease (Licastro *et al.*, 2000).

Another plaque-associated acute-phase protein that has been implicated in the development of amyloidosis is α2-macroglobulin. Blacker *et al.* (1998) first reported a genetic association between polymorphism in the α2-macroglobulin gene and Alzheimer's disease. Since then, many studies have confirmed this association (Liao *et al.*, 1998; Myllykangas *et al.*, 1999; Dodel *et al.*, 2000). However, the genotype of the α2-macroglobulin gene showing association with Alzheimer's disease has been different in these studies, and no association was found in some studies (Crawford *et al.*, 1999; Wavrant-DeVrieze *et al.*, 1999).

Recently, polymorphism of interleukin genes has been associated with Alzheimer's disease. Investigators have reported an association between the C allele of a variable number of tandem repeat polymorphism in the 3′ flanking region of the IL-6 gene (IL-6vntr) and delayed initial onset and reduced Alzheimer's disease risk (Papassotiropoulos *et al.*, 1999). This allele has previously been shown to influence the regulation of IL-6 expression and to reduce IL-6 activity in humans (Murray *et al.*, 1997). No association between IL-6 gene polymorphisms and Alzheimer's disease risk was found in other studies (Bagli *et al.*, 2000; Bhojak *et al.*, 2000). However, a strong linkage disequilibrium between IL-6vntr and IL-6prom was found, suggesting an interaction between IL-6vntr and IL-6prom that modifies Alzheimer's disease risk (Bagli *et al.*, 2000).

Four independent studies (three clinical, one using post-mortem material) have now shown increased risk for Alzheimer's disease associated with certain polymorphisms in the genes encoding the alpha and beta isoforms of IL-1 (Grimaldi *et al.*, 2000; Du *et al.*, 2000; Nicoll *et al.*, 2000; Rebeck, 2000). The IL-1A 2/2 genotype was associated with an increased risk of early-onset Alzheimer's disease (Grimaldi *et al.*, 2000; Rebeck, 2000) and late-onset Alzheimer's disease (Du *et al.*, 2000; Nicoll *et al.*, 2000), and with an earlier age of onset, carriers of this genotype showing an onset of disease 9 years earlier than IL-1A C/C carriers (Grimaldi *et al.*, 2000). However, IL-1A genotype does not change the rate of progression of Alzheimer's disease (Rebeck, 2000). Homozygosity for both allele 2 of IL-1A and allele 2 of IL-1B conferred even greater risk for Alzheimer's disease (odds ratio 10.8) (Nicoll *et al.*, 2000). There was no evidence for an interaction between the IL-1A and the apoE ε4 polymorphisms (Du *et al.*, 2000). IL-1 genotypes may confer risk for Alzheimer's disease through IL-1 overexpression. Recent studies showed that a common polymorphism within ACT and IL-1β genes affected plasma levels of ACT or IL-1β, and Alzheimer's disease patients with the ACT T,T or IL-1β T,T genotype showed the highest levels of plasma ACT or IL-1β (Licastro *et al.*, 2000).

TRANSGENIC ALZHEIMER'S DISEASE MOUSE MODELS AND NEUROINFLAMMATION

The development of transgenic animals that partly replicate Alzheimer's disease pathology and display some of the hallmark lesions of Alzheimer's disease pathology provides a means to monitor various aspects of the disease. Extensive Aβ deposition and development of thioflavine positive plaques with associated activated astrocytes and microglia have been observed consistently in different models (Frautschy *et al.*, 1998; Masliah *et al.*, 1999; Mehlhorn *et al.*, 2000; Stalder *et al.*, 1999). However, neuronal loss has been modest, and there are no reports of paired helical filaments, i.e. tangles, in these models. Differences in mouse strains have been reported that may affect the extent of the neuropathology observed in transgenic Alzheimer's disease models.

One potentially significant difference involves the activation of complement. Some strains are deficient in C5, which is a critical component of the MAC (Pasinetti, 1996). Other studies have reported complement proteins associated with amyloid aggregates in transgenic models that overexpress mutant human βPP genes. However, the mouse C1q lacks two of the positively charged arginine residues in the A-chain critical for the binding of fibrillar Aβ (Jiang *et al.*, 1994; Velazquez *et al.*, 1997). Mouse C1 is activated less effectively by fibrillar Aβ than human C1 (Webster *et al.*, 1999). Transgenic mice overexpressing mutant forms of human presenilin 1 or 2 produce rodent Aβ, which may potentially activate mouse C1 more efficiently than human Aβ. However, despite overproduction of Aβ, these models lack the accumulation of fibrillar Aβ (Borchelt *et al.*, 1997; Holcomb *et al.*, 1998) that activates complement. Thus, these mice lack the appropriate substrate for Aβ-mediated complement activation.

The acute-phase response is also quite different in mouse compared with that in human (Szalai *et al.*, 1995; Zahedi and Whitehead, 1993). However, recent data have shown that some

models display enhanced microglial staining for the proinflammatory cytokines TNF-α and IL-1β (Benzing *et al.*, 1999), increased expression of M-CSFR on microglia (Murphy *et al.*, 2000), and IL-6 immunoreactive astrocytes surrounding fibrillar Aβ (Benzing *et al.*, 1999). These mice show evidence of increased ubiquitin (Smith *et al.*, 1998) and AT-8 immunoreactivity (Hsiao *et al.*, 1996), suggesting neuritic damage.

RELATIONSHIP BETWEEN NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND ALZHEIMER'S DISEASE

Data from 20 retrospective epidemiological studies and two prospective, longitudinal studies (Rich, 1995; Stewart *et al.*, 1997; McGeer and McGeer, 1998; Prince *et al.*, 1998) have suggested that the use of nonsteroidal anti-inflammatory drugs (NSAIDs) may delay the onset and slow the progression of Alzheimer's disease. NSAID consumption may reduce the risk of Alzheimer's disease by up to 50% (Breitner *et al.*, 1995; Stewart *et al.*, 1997). In studies, there was a greater risk reduction when NSAID treatment began more than 2 years before diagnosis (Stewart *et al.*, 1997) and in subjects younger than 75 years old (Prince *et al.*, 1998). Studies on clinically normal patients have reported that NSAID use did not affect the plaque counts in the mesial temporal cortex, whereas others showed that the use of NSAIDs decreased the number of activated microglia (Mackenzie and Munoz, 1998). Also, some investigators reported that long-term NSAID had no effect on the progression of the pathological changes in Alzheimer's disease patients, despite a beneficial effect on cognitive performance (Halliday *et al.*, 2000), whereas others have shown that regular use of NSAIDs resulted in a reduction in glial activation in the Alzheimer's diseased brain (Alafuzoff *et al.*, 2000).

The mechanisms by which NSAIDs may reduce the risk of Alzheimer's disease is unknown. One possibility is that they decrease amyloid-associated neurotoxic inflammatory reaction (Netland *et al.*, 1998). NSAIDs may also attenuate the production of inflammatory cytokines and other products of reactive glia, such as apoE, which have been implicated in amyloid deposition.

NSAIDs may also directly reduce production of Aβ, as suggested in transgenic models and *in vitro* experiments (Dzenko *et al.*, 1997; Lim *et al.*, 2000; Netland *et al.*, 1998). *In vitro* experiments have shown that cyclo-oxygenase (COX) inhibitors decrease production of prostaglandins that may induce neuronal degeneration (Pasinetti, 1998). Another target for NSAIDs is the stimulation of peroxisome proliferator-activated receptor-γ (PPAR-γ). PPAR-γ agonists inhibit Aβ-stimulated expression of IL-1 and TNF-α by microglia (Combs *et al.*, 1999). *In vitro* experiments have shown that inflammatory mediators modulate bPP metabolism and production of Aβ (Del Bo *et al.*, 1995; Forloni *et al.*, 1992; Vasilakos *et al.*, 1994), and contribute to the conformational change of Aβ into neurotoxic fibrillary form.

Recently, investigators reported that chronic use of ibuprofen at a dose high enough to inhibit COX and stimulate PPAR-γ reduced levels of IL-1β, glial fibrillary acidic protein (GFAP), activated microglia, dystrophic neurites, amyloid plaques and Aβ in ageing transgenic mice, which overexpress the 695-amino acid form of human βPP containing a double mutation found in a Swedish kindred with familial Alzheimer's disease (Lim *et al.*, 2000). These results indicate that ibuprofen can modulate the development of some aspects of Alzheimer's disease pathology.

CONCLUSIONS

Even though Bolsi noted in 1927 argentophilic reactive cells in the surrounding of senile plaques in Alzheimer's diseased brains, the significance of glial cells in Alzheimer's disease has only recently received attention. Identification of microglia in the Aβ protein aggregates, i.e the plaque configuration, indicates that inflammatory mechanisms operate in the pathogenesis of Alzheimer's disease. It seems unlikely that inflammatory mechanisms are the initiators of Alzheimer's disease, but they are likely to be of importance in the progression of the disease. Much evidence has linked the Aβ protein to microglia, the principal immune effector element of the brain. Microglia have been implied to be involved in the synthesis, fibrillization and clearance of this deleterious protein found constantly in Alzheimer's diseased brains. Furthermore, microglia have been linked to neuritic pathology and neuronal death via cytokines, complement activation and acute-phase reactions. Astrocytes, producers of numerous cytokines after stimulation, have also been linked to the hallmark lesions of Alzheimer's disease. There is no doubt that inflammation is involved in the pathogenesis of Alzheimer's disease, but the question still remains: how?

Psychophysiology: Event-Related Potentials and Psychophysics in Dementia

Claire Murphy and Spencer Wetter

Dementia is defined in the *Diagnostic and Statistical Manual of Mental Disorders* 4th edition (DSM-IV) as a deficit in memory and in at least one additional cognitive domain (American Psychiatric Association, 1994). Two major subdivisions of dementia have been posited: cortical and subcortical (Brandt, 1991; Brandt *et al.*, 1988; Butters *et al.*, 1978; Butters *et al.*, 1985; Folstein *et al.*, 1990; Huber *et al.*, 1986; Salmon *et al.*, 1989). Cortical dementias (most prevalently Alzheimer's disease) are marked by early neuropathology in areas of the cerebral cortex (often the temporal and frontal lobes). Subcortical dementias (e.g. Huntington's disease and Parkinson's disease) result in early damage to subcortical areas such as the basal ganglia and substantia nigra. These two forms of dementia have been dissociated clinically by differing patterns of neuropsychological deficits. Specifically, cortical dementias are associated with deficits in recall and recognition memory, aphasia, agnosia and apraxia (Brandt *et al.*, 1988; Huber *et al.*, 1986; Salmon *et al.*, 1989). Subcortical dementias result in slowed thinking, difficulties in recall but not recognition memory, and deficiencies in sustained attention and cognitive flexibility (Folstein *et al.*, 1990; Brandt, 1991).

The electroencephalogram (EEG) is a measure of ongoing neuroelectrical brain activity recorded from the scalp. The event-related potential (ERP) is a brain potential derived from averaging the EEG signal during a recording epoch that corresponds to evaluation of a sensory stimulus. The components of these electrophysiological responses reflect brain function and integrity. The use of electrophysiological techniques to better understand and quantify the deficits associated with dementia have been studied extensively in the past two decades, beginning with Goodin *et al.* (1978). Such techniques offer an objective and quantitative measure of sensory and cognitive functioning, without the cognitively laden demands of neuropsychological testing. They can be useful in understanding severely demented patients, and they may prove useful in detecting individuals at preclinical or very early stages of dementia. Certain electrophysiological components (e.g. the latency of the P3 component of the auditory ERP) may be useful in differentiating demented from other psychiatric patients (Figure XV-7.1). The purpose of this chapter is to review the empirical evidence for electrophysiological performance in individuals with dementia, with an emphasis on later components of brain potential waveforms because these are highly associated with the cognitive changes resulting from dementia.

ALZHEIMER'S DISEASE

Alzheimer's disease is a progressive neurodegenerative disorder marked by severe memory loss and dementia resulting from the formation of neuritic plaques and neurofibrillary tangles in the brain. Risk factors for Alzheimer's disease include age (Katzman and Kawas, 1994; Farrer *et al.*, 1995), low education (Katzman, 1993; Mortimer and Graves, 1993; Stern *et al.*, 1999), positive family history (van Duijn *et al.*, 1991; Farrer *et al.*, 1995), past head trauma (Heyman, 1998; Rasmusson *et al.*, 1995), Down's syndrome (Wisniewski *et al.*, 1985; Motte and Williams, 1989), and the ε4 allele of the apolipoprotein E gene (ApoE) (Corder *et al.*, 1993a; Poirier, 1993). Definitive diagnosis of Alzheimer's disease is made only by post-mortem autopsy or biopsy (McKhann *et al.*, 1984). When the patient is living, a provisional diagnosis of probable Alzheimer's disease can be obtained by clinical examination, neuropsychological testing, history, and the exclusion of other disorders. Diagnosis is imperfect, hence the development of additional assessment tools to improve the sensitivity and specificity of early diagnosis is of great interest. The potential for psychophysiological measures to aid in the diagnosis of Alzheimer's disease is of particular interest.

Auditory P300 in Alzheimer's Disease

The potential clinical utility of the auditory ERP has received considerable attention. Early components of the ERP (N1, P2 and N2) are considered to be more exogenous measures that reflect the processing of the stimulus by auditory cortex (Polich, 1993). The P300 (P3) component is more endogenous in nature. It reflects an individual's ability to attend to and evaluate a stimulus (Kramer and Strayer, 1988; Wickens *et al.*, 1983), and its latency is considered to be a measure of stimulus classification speed (Donchin and Coles, 1988). The P3 is typically elicited during the 'oddball' paradigm, in which a standard stimulus with a high probability of occurrence is presented along with a target stimulus with a low probability of occurrence. The processing of the target stimulus (the oddball) elicits the P3. Early studies suggested that individuals with Alzheimer's disease may produce abnormal P3s, specifically lower amplitudes and longer latencies, and that these might be associated with the degree of dementia (Goodin *et al.*, 1978; Squires *et al.*, 1980a; Pfefferbaum *et al.*, 1984). Polich (1991) reviewed eight studies investigating auditory ERPs in Alzheimer's disease, which exhibited a great deal of variability in the percentage of patients who had P3 latencies two or more standard deviations above the mean for normal controls. The range of these percentages was 13–83% (Table XV-7.1).

Considerable controversy has ensued over the clinical utility of the auditory P3. Squires *et al.* (1980a) and Gordon *et al.* (1986) reported that 74% and 80%, respectively, of demented individuals had prolonged auditory P3 latency, compared with 3% and 12% of psychiatric patients diagnosed with depression and schizophrenia. Goodin (1990) suggested that these findings show promise in the

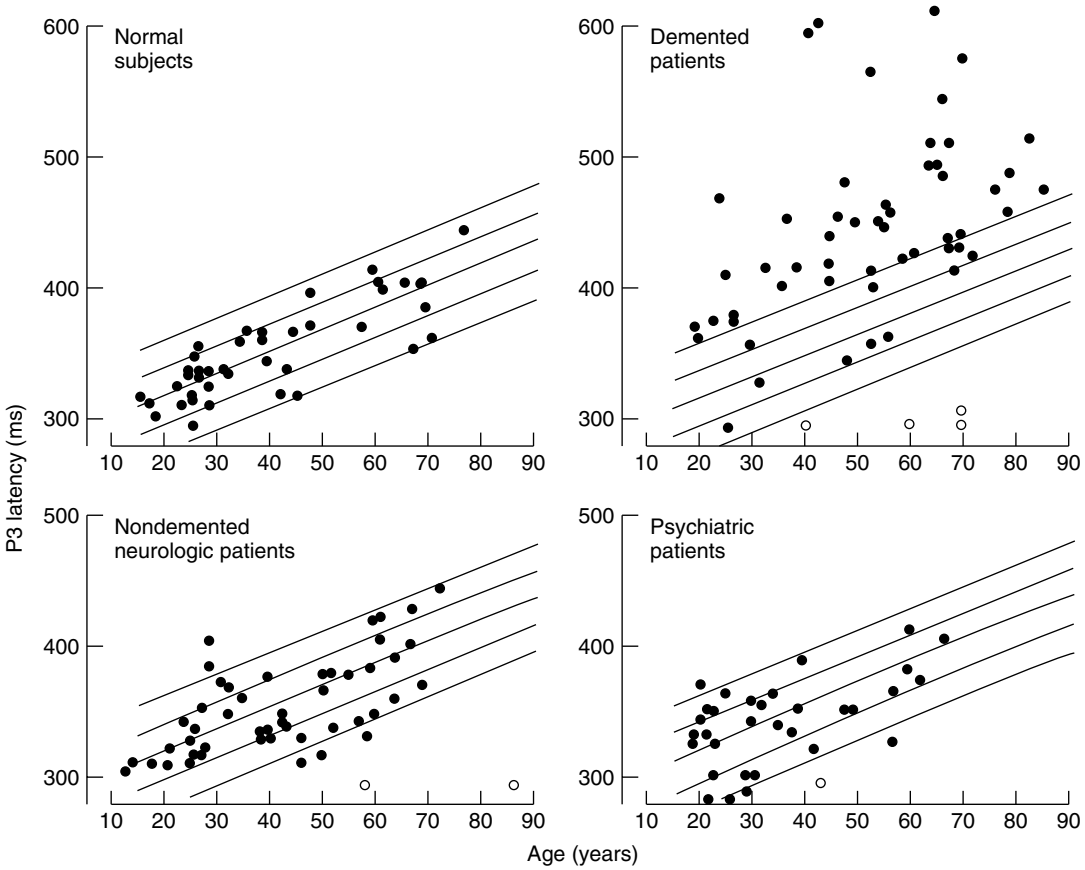

Figure XV-7.1 Auditory P3 latency by age from normal subjects, demented subjects, non-demented neurologic patients, and psychiatric patients. Reproduced by permission from Polich, J., 1991. P300 in the evaluation of aging and dementia. *American Journal of EEG Technology* 31, 201–231

Table XV-7.1 Characteristics of auditory P3 dementia studies (from Polich, 1991)

Study	Dementing illness	*n*	Age	Mini-mental state examination	Patients P3 > 2 SD (%)	Task and performance
Goodin *et al.* (1978)	Pre-senile, organic, CVA, etc.	27	55.3*	20.7	70	Count: 2–3 errors
Squires *et al.* (1980a)	Alzheimer's, CVA, etc.	58	50.7*	19.6	80	Count: 'instructions had desired effects'
Syndulko *et al.* (1982)	Alzheimer's	12	66.9	20.9	83	Count: NR
Brown *et al.* (1983)	Alzheimer's, multi-infarct, Parkinson's	18	74.0	14.7	72	Count: NR, tapping task for some patients
Pfefferbaum *et al.* (1984)	Alzheimer's, alcohol-related, CVA, etc.	37	56.8	22.4	22–30	Button press; ERPs: correct response only
Polich *et al.* (1986)	Alzheimer's, CVA, alcohol-related	39	70.6	3.9**	31	Finger-tap: 'most patients had little difficulty'
Gordon *et al.* (1986)	Primary, degenerative multi-infarct	20	77.0	≤25.0	63	Count: patients reminded of task; often wrong
Patterson *et al.* (1988)	Alzheimer's, multi-infarct	15	71.1	18.3	13	Button press: ERPs, correct response only

*Estimated; **mean Reisberg scale; CVA, cerebrovascular accident; NR, not reported.

utility of the P3 to differentiate dementia from depression (defined as 'pseudodementia' at the time). He also suggested that the P3 might be potentially useful in tracking the course of a degenerating disorder, testing response to treatment, or detecting dementia in those at risk. Pfefferbaum *et al.* (1990) also examined the existing literature at the time, but they concluded that the auditory P3 is neither consistently large nor specific enough to any particular disorder to be depended upon for diagnosis. More recent research has supported longer latencies and smaller amplitudes in Alzheimer's disease patients, but with varying degrees of sensitivity and specificity (Filipovic *et al.*, 1990; Verleger *et al.*, 1992; O'Mahony *et al.*, 1994; Cohen *et al.*, 1995; Yamaguchi *et al.*, 2000). Interestingly,

two studies found delayed P3 latency only at the Fz electrode site, with normal latencies at Cz and Pz sites (Verleger *et al.*, 1992; O'Mahony *et al.*, 1994). Onofrj *et al.* (1991) reported that a subset (37%) of patients with dementia (AD, multiple sclerosis, and progressive supranuclear palsy) did not produce a P3 component from the auditory oddball paradigm, suggesting that some patients with dementia (regardless of type) may have severe damage to areas of the brain that generate the P3. Cohen *et al.* (1995) again suggested the potential clinical utility of the auditory P3 by reporting that (1) P3 latency and amplitude (using an active oddball paradigm) predicted functional outcome (activities of daily living) in dementia, and (2) P3 latency (using a passive oddball paradigm) was the best predictor of mortality among dementia patients (even more than neuropsychological test performance). Such results support the potential utility of electrophysiological techniques to predict functional outcome of demented patients. However, if the auditory P3 is to be clinically useful, then much work needs to be done to reduce variability, identify more homogeneous patient groups for research purposes, and further understand the cognitive processes associated with the auditory oddball P3 (Polich and Kok, 1995; Barrett, 2000).

The N400 Effect

Another ERP component that has provided useful information regarding impaired and spared abilities in AD is the N400. This negative component reflects a semantic expectancy, such that the presentation of a sentence with an incongruent or unexpected final word results in a large N400 effect (Kutas and Hillyard, 1980). When the final word is as expected, the N400 is significantly smaller. The N400 effect has been shown to be smaller in AD to incongruent words (Castaneda *et al.*, 1997; Ostrosky-Solis *et al.*, 1998; Schwartz *et al.*, 1996), which likely reflects the difficulties AD patients have with processing semantic information. Ford *et al.* (1996) found that unlike controls (who had large N400s to semantically unprimed words and small N400s to semantically primed words), AD patients produced large N400s to semantically primed words. This appears to reflect a breakdown in semantic knowledge (the stem of the sentence does not prime the final word properly). However, some semantic knowledge in AD appears to be spared. For instance, recent researchers (Hamberger *et al.*, 1995; Ford *et al.*, 1996; Ford *et al.*, 2001) have reported that AD patients demonstrate an N400 priming effect. For example, for these patients, words that did not match pictures had greater N400 amplitude than those that matched pictures (Ford *et al.*, 2001). Interestingly, AD patients were unable to name many of the pictures, yet they still demonstrated the N400 effect. Such evidence suggests that even though AD patients have anomia, knowledge of the pictures was intact enough to activate cortical responses. These findings suggest that the N400 may provide useful information about the degeneration of semantic knowledge in AD.

Visual Evoked Potentials in Alzheimer's Disease

Visual evoked potentials (VEPs) were first suggested to be delayed in populations with dementia in 1976 (Visser *et al.*, 1976). The most frequently used stimuli have been visual flashes, which elicit flash VEPs (FVEPs). These have been reported to be delayed in Alzheimer's disease in a number of studies (Harding *et al.*, 1981; Cosi *et al.*, 1982; Wright *et al.*, 1984; Philpot *et al.*, 1990). However, not all investigators have demonstrated such a delay in mild-to-moderate Alzheimer's disease (Coben *et al.*, 1983; Ray *et al.*, 1991). Coben *et al.* (1983) did report latency delays for VEPs elicited by the presentation of a chessboard that was shifted either to the left or right, and they suggested that this paradigm might be more useful than FVEPs in identifying visual processing deficits in Alzheimer's disease. Swanwick *et al.* (1996) combined the FVEP with the auditory P300 in a single study. The authors reported that the FVEP might be more sensitive to cognitive dysfunction than the P300. Using a discriminant function analysis, they combined two FVEP measures (P2 and N2) and two auditory ERP measures (N2 and P3). This function proved to correctly classify subjects with a sensitivity of 80% and a specificity of 80%. Thus, a combination of ERP paradigms (perhaps in conjunction with neuropsychological data) might well be required to accurately predict outcome in the individual Alzheimer's disease patient.

Olfaction in Alzheimer's Disease

Alzheimer's disease is associated with impairment in odour identification, odour recognition memory and odour threshold, and these olfactory deficits may be useful as behavioural markers that contribute to accuracy in early assessment of Alzheimer's disease (Murphy, 1999; Murphy *et al.*, 1987: Murphy *et al.*, 1990; Nordin *et al.*, 1995; Nordin and Murphy, 1996; Nordin and Murphy, in press; Serby *et al.*, 1985). Both Alzheimer's disease patients and those at risk for the disease show deficits in odour identification, suggesting that this measure may be particularly useful in early diagnosis (Murphy, 1999). Alzheimer's disease patients score in the normal range on the picture identification test (PIT), demonstrating that they have the cognitive ability to perform an odour identification test (Morgan *et al.*, 1995), and they have normal taste threshold, indicating that they are capable of performing a threshold task (Murphy *et al.*, 1987: Murphy *et al.*, 1990). People at risk for Alzheimer's disease because of mild cognitive impairment show deficits in odour identification (Nordin and Murphy, 1996). The sensitivity and specificity of odour identification testing for Alzheimer's disease is very high and rivals many tests used in existing batteries for neuropsychological assessment of the disease (Morgan *et al.*, 1995; Morgan and Murphy, in press; Murphy, 1999). The olfactory deficits seen in Alzheimer's disease may be related to the existence of neuritic plaques and neurofibrillary tangles throughout olfactory-related brain structures. Indeed, the magnitude of olfactory threshold impairment is related to the degree of dementia (Murphy *et al.*, 1990).

The earliest changes in Alzheimer's disease patients take place in the mesial temporal lobe, particularly in the entorhinal and transentorhinal areas important for olfactory processing (Braak and Braak, 1992; Braak and Braak, 1994; Braak and Braak, 1997; Esiri and Wilcox, 1984; Pearson *et al.*, 1985; Price *et al.*, 1991). Indeed, disconnection of the entorhinal and transentorhinal areas from the hippocampus has been hypothesized to underly dementia in Alzheimer's disease (Braak and Braak, 1992; Braak and Braak, 1994; Braak and Braak, 1997). The very high sensitivity and specificity of odour identification tasks in discriminating between Alzheimer's disease patients and normal people suggests that they reflect the presence of underlying neuropathology. Significant neuropathological changes are seen in areas critical to processing olfactory information, even in the early stages of Alzheimer's disease. Murphy *et al.* (submitted) investigated whether performance on olfactory tasks (odour threshold and odour identification) was related to volumetric magnetic resonance imaging (MRI) measures of mesial temporal areas central to olfactory information processing and important in the neuropathology of early Alzheimer's disease. Participants were patients with probable Alzheimer's disease and normal age-matched controls, all diagnosed at the UCSD Alzheimer's Disease Research Centre. Robust relationships were observed between mesial temporal lobe volumes and olfactory functional measures in both Alzheimer's disease patients and controls. Relationships between left hippocampal volume and the functional

measures were greater for Alzheimer's disease patients than for controls, and for the odour identification test ($r = 0.85$) and the Boston naming test than for odour or taste threshold. The findings suggest a neural substrate for the breakdown in functional performance on verbally mediated olfactory tasks in Alzheimer's disease.

Techniques for recording the olfactory ERP (OERP) have been developed (Kobal *et al.*, 1992; Murphy *et al.*, 1994; Pause *et al.*, 1996; Morgan *et al.*, 1999; Murphy *et al.*, 2000). Olfactory stimuli elicit the same waveform components (N1, P2, N2 and P3) as auditory and visual stimuli in ERP paradigms. Morgan and Murphy (in press) investigated olfactory functioning in Alzheimer's disease using the OERP. Figure XV-7.2 illustrates the finding that OERP latencies were significantly longer in Alzheimer's disease patients than in age- and gender-matched normal controls. These latencies were associated with dementia status and classified correctly up to 92% of participants. The OERP proved to be more sensitive at correctly classifying Alzheimer's disease patients and controls than the auditory ERP. The combination of the San Diego odour identification test and the OERP P3 latency resulted in a correct classification rate of 100%. These findings suggest that the OERP, in addition to the measures mentioned above, is a useful technique in the assessment of Alzheimer's disease.

Apolipoprotein E

A key risk factor for Alzheimer's disease is the presence of the $\varepsilon 4$ allele of the ApoE gene. ApoE binds to β A4 peptide, which is the primary component of senile plaques (Strittmatter *et al.*, 1993). It

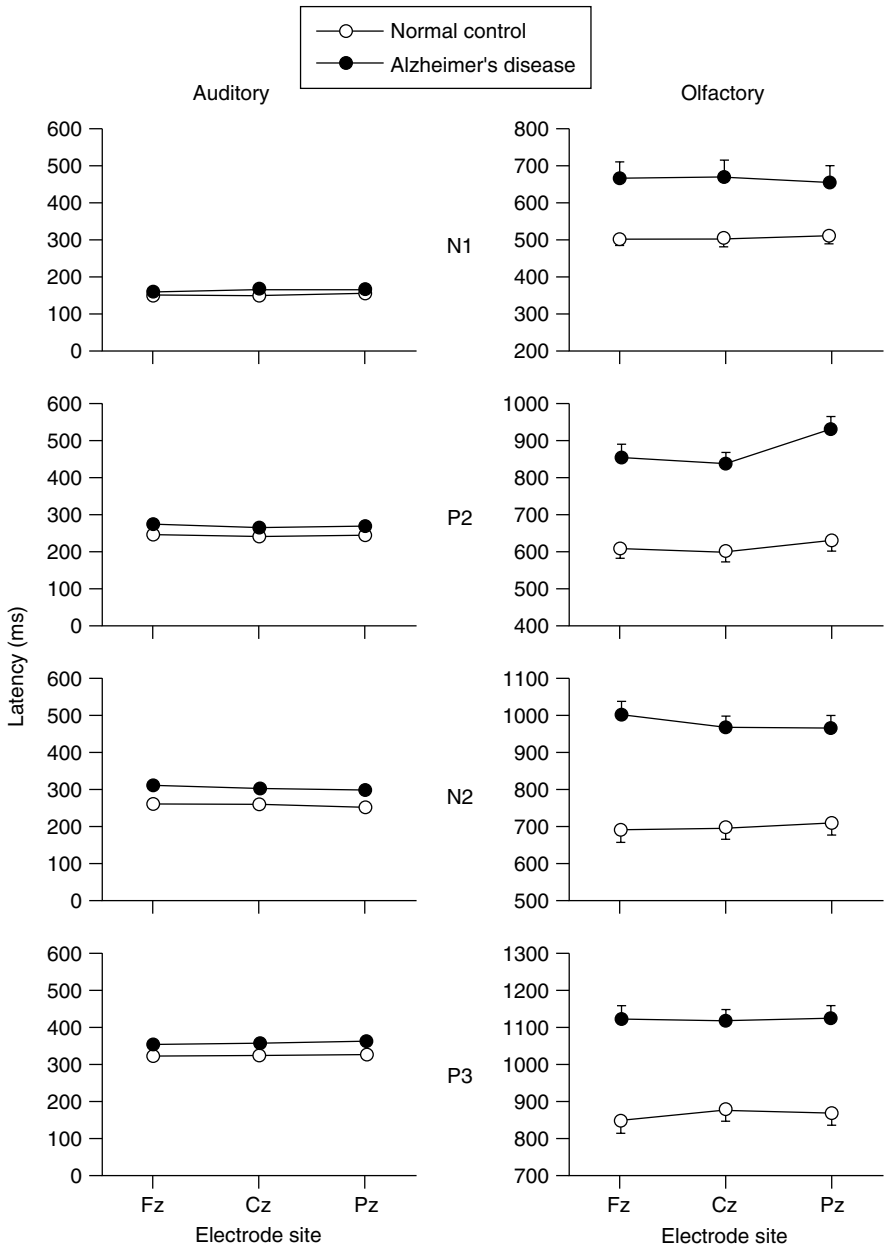

Figure XV-7.2 Auditory and olfactory ERP latencies as a function of electrode site for normal controls and Alzheimer's disease patients (from Morgan and Murphy, in press)

has also been implicated in the formation of neurofibrillary tangles (Namba *et al.*, 1991). The presence of at least one $\varepsilon 4$ allele has been strongly associated with Alzheimer's disease. It has been linked to both familial and sporadic Alzheimer's disease (Corder, *et al.*, 1993a; Corder *et al.*, 1993b; Poirier *et al.*, 1993; Saunders *et al.*, 1993).

The ApoE $\varepsilon 4$ allele has also been linked to deficits in olfactory functioning. Bacon *et al.* (1998) demonstrated that elderly individuals with at least one $\varepsilon 4$ allele demonstrated poorer odour threshold sensitivity than those without the $\varepsilon 4$ allele in the year that they were diagnosed with Alzheimer's disease. Murphy *et al.* (1998) demonstrated that non-demented elderly individuals with at least one $\varepsilon 4$ allele showed poorer performance at odour identification than those without the $\varepsilon 4$ allele. Of particular interest for the present discussion, Wetter and Murphy (2001) used the OERP to investigate older people with and without the $\varepsilon 4$ allele. Older individuals who are $\varepsilon 4$ allele positive demonstrated delayed latencies of the OERP compared with $\varepsilon 4$ allele-negative individuals. Such delays were not present in the auditory ERP (see Figure XV-7.3) for these individuals who are $\varepsilon 4$ allele positive. The magnitude of the OERP latency delays in the $\varepsilon 4$ allele-positive individuals was approximately 100 ms, in comparison with Alzheimer's disease patients,

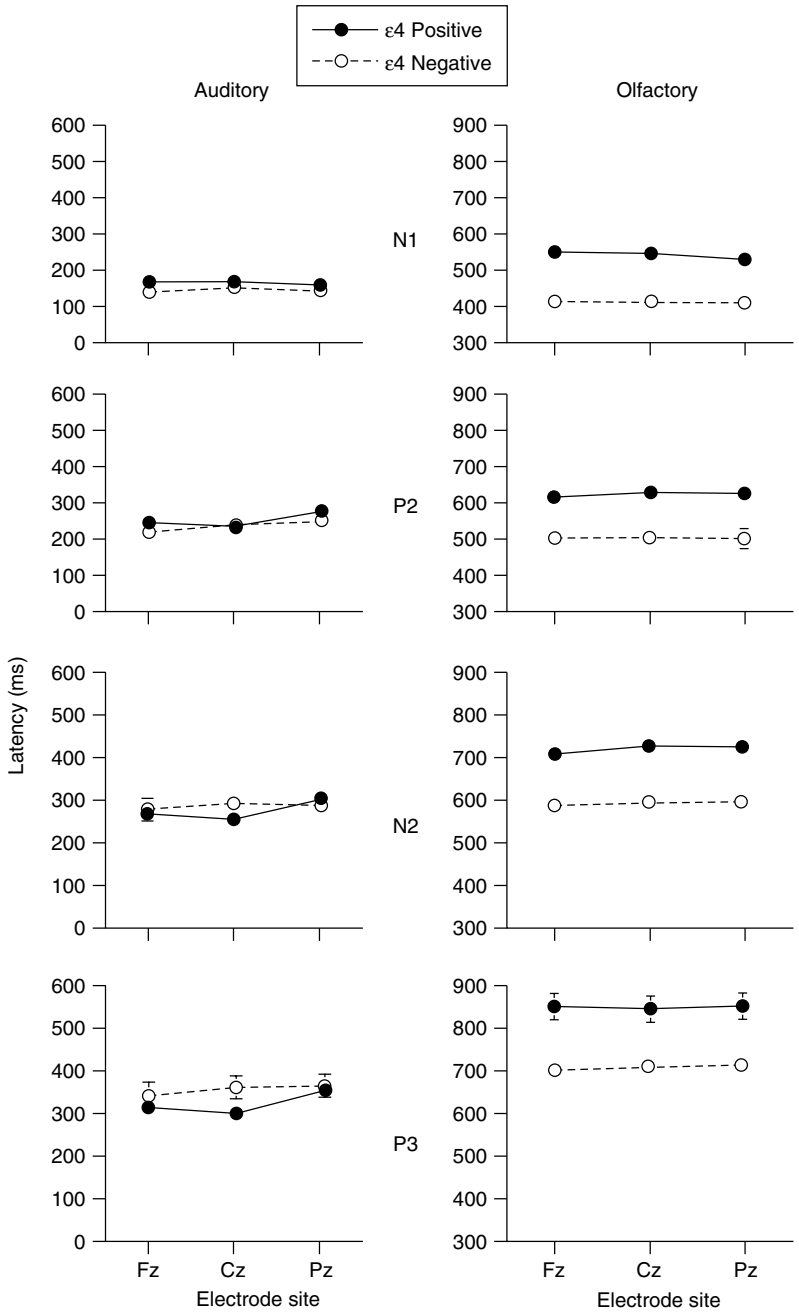

Figure XV-7.3 Auditory and olfactory ERP latencies as a function of electrode site for ApoE $\varepsilon 4$-positive and -negative individuals. Reprinted from *Neurobiology of Aging*, 22, Wetter, S. and Murphy, C., Apolipoprotein E $\varepsilon 4$ positive individuals demonstrate delayed olfactory event-related potentials, 439–447, Copyright (2001), with permission from Elsevier Science

who showed latency delays of approximately 200 ms relative to controls (Morgan and Murphy, in press). Thus, delays in the processing of olfactory information among elderly ApoE ε4-positive individuals appear to be on a continuum between normal controls and patients with Alzheimer's disease, indicating that these individuals, or a subset of them, might be demonstrating early signs of Alzheimer's disease.

DOWN'S SYNDROME

Patients with Down's syndrome who live to the fourth decade inevitably develop the clinical and neuropathological features of Alzheimer's disease: senile plaques and neurofibrillary tangles (Oliver and Holland, 1986; Schapiro and Rapoport, 1988; Brugge *et al.*, 1994; Nelson *et al.*, 1995). Wisniewski *et al.* (1985) demonstrated that the neuropathology increases with age, and that the number of plaques is associated with the degree of dementia. Adults with Down's syndrome and patients with Alzheimer's disease demonstrate a similar cholinergic deficiency (Yates *et al.*, 1980) and a degeneration of neurons in the nucleus of Meynert in the basal ganglia (Coyle *et al.*, 1983). Furthermore, there has been an increased prevalence of Down's syndrome births in families that have had a prevalence of pre-senile Alzheimer's disease (Heston *et al.*, 1981; Heyman *et al.*, 1983).

Since the initial event in Alzheimer's disease is damage in the entorhinal and transentorhinal areas of the brain, areas that process olfactory information (Price *et al.*, 1991; Braak and Braak, 1997), deficits in olfactory functioning resulting from this damage may prove to be an early indicator of Alzheimer's disease in Down's syndrome and in the general population (Morgan *et al.*, 1995; Nordin and Murphy, 1996). Early work demonstrated deficits in odour identification ability in Down's syndrome (Warner *et al.*, 1988; Hemdal *et al.*, 1993; Murphy and Jinich, 1996), and documentation of impairment in odour detection thresholds confirmed that the deficits were, indeed, olfactory (Murphy and Jinich, 1996). Both odour identification and odour threshold show greater impairment in older people with Down's syndrome than in children with Down's syndrome, suggesting that the impairment in olfactory function reflects increased neuropathology (Nijjar and Murphy, in press). Significant losses were also seen in odour recognition memory (Murphy and Jinich, 1996). Wetter and Murphy (1999) used

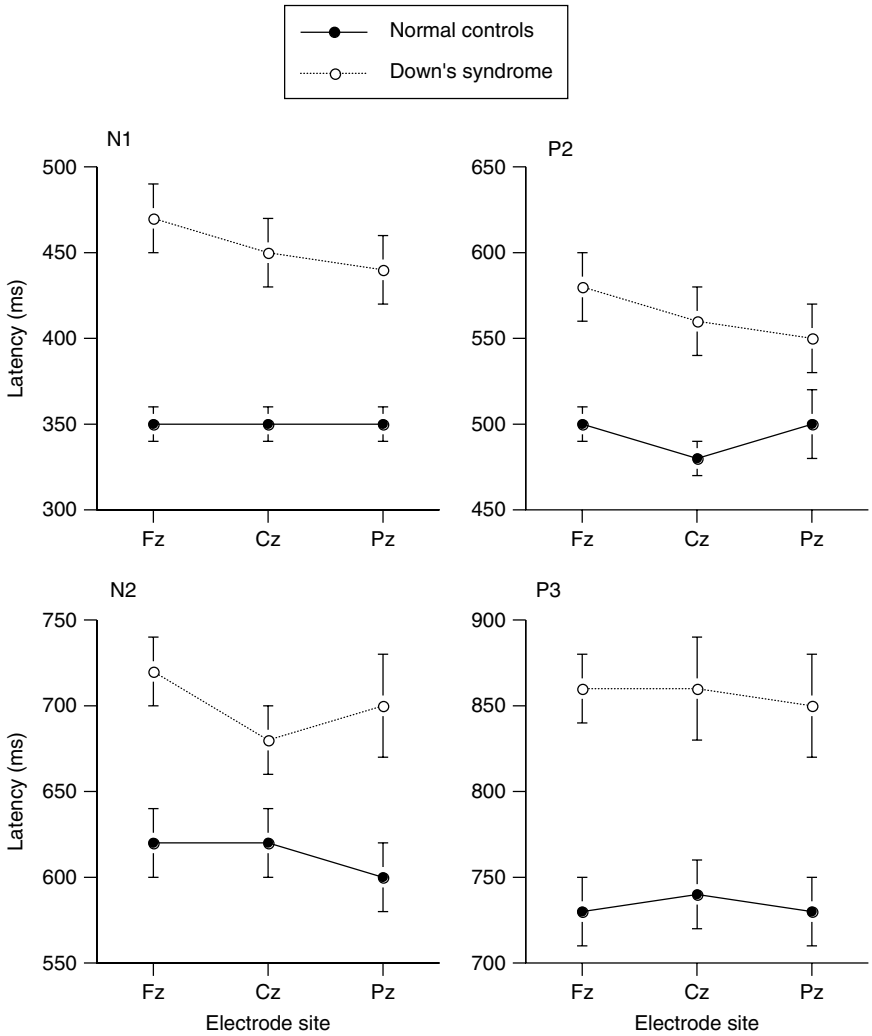

Figure XV-7.4 OERP latency as a function of electrode site for normal controls and Down's syndrome patients. Reprinted from Clinical Neurophysiology, 110, Wetter, S. and Murphy, C., Individuals with Down's syndrome demonstrate abnormal olfactory event-related potentials, 1563–1569, Copyright (1999), with permission from Elsevier Science

the OERP to investigate odour processing in the brains of older people with Down's syndrome. The people with Down's syndrome showed significantly longer latencies in both the sensory (N1, P2 and N2) and cognitive (P3) components of the OERP than normal controls (see Figure XV-7.4). Odour threshold was associated significantly with sensory OERP components. In addition, Down's syndrome subjects with a higher level of dementia showed significantly longer P3 latencies than those with lower dementia levels. Taken together, these studies suggest that measures of olfactory dysfunction in Down's syndrome may be useful in identifying incipient dementia in this population.

ERPs from other sensory modalities have been recorded in individuals with Down's syndrome. Research in auditory ERPs has demonstrated abnormalities in both early and late components. Abnormalities in brain stem responses in Down's syndrome include short latencies in some components, increased latencies in others, and/or lower amplitudes in general (Squires *et al.*, 1980b; Galbraith *et al.*, 1983; Sersen *et al.*, 1991; Kakigi and Kuroda, 1992; Miezejeski *et al.*, 1994). The latency of the auditory P3, a cognitive component of the ERP, has been demonstrated to increase compared with normal controls (Blackwood *et al.*, 1988), and progressively as an individual with Down's syndrome ages (Muir *et al.*, 1988). Other studies of auditory ERPs demonstrated that latencies of late components were delayed in Down's syndrome (Vieregge *et al.*, 1992; Diaz and Zurron, 1995).

Visual ERPs have also been recorded in individuals with Down's syndrome. As with auditory ERPs, VEP components are latency delayed in Down's syndrome (Kakigi *et al.*, 1993; Prasher *et al.*, 1994). In addition, amplitudes are significantly lower in Down's syndrome compared with normal controls (Kakigi *et al.*, 1993). As in adults, a P3 delay in rare auditory-visual events has also been demonstrated in children with Down's syndrome (Lincoln *et al.*, 1985). This delay suggests that the abnormalities in ERP components in the auditory and visual modalities in young Down's syndrome individuals may reflect their inherent cognitive deficits.

PARKINSON'S DISEASE

Auditory Event-Related Potential Deficits in Parkinson's Disease

Parkinson's disease is marked by destruction of the nigrostriatal dopaminergic system (Hornykiewicz, 1966), and is associated with motor (tremor), psychiatric (apathy, depression, irritability), and cognitive (memory retrieval deficits, bradyphrenia, initiation problems, and lack of cognitive flexibility) symptoms. The cognitive symptoms are consistent with those of a subcortical dementia, which were first identified in progressive supranuclear palsy (Albert *et al.*, 1974). These symptoms have been associated with deficits in the latency of auditory ERPs. Specifically, later components (N2 and P3) have been shown consistently to be delayed in demented Parkinson's disease patients (Goodin and Aminoff, 1986; Goodin and Aminoff, 1987b; O'Donnell *et al.*, 1987; Gil *et al.*, 1989; Hautecoeur *et al.*, 1991; Kutukeu *et al.*, 1998). Some evidence has demonstrated a differential effect of Parkinson's disease on early ERP components, with N1 delayed and P2 intact (Goodin and Aminoff, 1986; Goodin and Aminoff, 1987b). However, not all research is consistent with these findings (Hansch *et al.*, 1982; O'Donnell *et al.*, 1987; Hautecoeur *et al.*, 1991; O'Mahony *et al.*, 1993). Non-demented patients with Parkinson's disease demonstrate no ERP delays (Goodin and Aminoff, 1987a; Hautecoeur *et al.*, 1991; Tanaka *et al.*, 2000), suggesting that it is the dementia rather than other symptoms of Parkinson's disease that affects sensory information processing. P3 latency is also associated with deficits on neuropsychological measures in Parkinson's disease (for a review, see Ruzicka and EI Massioui, 1993).

Olfactory Deficits in Parkinson's Disease

Meta-analysis of psychophysical testing of odour identification, recognition and detection threshold suggests olfactory impairment in Parkinson's disease (Mesholam *et al.*, 1998), but the literature also suggests that olfactory impairment is not seen in all patients (Ansari and Johnson, 1975; Serby *et al.*, 1985; Doty *et al.*, 1988; Quinn *et al.*, 1987; Ward *et al.*, 1983). Ansari and Johnson (1975) found increased odour thresholds in less than half the Parkinson's disease patients they tested. Ward *et al.* (1983) examined odour detection and qualitative discrimination in 72 patients and reported odour identification deficits in more than half of them. Doty *et al.* (1988) confirmed odour threshold and odour identification deficits in Parkinson's disease. Deficits in odour identification in Parkinson's disease patients are typically reported to be independent of age, disease stage and duration (Quinn *et al.*, 1987; Ward *et al.*, 1983; Wszolek and Markopoulou, 1998). Dopaminergic or cholinergic treatment does not appear to affect odour identification impairment (Doty *et al.*, 1992a) or olfactory thresholds (Quinn *et al.*, 1987) in Parkinson's disease patients. Conditions similar to idiopathic Parkinson's disease have also been examined for olfactory functional deficits. Odour identification and odour detection thresholds are normal in both 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced parkinsonism (Doty *et al.*, 1992b) and progressive supranuclear palsy, which can be misdiagnosed as Parkinson's disease because of similar motor symptoms (Doty *et al.*, 1993). Interestingly, although an important characteristic of most patients with Parkinson's disease is tremor, patients with essential tremor do not show olfactory impairment (Busenbark *et al.*, 1992).

Olfactory Event-Related Potentials in Parkinson's Disease

Hawkes and colleagues examined OERPs in a small number of Parkinson's disease patients (Hawkes *et al.*, 1997; Hawkes and Shephard, 1998). They reported delayed brain response at P2 in a small number of patients, but with amplitudes comparable to controls. Interestingly, Hawkes *et al.* (1997) also reported pathological results in a group of eight cadavers that indicated the presence of Lewy bodies in every olfactory bulb, particularly in the anterior olfactory nucleus. A study published by Barz *et al.* (1997; see also Kobal and Hummel, 1991) found prolonged OERP latencies (N1, P2 and P3) in Parkinson's disease patients who were and were not taking antiparkinsonian medications. Interestingly, those who were taking the medications demonstrated more pronounced latency deficits than those who were not on medication. In addition, ERP latencies of all Parkinson's disease patients were similar to normal controls when stimulated with trigeminal stimuli. This finding suggests that the delays in OERP latency are specific to the olfactory system and likely reflect neuropathology in central brain areas that process olfactory, but not trigeminal, information.

HUNTINGTON'S CHOREA

Huntington's disease is an autosomal dominant and progressive neurological disease, characterized by movement disorder (chorea) and progressive cognitive deterioration. The disease is without cure, unremitting, and progresses to a typical 'subcortical' dementia. The latter is exemplified in bradyphrenia, impaired attentional mechanisms, problem-solving deficits, and a memory deficit in retrieval of information in fluency and recall tasks, but not in

recognition tasks. Patients encode information but have difficulty with retrieval of information without a cue (Butters *et al.*, 1978; Brandt, 1985; Butters *et al.*, 1985). Patients with Huntington's disease have neuropathy in the basal ganglia, principally the caudate and less in the putamen (Dom *et al.*, 1976; Vonsattel *et al.*, 1985), with significant loss in the entorhinal cortex (Braak and Braak, 1992) and the frontostriatal system.

Event-Related Potentials in Huntington's Disease

ERPs in the auditory and visual modalities have proven to be abnormal in Huntington's disease. Individuals with Huntington's disease demonstrate lower amplitudes than normal controls in both auditory (Josiassen *et al.*, 1984) and visual (Josiassen *et al.*, 1984; Lawson *et al.*, 1984; Hennerici *et al.*, 1985) modalities. In Huntington's disease patients, the cognitive P3 component of the ERP has consistently shown delayed latencies in both auditory (Rosenberg *et al.*, 1985; Filipovic *et al.*, 1990) and visual (Lawson *et al.*, 1984; Rosenberg *et al.*, 1985) modalities. Latency delays in early auditory ERP components have also been observed (Goodin and Aminoff, 1986; Hoemberg *et al.*, 1986). In addition to these findings in Huntington's disease patients with clinical symptoms, two studies have demonstrated abnormal ERPs in individuals at risk for Huntington's disease. Hoemberg *et al.* (1986) found that people at risk for Huntington's disease had delayed N2 and P3 latencies in an auditory ERP paradigm compared with controls. Josiassen *et al.* (1988) demonstrated lower ERP amplitudes in auditory and visual ERPs for people at risk for Huntington's disease compared with clinical and normal controls. Such findings suggest that early neuropathology of Huntington's disease can be detected using ERP paradigms.

MULTIPLE SCLEROSIS

Multiple sclerosis is marked by motor, psychiatric and cognitive abnormalities. Motor deficits include ataxia, ophthalmoplegia, nystagmus, facial palsy and dysarthria (Reder and Antel, 1983). Depression, emotional lability and disinhibition are common psychiatric symptoms (Rabins *et al.*, 1986; Honig *et al.*, 1992). Cognitive abnormalities are seen in the areas of attention, slowed information processing, and memory retrieval, with language function spared (Peyser *et al.*, 1980; Heaton *et al.*, 1985; Jennekens-Schinkel and Sanders, 1986). Research on auditory ERPs has reflected this cognitive decline. Much emphasis has been placed on the P3 component, which is delayed in multiple sclerosis (Polich *et al.*, 1986; Onofrj *et al.*, 1991; Geisser *et al.*, 1992; Honig *et al.*, 1992; Triantafyllou *et al.*, 1992; Gil *et al.*, 1993). Other components with delayed onset are N1 (Geisser *et al.*, 1992), P2 (Geisser *et al.*, 1992; Gil *et al.*, 1993), and N2 (Triantafyllou *et al.*, 1992; Gil *et al.*, 1993). P3 latency has been associated with demyelinative brain lesions, cognitive impairment, and duration of the disease (Geisser *et al.*, 1992; Honig *et al.*, 1992; Gil *et al.*, 1993). Geisser *et al.* (1992) demonstrated that N1, P2 and P3 latencies were delayed in demented multiple sclerosis patients but not in non-demented patients, suggesting that these electrophysiological abnormalities are related to the cognitive and not the other clinical symptoms of multiple sclerosis. Cooling of patients in order to alleviate sensory and motor disturbances does not appear to affect the latency of the auditory P3 (Geisler *et al.*, 1996).

Impairments in taste and odour identification have been reported in patients with multiple sclerosis (Catalanotto *et al.*, 1986; Cohen, 1965; Doty *et al.*, 1984; Pinching, 1977), although not without controversy. Neuropathological changes in these patients include the appearance of demyelinating plaques in a number of areas of the brain, including the frontal lobe and the mesial temporal lobe, areas important in olfactory function. Yousem *et al.* (1998) demonstrated not only impairment in odour identification (University of Pennsylvania Smell Identification Test, UPSIT) in approximately one-third of the sample of multiple sclerosis patients studied, but also a significant relationship between poorer performance on the UPSIT and increased numbers of plaques detected by MRI in the inferior frontal lobe and the temporal lobe. More recently, Doty *et al.* (1999) examined both UPSIT performance and plaque load in the inferior frontal and temporal lobes in five patients studied on three or four separate occasions over an 18–20-month period. They reported a close association between remission and exacerbation of the disease and plaque numbers and UPSIT scores, supporting the hypothesis that olfactory loss in multiple sclerosis reflects fluctuating plaque numbers. Thus, inconsistencies among earlier studies may well be related to patient selection and the disease status: patients in remission would be expected to demonstrate better performance, and samples of patients with greater disease progression would be expected to demonstrate greater olfactory impairment than samples with patients in early stages of the disease. Geisler *et al.* (2000) investigated OERP performance in multiple sclerosis and found that individuals had delayed latencies and lower amplitudes than normal controls.

AGEING

The ageing process affects brain anatomy and function. Of particular interest, ageing shares with neurodegenerative diseases some common pathology in the frontal and mesial temporal lobes. In the absence of dementia, senile plaques are often observed in elderly people in mesial temporal areas (Price *et al.*, 1991), and there are significant age-related losses in the hippocampus and frontal lobes (Jernigan *et al.*, 2001). The degree of neuropathy in normal ageing distinguishes it from neurodegenerative disease.

The auditory brain stem response is a sensitive indicator of hearing impairment and shows significant effects of age. The latency of the auditory P3 is delayed in old age and is considered to reflect the slowing of the brain with age (Goodin *et al.*, 1978). Similarly, the latency of the P3 components of the visual ERP and the OERP are delayed significantly in elderly people and have been demonstrated to be sensitive to the cognitive decline in old age (Kugler *et al.*, 1996; Murphy *et al.*, 2000).

Investigations of lifespan samples have demonstrated significant effects of age on the auditory and visual ERPs (See Polich, 1991 and Polich, 1997 for reviews). The ERPs showed significant effects of age, the most salient of which were a decrease in amplitude, an increase in latency, and a change in scalp distribution from posterior maximal to more equalized activity at midline sites. P3 amplitude was smaller and the latency shorter for the auditory than for the visual modality, and age effects were larger for P3 amplitude in response to auditory than to visual stimulation (Polich, 1997). Amenedo and Diaz (1998) reported that P2 amplitude increased linearly with advancing age at frontal sites but remained unchanged in middle-aged and elderly subjects. The results suggest age-related changes in inhibitory processes that prevent allocation of attentional resources to the task. Latencies of N2 and P3 increased linearly at Fz, Cz and Pz. Of interest, Bashore (1989) reported that older individuals who are more fit (defined by VO_2 max., i.e. maximum oxygen volume) show larger P3 amplitudes and shorter P3 latencies than older individuals who are less fit. These results are generally consistent with other data that suggest that cognitive function is facilitated by physical fitness in older people.

The P3 component becomes more frontally oriented in elderly subjects (Amenedo and Diaz, 1998; Fabiani *et al.*, 1998; Friedman *et al.*, 1997). Through adolescence and young adulthood the P3 is most robust when recorded from parietal locations. The shift

in elderly people is towards more equal signal intensity from midline sites, thus shifting the distribution in frontal areas relative to central and parietal sites, although the extent of this shift is modulated by task and processing characteristics (Friedman *et al.*, 1997). This may reflect the need to allocate more resources to the initial orienting process or to other frontal lobe functions, such as executive function in older individuals. Compromise of frontal lobe function as a result of neurodegenerative processes in the frontal lobes has been hypothesized (Fabiani *et al.*, 1998; Friedman *et al.*, 1997). Fabiani *et al.* (1998) showed that elderly subjects with frontal-maximal P3 scalp distributions had lower performance on standard neuropsychological tests of frontal lobe function than elderly subjects who showed posterior-maximal P3 scalp distributions. Amenedo and Diaz (1998) also reported a more uniform P3 scalp distribution in elderly subjects that only decreased significantly with advancing age in men. Consistent with a cognitive rationale for the age-related changes in P3 scalp distribution, the sensory component N1 shows no differences in scalp distribution between young and old subjects (Friedman *et al.*, 1993; Ford and Pfefferbaum, 1991).

Impairment of olfactory function as a result of normal ageing is well-documented (Murphy, 1983; Murphy, 1986; Murphy, 1993; Murphy, 1999; Murphy, *et al.*, 2000; Murphy and Cain, 1986; Schiffmann, 1993; Schiffmann, 1997). Olfactory threshold sensitivity decreases in the elderly (Murphy, 1983; Venstrom and Amoore, 1968), and suprathreshold perception of the intensity of odours also decreases (Murphy, 1983). The ability to identify odours falls significantly over the lifespan (Murphy, 1981; Murphy, 1986; Schiffman, 1977), although women are slightly better at identifying odours than are men at all ages (Doty *et al.*, 1984). Memory problems are particularly salient in the elderly. Age impacts all aspects of odour memory: recognition, recall and identification (Murphy *et al.*, 1991; Murphy *et al.*, 1997). Recognition memory for odours is quite good in the young, remaining above chance for 6 months or longer. Elderly people's recognition memory for odours falls to chance between 1 hour and 2 weeks (Murphy *et al.*, 1991). Odour recall also shows significant impairment with age (Murphy *et al.*, 1997) when tested in a manner similar to the neuropsychological standard, the California Verbal Learning Test (Delis *et al.*, 1987). Thus, regardless of the psychophysical test, elderly people show poorer performance at detecting, perceiving, identifying, recognizing and recalling odours.

Assessment of olfactory function with the event-related brain potential has revealed both sensory and cognitive impairment in the elderly. The early sensory components of the OERP show longer latencies and lower amplitudes to odour stimulation in older people (Murphy *et al.*, 1994; Murphy *et al.*, 2000; Morgan *et al.*, 1997). Specifically, N1–P2 amplitude decreases by 1.5 μV per decade, and P2 latency increases by 2 ms per decade, as one ages from 20 to 70 years (Murphy *et al.*, 2000). These components are associated strongly with psychophysical measures of olfactory functioning, especially detection threshold (Murphy *et al.*, 1994). Older males tend to have the greatest deficits as indicated by the OERP, perhaps due to greater brain atrophy in the temporal lobes than females (Morgan *et al.*, 1997). The P3 shows significant effects of age on the speed of olfactory cognitive processing in the elderly, with an amplitude decrease of 2 μV per decade and a latency increase of 2 ms per decade from 20 to 70 years (see Figures XV-7.5 and XV-7.6) (Morgan *et al.*, 1999: Murphy *et al.*, 2000), with the most striking effects beginning to be apparent when participants reach the age of 50 years. In all of these functional measures, there is greater variability in performance in the elderly, suggesting that some older individuals are more resistant to the effects of age (Murphy, 1983; Murphy *et al.*, 2000).

It is important for healthcare providers to be educated about the loss of olfactory function in the elderly, and to understand that as elderly people are largely unaware of this loss (Nordin *et al.*, 1995),

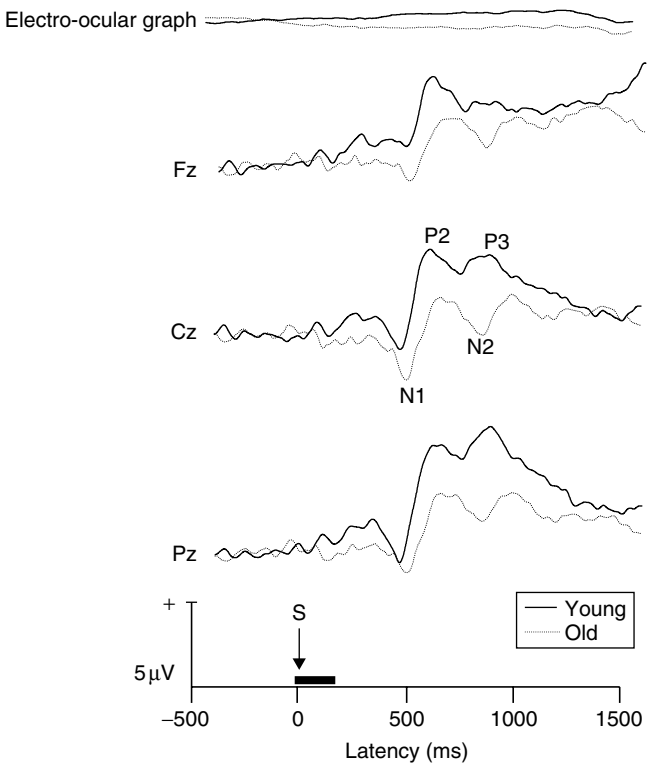

Figure XV-7.5 Grand averaged OERPs for each electrode site for young and older adults. The arrow on the voltage/time scale indicates stimulus onset (from Morgan *et al.*, 1999)

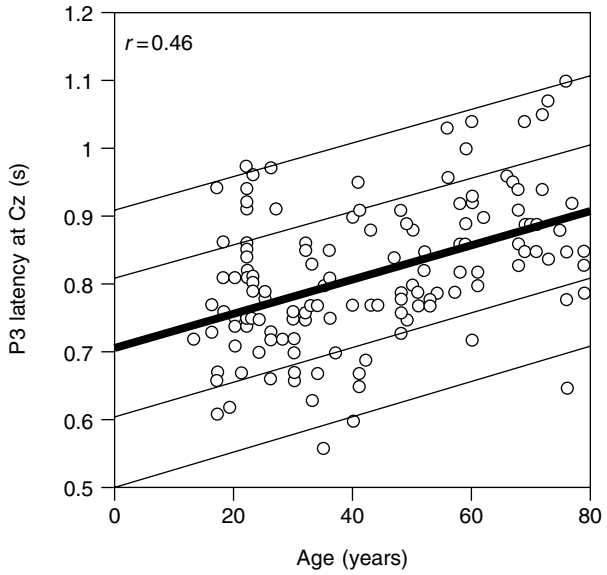

Figure XV-7.6 Rate of increase in latency of the P3 component (±1 and 2 SD) of the OERP, Cz electrode site, across the lifespan. Reprinted from *International Journal of Psychophysiology*, 36, Murphy, C., Morgan, C.D., Geister, M.W., Wetter, S., Covington, J.W., Madowitz, M.D., Nordin, S. and Polich, J.M., Olfactory event-related potentials and aging: normative data, 133–145, Copyright (2000), with permission from Elsevier Science

they are less likely to report impairment or to realize that they are at nutritional or safety risk.

CONCLUSION

The prevalence and debilitating nature of dementia has emphasized the need to deepen our understanding of the phenomenon in order to facilitate discovery of, and apply appropriately, treatments that will stop or slow the decline in cognitive functioning as they become available. Psychophysical and electrophysiological tests can be sensitive and specific in correctly classifying patients with dementia from controls. More investigations are needed to differentiate subtypes of dementia (e.g. vascular, Lewy body, Alzheimer's type) using psychophysical, neuropsychological, neuroimaging and neuropathological techniques. An important application of these techniques will be the identification of very early stages of dementia in order to quantify the subclinical expression of early brain pathology. ERPs show promise in providing this to clinicians, who may choose to include such measures along with neuropsychological tests when evaluating the presence of early dementia. Electrophysiological tests may also prove to be valuable in understanding late stages of disease, when cognitive impairment prohibits the use of neuropsychological test batteries. As such, the field of psychophysiology will be important in our ongoing efforts to understand and ultimately slow the progressive decline of dementia.

Neuropsychology of Cognitive Disorders

Martin A. Goldstein, Jennifer Woehr and Bruce H. Price

INTRODUCTION

Defining Cognitive Dysfunction

Cognitive disorders can be subdivided broadly into (1) congenital or childhood-onset disorders that disrupt development, and (2) primary or acquired secondary dementias with typically adult and especially late-life occurrence. Regardless of onset, cognitive dysfunction is a clinical syndrome, not a specific diagnosis. As such, it can be produced by a wide variety of causes, including genetic, intrauterine, perinatal, nutritional, environmental and/or degenerative causes. Since pathogenic processes can differentially affect functional neuroanatomy underlying different cognitive domains, a large variety of cognitive disorders exists with varying permutations of intellectual dysfunction. We will describe briefly the major cognitive disorder syndromes, with emphasis on their neuropsychological profiles.

Neuropsychological Assessment and Cognitive Disorders

Mental Status Examination

The mini-mental state examination (MMSE) is currently the most widely used quantitative mental status scale (Folstein *et al.*, 1975). The MMSE is reliable on repeat testing, and has a detection range useful for evaluating and monitoring progression of moderate to severe cognitive dysfunction. Further, it has been found to correlate with brain pathology. Its major disadvantage is its insufficient sensitivity to detect mild impairment. Also, the MMSE is insensitive to certain symptom clusters (e.g., as seen in frontotemporal lobar dementia (FTLD)). The most sensitive components of the MMSE are its attentional (e.g., spelling 'world' backwards) and delayed recall tasks. Experienced testers usually supplement the MMSE with more sensitive memory tasks, constructions (e.g., clock drawing), and executive function tests (e.g., word fluency); these increase the sensitivity of mental status testing to early dementia (Bondi *et al.*, 1996).

Early-stage cognitive impairment can be subtle (Bondi *et al.*, 1996). Highly functioning individuals can mask signs of impairment for a protracted time, and most routine mental status examinations (MSEs) have a ceiling effect. Normal results can persist, despite significant deterioration, especially for patients with above-average baseline cognitive performance. When history strongly suggests cognitive impairment, but the MSE is normal, more detailed psychometric testing is necessary to resolve the discrepancy.

Neuropsychological Evaluation

Although brief MSEs (e.g. MMSE) have been shown to be effective in screening for cognitive deficits in large-scale community-based studies, they cannot substitute for comprehensive neuropsychological assessment. Formal neuropsychological testing, with far greater diagnostic sophistication and standardized norms, is more quantitatively precise and qualitatively informative than brief cognitive evaluation procedures. Because neuropsychological tests offer psychometrically acceptable reliability and construct validity, they provide more accurate procedures for describing cognitive strengths and weaknesses. Test findings can be used to detect the presence and degree of cognitive dysfunction, or to delineate specific impairment profiles, thereby aiding identification of underlying pathologies (Bozeat *et al.*, 2000). Testing also helps to clarify possible contributions of normal ageing, encephalopathy and/or comorbid psychiatric disease. See Chapter X for a more detailed review of neuropsychological principles.

In addition to detecting subtle cognitive impairment, neuropsychological testing is essential for accurately tracking progression of cognitive decline, especially when it is necessary to monitor changes in specific cognitive domains or to evaluate efficacy of treatment. For patients suffering effects of acute trauma (who may recover function), or those with progressive neurological disorders (who ultimately experience functional decline), serial neuropsychological evaluations can be used to characterize cognitive changes over time. Ongoing neuropsychological evaluation is also useful in assessing progress (or lack thereof) of children with developmental delays. Perhaps most importantly, neuropsychological assessment techniques are useful in pinpointing relative areas of strength that can inform strategies for remediation and treatment planning.

Individual neuropsychological tests are frequently designed to assay specific areas of cognition. However, popular distinctions drawn between cognitive domains are, in fact, somewhat arbitrary, since no cognitive function exists purely in isolation. For example, 'pure' measures of verbal memory require patients to both process language and sustain attention to test stimuli. A deficit in either attention or language will consequently obfuscate performance on measures of 'memory'. Because most neuropsychological instruments de facto test more than one cognitive skill, assessment batteries typically rely on a combination of measures within and across cognitive domains to systematically eliminate confounds. In addition, qualitative behavioural observations throughout assessment can offer valuable data, such as test anxiety or use of compensatory strategies, which can negatively impact test validity.

Although measures of learning and retention are the most effective neuropsychological indices for differentiating between mildly demented and normal elderly patients, assays of language, executive function and constructional ability also have diagnostic value (Bondi *et al.*, 1996). For example, differential performance

Table XV-8.1 Cognitive domain dysfunction, associated disease states, and neuropsychological assessment

Cognitive domain	Relevant clinical syndromes	Commonly used assessment tools (adults)	Commonly used assessment tools (children)
Premorbid intelligence/academic achievement	Neurodegenerative disorders	Vocabulary subtest (WAIS-III)	Woodcock–Johnson Tests of Achievement
	Acquired brain injury	NAART	WIAT
	Toxic or metabolic encephalopathies	Barona/Wilson Method	WRAT
General intellectual ability	Learning disabilities	WAIS-III	Bayley Scales of Infant Development
	Pervasive developmental disabilities	WASI	Wechsler Preschool and Primary Scale of Intelligence
	Mental retardation	Stanford–Binet Intelligence Scale Raven's Progressive Matrices Woodcock–Johnson Test of Cognitive Ability Folstein MMSE	WISC-III Stanford–Binet Intelligence Scale Woodcock–Johnson Test of Cognitive Ability
Attention	Attention deficit disorder	Trails A Boston Cancellation Test Digit-span (WMS-III)	Trails A (intermediate) Denckla Cancellation Test Digit-span (WISC-III)
	Delirium	Spatial span (WMS-III) Continuous Performance Test	Arithmetic (WISC-III) Continuous Performance Test
	Neglect syndromes	Letter–number sequencing (WMS-III) PASAT	
	Affective disturbance	Dichotic listening	
Memory	Dementia syndromes	WMS-III Logical memory I & II, visual reproduction I & II	Wide range achievement of memory and learning
	Isolated amnestic syndromes	California Verbal Learning Test Rey–Osterrieth complex figure test Benton Visual Retention Test Famous Faces Test 7 Minute Screen	Rey Auditory Verbal Learning Test California Verbal Learning Test (Children's Version) Test of memory and learning
Language	Aphasia syndromes	Boston Naming Test Sentence repetition	PPVT
	Dementia syndromes	Boston diagnostic aphasia Examination Fluency tasks	TOLD-II, primary or intermediate CELF-III Vocabulary (WISC-III)
Visuospatial	Huntington's disease Stroke Nonverbal learning disability	Hooper Visual Organization Test Benton judgement of line orientation Block design (WAIS-III) Object assembly (WAIS-III)	TVPS-R Block design (WISC-III) Object assembly (WISC-III)
	Dementia syndromes	Cancellation tasks	
Visuomotor	Parkinson's disease Developmental delay	Grooved pegboard Fingertapping Gripstrength	Visual motor integration test Rey–Oesterrieth complex figure
Executive functioning	Acquired brain injury	Trails B Wisconsin Card Sort Test	Trails B (Intermediate) Wisconsin Card Sort Test
	Dementia syndromes	Stroop Color–Word Test Controlled Oral Word Association Test	Stroop Color–Word Test Rey–Osterrieth complex figure
	Attention deficit disorder	Animal naming Design fluency Go/no-go tasks	
	Psychiatric disorders		

CELF, clinical evaluation of language fundamentals; NAART, North American adult reading test; PASAT, paced serial addition test; PPVT, Peabody picture vocabulary test; TOLD, test of language development; TVPS, test of visuoperceptual skills; WAIS, Wechsler adult intelligence scale; WASI, Wechsler abbreviated scale of intelligence; WIAT, Wechsler individual achievement test; WISC, Wechsler intelligence scale for children; WMS, Wechsler memory scales; WRAT, wide range achievement test

of mildly demented patients with probable Alzheimer's disease and normal elderly control subjects on several types of verbal fluency tasks has greater than 90% sensitivity and specificity for the diagnosis of dementia (Bondi *et al.*, 1996). Similarly high sensitivity and specificity for dementia detection are demonstrated for category number achieved on a modified version of the Wisconsin card sorting task in a study comparing performances of mildly demented probable Alzheimer's disease patients versus normal elderly subjects (Bondi *et al.*, 1993).

Neuropsychological testing provides a systematic means for assessing individual cognitive performance relative to a normal reference population. Neuropsychological assessment tools are typically normed on the basis of age and education, yielding a standardized score range. Given the age-associated prevalence of most cognitive disorders, most patients referred for neuropsychological assessment of cognitive function are older adults (Bondi *et al.*, 1996). Normal age-related perceptual and motor performance changes influence both test material selection and performance interpretation, since such changes can impact neuropsychological performance independent of cognitive function (Bondi *et al.*, 1996). Norm-referenced scoring procedures for neuropsychological assessment are generally age matched. Consequently, normal age-related changes are incorporated into evaluation. Normative data up to age 90 years old are available for many of the more commonly used neuropsychological tests (Bondi *et al.*, 1996).

Following administration and scoring of a neuropsychological battery, an individual's performance is compared with that of the population at large and examined for population-based discrepancies. In addition, the individual's test profile is assessed for widely discrepant or outlying scores that may represent a significant relative weakness in the context of the individual's overall performance. Finally, the patient's cognitive profile must be evaluated in the context of both qualitative behavioural observations and thorough patient history, which includes information regarding physical, educational, psychiatric, social and occupational functioning.

Table XV-8.1 illustrates specific domains of cognitive function, gives examples of relevant clinical syndromes, and lists neuropsychological assessment tools commonly used to measure performance in each domain. It should be noted, however, that most neurological syndromes involve more than one area of cognitive dysfunction. As a result, Table XV-8.1 represents a descriptive but far from exhaustive list of cognitive challenges faced by people with these diagnoses. By extension, diminished performance on any one of these neuropsychological assessment tools is not necessarily pathognomonic for any specific diagnosis. Pattern recognition in the differential diagnosis of cognitive impairment is essential (Patterson *et al.*, 1999).

Aetiologically and neuropathologically distinct cognitive disorders are associated with different patterns of relatively preserved and impaired neuropsychological function. One major conceptual distinction is between degenerative syndromes affecting primarily cortical tissue (e.g. Alzheimer's disease, FTLD) and those affecting subcortical structures (e.g. Parkinson's disease, Huntington's disease, progressive supranuclear palsy (PSP)). For example, Alzheimer's disease, a prototypical cortical dementia, is classically characterized by prominent amnesia with additional deficits in language, abstract reasoning, visuospatial processing and executive function. In contrast, Huntington's disease, a prototypical subcortical dementia syndrome, usually has only moderate memory disturbance but prominent attentional dysfunction, problem-solving deficits, and arithmetic impairment (see below).

Evolving models of dementia pathogenesis have contributed to its conceptualization as a disease state with preclinical stages during which pathology exists but has not yet reached sufficient magnitude for clinical expression (e.g. mild cognitive impairment, preclinical Alzheimer's disease). This has prompted desire to develop ways to detect such states when symptom threshold for conventional clinical diagnosis has not yet been reached but some subtle functional deficit exists that potentially can be assayed. That is, as pathogenesis gradually progresses, so does cognitive impairment, which might be identified before neuronal degeneration reaches the level necessary to produce overtly detectable dementia. Although the precise length of this preclinical phase varies among neurodegenerative cognitive disorders, and between individuals, increasing evidence exists that subtle cognitive impairment can be detected several years before clinically evident dementia. Extensive efforts are under way to improve sensitivity and specificity of neuropsychological predictors of incipient dementia, and several studies have used a variety of neuropsychological measures to retrospectively examine performance of non-demented elderly subjects who subsequently became demented. For example, one study indicated that initial performance on the delayed recall measure of the selective reminding test, a recall measure from the Fuld object memory test, the digit symbol substitution subtest from the WAIS, and measures of verbal fluency are all significant predictors of subsequent dementia development (Masur *et al.*, 1994).

Investigators have attempted to improve the detection of incipient dementia with neuropsychological testing by limiting assessment to elderly patients who carry increased dementia risk (e.g. positive family history of Alzheimer's disease and/or genotype positive for apolipoprotein E (APOE) $\varepsilon 4$). For example, normal elderly with a positive family history of dementia perform worse than family-history-negative subjects on tests of learning and memory (Hom *et al.*, 1994). Similarly, non-demented elderly APOE $\varepsilon 4$-positive men exhibit poorer mean performance on visual memory testing than their APOE $\varepsilon 4$-negative dizygotic twins (Bondi *et al.*, 1996). Another study demonstrated that verbal learning and memory performance of non-demented APOE $\varepsilon 4$-positive subjects was qualitatively (though not quantitatively) similar to that of early-stage Alzheimer's disease patients (Bondi *et al.*, 1995).

DEVELOPMENTAL COGNITIVE DISORDERS

Mental Retardation

Mental retardation is a heterogeneous disorder of multiple potential aetiologies all involving subaverage cognitive function and skill performance with onset before age 18 years. Many cases of mental retardation, particularly mild retardation, have undetermined or idiopathic aetiologies.

Table XV-8.2 outlines the current diagnostic criteria for mental retardation, and Table XV-8.3 summarizes developmental deficits characterizing mental retardation syndromes of varying severities.

Table XV-8.2 Diagnostic criteria of mental retardation

A	Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered IQ test	
B	Concurrent deficits or impairments in present adaptive functioning in at least two of the following areas: communication, self-care, home living, interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, safety	
C	Onset before age 18 years	
Severity based on IQ score:	50–55 to 70	Mild
	35–40 to 50–55	Moderate
	20–25 to 35–40	Severe
	<20–25	Profound

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Mental Disorders*, 4th edition. American Psychiatric Press, Washington, DC

Table XV-8.3 Developmental characteristics of mental retardation syndromes

Severity	Preschool age (0–5 years): maturation and development	School age (5–20 years): training and education	Adult (21 years and over): social and vocational adequacy
Profound	Gross retardation; minimal capacity for functioning in sensorimotor areas; needs nursing care; constant supervision required	Some motor development present; may respond to minimal or limited training in self-help	Some motor and speech development; may achieve very limited self-care; needs nursing care
Severe	Poor motor development; minimal speech; generally unable to profit from training in self-help; little or no communication skill	Can talk or learn to communicate; can be trained in elemental health habits; benefits from systematic habit training; unable to benefit from vocational training	May contribute partially to self-maintenance under complete supervision; can develop self-protection skills to a minimally useful level
Moderate	Can talk or learn to communicate; poor social awareness; fair motor development; benefits from training in self-help; requires moderate supervision	Can benefit from training in social and occupational skills; unlikely to progress beyond second-grade academic level; may learn to travel alone in familiar places	May achieve self-maintenance in unskilled or semiskilled work under sheltered conditions; needs supervision and guidance when under mild social or economic stress
Mild	Can develop social and communication skills; minimal retardation in sensorimotor areas; often not distinguished from normal until later age	Can learn academic skills up to approximately sixth-grade level by late teens; can be guided toward social conformity	Can usually achieve social and vocational skills adequate to minimum self-support, but may need guidance/assistance under stress

Adapted from *Mental Retardation Activities*, US Department of Health, Education, and Welfare, 1983

Table XV-8.4 Diagnostic criteria for autistic disorder

A Total of six or more items from (1), (2) and (3)	(1) Qualitative impairment in social interaction, as manifested by at least two of the following: (a) marked impairment in use of multiple nonverbal behaviours, such as eye-to-eye contact, facial expressions, bodily postures and gestures to regulate social interaction (b) failure to develop peer relationships appropriate to developmental level (c) lack of spontaneous seeking to share enjoyment, interests or achievements with other people (e.g. by a lack of showing, bringing or pointing out objects of interest) (d) lack of social or emotional reciprocity. (2) Qualitative impairments in communication, as manifested by at least one of the following: (a) delay in, or total lack of, development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication, such as gesture or mime) (b) in individuals with adequate speech, marked impairment in ability to initiate or sustain a conversation with others (c) stereotyped or repetitive use of language or idiosyncratic language (d) lack of varied spontaneous make-believe play or social imitative play appropriate to developmental level. (3) Restrictive repetitive and stereotyped patterns of behaviour, interests and activities, as manifested by at least one of the following: (a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus (b) apparently inflexible adherence to specific nonfunctional routines or rituals (c) stereotyped and repetitive motor mannerisms (e.g. hand or finger flapping or twisting, or complex whole-body movements) (d) persistent preoccupation with parts of objects.
B Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years	(1) Social interaction (2) Social language communication (3) Symbolic or imaginative play

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

The neuropsychological profile of mental retardation varies widely, as the term does not reflect a discrete condition but the common functional impact of numerous aetiological entities. Even within individual conditions (such as Down's syndrome), phenotypic expression can vary widely. Regardless of aetiology, however, a diagnosis of mental retardation assumes a diminished level of cognitive performance that measures at least two standard deviations below the mean on standardized measures of intellectual performance. The diagnosis is generally made on the basis of formal assessments of overall intellectual functioning (IQ), such as the Wechsler or Stanford–Binet intelligence scales. Although children with mental retardation may gain cognitive abilities over time, the rate of acquisition generally lags far behind that of same-age peers.

Pervasive Developmental Disorders

Pervasive development disorders represent a heterogeneous set of disorders in which communication, adaptive skills and social interaction develop improperly or are lost in early childhood. The disorders manifest in early life, afflict multiple developmental domains, and cause persistent dysfunction. There are four recognized types: autistic disorder, Asperger's disorder, Rett's syndrome, and pervasive developmental delay; we briefly describe two of the more common of these, autism and Asperger's.

Autistic Disorder

Autistic disorder is characterized by severely impaired social communication and restricted stereotypical behavioural patterns

presenting by age 3 years. Table XV-8.4 summarizes the current diagnostic criteria.

Autism is not diagnosed primarily on the basis of cognitive findings but on qualitative deficits in social interaction. Cognitive functions can vary widely from individual to individual, although all patients with autism exhibit deficits in metacognitive executive skills and demonstrate some degree of language impairment. About half of children with autism never develop any functional language. Almost 75% of autistic children meet criteria for mental retardation, with about 40% having IQ scores below 55. In general, IQ scores in autism tend to reflect deficiencies in verbal sequencing and abstraction rather than deficiencies in visuospatial and memory skills, reflecting the primacy of language-based dysfunction. Interestingly, some autistic children demonstrate unusual or precocious cognitive abilities, even within a context of overall retarded function. Included among these cases are the 'savants', who have prodigious memory function, extraordinary calculating abilities, hyperlexia (early ability to read well) and/or musical abilities.

Asperger's Syndrome

Austrian physician Hans Asperger described a syndrome in which patients with normal intelligence exhibited qualitative impairment in reciprocal social interaction and behavioural oddities without developmental language deficits. Table XV-8.5 summarizes the current diagnostic criteria.

As with autism, Asperger's disorder is diagnosed primarily on the basis of anomalous social behaviour rather than on conventional cognitive dysfunction. Although children with Asperger's disorder perform within the normal range on formal cognitive measures and lack the severe expressive language deficits of autistic children, metacognitive conceptual abilities and receptive language function are impaired. There are notable abnormalities of affective speech expression and comprehension (understanding and use of prosody). Rote memory skills can sometimes be extraordinary, as with autism.

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is characterized by developmentally inappropriate deficiency of attention span and/or age-inappropriate features of hyperactivity and/or impulsivity. Diagnostic criteria are outlined in Table XV-8.6.

ADHD characteristics include hyperactivity, perceptual-motor impairment, emotional lability, general coordination deficit, attentional deficits, impulsivity, memory deficit, specific learning disabilities, disorders of speech and hearing, and equivocal neurological signs and electroencephalogram (EEG) abnormalities. About 75% of children with ADHD manifest behavioural symptoms of aggression and defiance. A conduct disorder is a frequent comorbidity (Kaplan *et al.*, 1994).

Diagnostic criteria for ADHD are generally more behavioural rather than neuropsychological. As a result, diagnosis can sometimes be assigned on the basis of undesirable behaviour alone in the absence of any true measure of attentional functioning. Consequently, before a diagnosis of ADHD is conferred, careful consideration should be paid to other factors that can result in behavioural dyscontrol (e.g. childhood trauma, depression, anxiety disorders). In addition, classroom behaviours associated with ADHD (e.g. academic task avoidance) may stem from academic difficulties related to learning disabilities, which make academic work intolerably frustrating. Conferring a diagnosis of ADHD without considering other mediating factors can result in oversight of significant psychosocial, psychiatric or learning difficulties.

'Attention' is a broad term encompassing numerous self-regulatory functions, ranging from basic capacity to maintain optimal arousal to far more complex functions, such as capacity to preferentially attend to some stimuli while simultaneously ignoring irrelevant stimuli (requiring ancillary executive functions). These children can have difficulty filtering distractions, maintaining sustained vigilance, focusing on multiple targets simultaneously, efficiently shifting focus, and/or inhibiting impulses. Not surprisingly, children with ADHD perform poorly on neuropsychological measures of attention (such as the continuous performance test, or the Wechsler digit-span subtest) and executive function (such as the Wisconsin card sort or the Stroop color word test). In addition, because attentional focus is critically important to acquisition of information, children with ADHD can fail to make adequate academic progress overall.

Table XV-8.5 Diagnostic criteria for Asperger's disorder

A	Qualitative impairment in social interaction, as manifested by at least two of the following:	(1) Marked impairment in use of multiple nonverbal behaviours, such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction (2) Failure to develop peer relationships appropriate to developmental level (3) Lack of spontaneous seeking to share enjoyment, interests or achievements with others (4) Lack of social or emotional reciprocity
B	Restricted, repetitive and stereotyped patterns of behaviour, interests and activities, as manifested by at least one of the following:	(1) Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal in intensity or focus (2) Apparently inflexible adherence to specific, nonfunctional routines or rituals (3) Stereotyped and repetitive motor mannerisms (4) Persistent preoccupation with parts of objects
C	Disturbance causes clinically significant impairment in social, occupational or other important areas of functioning	
D	There is no clinically significant general delay in language (e.g. single word use by age 2 years, communicative phrase use by age 3 years)	
E	There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behaviour (other than in social interaction) and curiosity about environment during childhood	

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

Table XV-8.6 Diagnostic criteria for ADHD

A Either (1) or (2)	(1) Inattention: six or more of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level		(a) Often fails to give close attention to details, or makes careless mistakes in schoolwork, work or other activities (b) Often has difficulty sustaining attention in tasks or play activities (c) Often does not seem to listen when spoken to directly (d) Often does not follow through on instructions, and fails to finish schoolwork, chores or duties in the workplace (e) Often has difficulties organizing tasks and activities (f) Often avoids, dislikes, or is reluctant to engage in tasks requiring sustained mental effort (g) Often loses things necessary for tasks or activities (h) Is often distracted easily by extraneous stimuli (i) Is often forgetful in daily activities
	(2) Hyperactivity–impulsivity: six or more of the following symptoms of hyperactivity–impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level	Hyperactivity	(a) Often fidgets or squirms (b) Often leaves seat in classroom or in other situations in which remaining seated is expected (c) Often runs about or climbs excessively in situations in which it is inappropriate (d) Often has difficulty playing or engaging in leisure activities quietly (e) Is often 'on the go' or often acts as if 'driven by a motor' (f) Often talks excessively
		Impulsivity	(a) Often blurts out answers to questions before questions have been completed (b) Often has difficulty awaiting turn (c) Often interrupts or intrudes on others
B Some hyperactive–impulsive or inattentive symptoms that caused impairment were present before age 7 years			
C Some impairment from the symptoms is present in two or more settings (e.g. school, work)			
D There must be clear evidence of clinically significant impairment in social, academic or occupational functioning			

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

Learning Disorders

Learning disorders are characterized by discrete impairments of academic skill acquisition within the context of normal overall intellectual ability. These disorders are diagnosed only when a significant discrepancy exists between scholastic achievement and overall cognitive function. The following sections outline current nosology.

Reading Disorders

Reading disorders are characterized by impaired ability to recognize words, slow and inaccurate reading, or poor comprehension in the absence of low intelligence or sensory deficits. Children may experience reading difficulties for a variety of reasons, including but not limited to difficulties with sound–symbol association and phonemic discrimination, difficulties with sound blending and word segmentation, and difficulties mastering automatic sight-recognition skills. Table XV-8.7 outlines *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 1994) criteria for reading disorder.

A variety of terms have been used in the past to describe reading disabilities, including dyslexia. Since reading disorders are frequently accompanied by other deficits (e.g. disorder of written expression, mathematics disorder, and/or one of the communication disorders), the term dyslexia was replaced by more general terms, such as learning disorder (Kaplan *et al.*, 1994).

Reading disorders are usually apparent by age 7 years (second grade). Children with ADHD have a higher risk of developing reading disorders. Psychoeducational diagnostic batteries should include standardized reading achievement tests (e.g. Standardized Reading Inventory (SRI), Woodcock Reading Mastery Test (Kaplan *et al.*, 1994).

Table XV-8.7 Diagnostic criteria for reading disorders

A	Reading achievement, as measured by individually administered standardized tests of reading accuracy or comprehension, is substantially below that expected given chronological age, measured intelligence and age-appropriate education
B	The disturbance interferes significantly with academic achievement or activities of daily living that require reading skills
C	If a sensory deficit is present, the reading difficulties are in excess of those usually associated with it

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

Disorders of Written Expression

Impaired written expression is often associated with other learning disorders, but it can appear in isolation. Current criteria are summarized in Table XV-8.8.

Children typically present in early grades with difficulties spelling words and expressing thoughts according to age-appropriate grammatical norms. Spoken and written language contain excessive grammatical errors and poor organization. Initially, children make simple spelling and grammatical errors in writing short sentences. Later, language dysfunction extends to improper diction and disorganized paragraph construction (Kaplan *et al.*, 1994).

Evaluation should begin with a standardized intelligence test, such as the Wechsler intelligence scale for children (WISC-R) or the revised Wechsler adult intelligence scale (WAIS-R) to gauge intellectual function before administering a standardized expressive writing test. Instruments commonly used to assess written

Table XV-8.8 Diagnostic criteria for disorder of written expression

A	Writing skills, as measured by individually administered standardized tests (or functional assessments of writing skills), are substantially below those expected for chronological age, measured intelligence and age-appropriate education
B	Disturbance interferes significantly with academic achievement or activities of daily living that require composition of written text (e.g. writing grammatically correct sentences and organized paragraphs)
C	If a sensory deficit is present, writing skill impairment is in excess of that associated with it

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

Table XV-8.9 Diagnostic criteria for mathematics disorder

A	Mathematical ability, as measured by individually administered tests, is substantially below that expected given chronological age, measured intelligence and age-appropriate education
B	The disturbance interferes significantly with academic achievement or activities of daily living that require mathematics ability
C	If a sensory deficit is present, the difficulties in mathematical ability are in excess of those usually associated with it

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

expression abilities include the Test of Written Language (Hammill and Larsen, 1995) and the Wide Range Achievement Test (WRAT).

Mathematics Disorder

Mathematics disorder is a disability in performing arithmetic skills expected for intellectual capacity and educational level. Past terms have included dyscalculia and the disorder has previously been classified under the rubric of Gerstmann syndrome (a syndrome typically associated with dominant parietal lobe dysfunction manifesting as left–right confusion, finger agnosia, dyscalculia and dysgraphia). Table XV-8.9 outlines the current criteria for mathematics disorder (Kaplan *et al.*, 1994).

Definitive diagnosis can be made only after demonstration of average functioning on measures of general intellectual ability and markedly below-expected performance on standardized measures of arithmetic skills, including the WRAT, the Wechsler Individual Achievement Test (WIAT), and the Woodcock–Johnson Test of Achievement.

ADULT COGNITIVE DISORDERS

Defining Cognitive Dysfunction

Cognitive dysfunction can involve single or multiple domains. When an isolated deficit exists, memory impairment is the most frequent; amnestic disorders comprise this diagnostic category. More commonly, multiple cognitive domains are affected; such disorders of adult onset involve primarily the vast and heterogeneous syndrome category collectively known as dementia. Dementia can be defined as sustained or progressive decline in cognition and/or comportment caused by chronic brain dysfunction. In contrast to the conditions described above, which impede intellectual development, dementia involves loss of previously developed cognitive abilities. Dementia can occur by acute or, more commonly, insidious onset, can be reversible or irreversible, and can have an indolent or progressive course.

Impairments can occur in any combination of comportmental, cognitive, affective and perceptual domains, potentially affecting personal, social and/or vocational function(s). Many authors specify that impairment involve at least three of the following functional capacities: attentional matrix, language, memory, visuospatial skills, executive abilities and personality. Although memory loss is sometimes considered prerequisite to diagnosis, amnesia is neither ubiquitous nor necessarily prominent in all forms of dementia. Cognitive and social abilities can be affected differently by dementia: patients with severe but focal cognitive deficits can retain functional independence, while those with relatively mild impairments affecting socially critical functions may require extensive supervision.

Table XV-8.10 summarizes core components of the widely used DSM-IV dementia diagnostic criteria.

Dementia severity can be gauged in social terms as well as by the nature and degree of cognitive impairments. Dementia is considered mild when the patient continues to conduct basic activities of daily living (e.g. dressing, grooming, eating, toileting) without assistance. Patients with moderate dementia depend partly on others for these activities. In severe dementia, these functions must be provided by caregivers. The same terms are used to describe neuropsychological deficit severity (e.g. mild, moderate or severe memory loss).

To identify an underlying pathogenic disease process, all aspects of a patient's medical history, family history and clinical examination (medical, neurological, psychiatric) must be considered along with well-reasoned laboratory investigations (van Crevel *et al.*, 1999). Dementia features such as age at symptom onset, nature and severity of cognitive and behavioural deficits, and pattern of progression are considered in evaluating the differential diagnosis of a dementia (Patterson *et al.*, 1999). Neuropathological examination usually establishes the underlying disorder and constitutes the gold standard against which ante-mortem diagnostic accuracy is measured.

Since cognitive impairment must be measured against baseline performance, highest level of education, life achievements and premorbid personality traits should be established first. Since premorbid neuropsychological data are rarely available, the clinician must often rely on a history of cognitive deterioration provided by an informant. Several studies have demonstrated that informants (usually a close relative) are able to provide valid reports of progression in dementia patients. Family assessments of patient memory deficits have been found to correlate well with objective cognitive scores. Furthermore, informant judgements of patient cognitive status have been found to be reasonably accurate when compared with formal monitoring of patient progression. However, certain caveats need to be maintained. For example, informant report accuracy can be influenced by the relationship between the patient and the informant (e.g. spouses of memory-impaired patients report lower levels of impairment than do younger relatives) (McGlone *et al.*, 1990; Bondi *et al.*, 1996). Consequently, accuracy of reports of cognitive decline can be enhanced by interviewing multiple family members.

Different dementing processes often selectively involve different brain nuclei and/or neurotransmitter systems. Consequently, not all cognitive faculties are affected simultaneously. Neuropsychological profile is often dictated more by neuroanatomical lesion site than by specific histopathology. Several dementias reflect direct damage to cortical association areas (e.g. asymmetric cortical degeneration); in others, dysfunction is secondary to impairment of interconnected subcortical regions, such as basal ganglia, thalamus and limbic structures. Disruption of white-matter pathways, whether multifocal (as in multiple sclerosis) or confined to single areas such as the internal capsule genu (as in strategic infarct dementia), can critically slow or disconnect neocortical areas. Degeneration of brainstem and/or basal forebrain nuclei, which normally provide ascending cholinergic and monoaminergic neurotransmitter supply to neocortical association areas, can cause profound dementia.

Table XV-8.10 Selected DSM-IV dementia criteria

Dementia of the Alzheimer's type	Development of multiple cognitive deficits manifested by: • memory impairment • one or more of the following: – aphasia – apraxia – agnosia – executive dysfunction Cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning The course is characterized by gradual onset and continuing cognitive decline The cognitive deficits in criteria A1 and A2 are not due to any of the following: • other CNS conditions • systemic conditions • substance-induced conditions The deficits do not occur exclusively during the course of a delirium
Vascular dementia	Development of multiple cognitive deficits, manifested by: • memory impairment • one or more of the following: – aphasia – apraxia – agnosia – executive dysfunction The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning Focal neurological signs and/or symptoms or laboratory evidence indicative of cerebrovascular disease, which are judged aetiologically related to the disturbance The deficits do not occur exclusively during the course of a delirium

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. American Psychiatric Association, Washington, DC

Table XV-8.11 Classifying cognitive dysfunction

Cognitive impairment	Primary or secondary process	Potential reversibility	Example
Encephalopathy	Secondary	Usually reversible	Toxic/metabolic
Dementias	Secondary	Sometimes reversible	Vitamin B_{12} deficiency
		Irreversible	Creutzfeldt–Jakob disease
	Primary	Irreversible	Alzheimer's disease

Differentiating Cognitive Dysfunction from Other Mental Disorders

Although there can be considerable phenomenological overlap of cognitive impairment aetiologies (e.g. subdural haematoma can manifest as delirium or reversible dementia), knowledge of the conceptual distinctions shown in Table XV-8.11 facilitates the approach.

Only 10–15% of dementias are reversible, and only a fraction of these are completely reversible (Freter *et al.*, 1998).

Delirium/Encephalopathy/Acute Confusional State

Several terms are applied to acute or subacute sensorium disturbance. The terms delirium, encephalopathy, and acute or subacute confusional state are clinically equivalent and can be used interchangeably. Since almost any systemic or primary central nervous system (CNS) syndrome can cause an encephalopathic derangement, potential delirium aetiologies are multiple.

The sine qua non clinical feature of delirium is clouded sensorium. Although dementia involves cognitive impairment within the context of an awake patient with clear sensorium, acute confusional states are frequently misdiagnosed as dementia. When a delirium is superimposed on an underlying dementia, cognitive abilities can decline precipitously. Although dementia and delirium can be comorbid, delirium is differentiated by an acute or subacute onset occurring within hours or days. While demented patients without delirium frequently demonstrate preserved attentional capacities, patients with delirium experience fluctuations in levels of consciousness, with consequent gross attentional impairments. Patients may have difficulty focusing, sustaining and shifting attention in a productive or goal-directed manner, with consequent disorientation and secondary memory deficiency. Hallucinations are frequent and can involve any sensory modality. Dysarthria is a common correlate.

Because delirium involves a fluctuating course, a thorough assessment should seek to identify variations in cognitive performance by either history or direct observation. However, patients with delirium are typically compromised to the extent that they are unable to tolerate extensive testing. Brief, time-limited measures are therefore useful in identifying fluctuating cognition over time. The digit span and orientation subtests from the Wechsler Memory Scales (WMS) III prove useful in this regard. When variable performance on these tasks is accompanied by dysarthria or hallucinations, a diagnosis of delirium should be considered and an acute physiological aetiology sought.

Amnestic Syndromes

Amnesia, a disorder of memory, can occur as a component of a multifaceted mental status change, such as delirium or dementia, or as an isolated abnormality. When occurring as an isolated cognitive

deficit, it is useful to consider amnesia as a distinct nosologic category.

'Memory' is not a discrete entity, but rather a complex amalgamation of cognitive processes underlying the acquisition, consolidation, accession and mutation of neural representations of past experience. As such, memory represents the end-product of multilayered cognitive operations performed by multiple interdependent neural substrates. While medial-temporal, diencephalic and frontal systems figure prominently in memory functioning, the pathways connecting these regions are equally important. Hence, amnesia can result from disruption of any one of many cognitive circuits. Table XV-8.12 summarizes the neural substrates of specific memory processes and associated anatomic regions (see Chapter X for a more detailed discussion of normal memory function).

True amnesia, i.e. distinct memory impairment isolated from any other cognitive deficit, is relatively rare. Patients with true amnesia typically experience deficits in explicit memory, usually anterograde (see below). Implicit memory systems frequently remain intact, such that procedures, habits, skills and classically conditioned responses may still be acquired in the absence of conscious awareness (O'Connor and Morin 1998). As a consequence, patients may modify responses to environmental stimuli while lacking awareness of events leading to the behavioural change.

Damage to the medial-temporal lobe, including the hippocampus, is classically associated with memory consolidation dysfunction and rapid forgetting. Retrieval problems are often associated with diencephalic lesions, particularly those involving the mammillary bodies and thalamic nuclei (Lezak, 1995). Retrieval deficiency is also commonly associated with disruption of white-matter tracts, as seen in small-vessel ischaemia, diffuse axonal injury or autoimmune deficiency syndrome (AIDS) dementia complex (Filley, 2001).

Regardless of aetiology, memory deficits exist on a multidimensional continuum, such that memory dysfunction may be either mild or severe, global or circumscribed, and anterograde or retrograde, depending on extent and location of neurolopathology. Retrograde amnesia is characterized by the inability to recall information before disease onset, while anterograde amnesia is marked by impaired capacity to form new memories after a precipitating event. Although pure anterograde amnesia (i.e. in the absence of any significant retrograde component) is a common form of amnesia, retrograde amnesia almost never occurs in the absence of an accompanying anterograde amnesia of equivalent or greater severity (Kopelman, 1987; Lezak, 1995).

Patients with primarily anterograde amnesia (e.g. Korsakoff syndrome) attempt to fill in memory gaps with false recollections (confabulations), which can take the form of elaborate contrivances or genuine memories misplaced in time, while distant long-term memory is relatively preserved, perhaps because well-established memories are stored more diffusely. The most deeply ingrained memories, such as one's own name, are almost always spared in neurological memory disturbances. In contrast, personal memories may be impaired prominently or exclusively in psychogenic amnesias.

A comprehensive neuropsychological assessment addressing multiple aspects of cognition is required in order to establish whether memory deficits are circumscribed (as in amnesia) or part of a broader cognitive syndrome such as dementia. Measures of retrograde (or remote) memory tend to be less objective and have norms that are less precise than measures of new learning, as autobiographical memory requires independent verification by the examiner, and patient knowledge of historical events lends itself to idiosyncratic variation. Despite this, tools such as the Autobiographical Memory Interview, the Famous Faces Test (which assesses knowledge of well-known historical figures), and the Transient Events Test (which measures knowledge of high-profile news items and historical events) have been developed to yield a broad overview of remote memory functioning. One advantage of these structured assessment tools is that they allow for temporal grading of remote memory loss. Neuropsychological measures addressing both retrograde and anterograde memory functioning can help characterize memory dysfunction, so that optimal rehabilitation strategies and environmental supports can be implemented.

Memory-specific neuropsychological assessment tasks designed to address new learning (which are included in most neuropsychological assessments regardless of the referral question) probe encoding, storage and retrieval skills. Tests such as the WMS-III, the California Verbal Learning Test (CVLT), Rey–Osterreith Complex Figure, and Warrington Recognition Memory Test are frequently used to gauge both verbal and nonverbal aspects of memory. These neuropsychological tasks present the patient with verbal and/or nonverbal material and require the patient immediately to reproduce information from memory (to assess initial perceptual and encoding capacities). After a circumscribed period of time, the patient is asked to recall information independently, assessing memory storage and retrieval capabilities. Following the independent recall (or 'free-recall') condition, the patient is presented with multiple-choice cues to assess overall retention rates in the absence of retrieval demands. If the patient performs significantly better with cueing, then it can be assumed that they have recorded and stored the information over time but are having relative difficulty retrieving the information as needed (similar to the 'tip of the tongue' phenomenon that most of us experience from time to time). In all, neuropsychological tasks assessing memory attempt to pinpoint whether a memory deficit is present, identify the type and degree of memory impairment, and determine whether the memory deficit is isolated (as in true amnestic syndromes) or occurring in conjunction with other cognitive anomalies.

Imaging and autopsy studies frequently reveal bilateral hippocampal and/or related structure (e.g. dorsomedial thalamus) abnormalities.

Table XV-8.12 Functional neuroanatomy and memory system classification

Length of storage	Long-term memory					Short-term memory
Awareness	Explicit		Implicit			Explicit
System	Episodic memory	Semantic memory	Simple classical conditioning	Procedural memory	Priming	Working memory
Anatomy	Medial-temporal lobe, diencephalon	Inferior and lateral temporal lobe	Amygdala, limbic system (autonomic) Cerebellum (motoric)	Basal ganglia, cerebellum	Cortical sensory association areas	Prefrontal cortex

Normal Ageing

One of the most controversial challenges in clinical neuroscience is where to demarcate normal from pathologic age-related cognitive changes. Potential contamination of some normative ageing study populations with subjects in the earliest stages of dementia highlights the difficulty (Goldman *et al.*, 2001). Although interpretation of normal cognitive ageing is complicated by daunting methodological issues, cognitive functions that should remain relatively preserved over the lifespan include temporal orientation, immediate attention, vocabulary and most visuospatial skills. Delayed recall in healthy elderly people is generally preserved into the tenth decade. Mild age-related decrements involve difficulties with sustained attention, greater visual than verbal memory recall, confrontation naming, mental flexibility and response speed (Quinn and Kaye 2001). Episodic memory declines with age, but semantic, implicit, procedural, recognition and working memory remain relatively intact (see Chapter X for detailed definitions of these constructs). Further, mild age-related cognitive decrements may be counterbalanced by improvements in vocabulary, judgement, insight and wisdom. In sum, normal cognitive ageing, even into the ninth decade, is compatible with independent living. It is therefore invalid to attribute significant memory complaints or other cognitive impairment merely to the consequences of normal ageing.

Various terms, such as age-associated memory impairment, benign senescent forgetfulness, and isolated amnestic disorder, have been used to define a category intermediate between cognitive changes associated with normal ageing and dementia. This issue is addressed below. For now, we summarize consensus opinion regarding normal age-related cognitive changes in Table XV-8.13 Neuropsychological tests demonstrating greatest age-related sensitivity are listed in Table XV-8.14 and Table XV-8.15 provides quantitative data from the Oregon Brain Aging Study.

A general slowing in processing time spans all cognitive domains. Not surprisingly, the most significant age-related declines in neuropsychological test performance are on timed tests (Quinn and Kaye, 2001).

In addition to functional parameters, certain neuroanatomical indices, obtainable *in vivo* by neuroimaging, can also distinguish normal from pathological ageing. For example, hippocampal and temporal volume are significantly greater in subjects who remain cognitively stable compared with those developing dementia, and rate of change of temporal (but not hippocampal) volume is greater

Table XV-8.13 Cognitive changes associated with normal ageing

Functional domain		Finding with normal ageing
Attention	Sustained	Preserved into eighth decade
	Selective	Preserved into ninth decade
Memory	Registration	Preserved
	Short-term	Declines
	Long-term	Preserved
	Working	Impaired
Language	Syntax	Preserved
	Naming	Gradual decline
Executive function	Integration	Declines
	Planning	Declines
	Response-inhibition	Declines
Visuospatial function	Perceptual	Declines
	Constructional	Declines
Processing speed		Gradually progressive slowing

in subjects developing dementia than cognitively stable subjects (Bozoki *et al.*, 2001).

Functional brain imaging can also help to distinguish normal from pathological ageing. For example, functional neuroimaging has been used to compare task-related brain network activation in Alzheimer's disease patients with age-matched controls. Positron emission tomography (PET) scans of symptomatic Alzheimer's disease patients demonstrate task-difficulty-dependent activation of brain networks distinct from those recruited by healthy elderly people. Such alternative network activation may indicate compensation for processing deficits, and transition from normal to alternative brain networks may indicate a point at which ageing has functionally transgressed from normal to pathological (Stern *et al.*, 2000; Bookheimer *et al.*, 2000).

COGNITIVE DISORDER SUBTYPES

Differential Diagnosis of Cognitive Disorders

Alzheimer's disease is the most common cause of dementia, being responsible for up to two-thirds of cases. The remaining one-third are caused by a wide variety of aetiologies.

Differentiation between cortical and subcortical dementia profiles can be clinically useful, although it is often anatomically incorrect as pathology is rarely limited to cortical or subcortical regions. Deficits caused by subcortical disease include slowed and inefficient cognitive processing, as well as alterations in personality, mood and behaviour. Other disorders (e.g. Creutzfeldt–Jakob disease (CJD), dementia with Lewy bodies (DLB), neurosyphilis) can involve both cortical and subcortical structures. Amnesia, cognitive disorganization and impaired visuospatial skills can be caused by either cortical or subcortical lesions. We will consider neuropsychological comparison of cortical and subcortical dementias in more detail when reviewing Huntington's disease below. For now, Table XV-8.16 contrasts the clinical features of cortical and subcortical dementias.

Primary Cognitive Disorders

Mild Cognitive Impairment

Some elderly people exhibit age-related memory deficits but are not considered to have dementia because general intellect is preserved and there is no significant impairment in activities of daily living. The concept of so-called mild cognitive impairment (MCI) has been the subject of increasing clinical and empiric attention. Patients with MCI can have memory dysfunction similar to that of mild Alzheimer's disease patients, while the balance of cognitive functions is similar to that of to healthy age-matched controls (Small, 2001). MCI is a consideration in the differential diagnosis of cognitive impairment. When diagnosed, it carries significant implications for long-term patient monitoring. Table XV-8.17 summarizes the current diagnostic criteria for MCI.

The significance of MCI diagnosis is amplified by meta-analyses indicating that MCI patients have increased risk of progressing to dementia in general and Alzheimer's disease in particular.

There is converging evidence (epidemiological, psychometric, neuroimaging, neurogenetic, etc.) that MCI is characterized by a symptomatological pattern and prognosis that, while remaining relatively benign in many cases, increasingly appear to exist within the same disease spectrum as other neurodegenerative cognitive disorders, such as Alzheimer's disease (Bozoki *et al.*, 2001; Morris *et al.*, 2001). Hippocampal atrophy demonstrated on structural neuroimaging has been shown to predict conversion to dementia in MCI patients (Bozoki *et al.*, 2001). PET scans of MCI patients reveal a pattern of hypometabolism resembling that

Table XV-8.17 Mild cognitive impairment criteria

Memory complaint, preferably corroborated by an informant
Objective memory impairment
Normal general cognitive function
Not demented

Adapted from Petersen *et al.* (2001)

of Alzheimer's disease patients more than that of healthy elderly controls (Bozoki *et al.*, 2001). There is also some preliminary evidence that cerebrospinal fluid (CSF) measures of Alzheimer's disease-related pathology, e.g. CSF tau and β-amyloid, might predict dementia conversion among MCI patients (Diaz-Arrastia and Baskin, 2001). Not unexpectedly, age is a strong predictor of conversion from MCI to dementia (Celsis, 2000).

The annual conversion rate of MCI to frank dementia is estimated at 12–15% (Morris, *et al.*, 2001).

Neurodegenerative Dementias

Alzheimer's Disease

Although Alzheimer's disease was previously considered a diagnosis of exclusion, it can in fact be diagnosed confidently on the basis of several inclusion and exclusion criteria. Table XV-8.18 outlines current National Institute of Neurologic, Communicative Disorders and Stroke Alzheimer's disease diagnostic criteria; Table XV-8.19 summarizes the DSM-IV criteria.

Preclinical Alzheimer's Disease There is evidence for a preclinical stage of Alzheimer's disease (distinct from MCI), i.e. Alzheimer's disease may have a long stage of neuropathological change that precedes symptom appearance (Goldman *et al.*, 2001). Cognitive decline before conventional Alzheimer's disease diagnosis is made can be marked by deficits in multiple domains and is associated with subtle interferences with social and occupational function. The presence of such cognitive deficits, even when minimal, is highly correlated with neuropathological Alzheimer's disease (Goldman *et al.*, 2001).

However, although the term 'preclinical Alzheimer's disease' has been used to characterize the period from mild cognitive symptom onset (usually marked by mild deficits in episodic memory and abstract reasoning, thereby perhaps better characterized as MCI) to the time of Alzheimer's disease diagnosis, data suggest that the term should refer solely to a condition of histopathological Alzheimer's disease unaccompanied by any cognitive impairment (Goldman *et al.*, 2001). Careful comparison of psychometric measures of patients with healthy brains (characterized by absence of senile plaques or by only patchy neocortical plaque deposition), non-demented patients with autopsy-confirmed neuropathological Alzheimer's disease, and patients with early symptomatic Alzheimer's disease reveals that non-demented patients with neuropathological Alzheimer's disease do not differ significantly in cognitive performance from individuals with healthy brains (Celsis, 2000; Goldman *et al.*, 2001). Hence, pathologically confirmed preclinical Alzheimer's disease is not necessarily associated with significant cognitive impairment, even on measures shown to be sensitive to very mild Alzheimer's disease. Since neuritic/senile plaques and neurofibrillary tangles, the neuropathological hallmarks of Alzheimer's disease, can be found in adults without any significant cognitive impairment, neuronal pathology leading to Alzheimer's disease likely begins years before any clinical changes occur (Goldman *et al.*, 2001).

Functional neuroimaging studies seem to support the nosologic validity of the concept of a truly preclinical Alzheimer's disease state. Functional neuroimaging employing neuropsychological activation tasks (enabling subtraction comparison of regional brain activities during activation versus resting states) can reveal more subtle alterations in brain function before emergence of even mild cognitive impairment. PET and functional magnetic resonance imaging (fMRI) studies reveal that neural activity magnitude and spatial extent often increase with cognitive task demand. Brain activity in Alzheimer's disease-affected regions observed during memory task performance is greater in APOEε4 allele carriers than in APOEε3 allele carriers. Such differing brain activation patterns suggest the need for greater cognitive effort among those at higher genetic risk for Alzheimer's disease than lower Alzheimer's disease risk counterparts performing the same task (Stern *et al.*, 2000). Further, PET studies have identified parietal, temporal and prefrontal

Table XV-8.18 National Institute of Neurologic, Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association criteria for diagnosis of Alzheimer's disease

Criteria	• Dementia established by clinical examination and standardized brief MSE and confirmed by neuropsychological tests • Deficits in two or more areas of cognition • Progressive worsening of memory and other cognitive function • No disturbance of consciousness • Onset between age 40 and 90 years • Absence of other systemic or neurological disorders sufficient to account for the progressive cognitive deficits
Features supporting diagnosis	• Progressive deterioration of specific cognitive functions, such as language (aphasia), motor skills (apraxia) and perception (agnosia) • Impaired activities of daily living and altered pattern of behaviour • Family history of a similar disorder, especially if confirmed neuropathologically • Normal lumbar puncture • Normal pattern or nonspecific changes in EEG • Evidence of cerebral atrophy on CT, with progression on serial observation
Features against diagnosis	• Sudden onset • Focal neurological findings, such as hemiparesis, sensory loss, visual field deficits, and incoordination early in the course of the illness • Seizures or gait disturbance at the onset or very early on in the course of the illness

Adapted from McKhann *et al.* (1984)

Table XV-8.19 DSM-IV criteria for diagnosis of Alzheimer-related dementia

A Development of multiple cognitive deficits manifested by both:
  (1) Memory impairment (impaired ability to learn new information or to recall previously learned information)
  (2) One or more of the following cognitive disturbances:
    (a) Aphasia
    (b) Apraxia
    (c) Agnosia
    (d) Disturbance of executive function

B The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning

C The course is characterized by gradual onset and continuing cognitive decline

D The cognitive deficits in criteria A1 and A2 are not due to any of the following:
  (1) Other CNS conditions that cause progressive deficits in memory and cognition
  (2) Systemic conditions that are known to cause dementia
  (3) Substance-induced conditions

E The deficits do not occur exclusively during the course of delirium

F The disturbance is not accounted for better by another axis I disorder

Adapted from American Psychiatric Association, 1994. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn. American Psychiatric Association, Washington, DC

deficits in glucose metabolism in cognitively normal APOEε4 allele-positive middle-aged individuals in whom Alzheimer's disease is unlikely to develop for decades (Bozoki *et al.*, 2001).

Clinical Alzheimer's Disease Although mild memory dysfunction is likely to be the first evidence of Alzheimer's disease, Alzheimer's disease can present in a variety of ways. Language disturbances (e.g. word-finding difficulty), behavioural changes (e.g. decreased self-care) and/or personality changes (e.g. increased irritability) can characterize initial presentation, thereby making incipient Alzheimer's disease more difficult to identify. Moreover, years can elapse between onset of such changes and even a probable diagnosis of Alzheimer's disease. Nevertheless, typical Alzheimer's disease presentation involves gradual memory impairment and related functional ineffectiveness over 1–2 years. Anterograde amnesia with rapid attrition of recall is the clinical hallmark of Alzheimer's disease. Although Alzheimer's disease can begin with deficits in many possible domains, episodic memory impairment (wherein important conversations or events are entirely forgotten) is usually the heralding sign, followed by increasingly obvious declines in judgement, reasoning and word-finding ability (Salmon and Bondi, 1997). Disease progression is continuous, although the rate can vary both intraindividually and interindividually. This pattern of continuous deterioration generalizes across Alzheimer's disease aetiology (familial or sporadic), clinical onset (early or late), sample composition (hospital or community) and assessment method.

Delusions are present in up to 75% of cases, and hallucinations are reported in up to half of Alzheimer's disease patients (Lyketsos *et al.*, 2001). Hallucinations tend to appear as Alzheimer's disease progresses into its middle phases (Wilson *et al.*, 2000). Functional imaging studies have demonstrated that Alzheimer's disease patients who manifest psychosis may have disproportionate dysfunction of bilateral dorsolateral frontal, left anterior cingulate, left ventrostriatal, left pulvinar and dorsolateral parietal structures (Mega *et al.*, 2000). Longitudinal studies have found the presence of psychosis to be associated with more rapid cognitive decline (Gormley and Rizwan, 1998). Depression is a common comorbidity, and patients with a family history of major depression are at increased risk (Butt and Strauss, 2001).

Late Alzheimer's disease produces nearly global cognitive and behavioural deficits, reflecting massive neocortical dysfunction. Although Alzheimer's disease usually begins insidiously, progressive intellectual decline and behavioural dysfunction can end in death within 5–10 years of onset.

Early-Onset Alzheimer's Disease Alzheimer's disease beginning before the age of 60 years is usually associated with more than cognitive dysfunction. Early Alzheimer's disease patients more frequently manifest comportmental changes, gait instability and extrapyramidal signs. Early-onset Alzheimer's disease is more often familial: having a first-degree relative with Alzheimer's disease, or being positive for the APOE4 allele, has greater prognostic significance in patients with memory loss at a young age (see below) (Hardy, 2001). Patients with trisomy 21 (Down's syndrome) have a high incidence of Alzheimer's disease beginning in the fourth decade.

Neuropsychological Assessment

The neuropsychological profile of Alzheimer's disease patients (as confirmed by post-mortem examination) is well established. Attentional functioning is generally unimpaired and remains so well into the course of the disease (Fuld, 1982; Schachter *et al.*, 1989). However, while attention and memory encoding capacities are relatively spared, Alzheimer's disease patients manifest notable memory storage deficits with rapid decay of new learning. Unlike patients with subcortical or small-vessel ischaemic dementias, who perform well on delayed memory tasks when presented with multiple-choice cues, Alzheimer's disease patients fail to effectively consolidate new information secondary to hippocampal degeneration. Alzheimer's disease patients generally demonstrate gross deficits on confrontation naming tasks (e.g. Boston naming test) early in the disease course (Cummings and Benson, 1989; Huff, 1990). Patients frequently make semantic paraphasic errors on naming tasks (e.g. calling a cactus a 'tree'), or make circumlocutious responses (calling a hammock a 'swing-chair' or a pen an 'ink-spreader'). Despite this, Alzheimer's disease patients typically benefit from phonemic cuing. Performance on timed verbal fluency tasks is also diminished early in the course of the disease, with decreased performance on semantic (categorical) tasks such as animal naming, while performance on phonemic (letter-specific) fluency measures may be relatively preserved. In all, this profile of performance (decreased memory storage, naming abilities, and semantic fluency in the context of average attentional abilities and letter fluency) distinguishes early Alzheimer's disease from other dementing processes with a relatively high degree of accuracy.

In addition to memory storage and naming difficulties, Alzheimer's disease patients frequently demonstrate cognitive dysfunction broadly associated with other types of dementing illnesses. Executive dysfunction may be present even in early stages of the disease, with decreased judgement, insight, reasoning and abstraction capabilities (McGlynn and Kaszniak, 1991; Schacter, 1991). In middle and late stages of the disease, cognitive dysfunction becomes increasingly severe and diffuse. Visuospatial problem-solving abilities diminish, and patients frequently become apraxic. Language continues to deteriorate, and patients gradually lose the capacity to recall even remote information. Retrograde memory loss tends to follow a temporal grading, with memory for relatively recent events deteriorating first, followed by a deterioration in memory of temporally distant events (Kopelman *et al.*, 1989; Nebes, 1992a; Nebes, 1992b). In late stages, patients are frequently inattentive, minimally responsive, and unable to recognize or communicate their needs.

Several clinical inventories and scales are available for evaluating Alzheimer's disease and monitoring progression (Knopman *et al.*, 2001). The Alzheimer's disease assessment scale–cognitive subscale (ADAS-Cog) is an objective, clinically validated, 11-item cognitive assessment instrument used routinely in clinical trails of dementia. It examines selected aspects of cognitive domains, including memory, language, orientation and praxis. Score ranges from 0 to 70, with 70 representing the worst degree of impairment; the average score of Alzheimer's disease patients with mild to moderately severe Alzheimer's disease is 15–25.

Many studies evaluating the diagnostic utility of neuropsychological tests have analysed patients with clinically diagnosed probable Alzheimer's disease (of mild to moderate dementia severity) and compared their performance with that of carefully screened healthy older adults. Although Alzheimer's disease patients are impaired in a wide variety of cognitive functions, the most effective neuropsychological measures for distinguishing between mild to moderate Alzheimer's disease patients and healthy elderly people are those that assess the ability to learn new information and to retain it over time. Comparisons of usefulness of measures of learning, retention, confrontation naming, verbal fluency and constructional ability for differentiating between very mildly demented patients with probable Alzheimer's disease and normal elderly adults have demonstrated that the highest diagnostic accuracy (up to 90% as confirmed by post-mortem histopathological analysis) is achieved with a cued recall measure on verbal memory tasks (Tierney *et al.*, 1988; Morris *et al.*, 1988).

Comparison of cognitive performance of probable Alzheimer's disease patients on various dementia rating scales has suggested that although most scales are adequate for tracking progression through

early and middle stages, the Mattis dementia rating scale (DMS) is especially useful for tracking cognitive decline in advanced stages, likely secondary to its inclusion of a wider difficulty range of test items (Bondi *et al.*, 1996).

Studies of the relationship between Alzheimer's disease neuropathological indices and cognitive function have also been performed. For example, quantitative measures of synaptic loss, senile plaques and neurofibrillary tangles in cortical association areas of patients with autopsy-proven Alzheimer's disease have been correlated with standardized cognitive examination performance before death (Cummings *et al.*, 1996). Of neuropathological variables, midfrontal synaptic density appears to have the greatest correlation with global cognitive impairment measures. Similarly, midfrontal synaptic density seems to account for the greatest amount of variance in cognitive scores in regression analyses, including all neuropathological variables (Cummings *et al.*, 1996; Cummings and Cotman, 1995).

Neuroimaging

Structural imaging in Alzheimer's disease can reveal medial-temporal atrophy; more generalized cerebral atrophy is seen only after a substantial amount of neuronal death. Coronal magnetic resonance imaging (MRI) is particularly useful for detecting hippocampal atrophy. Possible findings in early-onset or familial Alzheimer's disease are atrophy disproportionate to age, ventricular enlargement, and asymmetric medial-temporal atrophy.

Functional brain imaging by PET or single position emission computerized tomography (SPECT) reveals characteristic (but nonspecific) bilateral temporoparietal hypoperfusion and/or hypometabolism in up to 85% of cases, a finding that can predate symptom onset (Celsis, 2000). PET may be superior to MRI measures of hippocampal atrophy since cerebral glucose metabolism changes antedate onset of memory decline while structural MRI hippocampal changes do not (Scheltens, 1999).

Frontotemporal Lobar Dementia

Certain forms of degenerative disease disproportionately affect circumscribed areas of the frontal and/or frontotemporal cortex, producing a variety of clinical syndromes grouped diagnostically under the term 'frontotemporal lobar dementia'. Although it is the third most frequent cause of degenerative cortical dementia after Alzheimer's disease and DLB (some epidemiological studies place FTLD second), FTLD is much less common than Alzheimer's disease, DLB and vascular dementia, especially in very early dementia patient populations. Nevertheless, FTLDs are important to recognize because (1) although insidious in onset, they usually progress to severe disability and sometimes fatality; (2) their symptomatology can mimic other disease states (particularly primary affective psychiatric disturbance); and (3) management requirements are very different from those of other dementias.

While the generic term FTLD refers to progressive circumscribed frontotemporal degeneration, distinct clinical syndrome phenomenology is determined primarily by neuropathological distribution. Based on such differential neuroanatomic involvement, three prototypic neurobehavioural syndromes are recognized: frontal variant FTLD (fvFTLD) (predominantly frontal pathology), semantic dementia (predominant anterior temporal pathology), and progressive nonfluent aphasia (mixed frontal, superior temporal), (Hodges, 2001). We briefly review each of these below.

Because of the complexity of the symptom and pathological spectra of FTLDs, optimal evaluation and management require cooperation across four disciplines: neurology, psychiatry, neuropsychology and neuroimaging.

Frontal Variant Fronto Temporal Lobar Dementia

fvFTLD is the most common FTLD (Hodges, 2001). Functional neuroanatomical division of the frontal lobe into three separate regions (medial, orbitobasal, dorsolateral) provides a conceptual basis for organizing fvFTLD symptomatology. For example, abulia can be associated with medial frontal–anterior cingulate involvement, social disinhibition and impulse dyscontrol with orbitobasal involvement, and executive dysfunction with dorsolateral prefrontal cortex involvement. Symptom admixtures commonly occur with disease progression (Hodges, 2001).

Personality alteration is prominent but highly variable, ranging from reduced volition and affective blunting to aggression and gross social inappropriateness. Such marked behavioural disturbances can be attributed erroneously to primary psychiatric disease, often prompting initial patient presentation to a psychiatrist. For example, progressive apathy can be mistaken for depression. Alternatively, contextually inappropriate ebullience and impaired judgement can mimic the main phase of bipolar disorder (Hodges, 2001).

Multiple potential behavioural changes can manifest. Activity often becomes stereotyped. Rituals (e.g. eating the same food at the same time every day), verbal/ideational perseveration (e.g. repeated use of the same catchphrase), and behavioural perseveration (e.g. watching the same video over and over) are common. Speech output frequently becomes abridged, sometimes culminating in mutism (often associated with an amotivational/hypokinetic state), although episodic speech excess/pressure can occur in some fvFTLD patients with prominent disinhibition. Patients often display a food preference change (increased sweets), and behavioural features of Kluver–Bucy syndrome (e.g. hypersexuality, placidity, hyperorality) can occur (Hodges, 2001).

The term 'dysexecutive syndrome' has been applied to the constellation of cognitive deficits in fvFTLD. Dysfunction routinely involves cognitive domains, including attention, abstraction, planning, organization, problem solving, judgement and mental flexibility. Primary elements of language, perception and spatial function are well preserved. Typically not significantly amnesic, patients are usually well oriented. Memory deficits tend to be a secondary epiphenomenon of frontal regulatory disturbances (i.e. inattention with consequent encoding deficiency, defective strategies for learning and retrieval) rather than manifestations of a primary anterograde amnesia. Executive deficits are typically more evident in inert, avolitional patients than in overactive, disinhibited patients. Poor insight regarding these impairments sadly complicates patient management (Hodges, 2001).

Pick's disease is the primary form of fvFTLD. A distinctive but inconsistent neuropathological correlate of Pick's disease is the Pick body, a basophilic intraneuronal inclusion, affecting neocortical temporal and hippocampal neurons. Atrophy involving the frontotemporal cortex and subjacent white matter is severe, ultimately producing 'knife-edge' gyri (ulegyria) in these regions, with abrupt transitions between mildly and severely involved sectors (e.g. between the anterior and posterior segments of the superior temporal gyrus).

Neuropsychological testing plays an essential role in fvFTLD evaluation (Hodges *et al.*, 1999). Simple cognitive screening tests, such as the MMSE lack sensitivity for early signs of executive dysfunction and are therefore unreliable for detection and monitoring of fvFTLD. Useful neuropsychological tests are the Wisconsin card sorting test, the Stroop test and the verbal fluency challenge. Test profiles typically reveal frontal system deficits, including attention, verbal fluency, abstraction and executive function. Quantifiable tests involving decision making and risk taking, which are better able to detect orbitobasal frontal function, have been developed (Gregory *et al.*, 1999).

Anterograde memory performance is variable; fvFTD patients tend to do worse on recall than recognition tasks. Nontemporally graded remote memory loss can occur late in the disease course. The most striking neuropsychological finding is how well subjects perform on tests of visuospatial ability, particularly when organization aspects are minimized (Gregory *et al.*, 1999).

Structural neuroimaging usually demonstrates bilateral and relatively symmetrical frontal atrophy. However, this is not universal, especially early in the disease process. Functional imaging may be more sensitive for early diagnosis of fvFTLD. T_{99}SPECT is probably the most sensitive and can detect frontal hypoperfusion before atrophy is evident (Miller and Gearhart, 1999).

Frontotemporal Lobar Dementias with Primarily Language Disturbance

Like other FTLD diagnostic subdivisions, controversy exists regarding nosological classification of FTLDs whose primary symptomatology involves language disturbance. A syndrome initially suggested by Pick, Mesulam's initial report of patients with gradually progressive dysphasia within the context of preserved intellect and insight sparked contemporary interest in the phenomenon commonly called primary progressive aphasia (PPA). Although language disturbances in such FTLD-related dysphasias are heterogeneous, two distinct clinical prototypes can be identified: progressive fluent aphasia, also known as semantic dementia, and progressive nonfluent aphasia.

It is important to recognize patients with progressive aphasia since, because of the 'focal' nature of their deficit (i.e. isolated language impairment), patients can be mistaken for stroke, neoplastic or even Alzheimer's disease cases. In general, language impairment remains an isolated but increasingly severe aphasia in about half of cases; the balance eventually progresses to a more global dementia.

Temporal Lobe Variant Frontotemporal Dementia Semantic dementia (Table XV-8.20) involves progressive dysnomia and word comprehension impairment in the context of fluent, grammatical speech (it is therefore grossly similar to Wernicke's aphasia). There is relative preservation of repetition, as well as ability to read aloud and write orthographically regular words (i.e. words whose phonemes follow regular rules of spelling representation). Patients can also display associative agnosia (impaired understanding of visual percepts); thus there is loss of meaning for both verbal and nonverbal elements (Hodges *et al.*, 1999).

Patients with semantic dementia typically present complaining of word-finding difficulty. Though often painfully aware of their worsening expressive vocabulary, patients are frequently unaware of their impaired comprehension. Since syntactic and phonological language structures remain intact, clinical signs are relatively subtle in early stages (Hodges *et al.*, 1999).

Although behavioural symptoms are generally absent or minimal at presentation, fvFTLD-like features can emerge at later stages.

Semantic dementia patients are globally impaired on semantic memory tests. This is most apparent on tasks requiring verbal output, such as category fluency tests, picture naming and verbal definition tasks. Although able to read and write words with regular spelling-to-sound correspondence, semantic dementia patients have difficulty reading and writing irregular words. This pattern, known as surface dyslexia/dysgraphia, has been attributed to loss of semantic support for pronunciation and/or spelling of irregular words. Episodic memory is relatively spared, although quantitative assessment reveals impaired recall of more distant life events (a reversal of the usual temporal gradient of Alzheimer's disease) (Gregory *et al.*, 1999).

Structural neuroimaging reveals anterior temporal neocortical atrophy, with inferior and middle temporal gyri predominantly affected. Asymmetries of temporal involvement reflect relative severity of impairment for verbal versus visual concepts (word meaning versus object recognition). Functional changes on SPECT usually precede detectable structural alterations, demonstrating dominant greater than nondominant temporal hypoperfusion (Miller *et al.*, 1999).

Nonfluent Progressive Aphasia Progressive aphasia (Table XV-8.21) is a disorder of expressive language characterized by effortful speech production with phonological and grammatical errors. Comprehension is relatively preserved. The language disorder occurs in the absence of impairment of other cognitive domains, although behavioural changes of fvFTD may emerge late in the disease course. Patients present with complaints of speech dysfluency and distortion or word-finding difficulty.

The pattern of cognitive deficits in progressive nonfluent aphasia is, in many ways, the complement of that in semantic dementia. Patients perform well on tests of semantic memory, except those requiring phonological competence. Although conversational speech is severely disrupted, anomia is mild.

Table XV-8.20 Clinical features of semantic dementia

Core diagnostic features	Insidious onset and gradual progression		
	Language disorder characterized by:		
	– Content-impoverished but fluent speech		
	– Impaired naming and comprehension		
	– Semantic paraphasias		
	Perceptual disorder characterized by associative agnosia (impaired recognition of object identity)		
	Preserved perceptual matching and drawing reproduction		
	Preserved single-word repetition		
	Preserved ability to read aloud and write orthographically regular words		
supportive diagnostic features	Speech and language	– Idiosyncratic word usage	
		– Surface dyslexia/dysgraphia	
		– Speech pressure	
		– Absence of phonemic paraphasias	
	Behaviour	– Loss of sympathy and empathy	
		– Narrow preoccupations	
		– Parsimony	
	Physical signs	– Akinesia, rigidity, tremor	
		– Absence or late primitive reflexes	
	Investigations	Neuropsychology	– Profound semantic loss
			– Preserved phonology, syntax
		EEG	Normal
		neuroimaging	Anterior temporal abnormalities

Adapted from Neary *et al.* (1998)

Table XV-8.21 Diagnostic features of progressive nonfluent aphasia

Core diagnostic features	Insidious onset and gradual progression Nonfluent spontaneous speech with at least one of the following: – Agrammatism – Phonemic paraphasias – Anomia		
Supportive diagnostic features	Speech and language		– Stuttering or oral apraxia – impaired repetition – Alexia, agraphia – Late mutism – Preservation of word meaning
	Behaviour		– Early preservation of social skills – Late behavioural changes similar to FTD
	Physical signs		– Late contralateral primitive reflexes – Akinesia, rigidity, tremor
	Investigations	Neuropsychology	– Nonfluent aphasia – Absence of severe amnesia
		EEG	Normal or minor asymmetric slowing
		Neuroimaging	Dominant hemisphere frontotemporal abnormality

Adapted from Neary *et al.* (1998)

Structural neuroimaging shows Sylvian fissure widening with atrophy of the insula, inferior frontal and superior temporal lobes (dominant greater than nondominant) (Miller and Gearhart, 1999).

Posterior Cortical Atrophy

Posterior cortical atrophy (PCA) is a lobar dementia characterized by initial disturbances of visual perception and integration. Involvement of the occipitoparietal region produces visuospatial and integrated attentional disturbances with relative sparing of personality, insight and memory until late in the disease. PCA is sometimes referred to as the visual variant of Alzheimer's disease. Progression to a global dementia occurs in most cases.

Parkinson's Disease

Nearly all Parkinson's disease patients develop cognitive deficits over the course of the disease, while up to 40% of patients go on to develop impairments sufficiently severe to comprise a true dementia (Brown and Mardsen, 1984). Cognitive impairment in Parkinson's disease is often under-recognized because of the overwhelming phenomenological prominence of motor disturbances. Parkinson's disease-related cognitive dysfunction can be considered a component of the spectrum of neuropsychiatric disturbances attendant to basal ganglia disorders (Rosenblatt and Leroi, 2000). McHugh has described such basal ganglia disease-related disturbances as marked by a 'triadic syndrome' comprising depression, dementia and dyskinesia (McHugh, 1989).

Parkinson's disease-related cognitive impairment is characterized by psychomotor slowing, executive dysfunction, memory impairment and visuospatial disturbances, as well as increased propensity for depression. Parkinson's disease-related cognitive dysfunction is reportedly more common in individuals with asymmetric onset of parkinsonism affecting the nondominant side and accentuated gait disturbance relative to tremor (McPherson and Cummings, 1996).

Parkinson's disease-related cognitive deficits tend to exist on a continuum, with subtle dysfunction emerging early and progressive worsening over time. As subcortical projections to the frontal cortex deteriorate, patients demonstrate decreased cognitive functioning associated with loss of both subcortical and frontal functions (Freedman, 1990). Cognitive slowing is ubiquitous, and patients demonstrate many significant response latencies, even in response to simple questions. In addition, they typically exhibit diminished attentional capacities, including decreased mental tracking, divided attention, and sustained attentional capacities. Executive difficulties are also prominent. Parkinson's disease patients tend to perform poorly on measures of cognitive flexibility, such as tasks requiring establishment, maintenance or shifting of mental sets (e.g. Trails B, Wisconsin card sort test). The ability to conceptualize and solve problems can be impaired early in the disease course (Levin *et al.*, 1989), while judgement is often preserved. Visuoperceptual difficulties may also emerge as measured by performance on tasks that require patients to judge and match line orientation or construct designs from a model (Hovestadt *et al.*, 1987).

Although attentional difficulties can impact memory acquisition, patients tend to consolidate and retain new information until late in the disease course. Despite this, Parkinson's disease patients often demonstrate profound difficulties with memory retrieval, such that they are unable to independently access new learning unless presented with external cues (Pillon *et al.*, 1993). For example, on neuropsychological measures of memory (such as the logical memory subtest of the WMS), patients with Parkinson's disease tend to perform poorly on delayed recall tasks in which they are required to independently retrieve information (as when asked to spontaneously relate a story heard 20 minutes ago). However, when provided with a recognition format, such as multiple choice, these same patients (unlike Alzheimer's disease patients) may demonstrate unimpaired performance compared with normals. In contrast to Alzheimer's disease, language function remains relatively unimpaired until late in the disease course, with relatively preserved performance on confrontation naming. Parkinson's disease-related hypophonia should not be allowed to confound careful language function assessment.

Cognitive symptoms may respond partially to dopaminergic pharmacotherapy in early stages of the illnesses, but they tend to become refractory as the disease progresses and dementia becomes more severe. As elsewhere, treatment of comorbid depression is imperative for optimizing cognitive function.

Dementia with Lewy Bodies

DLB is probably the second most common type of degenerative dementia after Alzheimer's disease (Campbell *et al.*, 2001). DLB is defined clinically by the presence of dementia, gait/balance disorder, prominent hallucinations and delusions, sensitivity to traditional antipsychotics, and fluctuations in alertness (Papka *et al.*, 1998). DLB has clinical features that overlap diagnostically with Alzheimer's disease and Parkinson's disease.

DLB-related cognitive impairment can range from transient dysfunction to sustained dementia (Gomez-Tortosa *et al.*, 1998).

A superimposed fluctuation in alertness can sometimes mimic a delirium-like component. DLB-associated depressive features can include neurovegetative derangement, dysthymia and psychomotor agitation (Ballard *et al.*, 2001). Delusions, if present, are typically depression-congruent. The characteristic motor disturbance is parkinsonism, often with prominent bradykinesia; tremor is variable. Frequent falling is a common feature. Hallucinations tend to be visual and complex in nature (Fields, 1998). REM sleep is often disturbed. In contrast to the decrease in muscle tone normally accompanying REM sleep, DLB patients do not become atonic when attaining REM sleep. The result is that patients sometimes have a worrisome capacity to act out their dreams (i.e. develop REM sleep disorder).

Universally accepted diagnostic criteria still require validation (Lund and Manchester Groups, 1994; Serby and Samuels, 2001).

Prominent deficits in attention, language, executive function, memory retrieval and visuoconstruction skills are neuropsychological features of DLB (Fields, 1998; McKeith *et al.*, 1994). In general, DLB patients have greater visuospatial impairment and executive dysfunction than Alzheimer's disease patients. In contrast, sparing of memory storage in DLB distinguishes DLB memory impairment from that of Alzheimer's disease (McKeith *et al.*, 1994). Language dysfunction in DLB distinguishes its cognitive profile from Parkinson's disease.

Compared with Alzheimer's disease, DLB patients show less temporal lobe atrophy on structural MRI and more occipital lobe hypoperfusion on SPECT (Lobetesis *et al.*, 2001), but neuroimaging has not proven successful in differentiating DLB from Alzheimer's disease.

Lewy bodies are eosinophilic intracytoplasmic inclusions originally described in the brainstem (substantia nigra) of patients with Parkinson's disease; they occur with slight ultrastructural differences in neocortical and paralimbic neurons in several disorders. Lewy bodies are widely distributed in both the cerebral cortex and substantia nigra in DLB (Lewy bodies are usually confined to the substantia nigra in Parkinson's disease) (Lowe and Dickson, 1997).

As neuroleptic use becomes a complicated task in any dementia with comorbid parkinsonism (since neuroleptic-related dopamine blockade can worsen parkinsonian motor disturbance), this caution becomes imperative in DLB. DLB patients are often exquisitely sensitive to neuroleptics, which can precipitously worsen overall cognitive function. Cholinesterase inhibitors have shown some efficacy for DLB-related cognitive and behavioural symptoms.

Progressive Supranuclear Palsy

About 7% of patients with parkinsonian motor abnormalities suffer from PSP a disorder affecting volitional eye movements early in its course. Typical findings are impaired vertical (primarily downward) eye movements, axial/truncal postural disturbance and bulbar dysfunction. Unlike Parkinson's disease, PSP-associated resting tremor is minimal, symptom onset is symmetrical, and disease progression is rapid (Litvan and Hutton, 1998).

PSP causes a dementia similar to that of PD in 50–75% of affected individuals. However, the neuropsychological profile of PSP has not been documented as consistently as that of Parkinson's disease, and there appears to be significant variation among patients. Despite this, the general pattern of performance on neuropsychological tasks includes cognitive slowing, attentional deficits, executive dysfunction, impaired visual scanning (due to oculomotor deficits), motor dysfunction and sequencing difficulties (Grafman *et al.*, 1990; Grafman *et al.*, 1995; Litvan *et al.*, 1989).

Although memory dysfunction can occur at nearly every stage of memory processing, deficits in memory storage tend to be not as severe as those seen in Alzheimer's disease (Pillon *et al.*, 1994). Mild word-finding difficulties and naming deficits are seen frequently, and executive deficits such as impaired cognitive flexibility, abstraction and reasoning capabilities may emerge early in the disease course. As in all subcortical dementias, cognitive slowing, executive dysfunction and memory retrieval are prominent features.

Dementia Pugilistica

Although a 'secondary' dementia by virtue of its association with boxing or other modes of repeated head trauma, this syndrome is described here because of its neurohistopathological similarities with Alzheimer's disease and Parkinson's disease. Dementia pugilistica, or punch drunk syndrome, was originally described in boxers and is characterized by the combination of dementia and parkinsonism occurring as a late consequence of repeated head trauma. Brain imaging often reveals diffuse cerebral atrophy and cavum septum pellucidum. Histopathological hallmarks include neuronal loss and diffuse neurofibrillary tangles. Diffuse beta-amyloid immunoreactivity within senile plaques and blood vessels has recently been identified in dementia pugilistica brains; along with other evidence, this suggests an important association between head trauma and Alzheimer's disease.

Huntington's Disease

Huntington's disease is a progressive, eventually fatal neuropsychiatric disease with a prevalence of 5–10 per 100 000 in the general population. A prototypical genetically based neurodegenerative disorder, Huntington's disease is inherited as an autosomal dominant trait with complete penetrance.

One-third of Huntington's disease patients have psychiatric changes at onset, and almost all suffer progressive cognitive decline (Squitieri *et al.*, 2001). Patients display multiple deficits attributable to frontostriatal circuit dysfunction. Meta-analyses of Huntington's disease cognitive studies demonstrate deficiencies of delayed recall, memory acquisition, cognitive flexibility, abstraction, manual dexterity, attention and verbal skill. In general, cognitive symptoms are associated with the severity of motor impairment (Zakzanis, 1998).

The neuropsychological profile is consistent with other subcortical dementias, with prominent executive and memory retrieval deficits (Pillon *et al.*, 1993). Huntington's disease patients can also exhibit impaired concentration and memory encoding, however, and they are especially sensitive to interference effects (Folstein *et al.*, 1990). For example, on memory tasks such as the CVLT, Huntington's disease patients are likely to show rapid decay of established new learning if asked to immediately encode additional information. Executive deficits include impulsivity, disinhibition and difficulty with planning and organization. Visuoperceptual difficulties occur early in the course of the disease and may include problems with left–right orientation and perceptual fragmentation (in which patients may focus on small details of an object while failing to appreciate the gestalt) (Josiassen *et al.*, 1983). Language functioning tends to be preserved until the late stages of the disease. Ultimately, Huntington's dementia evolves into severe, global cognitive deficits, which progress throughout the course of the illness.

Huntington's Disease as a Prototypical Subcortical Cognitive Disorder

Huntington's disease serves as a useful prototype for comparing neuropsychological differences between cortical and subcortical dementias. For example, Huntington's disease and Alzheimer's disease patients can be subdivided by pattern of respective memory deficits. Alzheimer's disease patients demonstrate severe episodic memory deficit seemingly resulting from ineffective consolidation of new information. In contrast, the memory disorder of Huntington's disease is thought to be secondary to difficulty initiating a systematic retrieval strategy for recalling information from either episodic or semantic memory. Although, like Alzheimer's disease patients, Huntington's disease patients have difficulty learning and recalling information in a free-recall task, they exhibit marked improvement when switched to a recognition task (Bondi *et al.*, 1996).

Cortical and subcortical dementias can also be differentiated by remote memory testing. Whereas Alzheimer's disease patients display severe retrograde amnesia with temporal grading in early stages (i.e. distant memories are recalled better than more recent memories), Huntington's disease patients have relatively preserved retention and, like other subcortical dementias, manifest only mild retrograde amnesia without temporal grading (Bondi *et al.*, 1996).

Based on such different memory impairment mechanisms, Huntington's disease and Alzheimer's disease patients can be differentiated fairly accurately by certain memory tests (e.g. CVLT, which can discriminate component memory functions and consequently disorders affecting them differentially) (Bondi *et al.*, 1996).

Another major distinction between cortical and subcortical dementias can be appreciated in semantic function: while cortical dementias are often marked by progressive deficits, there is little or no impairment in subcortical dementias. This has been studied by the use of multidimensional scaling, which provides a method for generating a spatial representation of the degree of conceptual association among semantic memory elements. Semantic maps can be created of cognitive spatial representation clusters according to the degree of relatedness in the patient's semantic network along specific conceptual dimensions, such that the distance between concepts reflects association strength. A study comparing such cognitive maps of Huntington's disease, Alzheimer's disease and normal elderly control subjects demonstrated that while Alzheimer's disease patients reveal a breakdown in the structure and organization of semantic memory, resulting in greater reliance on concrete perceptual characteristics, Huntington's disease patients do not differ significantly from normal controls (Chan *et al.*, 1993; Bondi *et al.*, 1996).

Qualitative analysis of other neuropsychological testing errors can further reveal differential performance between cortical and subcortical dementias. For example, whereas Huntington's disease patients make graphic, visuospatial and planning errors in both the command and copy conditions of a constructional task (e.g. clock drawing), Alzheimer's disease patients make conceptual errors (e.g. misrepresenting a clock by drawing a face without numbers or with incorrect numbers) in the command condition but not in the copy condition (Freedman *et al.*, 1994; Bondi *et al.*, 1996).

Cortical-Basal Ganglionic Degeneration

Cortical-basal ganglionic degeneration (CGBD) is a relatively rare neurodegenerative disease beginning in the sixth decade or later, marked by asymmetric rigidity and postural disturbances predisposing to falls. Focal myoclonus and tremors can be associated features.

The neuropsychological profile of CGBD-related dementia has not been well validated, although features of both cortical and subcortical dementias are generally present. CBGD patients demonstrate executive dysfunction similar to PSP (Pillon *et al.*, 1995). Apraxias are characteristic of the dementia of CBGD and are usually apparent before cognitive dysfunction in other domains (Troster, 1998). Approximately 60% of patients experience 'alien limb syndrome', a phenomenon in which the affected limb assumes positions or carries out actions disconnected from the patient's awareness.

CBGD is often associated with asymmetric cortical atrophy affecting the frontoparietal neocortex, with attendant reductions of cerebral metabolism in that region. Neuropathological findings include patchy neuronal loss and gliosis in the cerebral cortex and substantia nigra, as well as a characteristic intraneuronal nigral inclusion body.

CBGD typically progresses to global dementia, and death usually ensues within 5–10 years. There is no known treatment.

Secondary Cognitive Disorders

Potentially Reversible Secondary Dementias

Few processes that damage the brain sufficiently to cause dementia are readily reversible. Even when a potentially reversible cause of a dementia is identified, actual reversal is often elusive. Nevertheless, certain structural, nutritional, metabolic, infectious and psychiatric disorders can produce cognitive decline lasting weeks or months that potentially can be reversed or at least ameliorated if detected and treated. Underscoring the importance of prompt consideration and investigation of reversible aetiologies are studies demonstrating that the earlier intervention is initiated, the greater the likelihood of actual clinical improvement (Freter *et al.*, 1998; Steffens-and Morgenlander, 1999).

Meta-analyses of dementia aetiology studies have revealed at least potential reversibility in approximately 13% of patients (Freter *et al.*, 1998). The most frequent causes of reversible dementias are depression and iatrogenic (e.g. adverse drug effect), which together constitute about 50% of reversible dementias (Freter *et al.*, 1998).

Primary Psychiatric Disturbances

Depression

Dementia and depression are not only often comorbid but can also appear remarkably similar. Up to 55% of elderly with depression develop cognitive impairment phenomenologically consistent with a dementia syndrome; this has commonly been called pseudodementia, but it is called more correctly the dementia of depression or depression-related cognitive impairment (DRCI). Meta-analyses demonstrate that new antidepressants not only treat depression comorbid with dementia but can also improve cognitive function, suggesting a high prevalence of superimposed DRCI among dementia patients in general (Meyers, 1998).

Patients with DRCI are more likely to complain of memory and concentration problems than patients with degenerative dementia. Also, in contrast to patients with degenerative dementia, those with depression can do reasonably well on formal mental status testing when confounds such as motivation and attention are minimized. Careful bedside mental status or neuropsychological assessment is necessary to establish dementia in a patient with both affective symptomatology and cognitive deficits.

While recall is impaired in both dementia and DRCI, DRCI patients usually have preserved recognition while degenerative (cortical) dementia patients show impaired recognition and more intrusion errors. Cognitive testing in DRCI reveals performance variability partly dependent on variations of attention and effort during memory encoding. Examiner tenacity at ensuring successful embedding of short-term memory items is essential to distinguish the memory epiphenomenon of depression-related attention impairment from a primary memory disturbance.

Key differences can often be elicited in language functions, which are generally preserved in DRCI but frequently become impaired in degenerative dementia. Similarly, apraxias, visuospatial deficits and gross executive dysfunction, common features of degenerative dementias, are seen in only the most severe forms of DRCI.

Clues suggesting depression include prior history of mood disorder in the patient or family, onset over days to weeks, marked psychomotor retardation or agitation, mood-congruent delusions (e.g. paranoia), precipitation by an identifiable stressor, and explicit patient complaints of concentration or memory difficulty. However, geriatric depression can be extremely protean in its manifestations. Symptoms and signs of depression in the elderly can be much more subtle than typical adult presentations. Sometimes, the only sign can be disturbance of neurovegetative function, e.g. deranged sleeping pattern or decreased appetite. A low threshold to consider diagnosis of depression and initiate an empirical treatment trial should

be maintained. DRCI is potentially reversible with antidepressants or electroconvulsive therapy (ECT). Highly anticholinergic antidepressants can worsen cognitive deficits.

Of note, depression can itself be an early symptom of several degenerative dementing processes (Meyers, 1998). Despite initial improvement via antidepressant therapy, almost half of elderly patients with depression-related cognitive dysfunction develop irreversible degenerative dementia within 5 years. Those patients with depression unaccompanied by cognitive impairment develop dementia at rates more comparable to those of the general population. Therefore, once an episode of depression complicated by cognitive impairment is documented in an elderly patient, that patient should be monitored closely for signs of relapse and incipient dementia thereafter.

Regrettably, neither clinical features nor currently available biological markers reliably differentiate elderly patients with a primary dementia from those with DRCI.

Structural Psychiatric Disturbances

Normal-Pressure Hydrocephalus

Normal-pressure hydrocephalus (NPH) can be a structural cause of dementia potentially treatable by surgery. NPH classically presents as a triad of gait apraxia, urinary urgency/incontinence, and mental status changes. Usually developing in late-middle or old age, psychomotor slowing combines with cognitive findings suggestive of a mixed cortical and subcortical dementia. Importantly, parkinsonism, sensory complaints and depression can be associated findings.

NPH usually develops over weeks to months. A gait disorder is often the initial manifestation, typically in the form of a gait apraxia characterized by apprehension and unsteadiness on standing and difficulty initiating ambulation despite absence of weakness or ataxia on isolated testing. The patient can perform leg movements associated with walking, bicycling or kicking, and can trace figures with the feet while lying or sitting, but is unable to do so while legs are bearing weight. Often described as broad-based and 'magnetic', as if glue-footed, NPH-related gait dysfunction is also notable for impaired turning marked by the need for multiple small steps in order to effect a 180° turn. Pyramidal signs, including spasticity, hyper-reflexia and extensor plantar responses, are sometimes present. Extrapyramidal and parkinsonian features (hypokinesia, bradykinesia, cogwheel rigidity) can occur. Motor perseveration and frontal release signs (e.g. grasp reflexes) can sometimes be seen. Urinary incontinence is usually a later development.

NPH-related cognitive impairment is usually insidious in onset. Initially characterized by generalized slowing and apathy, global cognitive dysfunction ensues if untreated (Pinner *et al.*, 1997). Memory deficiency is common; other focal cognitive signs such as aphasia and agnosia are rare. NPH presenting solely as a psychiatric disturbance (e.g. paranoid psychosis) without the classic neurological triad has been reported. Comorbid Alzheimer's disease can often occur, with consequent admixtures of clinical symptomatology (Savolainen *et al.*, 1999).

NPH can be idiopathic or secondary to conditions that interfere with CSF absorption. Communicating hydrocephalus is most likely the result of alterations in clearance and/or flow of CSF, causing ventricular enlargement and secondary susceptibility of brain parenchyma to mechanical and/or ischaemic injury. Impaired CSF absorption via arachnoid granulations of hemisphere convexity subarachnoid space can result from the meningeal fibrosis, which can be a complication constituting the final common pathohistological outcome of multiple meningo-encephalitic and cerebrovascular processes. Predisposing factors such as subarachnoid haemorrhage, meningitis or head trauma can sometimes be identified. Ventricular enlargement can stretch frontocerebellar nerve fibres as they circumnavigate the ventricles, disturbing gait and bladder function. Deranged ventricular CSF flow on adjacent basal ganglia structures might be responsible for the development of parkinsonian features.

Neuroradiological correlates include communicating/nonconstructive hydrocephalus (enlarged ventricles out of proportion to prominence of cortical sulci), anterior third ventricle enlargement, downward extension of mammillary bodies, bowing of corpus callosum, and a flow-void in the fourth ventricle on T2-weighted MRI. Radionuclide cisternography can show ventricular isotope accumulation, delayed clearance, and failure of ascent over the cerebral convexities. SPECT can reveal frontal or diffuse hypoperfusion.

If a specific cognitive impairment profile can be identified in NPH, then earlier differentiation from other dementia types, and thereby earlier intervention initiation, can be facilitated (Golomb *et al.*, 2000). Based on previous neuropsychological evidence of apparently greater effect of NPH on executive function, attempts to identify an NPH-specific cognitive impairment profile have utilized tests relatively sensitive to frontal lobe function to examine whether such tasks are particularly susceptible to NPH-induced damage. Results of such studies reveal that there are two distinctive patterns of cognitive change in NPH: (1) predominantly executive (only later becoming more global), frequently not relieved significantly by shunting, and (2) generalized dementia detectable by gross measures (e.g. MMSE), in which shunting can reverse dementia (Iddon *et al.*, 1999).

Some patients, especially those with hydrocephalus from meningitis or subarachnoid haemorrhage, can improve following ventriculoatrial, ventriculoperitoneal or lumboperitoneal shunting.

Subdural Haematoma

Subdural haematoma (SDH) is the most readily treatable intracranial mass lesion that can cause cognitive dysfunction. Patients aged 50–70 years are most commonly affected. The most frequently identified precipitating factor is head trauma. SDH is bilateral in about one-sixth of cases.

SDH can be clinically quiescent without overt symptoms evident for months. Headache is the most common initial symptom. Cognitive dysfunction (ranging from mild, nonspecific confusion to significant dementia) and contralateral hemiparesis are the most frequent signs, followed by papilloedema and extensor plantar responses.

SDH can usually be visualized on noncontrast computerized tomography (CT) as an extra-axial crescent-shaped hypodensity. Usually involving a portion of or, less commonly, an entire cerebral convexity, SDH can also occur above and below the tentorial dural regions. Neuroimaging should be reviewed carefully for evidence of bilateral subdural collections. SDH age can be estimated on CT by evolution of subdural defect from hyperdense (bright), representing recently accumulated blood, progressing through successive shades of grey, culminating in isodense collections that sometimes require contrast infusion to be visualized.

Neoplastic Psychiatric Disturbances

Cancer can cause cognitive impairment in many ways. Although rarely reversible, the potential for partial reversibility or even cure exists, hence our inclusion of this subclass here.

Brain tumours manifesting solely by progressive cognitive impairment are relatively infrequent. Nevertheless, certain slow-growing intracranial neoplasms occurring in strategic locations (e.g. frontal or temporal meningioma) represent a curable cause of secondary dementia. When otherwise clinically covert (i.e. absence of noncognitive neurological signs), the threshold for performing screening neuroimaging becomes key. Related cognitive dysfunction can range from subtle focal dysfunction (e.g. anterograde explicit memory) to severe diffuse (e.g. stupor) dysfunction.

Metabolic Psychiatric Disturbances

Almost any metabolic abnormality can potentially impact cerebral function to such an extent as to cause cognitive dysfunction. Here, we summarize a prototypical example of a metabolic disturbance associated with chronic cognitive dysfunction.

Wilson's Disease

Wilson's Disease, also known as hepatolenticular degeneration, is an autosomal recessive disorder of copper metabolism producing neurological and hepatic dysfunction. Prevalence is approximately 30 per million. A gene defect has been localized to the long arm of chromosome 13. Pathogenesis involves decreased copper binding to the transport protein ceruloplasmin, resulting in excessive circulating unbound copper, eventually depositing in a variety of tissues, including the brain, liver, kidney and cornea. Although the average age of onset is 11 years for patients presenting with hepatic dysfunction and 19 years for those with neurological manifestations, the disease can remain clinically covert until the sixth decade.

Ocular and hepatic abnormalities are the most prominent non-neurological complications of the disease. Kayser–Fleischer rings, pathognomonic for Wilson's disease, are bilateral brown corneal rings resulting from copper deposition present in virtually all patients with neurological involvement. Hepatic involvement can take the form of an asymptomatic rise in liver enzymes, hepatitis or jaundice; if chronic, cirrhosis can ensue with portal hypertension-related complications.

Neurolopsychiatric manifestations reflect disproportionate involvement of the caudate, putamen, cerebellum and cortex. Signs can include facial grimacing, dysarthria, dysphagia, hypokinesia, abnormal posture, rigidity, resting and/or postural tremor, choreiform movements and ataxia. There is a tendency for dystonia or parkinsonism with hyper-reflexia and extensor plantar responses to predominate with disease onset before age 20 years; older patients tend to exhibit tremor, chorea and/or ballismus. A wing-beating tremor is a frequent late manifestation.

The cognitive impairment of Wilson's disease is consistent with a subcortical dementia profile marked by generalized thought process slowing, concentration impairment, and memory deficits in the absence of aphasia, apraxia or agnosia (Lang *et al.*, 1990; Lang, 1989). Research investigating whether visuomotor slowing in Wilson's disease is more a product of motor involvement than cognitive deficiency has been performed using specially designed neuropsychological batteries controlling for manual dexterity effects: tests confirm motor defect-independent slowing. Psychomotor impairment in Wilson's disease may result from impaired corticobasal ganglionic interaction. Associated psychiatric signs include affective and personality changes.

Diagnostic testing reveals decreased serum copper, low ceruloplasmin levels, elevated 24-hour urinary copper excretion, and abnormal liver function tests. Neuroimaging often demonstrates bilateral basal ganglia atrophy with compensatory ventricular dilatation. Inconsistently present but relatively unique characteristics visualizable on structural neuroimaging are putaminal cystic degeneration and cavitary necrosis. Liver biopsy reveals marked excess copper as well as cirrhosis. The principal differential diagnosis based on clinical symptomatology is Huntington's disease.

Management includes copper chelation via penicillamine and restriction of dietary copper. Treatment response can take months. Treatment is lifelong. Most patients treated early can expect a complete or nearly complete recovery.

Endocrine Disorders

Multiple endocrinological disturbances can potentially contribute to cognitive dysfunction. We focus on two prototypic endocrinopathies known to be able to cause reversible dementias.

Hypothyroidism

In addition to being a cause of an acute confusional state, hypothyroidism (myxoedema) can cause a reversible global dementia characterized by generalized slowing and nonspecific memory impairment. Psychiatric signs include depression sometimes complicated by psychotic features including paranoia and hallucinations. Associated neurological manifestations can be helpful in suggesting hypothyroidism as an underlying cause of dementia. Symptoms can include headache, tinnitus, paraesthesias and generalized weakness. Signs include delayed relaxation of deep tendon reflexes, hearing impairment, and typical stigmata of hypothyroidism (e.g. dry skin, pretibial myxoedema). Thyroid function tests usually confirm diagnosis. Cognitive dysfunction usually reverses significantly with thyroid hormone replacement.

Hypocortisolism

Patients with severe or chronic adrenal insufficiency can present with mild to moderate cognitive impairment (5–20%), depression (20–40%) and/or psychosis (20–40%). At least partial reversibility of hypocortisolism-related dementia via exogenous steroid repletion is the rule.

Nutritional Disorders

Vitamin B12 Deficiency

Vitamin B12 (cyanocobalamin) deficiency can produce many neurological complications, including cognitive dysfunction ranging from a mild confusional state to severe dementia and/or psychosis (megaloblastic madness).

Although presenting symptoms are most commonly due to anaemia, neurological abnormalities can precede development of macrocytic anaemia. Potential signs include peripheral neuropathy, subacute combined degeneration of the spinal cord, nutritional amblyopia, distal paraesthesias, gait ataxia, bandlike tightness around the trunk or limbs, and Lhermitte's sign (electric shock-like sensation along spine precipitated by rapid neck flexion). Associated leukopoenia or thrombocytopoenia can signal the disease presence via infection and or bleeding, respectively.

Like the acute confusional state associated with vitamin B12 deficiency, the cognitive impairment of B12 deficiency can occur with or without haematological manifestations. Vitamin B12-related cognitive impairment consists of global dysfunction with generalized slowing, impaired concentration and memory deficits (Larner *et al.*, 1999). Psychiatric disturbances are often prominent, including depression, mania and psychosis with paranoia and hallucinations (Zucker *et al.*, 1981).

Diagnostic clues include glossitis, yellow skin discoloration and/or cutaneous hyperpigmentation. Spinal cord involvement is manifested by impaired vibratory and joint position sense, sensory ataxia, spastic paraparesis, extensor plantar responses, decreased deep tendon reflexes (especially in the legs), and urinary retention. Laboratory investigations reveal low vitamin B12 levels (important to check since folate deficiency can cause the same set of haematological abnormalities), macrocytic anaemia, leukopoenia with hypersegmented neutrophils, and thrombocytopoenia with giant platelets. Schilling's test helps identify the origin of vitamin B12 deficiency (the most frequent cause is pernicious anaemia). Serum methylmalonic acid and homocysteine can also be useful measures. They are elevated in both absolute vitamin B12 deficiency and in relative deficiency (when tissue vitamin B12 stores are low but the serum vitamin B12 level is still normal). Some patients, particularly the elderly, with normal vitamin B12 levels but elevated serum methylmalonic acid can manifest neuropsychiatric abnormalities, including cognitive impairment. Treatment of patients with such covert vitamin B12 deficiency can often produce at least partial improvement.

Wernicke Encephalopathy, Korsakoff's Syndrome, and Alcohol-related Cognitive Impairment

Wernicke encephalopathy is produced by thiamine (vitamin B1) deficiency, a condition associated most commonly with alcoholism-related nutritional deficiency, but also a component of many other syndromes involving nutritional compromise (e.g. hyperemesis gravidarum, cancer).

Pathologically, Wernicke encephalopathy is characterized by neuronal loss, demyelination and gliosis in periventricular grey matter regions. Regions most commonly involved include the medial thalamus, mammillary bodies, periaqueductal grey matter and cerebellar vermis, as well as oculomotor, abducens and vestibular nuclei. MRI can demonstrate corresponding regional anormalities (Rourke and Loberg 1996).

Onset of Wernicke encephalopathy is typically abrupt but can be insidious. The classic syndrome comprises the triad of ophthalmoplegia, ataxia and encephalopathy. However, in one post-mortem study, the complete triad was present in only-one-third of patients with Wernicke-related lesions. The most common ocular abnormalities are nystagmus, VI nerve palsy, III nerve palsy, horizontal gaze palsy, and/or vertical gaze palsy. Ataxia is typically cerebellar, primarily affecting gait; this can be aggravated by peripheral neuropathy-related sensory ataxia. Most patients have peripheral neuropathy (often a multifactorial amalgam of Wernicke encephalopathy- and alcohol-related) with absent ankle jerks. Hypothermia and hypotension can occur, presumably secondary to hypothalamic involvement. Pupillary abnormalities, including mild anisocoria, and/or sluggish light reactivity are seen occasionally. Cognitive examination reveals global confusion consistent with a subacute delirium (Halliday *et al.*, 1994). Untreated, Wernicke encephalopathy can progress to stupor and coma.

Treatment requires prompt thiamine administration. Parenteral thiamine is continued for several days to ensure repletion of tissue stores. Ocular abnormalities usually begin to improve within days, while ataxia and confusion improve within weeks. Opthalmoplegia, vertical nystagmus and acute confusion are generally reversible, usually within 1 month. Horizontal nystagmus and ataxia, however, resolve completely in only about 40% of cases.

The major long-term complication of Wernicke encephalopathy is a residual alcohol amnestic disorder commonly known as Korsakoff's syndrome. Korsakoff's syndrome is primarily a memory disorder of moderate to severe anterograde greater capacity, with marked increased sensitivity to interference (Butters 1988). A temporally graded retrograde amnesia is less prominent. Other cognitive deficits (e.g. visuoperceptual, perceptual-motor) are variably present and likely represent other comorbid long-term, alcohol-related impairments. Disorientation when present is usually secondary to recent memory impairment. Confabulation and impaired insight are common (Rourke and Loberg, 1996). Executive deficits suggesting frontal lobe dysfunction sometimes occur. Attention and concentration are usually normal, and language is usually unaffected (Salmon and Butters, 1987). Consequently, a large disparity between general IQ and memory performance (e.g. MQ from the WMS) is common.

Although Korsakoff's syndrome is the expected outcome of Wernicke encephalopathy, yielding the diagnostic rubric Wernicke–Korsakoff syndrome (WKS), either component can occur without the other (Blansjaar and van Dijk, 1992; Torvik *et al.*, 1982).

Neuropsychological deficits resulting more directly from alcohol use (separate from those comprising WKS secondary to thiamine deficiency) represent a much more heterogeneous set of impairments (Rourke and Loberg, 1996). Deficits involving attention, visuospatial, perceptual-motor, memory and executive function have all been described. Pathogenic mechanisms remain to be elucidated, along with better characterization of cognitive impairment constellations (Rourke and Loberg, 1996).

Inflammatory Disorders

A variety of inflammatory disorders can affect cognitive function. Primary (e.g. primary CNS angiitis) and systemic vasculitides (e.g. Churg–Strauss vasculitis), granulomatous disorders (e.g. neurosarcoidosis), and other autoimmune syndromes (e.g. Hashimoto's encephalitis) can contribute to cognitive impairment. These are especially important to identify since associated dementias can be at least partially reversible via anti-inflammatory or immunosuppression therapy.

Secondary Dementias: Usually Irreversible

Vascular Dementias

Strokes, small and large, ischaemic and haemorrhagic, cortical and subcortical, together represent the second most common cause of dementia, accounting for up to 10% of late-life cognitive impairment (Leys *et al.*, 1998) Up to 25% of stroke patients are demented after stroke (Leys *et al.*, 1998; van Kooten and Koudstaal, 1998).

Diagnostic criteria for vascular dementia are more controversial than those for other dementia aetiological subtypes and still require validation by systematic clinicopathological study (Lopez *et al.*, 1999). Vascular dementia criteria currently in use include the State of California AD Diagnostic and Treatment Centers Criteria (the California criteria), the National Institute of Neurologic Disorders and Stroke, the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria, the Hachinski Ischaemic Score (HIS), and those found in DSM-IV (Nyenhuis and Gorelick, 1998; Scheltens and Hijdra, 1998).

Recent neuropathological analyses offer perspective on the difficulty in correctly diagnosing cerebrovascular pathology in dementia. Rather than considering vascular dementia as present or absent, these studies distinguish between any vascular lesions versus pure vascular pathology (where vascular pathology was both sufficient to account for cognitive symptoms and unaccompanied by other pathology). In one study, although at least some vascular pathology existed in up to 41% of dementia cases coming to autopsy, pure vascular pathology accounted for dementia in only approximately 10% (Nolan *et al.*, 1998).

A diagnosis of vascular dementia is supported by sudden onset of cognitive impairment in two or more domains, step-wise deterioration, asymmetries on neurological examination, neuroimaging evidence of stroke, and presence of cerebrovascular risk factors. Vascular dementia progresses characteristically in a step-wise fashion, with new episodes of minor or major deterioration reflecting additional vascular events.

Vascular dementia can take several forms, as outlined in Table XV-8.22

Table XV-8.22 Categories of vascular dementia

Category	Clinical presentation
Lacunar infarctions	Progressive dementia, focal deficits, apathy, frontal lobe syndrome, possibly absent history of clinically recognized strokes
Single strategic infarctions	Sudden-onset aphasia, agnosia, anterograde amnesia, frontal lobe syndrome
Multiple infarctions	Step-wise appearance of cognitive and motor deficits
Mixed Alzheimer's disease–vascular dementia	Progressive dementia with remote or concurrent history of stroke
White mater infarctions, Binswanger's disease	Dementia, apathy, agitation, bilateral corticospinal/bulbar signs

Marked differences in the clinical presentation of these variants make it inappropriate to regard vascular dementia as a unitary diagnostic entity (Nyenhuis and Gorelick, 1998). Rather, vascular dementia represents a group of dementia aetiologies sharing the general common pathogenesis of brain injury secondary to derangement of cerebrovascular functional and/or structure. A pleomorphic nature thereby arises from variations in type and location of cerebrovascular compromise (Looi and Sachdev, 1999).

Multiple small infarctions of subcortical white-matter pathways, disconnecting circuitry among cognitively important cortical centers, causes a leukoencephalopathy previously called Binswanger's disease. The resulting clinical situation has been analogized to a highway damaged by potholes: destinations remain intact but travel between destinations is slowed.

In the majority of patients assessed for dementia, an exclusive and highly certain diagnosis of vascular dementia can rarely be made. Instead, clinicians are often confronted with patients having some vascular pathology features together with a history that can otherwise seem more compatible with a diagnosis of AD. Such clinical and pathological admixtures are a common presentation for cerebrovascular disease (Nyenhuis and Gorelick, 1998).

SPECT frequently reveals a scattered/patchy pattern, reflecting the variable localization of vascular-based insults.

Treatment of vascular dementia consists primarily of identifying and correcting predisposing cerebrovascular risk factors. The overall rate of progression can be slow compared with other causes of dementia, but some patients suffer an accelerated decline.

Cerebral Autosomal Dominant Arteriopathy Subacute Infarcts and Leukoencephalopathy

Cerebral autosomal dominant arteriopathy subacute infarcts and leukoencephalopathy (CADASIL) is an increasingly recognized clinicopathological syndrome. CADASIL causes subcortical lacunar infarction and dementia in over 80% of cases (Salloway and Hong, 1998). CADASIL can appear very similar to hypertensive microvascular disease (Binswanger's disease). Signs and symptoms of CADASIL tend to appear between the ages of 40 and 60 years, but changes are apparent on MRI much earlier. Approximately 30% of patients have migraines with aura; mood disorders are common. Neuropathological findings include smooth muscle hypertrophy in small arteries, demyelination, gliosis in subcortical white matter and basal ganglia, and corpus callosum involvement. Given the autosomal dominant hereditary basis of this disease, family history is key.

Neoplastic Disease

Dementia secondary to cancer was briefly mentioned above under potentially reversible secondary dementias. Irreversible cancer-related dementias are unfortunately much more common. Direct mechanisms of cognitive disruption include primary and metastatic brain tumours and leptomeningeal disease. Indirect/systemically mediated mechanisms include neoplasm-related metabolic, haematological and/or endocrinological derangements causing secondary CNS dysfunction. Although oncological disease affecting the CNS is usually heralded by focal neurological signs, a nonspecific dementia can sometimes be the sole presenting manifestation.

Paraneoplastic limbic encephalitis (PLE) is a rare disorder characterized by variably progressive cognitive and affective changes; less often, focal motor and/or sensory signs can occur. PLE is both an inflammatory and a degenerative disorder of certain CNS grey matter regions occurring as a rare complication of a non-CNS cancer (Gultekin *et al.*, 2000). Symptoms typically precede diagnosis of the underlying cancer (Posner, 1995).

Symptoms usually develop over the course of several weeks. The disorder is characterized by profound impairment of recent memory corresponding to an inability to learn new information. Attention and registration are unaffected, and remote memory is less impaired. Confabulation occurs in some cases. Affective symptoms, especially anxiety and/or depression, are common early features. Hallucinations are variable. The primarily amnestic syndrome sometimes progresses to a global dementia. Depending on the extent to which grey matter regions outside the limbic system are involved, cerebellar, pyramidal, bulbar and peripheral nerve disturbances can coexist with cognitive/affective/behavioural symptomatology (Gultekin *et al.*, 2000; Posner, 1995).

MRI can reveal abnormal signal intensity in the medial temporal lobes. Diffuse slowing or bitemporal slow waves and spikes are sometimes seen on EEG. CSF often demonstrates a modest mononuclear pleocytosis and mildly elevated protein. Serological tests for detection of paraneoplastic antineuronal antibodies have become increasingly available. Excluding other potentially treatable disorders is of primary importance before settling on a diagnosis of PLE.

PLE can be static, progressive or even remitting. No specific treatment is available except management of the underlying malignancy.

Radiation

The effects of radiation therapy on the brain can be extremely variable in type and time of onset; late effects, in the order of 10 years after treatment, are seen frequently. Clinical expression depends in part on radiation type (e.g. focal bean or whole brain) and amount. MRI is diagnostic.

Extensive white-matter disease is the most common type of complication, with neuropsychological deficits predictably consistent with leukoencephalopathy.

Infectious Dementias

Chronic CNS infectious processes can sometimes cause dementia as a primary manifestation; we briefly describe some major types.

Viral Encephalitides

Viral encephalitis is caused by viral infection of the brain parenchyma, producing neuronal and glial degeneration, inflammatory infiltration, oedema and tissue necrosis. A specific pathogen remains unidentified in up to 75% of presumed viral CNS infection cases. Indeed, the confusing term 'aseptic meningitis' is a testament to the historic difficulty of isolating definitively an aetiological agent in presumed viral meningitides.

Amplification of viral nucleic acids from CSF, as done by the polymerase chain reaction (PCR) for example, has improved diagnosis considerably of several acute, subacute and chronic viral CNS infections. In autoimmune deficiency syndrome (AIDS), PCR can help differentiate lesions due to human immunodeficiency virus (HIV) itself or to opportunistic infections such as progressive multifocal leukoencephalopathy (PML) caused by JC virus or cytomegalovirus (CMV)-related complications.

Herpes Encephalitis Herpes simplex virus (HSV) causes the most common form of sporadic potentially fatal encephalitis in children older than 6 months and adults worldwide. CNS HSV infection is divided into two groups: neonatal HSV infection, caused by HSV-2, and herpes simplex encephalitis (HSE), which occurs in children outside the neonatal period and adults and is caused by HSV-1. HSE in older children and adults is caused by both primary and recurrent HSV infection. Approximately two-thirds of cases are caused by virus reactivation (Whitley, 1997).

HSE is characterized pathologically by intense meningitis and destructive changes in the brain parenchyma. Inflammation with

accompanying necrosis and haemorrhage occur, often maximally involving the frontal and temporal lobes. Temporal brain regions are most involved quantitatively in autopsy studies (Whitley, 1997).

HSE initially presents as a focal encephalitis. Neurolopsychiatric signs found early in the disease course (e.g. aphasia, confusion, behavioural changes) can progress to a fulminant illness characterized by recurrent focal or generalized seizures, coma and death. Hemiparesis is evident at the time of presentation in approximately one-third of cases. Although variable, the most common residual neuropsychological sequela is memory impairment. Owing to HSV's anterior temporal tropism, anterograde amnesia, frequently severe, is the usual manifestation (Whitley, 1997).

Routine blood tests reveal peripheral leukocytosis. Lumbar puncture demonstrates elevated pressure. CSF studies show normal or mildly decreased glucose, mildly elevated protein and pleocytosis. Red blood cells and xanthochromia are frequently seen. Virus is rarely recovered from the CSF, and detection of HSV antibodies in the CSF is not sensitive or specific enough to make a treatment decision. PCR has become the mainstay of non-invasive diagnosis, while isolation of HSV from brain biopsy specimens remains the diagnostic gold standard.

CT can demonstrate temporal hypodensity and contrast enhancement but is often normal during the first week of disease. MRI can reveal temporal lobe pathology, including loss of grey–white differentiation, oedema and haemorrhagic components during the first week of disease. HSE produces dramatic EEG changes (e.g. paroxysmal lateralizing epileptiform discharges (PLEDs)) that, while not pathognomonic, are highly suggestive (80% of biopsy-proven cases).

Treatment with antiviral therapy (e.g. acyclovir) can be life-saving.

Human Immunodeficiency Virus Up to 70% of HIV patients develop neurological complications, including cognitive disturbances. Although neuropsychiatric disease typically occurs within the context of other AIDS-defining illnesses, neuropsychiatric signs can herald AIDS in up to 20% of HIV patients (Berger and Simpson, 1997). The spectrum of neuropsychiatric disorders complicating HIV-1 infection is extremely diverse. CNS complications can be divided into those due to HIV infection itself and those due to HIV-related secondary aetiologies, e.g. opportunistic infections.

HIV-associated dementia has been reported in up to 15% of HIV-infected adults. Although pathogenesis remains unclear, there is a correlation between CSF HIV load and neuropsychological function. Magnetic resonance spectroscopy has demonstrated abnormalities in cognitively normal HIV patients. AIDS dementia complex (ADC) is an increasingly frequent infectious cause of dementia. Estimated to occur in at least 25% of AIDS patients, ADC produces psychomotor slowing, attention decrement and personality changes (Berger and Simpson, 1997).

Scales demonstrated to have enhanced specificity and sensitivity for detecting cognitive impairment in HIV/AIDS patients include the HIV dementia scale (HDS) and executive interview (EXIT) (Beghuis *et al.*, 1999).

Creutzfeldt–Jakob Disease CJD is one of the slow virus infections, also known as prion diseases after the presumed infectious agent, and transmissible spongiform encephalopathies (TSE) after the histopathological changes associated with these infections.

Prion diseases are categorized into three groups: sporadic, inherited and acquired. Most slow virus infections — approximately 85% — are sporadic. CJD is the most common human TSE. A new variant of sporadic CJD likely caused by the same agent as bovine spongiform encephalopathy (BSE) was first described in 1996. CJD occurs primarily as a sporadic illness with an annual incidence of about one per million in the general population (Poser *et al.*, 1999).

CJD produces a rapidly developing progressive dementia, which can be clinically variable. Initial complaints in approximately one-third of patients are constitutional, consisting of fatigue, disordered sleep or decreased appetite. Another third have non-focal neuropsychiatric features at onset, e.g. confusion or atypical behaviours. The remainder can present with prominent signs of corticospinal and extrapyramidal dysfunction, including gait disturbance and rigidity, as well as focal neurological features, including ataxia, visual loss, aphasia, hemiparesis or focal amyotrophy, sometimes leading to an erroneous initial clinical impression of stroke or motor neuron disease. Diagnosis becomes clearer with the onset of cognitive decline and emergence of and startle myoclonus to abrupt sound or touch. Pyramidal, extrapyramidal and cerebellar signs eventually occur in the majority of patients. Seizures, especially myoclonic, occur in up to 20% of patients. In all reports of new variant CJD, psychiatric symptoms (e.g. depression, anxiety, personality changes) were followed within a median of 6 months by neurological symptoms such as dysaesthesias and paraesthesias. Terminal stages of CJD are characterized by progressive loss of neuropsychological function leading to akinetic mutism (Asher, 1997).

There can be characteristic EEG changes. Early in the disease course, EEG may show nonspecific slowing. Later, periodic, biphasic or triphasic synchronous sharp-wave complexes are superimposed on a slow background rhythm. Periodic triphasic complexes have shown a high sensitivity and specificity for CJD detection (Asher, 1997).

Until recently, CJD diagnosis relied on clinical symptoms, characteristic EEG pattern, and brain biopsy assessment. Introduction of 14-3-3 CSF protein Western blot immunodetection has greatly improved the diagnostic accuracy (sensitivity up to 99% and specificity up to 96%) (Collins *et al.*, 2000). MRI often demonstrates a characteristic 'cortical ribboning' on diffusion-weighted imaging (Poser *et al.*, 1999). Definitive diagnosis still requires identification of abnormal prion protein and/or related neuropathology in brain tissue. Brain pathology consists of a vacuolar (spongiform) degeneration.

CJD is uniformly fatal, with progression to death within 12–18 months of symptom onset. Management is supportive, and there is no cure.

COGNITIVE DISORDERS, NEUROPSYCHOLOGICAL FUNCTION, AND NEUROIMAGING

New neuroimaging modalities provide extraordinary capacity for *in vivo* exploration of the correlation of neuropsychological function and dysfunction with corresponding neurocircuitry. Data derived from such investigations are appropriately informing our knowledge of the neuropsychology of cognitive disorders and relevant functional neuroanatomy.

Structural Neuroimaging

Structural neuroimaging can be an essential aid in determining the structural neuroanatomy underlying cognitive impairment.

CT generally provides adequate data for evaluation of atrophy, ventricular system integrity, most haemorrhages (epidural, subdural, subarachnoid, intraparenchymal), and mass effects (of tumours, abscesses, etc.). Consequently, CT is usually adequate to exclude most structural causes of cognitive dysfunction.

Although CT usually yields adequate screening data, MRI's capacity for multiplanar views and multiple imaging sequence modalities provides vastly more information about potential vascular, neoplastic, inflammatory and infectious aetiologies of cognitive impairment. Sagittal MRI is especially useful for demonstrating selective lobar atrophies (e.g. the focal atrophy attendant

to frontotemporal dementias, e.g. 'knife-like' gyri of Pick's disease). Only gadolinium-enhanced magnetic resonance images are truly adequate for evaluating certain serious and potentially treatable conditions (e.g. leptomeningeal disease).

Presymptomatic hippocampal atrophy on MRI has been demonstrated in asymptomatic individuals at risk of autosomal dominant AD (De Leon *et al.*, 1997). In clinically diagnosed AD of moderate severity, MRI-based volumetric measurements show a reduction of up to 40% in the size of the hippocampus, amygdala, thalamus and anterior temporal lobe (Pantel *et al.*, 1997). Neuropsychological assessments of recent memory are highly correlated with visually rated hippocampal atrophy on MRI, which in turn is associated strongly with neurofibrillary pathology in AD (Scheltens, 1999).

Despite the promising utility of structural neuroimaging in the assessment of cognitive disorders, problems with interpretation are common: (1) some patients can have completely normal structural scans; (2) sulcal widening and ventricular dilatation are found in many elderly cognitively intact individuals; (3) some non-demented patients can have multiple lesions without cognitive impact; (4) the degree of atrophy is not a reliable predictor of dementia severity; (5) hippocampal atrophy is nonspecific; and (6) common T2 MRI sequence abnormalities are extremely nonspecific and bear an unclear relationship to the type and severity of cognitive impairment.

Functional Neuroimaging

Single-Photon Emission Computed Tomography

Perfusion abnormalities in certain cognitive disorders frequently reflect pathological changes underlying cognitive demise. SPECT has been employed widely in the investigation of dementia. Some studies combining assessment of hippocampal atrophy on structural neuroimaging with cerebral blood flow studies on SPECT have yielded high sensitivity and specificity rates in discriminating AD patients from normal controls. Although encouraging, these figures are not consistently better than those obtained by diagnosis with established clinical criteria. The added value of SPECT is greatest for a positive test among patients with mild dementia in whom there is doubt regarding diagnosis (Scheltens, 1999).

Positron Emission Tomography

Like SPECT, PET is able to demonstrate functional abnormalities correlating with structural changes. However, PET has the added potential value of quantifying neurotransmitter (e.g. cholinergic) and other neurochemical changes. For example, a direct comparison of PET and SPECT in their ability to differentiate AD from vascular dementia revealed higher diagnostic accuracy for PET regardless of dementia severity (Scheltens, 1999).

Functional Magnetic Resonance Imaging

fMRI offers the advantage of functional neuroimaging without the need for intravenous administration of radioactive isotopes. More powerful machines (providing finer structural resolution) and advanced methodologies involving neuropsychological probes (providing event-related temporal resolution) are being employed to better characterize the neuropsychology of cognitive disorders.

NEUROANATOMY OF COGNITION

Introduction

Amnesia is the lack or failure of memory, which can be of organic or psychic origin, and can be either transient or permanent. Diseases that cause amnestic syndromes are rarely focal and very often simultaneously affect several regions of the brain. Dementia is defined as a syndrome characterized by memory loss and the presence of at least one of agnosia, apraxia and aphasia, resulting in a decline from a previously higher level of intellectual function of sufficient severity to interfere with social or occupational performance or both. The intellectual deterioration should involve more than a single cognitive function, and while memory is typically involved in an early stage, attention, language, visuospatial skills, perception and problem-solving skills are also affected.

Neurodegenerative disorders, such as Alzheimer's disease, can serve as models for the dissection of the neuroanatomy of memory. In other instances, neurotrauma or surgical interventions will cause localized defects, resulting in amnesia or other cognitive disturbances. The unravelling of the anatomical basis of memory should involve the study of the brain regions involved, their interconnections, and their functions in terms of neurotransmitter use.

In what follows, the anatomical structures involved in memory processing will be introduced, and several neurodegenerative disorders that perturb memory and other cognitive functions will be described.

Anatomical Substrate of Memory

Limbic System

The limbic system is the anatomical substrate of behaviours, including social behaviours that assure the survival of the individual and the species. Within the limbic system, there are more or less specialized functional systems that are involved with particular aspects of behaviour.

Historically, the limbic system has taken an important place in the neuroanatomy of memory (Shaw and Alvord, 1997). The concept of the 'limbic lobe' was first put forward by Paul Broca in 1878 to designate the structures on the edge (the 'limbus') of the neocortex (Broca, 1878). Broca defined the limbic lobe as the hippocampal and the cingulate gyri. In addition to the limbic cortex, a number of subcortical structures, including the hippocampus, the amygdala and the septal nuclei, form part of the limbic system. Depending on the authors, other structures, such as the posterior frontal cortex, raphe nuclei, ventral tegmental nucleus and nucleus basalis of Meynert, are also considered to be part of the limbic system (Braak and Braak, 1992). Since the work of Papez (1937), numerous refinements have been made to the limbic circuit model, which is now referred to by some authors as the 'limbic forebrain model'. The original 'limbic circuit of Papez' involved the mammillary bodies, fasciculus mamillothalamicus, cingulate gyrus, anterior thalamic nucleus, amygdala and hippocampus. Kornhuber (1988) added the thalamic mediodorsal nucleus to the Papez circuit. Markowitsch (1985) proposed a second limbic circuit, which could act complementarily or in parallel in information processing: the basolateral limbic circuit.

The hippocampal system and related structures are involved intimately in sensory processing and memory. It has been established that episodic memory is based on the transfer of information through so-called bottleneck structures that form part of this limbic system (Pritzel and Markowitsch, 1983). Amnesia results from disconnection of this intricate brain circuitry. The paramount role of the amygdala is illustrated by numerous case reports and by the study of amygdaloid lesions in neurodegenerative disorders, such as Alzheimer's disease (Sarter and Markowitsch, 1985a; Sarter and Markowitsch, 1985b).

Prefrontal Cortex

The prefrontal cortex is divided into the dorsolateral, medial and orbital regions. All three regions receive input from the mediodorsal thalamic nucleus, which relays information from the temporal cortex, the pyriform cortex and the amygdala. The traditional view is that the human prefrontal cortex is involved in emotion and performance more than concrete actions (Fuster, 1989). Any disturbances in perception, memory and thinking are considered secondary to emotional deficits. A major issue in the description of these patients was that some appeared joyful and unconcerned, while others appeared depressed (Mesulam, 1998). This led to the distinction of orbitofrontal regions, damage of which would result in disinhibited behaviour and emotional flatness, while injury of the dorsolateral regions resulted in an inhibited, depressed and even compulsive personality (Mesulam, 1998).

Seminal work revealing the role of the prefrontal cortex in memory and behaviour is found in the case description of Phineas Gage, who suffered massive damage to the prefrontal cortex due to a blow from a crowbar (Harlow, 1848), and in the description of numerous soldiers suffering from shrapnel wounds (Harlow, 1848). Markowitsch and Kessler (2000) described a young woman with massive impairment in executive functions and partial preservation of other cognitive functions, apparently caused by severe degeneration of the prefrontal cortex. This patient showed not only the typical cognitive and behavioural alterations due to combined orbitofrontal and dorsal frontal lesions, but also major disturbances of executive functions. She was unable to perform even the simplest task that demanded continued attention, and she was impressively deficient in visuoconstructional tasks.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Five frontal-subcortical circuits have been identified and named according to their function or cortical site of origin. The motor circuit, originating in the supplementary motor area, and the oculomotor circuit, originating in the frontal eye fields, are dedicated to motor function (Markowitsch, 1984). The dorsolateral prefrontal, lateral orbital, and anterior cingulate circuits subserve executive cognitive functions and aspects of personality and motivation, respectively (Mesulam, 1999). Each of the five circuits has the same member structures, including the frontal lobe, neostriatum, globus pallidus, substantia nigra and thalamus (Figure XV-9.1).

Within each of the circuits, there are two pathways: a direct pathway links the striatum with the globus pallidus interna/substantia nigra complex, and an indirect pathway projects from the striatum to the globus pallidus externa, and then to the subthalamic nucleus and back to the globus pallidus interna/substantia nigra (Alexander and Crutcher, 1990). Both direct and indirect circuits project from the globus pallidus interna/substantia nigra to the thalamus. Each circuit uses the same transmitters at each anatomic site. The circuits remain discrete throughout their courses. The relative anatomic positions of each circuit are preserved in each circuit structure; thus, the dorsolateral prefrontal cortex projects to the dorsolateral region of the caudate nucleus, the orbitofrontal region projects to the ventral caudate area, and the anterior cingulate cortex connects to the medial striatal-nucleus accumbens region. Similar anatomic arrangements are maintained in the globus pallidus and thalamus. There is progressive spatial constraint of the circuits at subcortical levels, with a reduction in the volume occupied by the circuits in subcortical compared with cortical regions.

The dorsolateral prefrontal-subcortical circuit originates in Brodmann's areas 9 and 10 on the lateral surface of the anterior frontal lobe. Neurons in these regions project to the dorsolateral head of the caudate nucleus (Selemon and Goldman-Rakic, 1985). Fibres from this region of the caudate project to the lateral aspect of the mediodorsal globus pallidus interna and rostrolateral substantia nigra pars reticulata via the direct pathway. The indirect pathway sends fibres to the dorsal globus pallidus externa, which in turn projects to the lateral subthalamic nucleus; fibres from the lateral subthalamic nucleus then terminate in the globus pallidus interna/substantia nigra pars reticulata (Goldman-Rakic and Selemon, 1990). Output from the basal ganglia projects to parvocellular portions of the ventral anterior and mediodorsal thalamus. The mediodorsal thalamus closes the circuit by projecting back to the circuit's origin in areas 9 and 10 of the dorsolateral frontal lobe (Goldman-Rakic and Selemon, 1990).

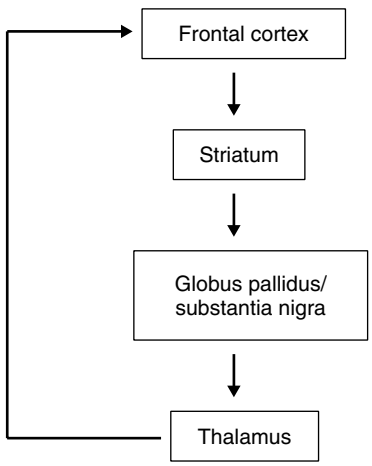

Figure XV-9.1 Frontal-subcortical circuits

The inferolateral prefrontal cortex originates in Brodmann's areas 10 and 11, and sends projections to the ventromedial caudate. This portion of the caudate projects directly to the most medial portion of the mediodorsal globus pallidus interna and to the rostromedial substantia nigra pars reticulata. The ventromedial caudate also sends an indirect loop through the dorsal globus pallidus externa to the lateral subthalamic nucleus, which then projects to the globus pallidus interna and substantia nigra pars reticulata. Neurites are sent from the globus pallidus and substantia nigra to the medial section of the magnocellular division of the ventral anterior thalamus as well as an inferomedial sector of the magnocellular division of the mediodorsal thalamus (Selemon and Goldman-Rakic, 1985). The circuit then closes with projections from this thalamic region to the lateral orbitofrontal cortex (Goldman-Rakic and Selemon, 1990).

Neurons of the anterior cingulate serve as the origin of the anterior cingulate-subcortical circuit. From Brodmann's area 24, they provide input to the ventral striatum (Goldman-Rakic and Selemon, 1990), which includes the ventromedial caudate, ventral putamen, nucleus accumbens and olfactory tubercle. This area is termed the limbic striatum. Projections from the ventral striatum innervate the rostromedial globus pallidus interna and ventral pallidum (the region of the globus pallidus inferior to the anterior commissure), as well as the rostrodorsal substantia nigra. There may also be a less well defined indirect loop projecting from the ventral striatum to the rostral pole of the globus pallidus externa (Haber *et al.*, 1990). The external pallidum in turn connects to the medial subthalamic nucleus, which returns projections to the ventral pallidum. The ventral pallidum provides limited input to the magnocellular mediodorsal thalamus. The anterior cingulate circuit is closed with projections from the dorsal portion of the magnocellular mediodorsal thalamus to the anterior cingulate (Goldman-Rakic and Selemon, 1990).

There are approximately three signature behavioural/cognitive syndromes that occur after damage to prefrontal cortex. Damage to the dorsolateral prefrontal circuit causes executive dysfunction. These patients have difficulty generating hypotheses and flexibly maintaining and shifting sets as required by changing task demands. Damage to the orbitofrontal circuit causes disinhibited, irritable and labile behaviour. This type of lesion also results in imitation and utilization behaviour. Unlike patients with dorsolateral damage, these patients may not have executive impairments. Damage to the medial frontal/anterior cingulate circuit causes akinesia, apathy and unconcern. Of course, patients may have damage to more than one of these frontal circuits, which can lead to a mixture of clinical deficits.

Hippocampus

The temporal lobe can be divided into a lateral part, involved in audition and speech, and a medial part, considered to be a part of the limbic system and involved in memory. The ventromedial temporal lobe consists of the parahippocampal gyrus, entorhinal cortex (ERC), hippocampal formation, uncus, amygdala and the cortex of the temporal pole. All sensory information passes through the unimodal and multimodal association areas, before converging on the amygdala and hippocampus (Figure XV-9.2).

Integrative neuroscience approaches have revealed that the dorsolateral prefrontal cortex, hippocampus and cingulate cortex are engaged in novelty detection and attention. The hippocampus occupies a central position in the limbic system. The hippocampal formation consists of the subiculum, the hippocampus proper and the dentate gyrus. The ERC is the gateway to the hippocampal formation and consists of a special six-layered cortex. The hippocampus is subdivided into different regions denominated by CA1, CA2, CA3 and CA4. The hippocampal gyrus consists of three layers, with the pyramidal cell being the most distinctive cell type. In addition to the

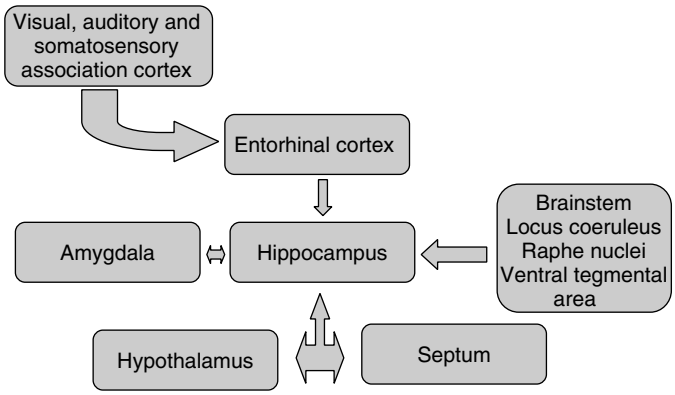

Figure XV-9.2 Connections of the human hippocampus

ERC, other inputs to the hippocampal formation are provided by the septal nuclei, hypothalamus and thalamus, as well as the brainstem.

Imaging studies have indicated that atrophy of the hippocampus correlates with impaired memory function and may be an early indicator of a subsequent cognitive decline. The hippocampus is associated with declarative memory, which is the memory of facts, experiences and information about events. While the hippocampus is involved in memory proper, the nearby amygdala is involved in emotion. The amygdala consists of a nuclear complex located inside the temporal lobe and consisting of basolateral nuclei, a central nucleus and corticomedial nuclei. The role of the amygdala is to associate a particular emotion to a current experience.

Neuropathological data concerning the progression of Alzheimer's disease indicate the hippocampus as an early focus of anatomical change. In addition, studies of subjects who are enrolled as being normal but subsequently decline have indicated that magnetic resonance imaging (MRI)-based hippocampal volumes can be predictive. Jack and colleagues have demonstrated the utility of volumetric measurements of the hippocampus as being useful in discriminating normal elderly subjects from a group of mild Alzheimer's disease patients (Jack *et al.*, 1999). Preliminary data on cross-sectional hippocampal volumes indicate that subjects with mild cognitive impairment have hippocampal atrophy beyond what we would expect for normal control subjects yet less than subjects with very mild Alzheimer's disease. Measures of the ERC have also been suggested as being useful at discriminating normal ageing from early cognitive impairment. While structural studies of the hippocampal formation are likely to be useful, functional imaging studies also show promise at assessing patients with very mild impairment.

Stimulus novelty facilitates memory encoding, suggesting that the hippocampus is likely to be involved in novelty processing (Izquierdo *et al.*, 2000). Animal research has linked the hippocampus with novelty or mismatch detection (Shaw and Alvord, 1997). The study of late evoked potentials in patients with posterior hippocampal region damage has shown normal parietal P3b activity but marked reductions of the frontocentral P3a response associated with novelty. A crucial question is whether the dorsolateral prefrontal cortex or the hippocampal region performs the initial novelty detection (Tulving and Markowitsch, 1998). Some studies indicate that a neocortical system controlled by the prefrontal cortex performs the initial deviancy/novelty detection (Eichenbaum, 1999). A prefrontal signal may then alert the hippocampal cortex to the fact that a potentially significant event requiring memory processing has occurred. Corticolimbic connections through the ERC or fornix-mammilothalamic-cortical pathways may also contribute to the novelty detection.

NEUROPATHOLOGY OF AMNESTIC DISORDERS

The Ageing Process and Mild Cognitive Impairment

Clinical Findings

With the advent of therapeutic agents for Alzheimer's disease, there has been increasing clinical emphasis on the early detection of mental decline in order that treatment strategies can be initiated as soon as possible. The emphasis on early detection in turn has led to attempts to characterize transitional states between normal ageing and dementia. Such states have also been viewed as part of the ageing process (e.g. age-associated memory impairment, minimal cognitive impairment) or alternatively as incipient or early-stage Alzheimer's disease. The term 'minimal cognitive impairment' (MCI) is intended to identify individuals with measurable, abnormal memory loss who lack decline in other cognitive abilities. There is general consensus that some aspects of cognition decline with age, whereas others may be preserved. In the absence of disease, however, it may be possible to compensate for the cognitive changes associated with age by using cues and other memory strategies, such that overall performance may be 'normal', albeit slower. However, some studies suggest that much of the cognitive decline previously attributed to age alone may instead reflect the effect of unrecognized very mild dementia. This point is supported by a recent population study of people aged 85 years, wherein decline in cognitive performance over 3 years was associated with individuals who had Alzheimer's disease at baseline or developed it during the study, whereas those individuals who remained free of Alzheimer's disease had little evidence of cognitive decline (Aevarsson and Skoog, 1996). Patients with MCI are at increased risk of developing Alzheimer's disease. Conversion rates to Alzheimer's disease vary between 10% and 15% per year, while in normal aged adults, this conversion rate lies between 1% and 2% (Morris *et al.*, 2001; Petersen *et al.*, 1997). The heterogeneity of this nosologic entity is well recognized, and its predictive value for Alzheimer's disease is limited (Shah *et al.*, 2000).

Neuropathology

The neuropathological substrate of patients with MCI is not known, as affected individuals do not normally die at this early level of cognitive dysfunctioning. A few case reports that have been published have been due to accidental deaths of patients who had previously been examined neuropsychologically. Autopsy studies have shown that even cognitively normal elderly individuals may sometimes meet the neuropathologic criteria for Alzheimer's disease. In a study of patients with a clinical dementia rating CDR (scale) of 0.5, corresponding to the level of dysfunction found in MCI, it was shown that most of the patients met the neuropathological diagnostic criteria of Alzheimer's disease (Morris *et al.*, 2001). All individuals had changes in the medial temporal cortex, and approximately half of them showed neocortical plaques and tangles consistent with Alzheimer's disease. Neuropathological data in early Alzheimer's disease have shown alterations in the ERC and hippocampus that may be involved in the disturbances of episodic memory found in the early stages (Braak and Braak, 1992). Currently, it is not clear what remains an acceptable number of Alzheimer's disease-type lesions in an elderly brain. As such, it appears that MCI patients span a spectrum of neuropathological findings, from those who are felt to be associated with ageing, such as neurofibrillary tangles and senile plaques in the medial temporal regions, to patients who would otherwise meet most neuropathological criteria for Alzheimer's disease. Inherent in this discussion is a characterization of the neuropathology of normal ageing.

Delirium

Clinical Findings

Delirium is characterized by a disturbance of consciousness with a change in cognition developing over a short period of time; it is often accompanied by the presence of visual and auditory hallucinations. Delirium is a common mental disorder in the elderly, with old age being a major risk factor; another major risk factor is dementia (Robertsson *et al.*, 1998). The presence of visual hallucinations, but not delusions or auditory hallucinations, was associated significantly with more systemic disorders and often multiple aetiologies causing the delirium. Psychotic symptoms are not uncommon in delirium, but specific psychotic symptoms may have different factors contributing to their development. In a recent study, the prevalence of psychotic symptoms in delirium was 42.7% ($n = 97$), with 27% of patients ($n = 61$) having visual hallucinations, 12.4% ($n = 28$) having auditory hallucinations, 2.7% ($n = 6$) having tactile hallucinations, and 25.6% ($n = 58$) having delusions (Webster and Holroyd, 2000). Visual hallucinations appear to be associated with a greater number of systemic disorders, but presumably other unknown factors are also associated with the development of psychotic symptoms in delirium (Webster and Holroyd, 2000).

Neuropathology

Delirium has been considered a syndrome of generalized dysfunction of higher cortical functions due to its breadth of symptoms. No particular neuropathological abnormalities have been associated with delirium. The prefrontal cortices, anterior and right thalamus, and right basilar mesial temporoparietal cortex may play a significant role in subserving delirium symptoms, and may be the final common pathway from a variety of aetiologies. This final common pathway may be responsible for certain core symptoms (disorientation, cognitive deficits, sleep–wake cycle disturbance, disorganized thinking, language abnormalities), while other symptoms (delusions, hallucinations, illusions, affective lability) may occur, depending on the aetiology. An imbalance in the cholinergic and dopaminergic neurotransmitter systems is most commonly implicated in causing delirium (Trzepacz, 1999).

Alzheimer's Disease

Clinical Findings

Alzheimer's disease is the commonest cause of dementia. Word-finding difficulty often parallels the onset of memory problems, and impaired reading comprehension and written language may also be seen. Changes in visual perception and praxis can also result in difficulties with activities of daily living, such as dressing or grooming. Except for the mental state, the neurological examination is usually normal. Extrapyramidal features, including rigidity, bradykinesia, shuffling gait and postural change, are relatively common, but primary motor and sensory functions are otherwise spared. Analysis of 100 autopsy-confirmed cases with Alzheimer's disease indicated that the average duration of symptoms until death may be 10 years, with a range of 4–16 years. Women are affected more commonly than men, and disease duration tends to be longer for women. The decline in intellectual ability generally starts between age 50 and 65 years, although onset at a younger age may occur, especially with some of the familial autosomal dominantly inherited forms.

Neuropathology

Grossly visible changes in the brains of Alzheimer's disease patients are similar to the changes observed in normal ageing, although the brain weight of Alzheimer's disease patients is often less than 1000 g. Examination of the brain discloses frontal and temporal cortical and subcortical atrophy, with thinning of the cortex and widening of the sulci (Figure XV-9.3). The ventricles are enlarged, and atrophy is most pronounced in the medial

Table XV-9.1 Components of intraneuronal inclusions

Structural protein	Stress protein	Classic name	Disease
Neurofilament	Ubiquitin, β-crystallin	Lewy body	Parkinson's disease
		Cortical Lewy body	Diffuse Lewy body disease
		Dystrophic neurites	Pick's disease
		Ballooned neurons	CBGD
		Lewy body-like inclusions in ALS	ALS
Tau	Ubiquitin	Neurofibrillary tangles	Alzheimer's disease
		Neuropil threads	Progressive supranuclear palsy
		Pick's bodies	Pick's disease
		Neuropil grains	CBGD
			Dementia with grains
		Gliofibrillary tangles	CBGD, PSP
		Glial cytoplasmic inclusions	MSA
Unknown	Ubiquitin	Marinesco body	Ageing, nonspecific
Actin	None	Hirano body	Ageing, nonspecific

ALS, amyotrophic lateral sclerosis; CBGD, corticobasal ganglionic degeneration; MSA, multiple system atrophy; PSP, progressive supranuclear palsy.

temporal lobes, with the hippocampus being disproportionately small. Microscopically, one observes neurofibrillary tangles, senile plaques and granulovacuolar degeneration. Additionally, amyloid angiopathy is often observed.

Neurofibrillary Tangles

The cellular cytoskeleton is an intricate cytoplasmic organelle linking the cellular membrane with the nuclear envelope. As well as its obvious structural function, the cytoskeleton may play a role in transcellular signalling and axonal transport. It is composed of three major classes of proteins forming filaments: the microfilaments (5 nm), the intermediate filaments (10 nm), and the microtubules (22 nm). Microfilaments are composed of actin. The intermediate filaments are made up of relatively tissue-specific proteins. In the nervous system, neurofilament is the neuronal intermediate filament and glial fibrillary acidic protein (GFAP) is the glial intermediate filament. Multiple forms of these proteins are present in the normal brain, and post-translational modifications, such as phosphorylation, can modify their functional characteristics. The microtubules consist of cylindrical aggregates of globular tubulin molecules. In addition to tubulin, microtubules contain a variety of microtubule-associated proteins (MAPs).

The most important MAP is the protein tau, which exists in multiple isoform and phosphorylation states. When the cell is stressed, the intermediate filament network immediately collapses to form perinuclear bundles or clumps. This molecular response may reflect increased phosphorylation or proteolysis of these proteins due to the influx of calcium. If the stress experienced by the cell is not lethal, then the cell deploys an adaptive response called the heat-shock response. The cell produces several proteins that may restore functional activity of partially denatured proteins; if the denaturing is too severe to permit restoration, then the proteins are marked for proteolysis. Proteins designated for destruction are conjugated with ubiquitin. Other stress proteins may be involved, including β-crystallin and a family of other heat-shock proteins. If the proteins conjugated to these stress proteins are not degraded, then these conjugated complexes aggregate to form intracellular inclusions. The inclusions in neurodegenerative disorders are examples of such aggregates. Ubiquitin immunoreactivity is seen in many intracellular inclusions, and is not specific to any particular disease. Ubiquitin immunoreactivity is much more sensitive than classical staining methods, and is therefore increasingly the method of choice in the detection of cellular protein inclusions. Hence, neurofilament, tau and synuclein can all be discerned.

Table XV-9.1 lists the components of various inclusions.

Neurofibrillary tangles are intraneuronal cytoplasmic collections of poorly soluble 7–9-nm paired helically wound filaments with a periodicity of 80 nm. These filaments share some antigenic sites with neuronal intermediate filaments, and are best stained with classical silver methods or thioflavin S. Tangles are found predominantly in projection neurons. Hyperphosphorylated tau protein is a major component of tangles, although neurofilament protein and ubiquitin are also present in significant amounts.

Tau consists of a family of post-translationally modified proteins that are normal components of the cytoskeleton (Figure XV-9.4). In the adult brain, differential splicing of a single gene located on chromosome 17 generates six isoforms of tau (Goedert, 1999). Three of these forms carry the segment specified by exon 10 and have four repeats of a microtubule-binding domain; the other three isoforms lack this fourth domain. Pathological accumulation of hyperphosphorylated tau comprises the abnormal inclusions in neurons and glia.

Tau proteins aggregate and are chemically modified in the inclusions, such as Alzheimer's neurofibrillary tangles and Pick bodies, of which they constitute the major component. Brain homogenates from Alzheimer's disease show three bands at 55, 64 and 69 kD (Delacourte, 1994). Dementia with Pick bodies yields a doublet at 55 and 64 kD, with an additional weaker band at 69 kD (Probst *et al.*, 1996; Buee and Delacourte, 1999). Corticobasal degeneration also yields a doublet, but at 64 and 69 kD (Buee

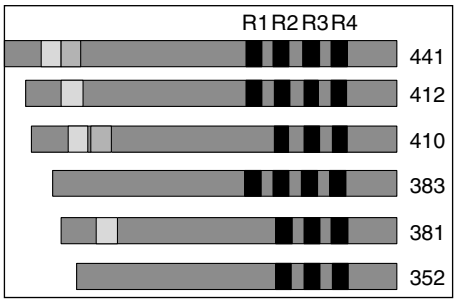

Figure XV-9.4 The microtubule-associated protein tau consists of six isoforms with three or four microtubule-binding regions (R) and one or two N-terminal inserts (light shading)

and Delacourte, 1999). Further analysis of these bands using exon-specific antibodies has shown that the pathological tau proteins in Alzheimer's disease comprise all six tau isoforms. In contrast, only the isoforms lacking the fourth microtubule-binding domain encoded by exon 10, and thus characterized as '3 repeat tau' are found in the inclusions in Pick's disease. Conversely, the inclusions of corticobasal degeneration and progressive supranuclear palsy contain the three isoforms with the fourth microtubule-binding domain encoded by exon 10 ('4 repeat tau') exclusively (Buee and Delacourte, 1999).

Senile Plaques

Senile plaques are extracellular 20–150-μm structures consisting of a central amyloid core surrounded by blunt, swollen neuritic processes; like tangles, they stain well with silver stains. Senile plaques come in different forms, amorphous and small amyloid deposits and diffuse plaques being considered an early stage of formation as they are found in normal ageing and in Down's syndrome patients. Some authors believe that the severity of dementia correlates well with the number of mature or neuritic plaques per unit area in the brain, while others hold that the neurofibrillary tangles correlate better with dementia. Terry *et al.* (1991) have shown that synaptic loss is best correlated with intellectual decline. All authors agree that diffuse plaques, which are large diffuse areas of staining devoid of central cores or swollen neuritic processes, do not correlate with the severity of dementia. The third microscopic hallmark of Alzheimer's disease is granulovacuolar degeneration, which appears as small (5 μm), clear, intraneuronal cytoplasmic vacuolation with each vacuole containing a single argyrophilic granule.

The guidelines developed by the multicentre Alzheimer's disease project CERAD (consortium to establish a registry for Alzheimer's disease) represent the most widely used diagnostic criteria. The CERAD protocol employs a semiquantitative evaluation of neuritic plaques coupled with the patient's age to reach an age-related plaque score (Mirra, 1997b). Three sections of neocortex, including the superior and middle temporal gyrus, middle frontal gyrus, and inferior parietal lobule, are examined at 100× using either the Bielschowsky silver technique or the more sensitive thioflavin-S staining technique (Mirra, 1997a). The thioflavin-S technique requires access to fluorescence microscopy and is not as widely available as silver staining. The number of plaques is designated as none, sparse, moderate or frequent. CERAD provides images illustrative of these plaque (and tangle) frequencies to help neuropathologists calibrate their estimates. Fewer plaques are tolerated in young people (age less than 50 years) than in the elderly (age greater than 75 years), and the presence or absence of a history of dementia is taken into account.

The Braak and Braak staging of Alzheimer's disease can be simplified into three tiers: involvement of the transentorhinal cortex in stages 1 and 2, the limbic system in stages 3 and 4, and finally the isocortex in stages 5 and 6 (Braak and Braak, 1996; Braak and Braak, 1997). Braak and Braak (1996) redirected attention to the neurofibrillary tangles and described the spread of tangles from the transentorhinal cortex and hippocampus (stages 1 and 2) to the limbic system (stages 3 and 4) to the isocortex, including the frontal, temporal, parietal and occipital neocortex (stages 5 and 6) as Alzheimer's disease progresses. They have provided compelling evidence that description of the distribution of neurofibrillary tangles is important in the neuropathological assessment of Alzheimer's disease. Individuals in stages 1 and 2 are generally asymptomatic, those in stages 3 and 4 have incipient or mild Alzheimer's disease characterized by episodic memory loss, and those in stages 5 and 6 have symptomatic Alzheimer's disease. There is, however, a relatively poor anatomoclinical correlation, with some individuals functioning at an adequate level despite the presence of numerous lesions in the isocortex.

Senile plaques contain beta-amyloid protein, a peptide consisting of 39–43 amino acids (Selkoe, 2000). This small amyloidogenic peptide is derived from proteolytic cleavage of a large transmembrane glycoprotein, amyloid precursor protein (APP). APP is synthesized in three major forms (695, 751 and 770 amino acid residues) by differential mRNA splicing (Selkoe, 2000). The two larger forms have regions that have homology with serine protease inhibitors. Beta-amyloid is toxic to mature neurons; this peptide may bind protease inhibitor receptors on cell surfaces, permitting the accumulation of extracellular proteases, leading to membrane and eventually cytoskeletal damage.

Mutations in the APP gene on chromosome 21 account for about 3% of autosomal dominant Alzheimer's disease, while mutations in the presenilin-1 gene are found in the majority of families (Rubinsztein, 1997; Cruts *et al.*, 1996). Mutations in the APP gene are also responsible for intracerebral haemorrhages due to amyloid angiopathy, and thereby cause dementia. We have described a novel APP mutation that results in an intermediate phenotype, with progressive dementia and stroke occurring in the same family (Cras *et al.*, 1998). Two forms of autosomal dominant familial Alzheimer's disease are linked to chromosomes 14 and 1, and result from missense mutations of integral membrane proteins (presenilin 1 and presenilin 2), which may be a receptor, membrane channel or protein involved in docking and fusion of membrane-bound vesicles. There is evidence that the presenilins may be involved in proteolytic processing at the cell surface required to release Notch and APP fragments into the extracellular space (De Strooper, 2000). *In vitro* experiments have shown that the presenilin mutations result in increased amyloid-beta protein production (Cruts and Van Broeckhoven, 1998). Familial forms of Alzheimer's disease tend to have earlier onset and a more aggressive course than sporadic or apolipoprotein E (ApoE) E4-linked Alzheimer's disease (Martin *et al.*, 1991). Homozygosity for the E4 allele of ApoE has been shown to confer increased risk for Alzheimer's disease, to advance the age of onset, and to result in a higher number of senile plaques (Hofman *et al.*, 1997). ApoE is involved in lipid transport and binds to the microtubule-associated protein tau under certain conditions, but the precise molecular basis of its relation to Alzheimer's disease pathogenesis remains unsolved.

Cholinergic Deficit

In terms of neurotransmitter alterations, Alzheimer's disease is characterized by a striking reduction in cortical acetylcholine, as reflected in the amount of choline acetyl transferase (ChAT) in the cortex (Davis *et al.*, 1999b). In biopsy cases, ChAT levels had a weak but definite correlation. This biochemical information led to the observation that the basal forebrain nucleus responsible for the majority of cortical cholinergic projections, the basal nucleus of Meynert, is depleted of cells in Alzheimer's disease (Ezrin-Waters and Resch, 1986). Early studies showed that the muscarinic cholinergic receptor was unchanged in Alzheimer's diseased brain despite losses of ChAT and accumulation of neuritic plaques. Other neurochemical abnormalities have been described in Alzheimer's disease, but cholinergic reduction remains the major alteration (Engelborghs and De Deyn, 1997; Mesulam *et al.*, 1983; Mesulam, 1986). Serotonin metabolism is decreased in regions of the cortex and some other regions in Alzheimer's disease. Biopsy studies showed that both serotonin and the metabolite 5-hydroxyindoleacetic acid (5-HIAA) were decreased in cortical biopsy samples, and that both uptake and release of serotonin were diminished in these samples.

The dorsal raphe nuclei of the brainstem are decreased in number, although not to as large an extent as either the cholinergic or neuradrenergic neurons (Aletrino *et al.*, 1992). The surviving neurons of the raphe often contain neurofibrillary tangles. While cholinergic

deficiencies have some correlations with levels of cognitive impairment, and cholinergic enhancement has been associated with cognitive improvement, serotonergic alteration does not appear to have cognitive correlates. Rather, depression and aggressive behaviour appear to be more associated with serotonergic loss (Bondareff, 1996). Tyrosine hydroxylase is the rate-limiting enzyme for noradrenaline synthesis and is diminished significantly in Alzheimer's disease (Torack and Morris, 1992). The source neurons for forebrain noradrenaline are in the locus coeruleus in the midbrain. Neurons are depleted in the locus coeruleus in Alzheimer's disease compared with controls. A hint of the anatomical connectivity that underlies the selective vulnerability in Alzheimer's disease is seen in the pattern of locus coeruleus neuron loss. Within the locus coeruleus, neurons in the anterior and medial portions of the nucleus are lost; these are the cells that project to the forebrain. The more caudal and lateral locus coeruleus regions are spared in the disease; these neurons project to the spinal cord and cerebellum, which do not show classic neurofibrillary tangles and plaques, and are not associated with clinical deficits. Parkinsonian symptoms do evolve in significant numbers of Alzheimer's disease cases, however (Ala *et al.*, 1997; Ala *et al.*, 1999). A large number of these cases have Lewy bodies and dopaminergic neuron loss in the substantia nigra (Ala *et al.*, 1997; Ala *et al.*, 1999).

Altered function or dysregulation of glutamate receptors can cause neural death through a cascade involving increased calcium entry into the cell (Blass and Gibson, 1991; Gooch and Stennett, 1996). The large pyramidal cells of the cortex and the hippocampus utilize glutamate as their neurotransmitters and have significant numbers of glutamate receptors (Jellinger *et al.*, 1991). The earliest site of neurofibrillary tangle deposition, the ERC, also utilizes glutamate as a transmitter, as do many of the affected neurons in the cortex. A number of other neurotransmitters lost in Alzheimer's disease are peptides, such as corticotrophin-releasing factor (CRF) and somatostatin (Davis *et al.*, 1999c). Loss of the small interneurons that utilize these transmitters, or downregulation of their function in response to diminished neural activity, may account for such findings. The relationship of these changes to either the sequence of pathology in the disease or the clinical behavioural changes remains unknown.

Diffuse Lewy Body Disease

Clinical Findings

Dementia with Lewy bodies, or diffuse Lewy body disease (DLBD), is a general term that describes patients with cognitive impairment related to the eosinophilic inclusions first described by F.H. Lewy (see Perry *et al.*, 1997). In autopsy series of demented patients, DLBD is a frequent finding. It is less common than Alzheimer's disease, but it occurs at least as frequently as vascular dementia. In 1995, an international workshop proposed clinical and neuropathological guidelines and nomenclature that proposed DLBD as a distinct clinical syndrome (McKeith and O'Brien, 1999). Dementia is the mandatory feature of DLBD. Furthermore, in order to meet the criteria, three core features have to be present: fluctuation of cognitive disturbances, parkinsonism and visual hallucinations. When two or three core features are present, the diagnosis of probable DLBD can be made; one core feature is consistent with possible DLBD. Many patients seem to have an insidious onset and show gradual progression (Kosaka, 1998). Age at onset overlaps with Alzheimer's disease, ranging from about 60 to 85 years. The duration from onset of dementia to death is variable and overlaps with Alzheimer's disease, but it is often shorter in DLBD. The name acknowledges the importance of Lewy's bodies in the dementia syndrome and retains flexibility about associated Alzheimer's disease pathology.

Neuropathological Findings

The neuropathology of DLBD has been documented extensively by Kosaka (2000), who drew attention to the neuropathology, describing Lewy bodies in subcortical sites such as the substantia nigra, nucleus basalis of Meynert and locus ceruleus, as well as cortical regions, especially in limbic areas. Due to their morphology, Lewy bodies are sometimes difficult to distinguish from rounded, globose-type neurofibrillary tangles. In about half of the patients, neurofibrillary tangles and senile plaques are also found in sufficient numbers to fulfil the diagnostic criteria for Alzheimer's disease. Therefore, some nosologic confusion arose when authors distinguished the Lewy body variant of Alzheimer's disease from the 'pure' form of DLBD (Brown *et al.*, 1998). However, as Alzheimer's disease lesions and Lewy bodies increase in prevalence with age, this may explain their co-occurrence by chance.

Classic Lewy bodies in the substantia nigra are brightly eosinophilic, with a hyaline core and a paler halo, while cortical Lewy bodies are faintly eosinophilic and lack a core (Figure XV-9.5). Immunostaining with antibodies against ubiquitin or alpha-synuclein facilitates the detection of all Lewy bodies and highlights Lewy neurites, degenerating neuronal processes found especially in the CA2-3 region of the hippocampus (Spillantini *et al.*, 1998). Spongiform changes in the hippocampus also occur in DLBD. Careful examination reveals Lewy bodies in the cortex of most if not all patients with idiopathic Parkinson's disease, but they are less abundant than in DLBD (Spillantini *et al.*, 1998). Counts of nigral and cortical Lewy bodies do not correlate with each other, or with the duration or age at onset of DLBD (Spillantini *et al.*, 1998). This disfavours the idea that Lewy bodies spread from the nigra to cortical regions (Perry *et al.*, 1997). In both Parkinson's disease and DLBD, the brain may show a combination of Alzheimer's disease lesions, senile plaques, neuritic changes, neurofibrillary tangles and Lewy bodies. In fact, Alzheimer's disease lesions coexist in most elderly patients with DLBD. Counts of diffuse and classic plaques do not differ significantly between Alzheimer's disease and DLBD patients who die at advanced stages of dementia, i.e. there is a similar amyloid burden. In the most common form of DLBD, associated Alzheimer's disease pathology consists mainly of senile plaques, with fewer neurofibrillary tangles than in 'pure' Alzheimer's disease, especially in the neocortex. Sufficient neuritic plaques, however, are found in many DLBD patients to meet pathology criteria for Alzheimer's disease, such as those of CERAD (Mattila *et al.*, 1998).

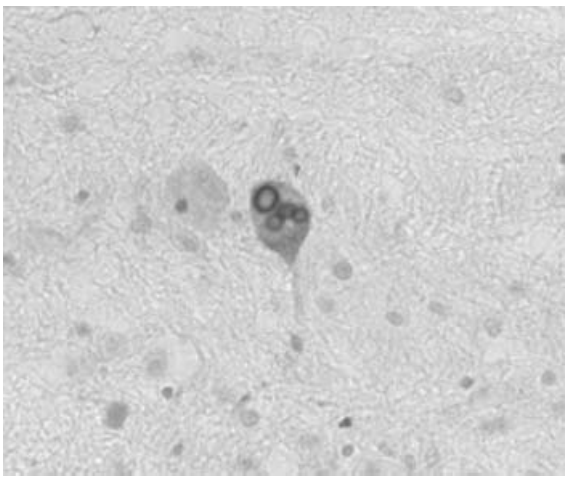

Figure XV-9.5 Cortical Lewy bodies are demonstrated with antibodies to alpha-synuclein (magnification 520×)

The basis of motor dysfunction in Parkinson's disease is well known, namely neuron loss in the substantia nigra leading to deficiency of nigrostriatal dopaminergic circuits. In DLBD, the origin of cognitive or behavioural symptoms is less clear. Neuronal dysfunction due to Lewy bodies could occur in cognitively important areas. These include the entorhinal regions, frontal, temporal or parietal association cortex, cingulate and amygdala. Neuron loss is not significant in cortical areas affected by Lewy bodies, but synaptic loss or dysfunction may be an alternative explanation (Mattila *et al.*, 2000; Goedert, 1999). Marked reduction of acetylcholine could be due to Lewy bodies in the nucleus basalis of Meynert, and decreased dopamine in the basal ganglia and cortex has also been demonstrated (Piggott *et al.*, 1999; Walker *et al.*, 1997). Additive effects of Alzheimer's disease pathology, especially in temporolimbic regions, could also have an impact on memory in DLBD (Hansen and Samuel, 1997). Lewy bodies may be clinically silent. For example, a few pathological series have examined the brains of supposedly normal elderly individuals (Davis *et al.*, 1999a): Nigral Lewy bodies were found in 5–10% of subjects over the age of 50 years. The frequency rose with age, reaching 12% by the ninth decade. The Lewy bodies were dubbed 'incidental' and thought to represent preclinical Parkinson's disease. In a later autopsy study, all available clinical records were reviewed carefully, and patients with neurological or psychiatric symptoms were rigorously excluded. The findings challenged the viewpoint that incidental Lewy bodies are relatively common: only 2.8% of 131 cases had Lewy bodies. More data are needed on Lewy bodies in well-characterized normal elderly subjects.

Vascular Dementia

Clinical

As for Alzheimer's disease, the incidence and prevalence of vascular dementia increase with age (Roman, 1999). Classically, vascular dementia is associated with the clinical picture of stroke: the sudden onset of focal neurological deficits (e.g. weakness, sensory loss, incoordination, speech disturbance). The nature of the neurological deficit depends on the location and the size of the occluded vessel and the presence of collateral circulation. Therefore, vascular dementia is a heterogeneous syndrome caused by small-vessel disease, large single or small strategically placed strokes (Roman, 1999). The natural history of vascular dementia is characterized by the sudden onset of cognitive impairment, followed, with each new ischaemic event, by further step-wise decline. Individuals with vascular brain injury are likely to be apathetic and depressed rather than agitated or psychotic (Cherrier *et al.*, 1997). Memory impairment is generally more variable and less severe than in Alzheimer's disease (Bentham *et al.*, 1997). With small-artery disease, diminished executive ability (e.g. planning, abstraction, evaluation, correction) is characteristic (Wallin, 1998; Erkinjuntti *et al.*, 1994); with large-artery stroke, aphasia, apraxia and neglect are often seen. Based on the wide variability in location and size of brain injury, there is no single characteristic pattern of behavioural and cognitive disturbance associated with vascular dementia.

MRI is exquisitely sensitive to structural changes in the periventricular and deep white matter (Barber *et al.*, 1999; Barber *et al.*, 2000; O'Brien *et al.*, 2000). White matter lesions (WML) are visualized as areas of increased signal intensity in T-2 weighted images, and as partially decreased signal intensity in T-1 weighted images. On computerized tomography (CT) scan, these lesions are also known as leukoaraiosis, or white matter hyperintensities. The frequency of WML increases with age and elevated blood pressure (Shintani *et al.*, 1998; Golomb *et al.*, 1995; Pasquier and Leys, 1998). Among patients with first lacunar stroke, the presence of leukoaraiosis is a poor prognostic sign, increasing the risk for recurrent stroke, dementia and death. The favoured, but still not well-established, explanation is that WMLs represent incomplete infarcts due to chronic or recurrent ischaemia. The regions that develop WMLs, namely the periventricular and deep white matter, receive their blood supply via long, narrow, penetrating endarterioles. A limited number of studies suggest that cognitive changes do not become apparent until WML volume reaches a threshold (Barber *et al.*, 2000).

Neuropathology

The likelihood that infarction leads to cognitive impairment is related to location, size and number of ischaemic lesions (Boston *et al.*, 1999). The key anatomical locations associated with cognitive impairment are expected to include multimodal association areas, limbic areas (e.g. hippocampus), and certain subcortical grey matter nuclei (e.g. head of the caudate, globus pallidus, and anterior and dorsomedial thalamus). The latter nuclei are key relay stations within frontal-subcortical loops. Anatomical locations less likely to cause cognitive impairment include primary motor-sensory cortex, putamen, posterior limb of the internal capsule, ventrolateral and ventroposterior nuclei of the thalamus, brainstem and cerebellum.

Large strokes are easily recognized on macroscopic examination of the brain, showing tissue loss and cavitation. Microscopically, neuronal loss and reactive gliosis can be recognized in the deeper cortical layers, while the subpial molecular layer is often spared in incomplete infarcts. Smaller cortical strokes are sometimes associated with meningeal amyloid angiopathy (Figure XV-9.6).

The confluent WMLs of vascular leukoencephalopathy are associated with tissue rarefaction, mild gliosis and a non-amyloid small-vessel sclerosis that occurs in the central, preferentially frontal deep white matter (Englund, 1998). Microvascular brain damage in the form of severe cribriform change and associated subcortical white matter damage and microinfarction were correlated with a history of dementia (Esiri *et al.*, 1997). Arteriolosclerosis is characterized by thickening of the media, deposition of collagen, and hyaline changes. In some families with APP mutations, vascular dementia was also observed (Haan *et al.*, 1992; Bornebroek *et al.*, 1997). Sporadic congophilic angiopathy is also frequently associated with vascular dementia (Yoshimura *et al.*, 1992; Esiri *et al.*, 1997).

Pick's Disease

Clinical Findings

Traditionally, Pick's disease has been considered a relatively rare disorder that is characterized by an initial presentation with emotional and behavioural changes indicative of frontal lobe changes (Litvan *et al.*, 1997b). However, the existence of Pick's disease as a unique entity is in doubt, and there is sufficient neuropathological and clinical overlap of classic Pick's disease, Pick variants, and other rare and poorly characterized non-Alzheimer's dementias that a unifying concept of dementia with focal atrophy has emerged under the name of 'frontotemporal dementia' (FTD) (Neary, 1999; Jackson and Lowe, 1996; Tanabe, 2000). Some authors propose to use the term 'Pick complex' to encompass the spectrum of focal cortical atrophies, FTD, corticobasal degeneration (CBD) and Pick's disease strictu sensu.

The mean age of onset for FTD is usually between the fifth and seventh decades. The first symptoms involve changes in personality, social behaviour, language or executive function, as FTD patients lose functions associated with select regions in the prefrontal and anterior temporal cortex. The disinhibition and antisocial behaviours due to orbital-basal involvement occur in approximately one-half of the patients with FTD, and can be presenting symptoms (Lebert *et al.*, 1998; Kertesz *et al.*, 2000). Kluver and Bucy

(1939) showed that after bilateral anterior temporal lobectomies, caged monkeys developed hyperorality, psychic blindness, hypermetamorphosis, blunted emotional response, hypersexuality and dietary changes. Later, studies were performed on animals returned to their social environment after similar ablations. Bilateral anterior temporal lobectomy, or selective bilateral amygdalectomy, led to less social interaction and loss of social rank. Franzen and Myers (1973) noted loss of facial expression, and diminished gestures and postures. Mothering was impaired, and the temporal lobectomized group had aggression towards their own babies but preserved, sometimes increased, interest in sex. These studies predicted the types of social deficits that characterize patients with bilateral temporal lobe degeneration.

Edwards-Lee *et al.* (1997) described ten patients with the 'temporal lobe variant' of FTD, in which there was selective involvement of the anterior temporal lobes with sparing of the frontal regions. Five of these patients were predominantly left-sided, while the other five had selective right-sided involvement. Patients with left-sided involvement suffer from 'semantic dementia' and exhibit severe losses of verbal facts and words but relative sparing of visual skills.

In some patients, there was enhanced ability to paint, draw, invent or play music (Miller *et al.*, 2000). In contrast, right-sided patients presented with irritability, impulsiveness, bizarre alterations in dress, limited and fixed ideas, ideological fanaticism, decreased facial expression, loss of empathy and increased visual alertness (Miller *et al.*, 2000). Both left and right temporal lobe patients exhibited intense visual (left) or verbal (right) preoccupations and compulsions. They showed normal working memory (Waltz *et al.*, 1999) and visuoconstructive abilities (Edwards-Lee *et al.*, 1997), while semantic naming, reading and writing (Hodges *et al.*, 1999) and facial recognition have been demonstrated to be impaired (Tyrrell *et al.*, 1990).

Neuropathology

The gross appearance of the brain in dementia with Pick bodies is usually striking for the contrast of the atrophic and preserved areas (Dickson, 2001). The atrophy may preferentially affect the frontal or the temporal lobes. Tissue loss is severe and therefore sometimes referred to as knife-edge atrophy. In contrast, there is usually preservation of the precentral gyrus and the posterior third of the superior temporal gyrus. There is marked variability in the involvement of subcortical structures, ranging from grossly preserved to severe atrophy of the caudate nucleus, substantia nigra and thalamus (Litvan *et al.*, 1997b; Rossor, 1999).

Microscopically, severe cortical neuronal loss with gliosis is seen, as are intraneuronal cytoplasmic oval silver-loving filamentous inclusions (Pick bodies) (Figure XV-9.7). In addition to classic Pick bodies, ballooned neurons with achromatic cytoplasmic inclusions are commonly seen. These ballooned neurons overlap with the neuronal changes seen in CBD. Neocortical neurons in layers II and upper III are preferentially involved, contrasting with the distribution of neurofibrillary tangles in Alzheimer's disease. Pick bodies are also found in the amygdala, the neostriatum and other subcortical nuclei. Ballooned neurons are always present in the deep cortical layers. Glial inclusions are not prominent, but include the occasional thorny astrocyte and oligodendroglial coiled bodies. There is severe loss of myelin and axons in the white matter, which may reflect additional damage to that secondary to neuronal loss.

In contrast to Alzheimer's disease, several studies have shown normal cortical levels of ChAT, acetylcholinesterase and somatostatin in dementia with Pick bodies (Kanazawa *et al.*, 1988; Meier-Ruge *et al.*, 1984).

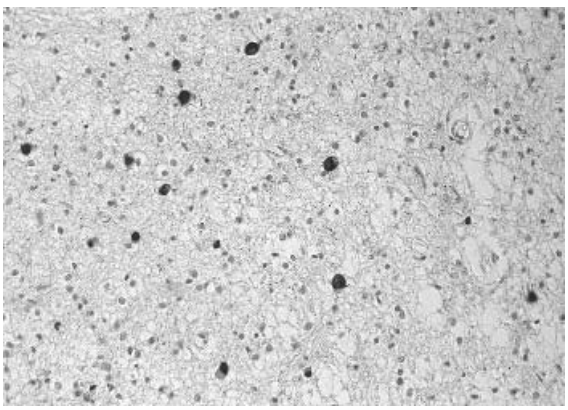

Figure XV-9.7 Pick bodies are immunoreactive with the monoclonal antibody AT8 directed to phosphorylated protein tau (magnification 186×)

Primary Progressive Aphasia

Clinical Findings

Mesulam (1982, 2001) described a series of cases of slowly progressive aphasia and subsequently named the syndrome primary progressive aphasia (PPA). Since then, the term has been used widely, although reports of similar patients have also appeared under various terminology, such as progressive aphasia without dementia, progressive nonfluent aphasia, and pure progressive aphemia (Westbury and Bub, 1997). Approximately 10% of dementias present primarily with progressive aphasia (Pasquier, 1999; Noble *et al.*, 2000). The initial presentation of PPA is often with word-finding difficulty or anomia. In this respect, PPA patients are not much different from Alzheimer's disease patients, except that they have relatively preserved memory and nonverbal cognition. However, Alzheimer's disease patients, by the time they present with word-finding difficulty, already have significant memory loss, disorientation, and constructional, visuospatial and other cognitive impairment (Greene *et al.*, 1996). Typical Alzheimer's disease presentation is loss of episodic memory with relative preservation of semantic memory and language. The initial 2 years of the disease symptomatology distinguishes the two groups of patients. This period was originally suggested by Mesulam as the operational definition of PPA, although in many publications it is not adhered to (Mesulam, 2001). The more typical clinical picture progresses from anomia to a nonfluent type of aphasia with increasing word-finding difficulty. Sometimes, patients are called 'logopoenic' yet are still considered 'fluent' when the word-finding difficulty is prominent but the overall phrase length is longer than four words and syntax is preserved. Decreasing speech output involves spontaneous speech and repetition to a lesser extent initially.

Neuropathology

In many patients with PPA, the clinical picture evolves into classical Alzheimer's disease, and corresponding neuropathological alterations are found at autopsy (Ikeda *et al.*, 1996; Li *et al.*, 2000; Mann *et al.*, 1993). There are also patients with PPA who develop motor neuron disease with a rapid course and bulbar symptoms, such as an increasing amount of dysarthria and dysphagia as indicated earlier, even though typical amyotrophy or spasticity of amyotrophic lateral sclerosis (ALS) may be absent (Tsuchiya *et al.*, 2000). Several cases of PPA with motor neuron disease have been described pathologically, with ubiquitinated, tau-negative inclusions in dentate fascia and neocortical neurons (Tsuchiya *et al.*, 2000). Patients with PPA may also develop unilateral extrapyramidal symptoms, associated with severe apraxia and 'alien hand', characteristic for CBD (Ikeda *et al.*, 1996). The pathology is indistinguishable from more typical cases of CBD. Of all the diseases of the Pick spectrum, PPA is the clinical entity that shows most overlap with the others.

Corticobasal Ganglionic Degeneration

Clinical Findings

The pathology of CBD was thought initially to be linked tightly to a distinctive asymmetric akinetic-rigid syndrome with associated involuntary movements and signs of cortical dysfunction (Litvan *et al.*, 1997a). More recently, however, a wider spectrum of clinical phenotypes has been recognized, including, but not limited to, presentations with dementia, agnosia, dyspraxia, dysphasia and altered behaviour (Boeve *et al.*, 1999). The classical syndrome of CBD usually presents in the sixth decade with a varied combination of symptoms, including stiffness, clumsiness, jerking and sensory impairment affecting the upper limbs. Alien hand phenomenon develops in approximately 50% of patients (Kompoliti *et al.*, 1998). Typical features of frontal lobe dementia at presentation or early in the clinical course include progressive loss of judgement with disinhibition (including distractibility, impulsiveness, compulsiveness or perserveration), social misconduct, or loss of initiative out of proportion to the degree of anterograde amnesia; affective symptoms, including depression, anxiety, emotional unconcern or abulia; and early primitive reflexes and incontinence. This disorder is characterized further by striking asymmetrical gait and speech apraxia, rigidity, myoclonus and cortical sensory loss, while dementia is usually a late manifestation.

Neuropathology

Recent advances have been made in the pathologic characterization of CBD coupled with recognition of overlapping features with other neurodegenerative diseases, specifically progressive supranuclear palsy (PSP) and Pick's disease. On gross examination, frontoparietal cortical atrophy is usually present but may be mild (Bergeron *et al.*, 1998; Feany *et al.*, 1996). The cortical atrophy is usually moderate in severity and not as sharply delineated as in Pick's disease, and can be correlated with the clinical presentation. Thus, atrophy of the frontal lobes would give rise to dementia, atrophy of the superior parietal regions and the precentral gyri to the CBD syndrome, and involvement of the frontal operculum and anterior superior temporal gyrus to PPA (Ikeda *et al.*, 1996; Black, 1996). The substantia nigra and locus coeruleus are always affected, and may be accompanied by atrophy of the globus pallidus and the dorsomedial thalamus (Black, 1996).

Pathologically, there is pre- and post-central cortical neuronal degeneration with achromatic intracytoplasmic neuronal inclusions (Halliday *et al.*, 1995; Black, 1996; Mori *et al.*, 1994). These inclusions are also found in the thalamus, subthalamic nucleus, red nucleus and substantia nigra. On haematoxylin and eosin-stained sections, the achromatic inclusions are very similar to Pick bodies, and immunohistochemical studies reveal that these inclusions share neurofilament/ubiquitin/crystallin and tau immunoreactivity (Sergeant *et al.*, 1999; Jackson and Lowe, 1996; Komori, 1999; Spillantini and Goedert, 1998).

The pathological findings in CBD also include the presence of cortical ballooned neurons, cortical glial plaques, and white matter oligodendroglial tau inclusions (Ikeda *et al.*, 1994; Takeda *et al.*, 1997). Neuronal loss and gliosis is most prominent in superficial cortical layers, and in the most severely involved areas status spongiosus may be observed. These changes are most evident in grossly atrophic areas, but they can be seen to a milder degree in less overtly atrophic cortex. Subcortical white matter gliosis commonly parallels the degree of cortical degeneration. Neuronal loss, gliosis and corticobasal inclusions are invariably found in the substantia nigra. Other deep grey structures may be involved, including the lateral thalamic nuclei subthalamic nucleus, locus coeruleus, globus pallidus, red nucleus, claustrum, striatum, amygdala, deep cerebellar nuclei and other brainstem nuclei.

Ballooned neurons demonstrate perikaryal swelling, dispersion of Nissl substance, an eccentrically located nucleus, loss of typical cytoplasmic staining (achromasia), and occasional cytoplasmic vacuolation. They are immunoreactive with antibodies to phosphorylated neurofilament epitopes and B-crystallin. Although ballooned neurons were once thought to be unique to Pick's disease (so-called 'Pick cells') and CBD, they have been increasingly recognized in some cases of PSP and, less commonly, in Alzheimer's disease, motor neuron disease and Creutzfeldt–Jakob disease (CJD) (Halliday *et al.*, 1995; Armstrong *et al.*, 1999). In CBD, ballooned neurons are typically plentiful in the cortex, with fewer present in the basal ganglia. CBD, Pick's disease and PSP have numerous

tau-immunoreactive neuronal and glial inclusions in cortical and subcortical regions. Cortical tau-immunoreactive neuronal inclusions in CBD are found in pyramidal and nonpyramidal neurons, and may have a distinctive perinuclear, coiled filamentous appearance, but in general they vary greatly in appearance. The clustering and distribution of ballooned neurons and tau-immunoreactive neurons in a pattern similar to lesions of Alzheimer's disease, Lewy body dementia and Pick's disease is consistent with the degeneration of cortico-cortical projections in CBD.

Corticobasal inclusions are weakly basophilic nigral neuronal inclusions initially thought to be specific for CBD. However, examination of additional cases has revealed considerable morphologic heterogeneity, thus these inclusions are not reliably distinguishable from tau-immunoreactive neurofibrillary tangles commonly associated with PSP. In CBD, cortical tau-immunoreactive neuronal inclusions are considerably more common than in PSP; however, both disorders have a similar density of these structures in deep grey matter and brainstem nuclei. Pick bodies are ubiquitin and tau-immunoreactive spherical cortical intraneuronal inclusions seen predominantly in the hippocampal dentate gyrus and frontotemporal cortex.

In PSP, CBD and Pick's disease, abnormal tau accumulates preferentially in specific subcellular regions of astrocytes (Komori, 1999). In CBD, astrocytic inclusions are more common in the cortex than in deep grey matter or the brainstem. Astrocytic plaques may be specific for CBD; they consist of distinctive annular clusters of thick, short, tau-immunoreactive deposits within distal processes of cortical astrocytes.

Frontotemporal Dementia

Clinical Findings

The mean age of onset for FTD is usually between the fifth and seventh decades, but it can be hard to determine when FTD begins because the illness is so insidious. The first symptoms are often subtle alterations in drive, personality, social behaviour, executive functions and sometimes language (Neary, 1999). These findings emerge because FTD patients lose these functions associated with select regions in the prefrontal and anterior temporal cortex. In contrast, Alzheimer's disease patients show early deficits in memory because the disease begins in the brain's memory regions. Benson and Stuss (1986) suggested a logical system for thinking about frontal lobe functions that helps to understand many of the findings of FTD patients with selective frontal involvement. However, different symptoms emerge in patients with selective temporal lobe involvement and sparing of frontal lobes (Edwards-Lee *et al.*, 1997). Furthermore, the relative involvement of the right versus left frontotemporal region is an important factor in the type of symptoms that a patient will manifest.

Table XV-9.2 lists the types of deficits that occur when certain brain regions degenerate.

The disinhibition and antisocial behaviours due to orbital-basal involvement occur in approximately one-half of the patients with FTD, and can be presenting findings (Bozeat *et al.*, 2000). Theft, hit-and-run accidents and indecent exposure commonly occur in FTD. In contrast, violent assaults upon others are rare. The behavioural disturbances of FTD place a special burden on families caring for such patients and is a major factor leading to nursing home placement. Patients with asymmetric right-sided disease are more likely to exhibit socially unacceptable behaviours than those with asymmetric left-sided involvement (Edwards-Lee *et al.*, 1997), while left-sided patients show more language disability (Mesulam, 2001).

The occurrence of FTD in families has been a long-standing observation, and the presence of a similar disorder in the family of a proband is supportive of the diagnosis of FTD (*Journal of Neurology, Neurosurgery, and Psychiatry*, 1994). Recently, progress has been made in linking FTD to particular chromosomes, and in identifying mutations in some familial and rare sporadic cases. Linkage of a substantial number of families to chromosome 17, and of a few families to chromosome 3, has been achieved (Foster *et al.*, 1997). Over ten mutations in the tau gene of chromosome 17 have been identified in FTD families (Heutink, 2000). The most common mutation occurs in exon 10, resulting in the conversion of proline to leucine (P301L) (Kodama *et al.*, 2000; Houlden *et al.*, 1999; Poorkaj *et al.*, 2001). These mutations appear to reduce the ability of tau to bind microtubules and promote microtubule assembly, resulting in tau inclusions in affected neurons, astrocytes and oligodendrocytes (Nasreddine *et al.*, 1999). Mutations have been identified in approximately 15% of familial FTD patients investigated and 0–4% of sporadic FTD cases investigated (Nasreddine *et al.*, 1999). There is substantial clinical and pathological heterogeneity among cases linked to chromosome 17. Patients have had classical FTD syndromes or disorders identified clinically as CBD, PSP, motor neuron disease, PPA and spastic paraplegia with dementia (Nasreddine *et al.*, 1999). Frontotemporal dementia with parkinsonism (FTDP-17) is an autosomal dominant disorder that presents clinically with dementia, extrapyramidal signs and behavioural disturbances in mid-life and progresses to death within 5–10 years. Pathologically, the disorder is characterized by variable neuronal loss and gliosis in the frontal and temporal lobes, limbic structures and midbrain (Hulette *et al.*, 1999).

In a related mutation (P301S), Bugiani *et al.* (1999) described an individual who presented with frontotemporal dementia, and his son, who had CBD demonstrating that the same primary gene defect in tau can lead to two distinct clinical phenotypes. Neuropathologically, the father presented with an extensive filamentous pathology made of hyperphosphorylated tau protein (Bugiani *et al.*, 1999).

Table XV-9.2 Frontal brain regions with lesional disturbances

Brain region	Hypothesized function	Deficit seen with dysfunction
Orbitobasal	Inhibition, social control	Disinhibited, impulsive, confabulatory, antisocial
Dorsolateral	Attention, working memory (area 46), alternating programmes, generate words, designs, ideas, self-awareness, generation of affect? (right > left)	Poor attention and focus, working memory deficits, poor organization, poor planning, poor word/design generation, poor insight, abnormal expression of affect
Medial frontal	Energy, motivation, drive	Apathy, abulia, depression

Neuropathology

Clinical pathology can be subdivided into three main neuropathological subtypes: frontal lobe dementia, Pick's disease and FTD with motor neuron disease, all characterized by distinct histological features (Jackson and Lowe, 1996).

Grossly, there is slight symmetrical frontal and anterior temporal atrophy with frontal ventricular enlargement (Jackson and Lowe, 1996). The atrophy is usually not as severe as in classic Pick's disease. No striatal, amygdala or hippocampal atrophy is seen. The cellular neuropathology is variable. In some instances, these conditions appear to be focal variants of Pick's disease, Alzheimer's disease or Lewy body disease (Jackson and Lowe, 1996). In others, the histopathology is not congruent with these disorders, raising the

possibility that some of the non-Alzheimer's dementias represent unique new diseases.

Pathologically, patients with FTD linked to chromosome 17 have variable involvement of basal ganglia and substantia nigra, may or may not have Pick bodies and ballooned neurons, and may or may not exhibit involvement of the spinal motor neurons (Foster *et al.*, 1997). Thus, no specific clinical syndrome or set of pathological changes identifies cases linked to chromosome 17 versus those without such linkage. Conversely, specific types of histopathological changes are not indicative of a corresponding unique genetic aetiology. The clinical and pathological heterogeneity associated with specific mutations suggests that additional genetic or environmental factors substantially modify the expression of the underlying genetic change.

Autopsied individuals from some kindreds with FTD display abundant neurofibrillary change, while others, including a single affected individual from Duke Family 1684, lack distinctive histological features and exhibit only mild neuronal loss and gliosis in limbic structures and subcortical nuclei when examined by routine silver stain (Hulette *et al.*, 1999).

Microscopically, there is microvacuolation and gliosis predominantly of the outer three laminae of cerebral cortex. Neurons are lost in laminae 2 and 3, but lamina 4 is relatively spared (Jackson and Lowe, 1996). No classic Pick bodies, ballooned neurons or Lewy bodies are seen. No neuronal inclusions immunoreactive to tau or ubiquitin are seen. The microscopic alterations are most marked in the frontal cortex. In some cases, there is mild to moderate loss of pigmented neurons of the substantia nigra (Jackson and Lowe, 1996). Patients exhibiting frontal lobe dementia plus these neuropathological findings are now classified has having FTD of the frontal lobe degeneration type.

Some patients have the clinical features of frontal lobe dementia but have much more pronounced frontal lobe atrophy; also, in addition to microvacuolation, gliosis and neuronal loss, they have ballooned or inflated neurons and Pick bodies. The gliosis may extend throughout the cortex and into the white matter. Such patients are classified as having FTD of the Pick type. This semantic manoeuvre leaves open the possibility that these patients have Pick's disease whilst maintaining sufficient flexibility to encompass atypical cases.

Finally, there is FTD of the motor neuron type, in which the previously described clinical and neuropathological findings are coupled with spinal motor neuron degeneration. The motor neuron loss is usually most severe in the cervical and thoracic segments. In Japan and, more recently, in Western countries, sporadic cases of ALS plus dementia have been described and designated amyotrophy dementia complex, which appears to be identical to FTD of the motor neuron type (Tsuchiya *et al.*, 2001; Mitsuyama, 2000).

Until recently, the presence of ubiquitin-positive intraneuronal inclusions in the dentate gyrus and the temporal and frontal cortex was usually associated with the motor neuron disease type. Such inclusions were also observed in a few sporadic cases of FTD with or without parkinsonism in the absence of motor neuron disease. We present here clinical, neuropathological and immunohistochemical data about a Swiss FTD family with FTD with parkinsonism-like features but without motor neuron disease. Spongiosis and mild gliosis were observed in the grey matter. No neurofibrillary tangles, Pick bodies, Lewy bodies, senile plaques or prion-positive signals were present. However, ubiquitin-positive intracytoplasmic inclusions were detected in various structures, but predominantly in the dentate gyrus. These observations support the existence of a familial form of FTD with parkinsonism with ubiquitin-positive intracytoplasmic inclusions (Kovari *et al.*, 2000).

The authors report a presenilin 1 (PSEN1) mutation (L113P) in a family with six cases of dementia. The patients had personality changes and behavioural disorders, whereas spatial orientation and praxis were preserved late in the course of the illness. Neuroimaging features were consistent with the diagnosis of FTD. The authors conclude that PSEN1 mutations can be associated with clinical features of frontotemporal dementia (Raux *et al.*, 2000).

Progressive Supranuclear Palsy

Clinical Findings

PSP, or Steele–Richardson–Olszewski syndrome, is characterized by supranuclear ophthalmoparesis (down gaze in particular), rigidity and gait disturbance. Furthermore, about 70% of PSP patients may exhibit dementia with signs of frontal dysfunction. Conversely, there are familial cases of FTD with tau mutations, such as pallidoponto-nigral degeneration, in which patients develop a progressive PSP-like syndrome followed by FTD (Reed *et al.*, 1998). Also, there are striking parallels between the neuropathology of PSP and FTD, and abnormalities in tau appear to lie at the pathological (Dickson *et al.*, 1996) and genetic (Baker *et al.*, 1997) basis for PSP and FTD.

Neuropathological Findings

Macroscopic examination of the brain shows cortical, subcortical and ponto-mesencephalic atrophy (Bigio *et al.*, 1999; Lantos, 1994). There is widespread diencephalic, mesencephalic, brainstem and cerebellar nuclear neuronal loss. Globose neurofibrillary tangles and variable neuron loss with gliosis occur in the globus pallidus, subthalamic nucleus, periaqueductal grey matter and substantia nigra. PSP is characterized neuropathologically by neuronal degeneration of the basal ganglia, brainstem and cerebellum. In addition, cortical neuronal degeneration associated with neurofibrillary tangles formation has been identified over wide areas of the brain in patients with PSP.

Hauw *et al.* (1994) published neuropathological criteria for PSP as proposed at a workshop held at the National Institutes of Health in 1993. The criteria distinguish typical, atypical and combined PSP. A high density of neurofibrillary tangles and neuropil threads in the basal ganglia and brainstem is crucial for the diagnosis of typical PSP. Tau-positive astrocytes or their processes in areas of involvement help to confirm the diagnosis. Atypical cases of PSP are variants in which the severity or distribution of abnormalities deviates from the typical pattern. Criteria excluding the diagnosis of typical and atypical PSP are large or numerous infarcts, marked diffuse or focal atrophy, Lewy bodies, changes diagnostic of Alzheimer's disease, oligodendroglial argyrophilic inclusions, Pick bodies, diffuse spongiosis, and prion protein-positive amyloid plaques. The diagnosis of combined PSP is proposed when other neurological disorders exist concomitantly with PSP (Hauw *et al.*, 1994).

Patients with PSP often develop dementia, and cortical pathology has been documented in PSP. Bigio *et al.* (1999) found striking cortical tau pathology in demented PSP patients, suggesting that neurofibrillary pathology is central to the cause of dementia in PSP. Cordato *et al.* (2000) found that PSP could be differentiated from other dementias by the marked atrophy of the internal globus pallidus.

The presence of tau-positive glial inclusions has been found to be a consistent feature in the brains of patients with PSP, CBD and Pick's disease. These inclusions are classified based on cellular origin as tau-positive astrocytes, presumably either fibrillary or protoplasmic, coiled bodies and glial threads. Immunohistochemically, their major structural component is abnormal tau proteins, similar to those found in Alzheimer's disease. Nevertheless, their morphology, including ultrastructural profile, has been suggested to be distinctive for each disease. The profile and extent of particular glial inclusions correlate well with disease phenotype. Highly

characteristic correlations include tufts of abnormal fibres in PSP, astrocytic plaques and dense glial threads in CBD, and ramified astrocytes and small Pick-body-like inclusions in Pick's disease (Komori, 1999).

Severe neurodegeneration within the dopaminergic pars compacta was seen in all cases of PSP. There was a striking 70% reduction in the number of pars reticulata neurons in PSP, with no cell loss observed in Parkinson's disease compared with controls (Hardman *et al.*, 1997).

Mackenzie and Hudson (1995) found significant numbers of achromatic neurons in the cerebral cortex in five out of seven cases that had been diagnosed pathologically as PSP.

We studied the distribution of alpha B-crystallin-positive degenerating neurons in cases with PSP and compared them with those in Pick's disease, Alzheimer's disease, senile dementia of Alzheimer type, and normal aged individuals. A large number of alpha B-crystallin-positive neurons was found in the cerebral cortices of four out of nine patients with PSP. In particular, alpha B-crystallin-positive ballooned neurons were observed frequently in deep cortical pyramidal cell layers of the limbic and paralimbic systems in these diseases. The involvement of the limbic and paralimbic systems may thus contribute to personality changes as well as to memory and cognitive impairment in some patients with PSP (Higuchi *et al.*, 1995).

Multiple System Atrophy

Clinical Findings

This group of disorders is characterized by extreme clinical variability and nosological uncertainty. Multiple system atrophies (MSAs) can be familial and are then transmitted either dominantly or recessively, but sporadic cases are very common. Olivopontocerebellar atrophy (OPCA) is one of the commonest and most variable of these conditions. Ataxia, rigidity, spasticity and oculomotor movement disturbances are present to variable degrees in combination. OPCA is currently classified as one of the MSAs, which also include striatonigral atrophy and the Shy–Drager syndrome.

Neuropathology

There is considerable clinical and pathological overlap among these syndromes. Glial cytoplasmic inclusions have been recognized as apparently unique cellular pathological markers of MSA. These are intracytoplasmic predominantly oligodendroglial argyrophilic inclusions that exhibit strong tau and ubiquitin immunoreactivity. Oligodendroglial cytoplasmic inclusion-rich structures occur in the suprasegmental motor systems, in the supraspinal autonomic systems and in their targets. In contrast, the visual and auditory pathways, olfactory structures, somatosensory systems, association and limbic cortical areas and subcortical limbic structures contain no or only a few glial cytoplasmic inclusions (Papp and Lantos, 1994). Alpha-synuclein has been implicated as a major component of the abnormal filaments that form glial cytoplasmic inclusions in MSA (Duda *et al.*, 2000).

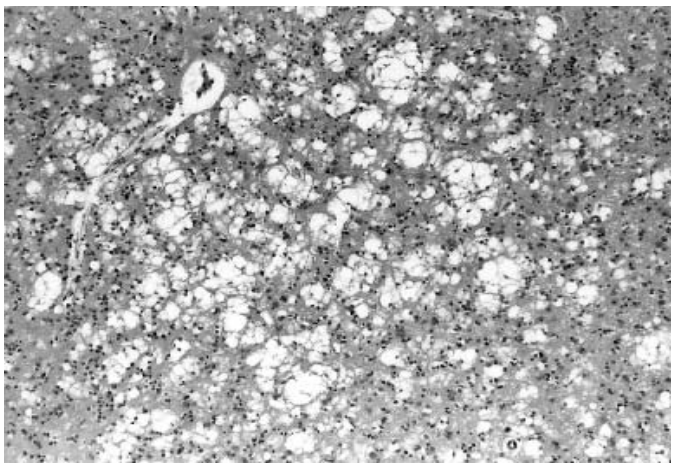
Transmissible Spongiform Encephalopathies

Clinical Characteristics

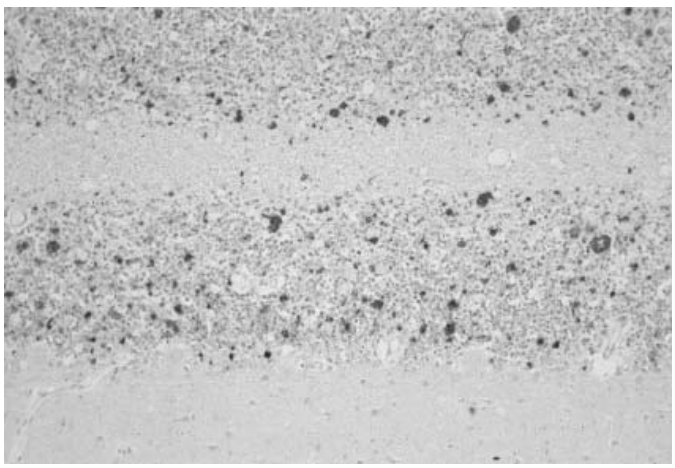
CJD is a rare spongiform encephalopathy that affects about one per one million inhabitants in most countries (Will, 1993). CJD is a transmissible spongiform encephalopathy characterized by a rapidly developing dementia associated with cerebellar, pyramidal and extrapyramidal signs, myoclonus and typical electroencephalographic (EEG) changes. The disease can be transmitted by direct intracerebral inoculation of infectious brain tissue, dura and cornea transplants, and injections of contaminated human growth and gonadotropic hormones. Prion diseases or transmissible spongiform encephalopathies affect both humans and animals. They include CJD, Kuru, Gerstmann–Sträussler–Scheinker syndrome (GSS), fatal familial insomnia, and some rare atypical dementias. A further classification of CJD can be made according to the mode of transmission: sporadic, iatrogenic, familial and the recently described variant CJD (vCJD), which has been linked to bovine spongiform encephalopathy (BSE) (Gambetti, 1999).

Neuropathology

Human spongiform encephalopathies display a large array of histopathological phenotypes. Three basic histological lesions can be observed in prion diseases: spongiosis, astrogliosis and neuronal loss (Figure XV-9.8). Prion protein deposits and rarely neurofibrillary tangles can be demonstrated with appropriate pretreatment and monoclonal antibodies. The relative amounts of these individual basic lesions and their rostrocaudal distribution within the brain result in the three basic pathological phenotypes that are commonly



(a)



(b)

Figure XV-9.8 Neuronal loss, spongiosis and reactive gliosis in the cortex of a patient with CJD. (a) Haematoxylin eosin stain (magnification 145×); (b) prion protein immunostain (magnification 320×)

distinguished in prion diseases — CJD, fatal familial insomnia (FFI) and GSS — as well as in the variants within these major phenotypes. A minority of cases, generally associated with insertion mutation, cannot be accommodated in any of these phenotypes and form a heterogeneous group (Gambetti, 1999).

Inherited Prion Diseases

At present, there are 23 known mutations and three polymorphisms in the prion protein gene (PRNP). These mutations are of three types: (1) point mutations, which include 14 mutations distributed predominantly in the carboxyl two-thirds of the PRNP coding regions; (2) insertional mutations, made of 24 additional base-pair repeats located between codons 51 and 91; and (3) stop codon mutations, one of which is known to result in the premature termination of synthesis and to yield a truncated prion protein. Moreover, the 129 M/V polymorphism may modify the expression of the mutation, resulting in a different phenotype according to the codon 129 present in the mutant allele. Therefore, it is more appropriate to identify each PRNP genotype associated with inherited prion diseases not only by the mutation but also by the codon 129 polymorphism. Currently, 28 disease-associated PRNP haplotypes are known that result in CJD, fatal familial insomnia, GSS, mixed CJD and GSS, and undefined phenotypes. The latter two phenotypes are seen in the insertion mutations (Gambetti, 1999).

Neuropathology of the Inherited Creutzfeldt-Jakob Disease Phenotype

The histopathology of inherited CJD is very similar to that of sporadic CJD and is characterized by spongiosis, gliosis and neuronal loss of the cerebral cortex, basal ganglia and, to a lesser extent, diencephalon and cerebellum. Astrogliosis and neuronal loss appear to be a function of the disease duration. The histopathological pattern is remarkable for the intense cerebral cortical gliosis often with large gemistocytic astrocytes and the loss of neurons, while many of those remaining are ballooned resulting in the disorganization of the cerebral cortical layers. Spongiosis is invariably present throughout the cerebral cortex; it is more severe at the level of the basal ganglia, while it is mild in the thalamus and brainstem and absent in the cerebellum (Gambetti, 1999).

Fatal Familial Insomnia Phenotype

The mean age at onset for 45 proven patients with fatal familial insomnia (30 homozygotes, 15 heterozygotes) is 50 ± 10 years (range 25–72 years) in homozygotes and 45 ± 11 years (range 20–56 years) in heterozygotes. The mean clinical course is 12 ± 4 months (range 6–21 years) in homozygotes and 21 ± 15 months (range 7–33 years) in heterozygotes (Gambetti *et al.*, 1995). Insomnia is an early symptom that progresses in some months to a total or almost total inability to sleep. The insomnia is not the trivial difficulty in initiating or maintaining sleep, as in other neurodegenerative diseases, but rather a severe, persistent and complete disorganization of sleep cycles. The inability to sleep is a more prominent early symptom that deteriorated rapidly in 129 homozygous patients. Indifference to surroundings, inability to express feelings or emotions, and prolonged episodes of stupor associated with automatic behaviour, such as enacting dreams, are other prominent clinical features. Coma precedes death by days or weeks. Difficulties in micturition, impotence, lacrimation, salivation and sweating, increased body temperature, high heart rate, and high blood pressure usually appear in the earlier stages of the disease. Tachypnoea, paradoxical breathing, loud snoring and obstructive apnoeas are later signs. Dysarthria and ataxic gait are the first motor disturbances and usually appear some months after insomnia and dysautonomia. Speech becomes progressively unintelligible; ataxic gait can evolve to astasia-abasia. Segmental and diffuse, spontaneous and evoked myoclonus can appear transiently. Motor disorders were more severe in 129 heterozygous patients. Diplopia and saccadic ocular movements, sporadic generalized tonic-clonic seizures, and dystonic attacks are transient and less consistent late signs. A progressive impairment of vigilance, attention and visuomotor performances associated with selective memory disturbances and behavioural features of a confusional state in the absence of a global decline in intellectual function are common findings. EEG background activity becomes progressively slow and less reactive. Visual, brainstem and somatosensory evoked potentials are normal. Sympathetic skin response is reduced or abolished. The duration of sleep EEG activity shortens and results in a complete or nearly complete inability to generate sleep patterns. Sleep spindle activities disappear. Only brief episodes of REM sleep or, more seldom, slow-wave sleep arise abruptly and randomly from wakefulness. Total sleep time decreases progressively. Body temperature, breathing and heart rates, and systemic blood pressure are persistently elevated, with reduced circadian oscillations. Cardiovascular balance is lost, with higher background and stimulated sympathetic activity. Adrenaline and noradrenaline plasma concentrations are persistently and markedly elevated. The hypothalamic-pituitary function is normal. Plasma cortisol concentration is abnormally high; corticotropin is constantly low. In addition, sleep-coupled (growth hormone, prolactin) and uncoupled (cortisol, corticotropin) hormones lack circadian oscillations. The nocturnal increase in melatonin secretion subsides progressively.

CT and MRI are normal. Positron emission tomography (PET) scan in seven patients showed an early severe hypometabolism of the thalamus associated with a milder impairment of the cingulate gyrus. The cerebral metabolic deficit is more widespread in heterozygotes (M/V) at codon 129, who have a longer clinical course.

The hallmark is loss of neurons and astrogliosis in the thalamus, which is present in all subjects, independently of the disease duration (Gambetti, 1999). The mediodorsal and anterior ventral thalamic nuclei are invariably and severely affected, while the involvement of other thalamic nuclei varies. The inferior olives also show neuronal loss and gliosis in most cases. In contrast, the pathology of the cerebral cortex varies in proportion to the disease duration and is more severe in the limbic lobe than in the neocortex. The entorhinal cortex and, to a lesser extent, the piriform and paraolfactory cortices show spongiosis and astrogliosis in most subjects. The neocortex is spared in subjects with a disease duration of less than 1 year, is focally affected by spongiosis and gliosis in those with a course between 12 and 20 months, and is diffusely involved only in subjects with a disease of longer duration (more than 20 months). In addition, the frontal, temporal and parietal lobes are affected more severely than the occipital lobe. The other structures are virtually normal or show only mild focal pathology. Overall, the thalamus is involved more severely and consistently than any other brain region. Therefore, on the basis of the pathology, fatal familial insomnia can be defined as a preferential thalamic degeneration (Gambetti, 1999).

Gerstmann–Sträussler–Scheinker Syndrome Phenotype

The GSS phenotype has only been observed linked to PRNP mutations. Currently, six point mutations in PRNP have been found to be associated with GSS. All variants share a relatively chronic course (longer than 2 years in most cases) and the presence of Congo red positive amyloid plaques composed of prion protein fragments. Despite this, they show striking phenotypic differences. The onset can be characterized by ataxia (102 and 117 mutations), spastic

paraparesis (105 mutation), extrapyramidal signs (217 mutation) or dementia (145, and 117 mutations). Pathologically, the amyloid plaques can coexist with significant spongiform degeneration (102 mutation), neurofibrillary degeneration (145, 198 and 217 mutations) or amyloid angiopathy (145 mutation).

Codon 129 has been shown to influence age at onset and duration of the disease in the phenotype associated with the 198 mutation. More recently, codons 129 and 219 on the mutant alleles have been shown to affect basic features of the phenotype of the P102L mutation as it was originally shown to occur in the D178N mutation associated with FFI and CJD (Gambetti, 1999).

Familial Creutzfeldt–Jakob Disease with Insertions

The PRNP gene has an unstable region of five variant octapeptide coding repeats between codons 51 and 91. Insertions ranging from one to nine extra repeats in this region have been found in 12 families and nine affected individuals from uninformative families (Gambetti, 1999). The phenotype associated with the insertion mutations shows a high variability, particularly in the duration of the disease, which ranges between 3 months and 15 years. The clinicopathological features range from the typical CJD phenotype, i.e. rapidly progressive dementia of less than 1 year duration, to a chronic disease of several years, lacking specific histopathological changes and, therefore, difficult to include in the CJD, GSS and fatal familial insomnia phenotypes. In this group, the common presenting signs include frontal release, dysphasia, apraxia, visual disturbances or personality disorders associated with memory loss. Cerebellar, extrapyramidal and pyramidal signs are also common. Chorea and generalized seizures are rare. EEG is either normal or characterized by a slow-wave activity. Eight cases out of the 34 reported had bilateral synchronous repetitive triphasic discharges, usually at a late stage of the disease. Among the 18 autopsied cases of this group, only six showed classic CJD pathology, five showed a mild and focal spongiosis, and in the others there were no distinctive pathological features (Gambetti, 1999).

The molecular basis underlying this variable phenotype is largely unknown. Patients carrying the shortest insertions (from one to four repeats) show the typical clinical CJD phenotype more often than those carrying an insertion longer than four repeats (67% versus 8%). In contrast, subjects with long insertions are more likely to display a long duration with atypical features. In addition, patients that carry the shortest insertion usually have a negative family history (100%), whereas those with an insertion longer than four repeats are more likely to be familial (82%). Thus, both the penetrance and the phenotypic expression appear to be influenced by the length of the extra repeat insertion.

The correlation between length of the extra repeat insertion and the disease phenotype also extends to the neuropathological features of the disease (Gambetti, 1999). While widespread spongiform degeneration is the typical finding in those patients carrying insertions of one to four extra repeats, in those with an insertion longer than four repeats the neuropathological changes are extremely variable, ranging from severe spongiform encephalopathy to cases lacking any obvious pathology. Preliminary analysis indicates that the number of the inserted octapeptide repeats and, again, the genotype at codon 129 of PRNP may play a role as modulator of the phenotypic expression of the disease.

Diffuse Axonal Injury

Some head-injured patients are severely impaired in the absence of gross lacerations or haematomas. These patients are generally comatose from the instant of injury and subsequently have only limited recovery. They have sustained widespread microscopic axonal injury evidenced by the presence of ruptured axons that retract to form spheroids. This syndrome is called diffuse axonal injury (DAI), and is believed to result from shearing forces that damage axons during acceleration or deceleration. There is strong evidence that this axonal alteration matures over a period of hours to days, and may therefore be amenable to therapeutic intervention. Initially, the axons appear normal, but soon there is focal accumulation of axoplasmic cytoskeletal components and organelles, indicating a malfunction of axonal transport. After several hours of increasing focal swelling, the axon splits and the severed ends retract. In grade 1 DAI, there is histological evidence of axonal injury in the white matter of the cerebral hemispheres, corpus callosum, brainstem and, less commonly, cerebellum. In grade 2 DAI, there is also a focal lesion in the corpus callosum. In grade 3 DAI, there is, in addition, a focal lesion in the dorsolateral quadrant or quadrants of the rostral brainstem. The focal lesions can often only be identified microscopically. DAI was identified in 122 patients of a series of 434 fatal non-missile head injuries (10 grade 1, 29 grade 2, 83 grade 3) (Adams *et al.*, 1989). In a series of 53 children with fatal head trauma, severe hypoxic brain damage was present in 77% of cases. While vascular axonal damage was found in 21 out of 53 cases, DAI was present in only three. Eleven additional cases, all infants, showed evidence of localized axonal injury to the craniocervical junction or the cervical cord (Geddes *et al.*, 2001). Study of DAI is providing insight into the brain's acute stress response, which may in turn give us clues about the cellular stress response in other neurological disorders. DAI, for example, results in a rapid upregulation of APP expression and formation of diffuse neuritic plaques.

Brain Imaging of Cognitive Disorders

P.H. Robert, J. Darcourt and M. Benoit

Imaging techniques are major tools for investigating brain–behaviour relationships. Brain imaging is one of the main instruments used in cognitive neuroscience, allowing the visualization and measurement of processes in the living brain. Measuring regional brain activity with general markers of brain function, such as blood flow and metabolic activity, is a highly successful way of elucidating the neuroanatomic substrates of cognitive processes. Using a subtraction method and dynamic positron emission tomography (PET) or functional magnetic resonance imaging (fMRI), it becomes possible to study the functional neuroanatomy of the healthy human brain during cognitive tasks. The main challenge is to design two tasks that differ in only one meaningful component. After subtraction, the resulting image shows a pattern of activation that is assumed to represent local blood flow changes associated with this task component.

In clinical practice, brain imaging is used as a complementary and powerful diagnostic tool in dementia and other neuropsychiatric diseases.

Brain imaging includes structural techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI), and functional techniques, such as PET, single positron emission computed tomography (SPECT), fMRI and magnetic resonance spectroscopy (MRS).

This chapter reviews structural and functional brain imaging findings in the main clinical syndromes chiefly characterized by cognitive disturbances.

ALZHEIMER'S DISEASE

Alzheimer's disease is characterized clinically by cognitive manifestations, which, in combination with behavioural disturbances, interfere significantly with activities of daily living. Memory impairment is an early and prominent cognitive symptom. Progression of the disease over time affects several brain regions, starting from the hippocampal, parahippocampal structures and entorhinal cortex, and extending to the cortical region, especially the posterotemporal and inferotemporal lobes (Braak and Braak, 1991; Geddes *et al.*, 1997).

Structural Imaging

CT is the oldest imaging technique used for scanning the brain. Today, in dementia CT is used only for differential diagnosis in order to exclude subdural haematoma, normal-pressure hydrocephalus, and other brain diseases such as tumours.

MRI provides the same information as CT but is more powerful in separating grey from white-matter signals and is not hampered by bone artefacts. It is useful for showing morphological modifications, such as cortical atrophy, ventricular dilation and enlargement of the subarachnoid spaces. Several studies (George *et al.*, 1987; Kido *et al.*, 1987) have shown temporal atrophy in early Alzheimer's disease. As a result, the internal temporal region has been a major focus of attention.

Linear and volumetric measurements of the hippocampus (Kesslak *et al.*, 1991), the parahippocampic gyrus (Ikeda *et al.*, 1994), the amygdala (Lehericy *et al.*, 1994), the subiculum and the perihippocampal clefts have been made (De Leon *et al.*, 1993). In Alzheimer's disease patients, these studies generally show marked atrophy (30–40%) relative to healthy controls. In the De Leon *et al.*, study of 80 subjects free of dementia at baseline, of the 25 patients who developed Alzheimer's disease 4 years later, 23 showed an increase of perihippocampal cerebrospinal fluid on baseline CT (91% sensitivity and 89% specificity). In the same way, the loss of brain volume, measured by MRI (Fox *et al.*, 1999), correlated with the global cognitive severity of dementia.

By studying histological sections of brains from patients with autopsy-confirmed Alzheimer's disease ($n = 16$) and from normal controls ($n = 4$), Bobinski *et al.* (1999) validated a method for measuring entorhinal cortex volume that relies on gyral and sulcal landmarks visible on magnetic resonance images. In another study (Bobinski *et al.*, 2000), the calculated number of neurons in the hippocampus and hippocampus/subiculum correlated strongly with the MRI-measured volume of these structures. Overall, the best MRI predictor of Alzheimer's disease is medial temporal lobe atrophy combined with medial occipito-temporal gyrus atrophy (Convit *et al.*, 2000). However, large studies of the specificity of these measurements are still needed.

Functional Imaging

The neurons affected in Alzheimer's disease are predominantly projection neurons. This neuronal alteration is reflected by a dysfunction of association cortical areas. This is supported, by PET data on regional cerebral glucose metabolism (regional cerebral metabolic rate of glucose, rCMRGL) reported consistently by many authors (Haxby *et al.*, 1986; McGeer *et al.*, 1986). These results indicate a typical pattern of hypometabolism that is most prominent in the temporoparietal region but is also present in frontal cortical association areas. Primary visual and sensory motor cortices are typically spared. SPECT studies (Bartenstein *et al.*, 1997; Jobst *et al.*, 1994; Hirsch *et al.*, 1997) have shown a reduction of regional cerebral blood flow (rCBF) in the same regions. Using hexamethyl propylene amineoxime (HMPAO) SPECT, Holman *et al.* (1992) found that patients with bilateral temporoparietal hypoperfusion had the highest probability of having Alzheimer's disease.

A software package for PET and SPECT (Frackowiak *et al.*, 1997), known as statistical parametric mapping (SPM), allows spatial normalization of images to a standardized stereotactic

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

space and statistical group image analysis. Using this technique, Kogure *et al.* (2000) demonstrated that rCBF was significantly bilaterally decreased in the posterior cingulate and precunei of patients with early mild Alzheimer's disease compared with healthy volunteers.

Studies correlating brain imaging data with clinical features and disease progression are also of great interest. Several authors (Robert *et al.*, 1992; Imran *et al.*, 1999; Ashford *et al.*, 2000) have shown that rCBF in the temporoparietal areas correlated negatively with the global severity of the disease. More specifically, PET studies of resting brain glucose utilization were conducted to determine the neural basis of the memory impairment in Alzheimer's disease. Verbal episodic memory was related to changes in a network including the mesial temporal cortex, thalamus, cingulate gyrus (left predominance) and parietotemporal and frontal association cortices of the right hemisphere (Desgranges *et al.*, 1998), whereas semantic memory performance correlated with activity in the left inferior temporal gyrus (Hirono *et al.*, 2001). Other studies showed that functional brain imaging can predict the rate of cognitive decline in Alzheimer's disease (Jagust *et al.*, 1996; Claus *et al.*, 1999).

Functional brain imaging is also useful for understanding the origin of behavioural disturbances observed frequently in Alzheimer's disease. Recently, SPECT was used to compare the rCBF pattern in two groups of ten demented subjects with and without aggression and agitation. Subjects with aggression had significant hypoperfusion of the left anterior temporal cortex and the right and left dorsolateral frontal cortex (Hirono *et al.*, 2000).

Apathy is another frequent behavioural manifestation of Alzheimer's disease and other organic brain disorders in the elderly. It is defined as a lack of motivation not attributable to a diminished level of consciousness, cognitive impairment or emotional distress (Marin *et al.*, 1991; Marin, 1995). SPECT studies of Alzheimer's disease subjects have shown a correlation between apathy and frontal and cingulate hypoperfusion (Craig *et al.*, 1996; Benoit *et al.*, 1999). In another study (Migneco *et al.*, 2001), 41 elderly subjects with Alzheimer's disease or organic personality disorders with dysexecutive syndrome were subdivided according to the presence or absence of apathy. SPECT images were compared using SPM. The major difference between subjects without and with apathy is the presence of an anterior cingulate hypoperfusion in the latter group (Figure XV-10.1). Using the same method, Alzheimer's disease patients with and without apathy were compared with healthy elderly controls (Figure XV-10.2). The apathy-free group had significantly lower perfusion of the inferior temporal and occipital regions. The apathy group had significantly decreased perfusion of the left anterior cingulate, the right inferior and medial gyrus frontalis, the left orbitofrontal gyrus, and the right gyrus lingualis. The differences in the brain areas with reduced perfusion between the apathy-free subjects (mainly the posterior regions) and the apathetic subjects (mainly the anterior regions) could indicate that behavioural disorders such as apathy participate in the heterogeneity of brain perfusion in Alzheimer's disease.

In the future, techniques such as SPM will play an important role in, for example, monitoring responses to cholinergic treatment of Alzheimer's disease.

Finally, brain imaging has also been used to map neurochemical processes in Alzheimer's disease. As a cholinergic deficit is most consistently found in the disease, major efforts have been made to develop PET or SPECT tracers of cholinergic systems. The density of muscarinic and nicotinic receptors (Nordberg *et al.*, 1995) appears to be diminished in the cortex of patients with Alzheimer's disease. However, methodologic limitations — due mainly to the influence of local changes in brain perfusion on cortical abnormalities in radioligand uptake — make it difficult to determine the pathophysiological significance of these results.

Recently, more specific tracers of cortical cholinergic function have been developed and modelled, such as markers of acetylcholinesterase, the acetylcholine-degrading enzyme, and ligands of vesicular acetylcholine transporters, which are potential markers of the integrity of cholinergic nerve endings. Other neurochemical anomalies have been identified *in vivo* in Alzheimer's disease. A marked cortical reduction in serotonin 5-HT2 receptors was found by Blin *et al.* (1993), affecting parietal and frontal cortices and, to a lesser extent, the occipital cortex. A cortical reduction in benzodiazepine receptors has also been described (Soricelli *et al.*, 1996).

Proton MRS (^{1}H-MRS) and phosphorus MRS (^{31}P-MRS) are other opportunities for studying the biochemical composition of brain tissue *in vivo*. The most consistent results come from ^{1}H-MRS concerning the amino acid *N*-acetylaspartate (NAA) localized exclusively in the neurons and the sugar-alcohol myo-inositol, which could be a marker of glial cell number. Several studies found a 15% decrease of NAA in the temporoparietal regions and the occipital and frontal lobes, and a 20% increase of myo-inositol in white and grey matter in Alzheimer's disease patients. The NAA/myo-inositol ratio as been proposed for discriminating

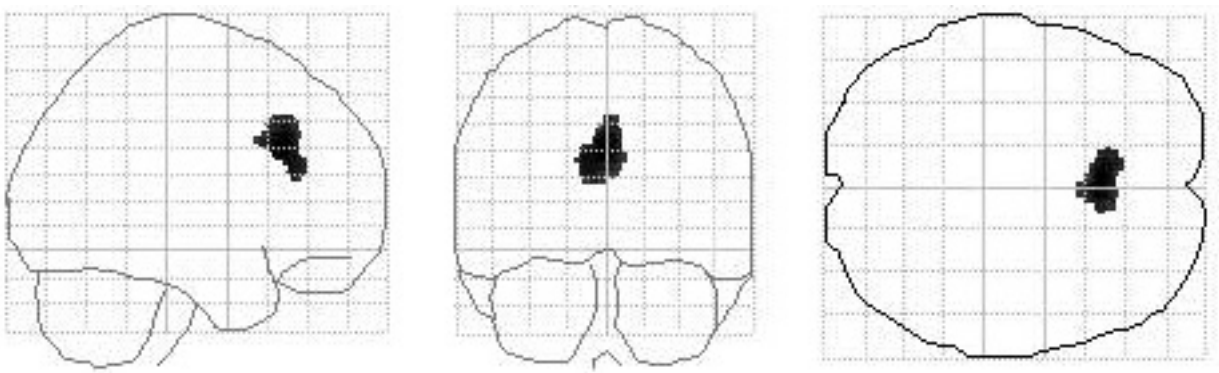

Figure XV-10.1 Anatomical correlate of apathy. Forty-one subjects with Alzheimer's disease or organic personality disorders according to ICD-10 diagnostic criteria were subdivided into two group of subjects: 21 subjects were apathetic and 20 were not. The groups were comparable in terms of age, sex, mini-mental state examination and diagnostic repartition. Brain perfusion was measured by ethylene-cysteine-dimer bicisate (ECD) brain SPECT, and the images were compared using SPM software. The Z map showed significant decreased ECD uptake for the apathetic patients in the anterior cingulate

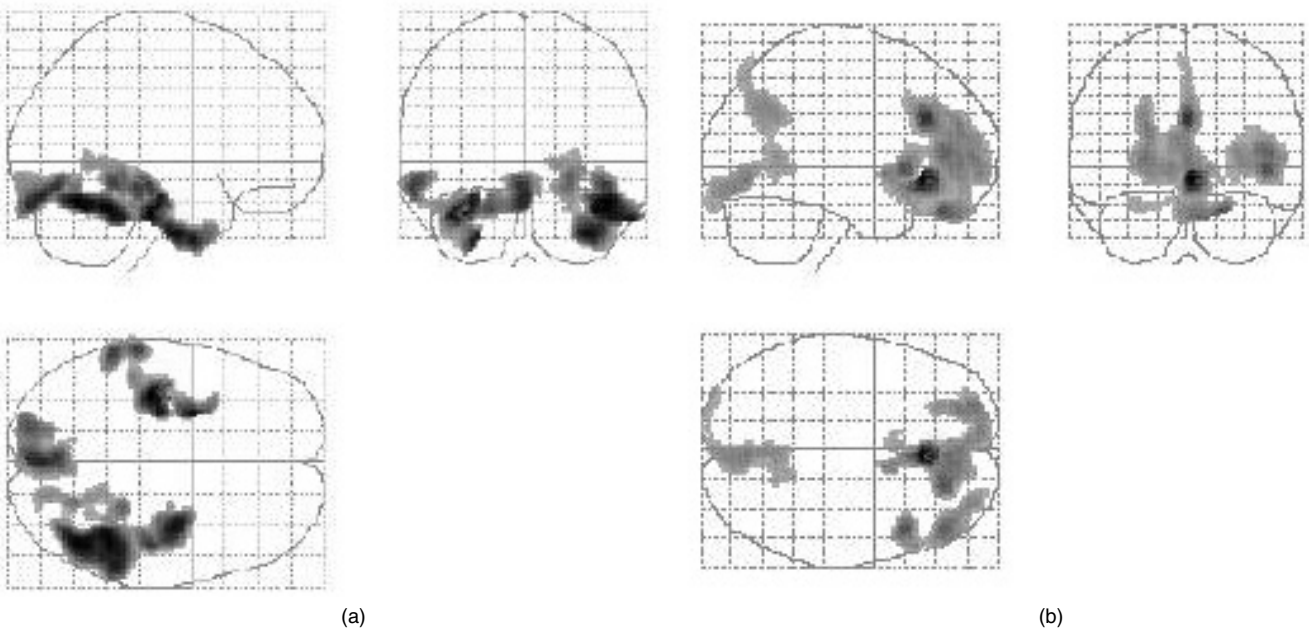

Figure XV-10.2 Fifteen Alzheimer's disease patients without apathy (mean age 76.6 years, SD 5.1) and 15 Alzheimer's disease patients with apathy (mean age 77.6 years, SD 6.1) were studied. The Neuropsychiatric Inventory (NPI) was used to evaluate apathy. Brain perfusion was measured by ^{99m}Tc-labelled ethylene-cysteine-dimer bicisate (ECD) SPECT. The images of the two groups (AD-NA, Alzheimer's disease without apathy; AD-A, Alzheimer's disease with apathy) were compared by SPM with corresponding images of 11 healthy elderly control subjects (obtained from the Society of Nuclear Medicine database). (a) AD-NA versus control; (b) AD-A versus control

Alzheimer's disease patients from aged-matched, controls and has been shown to correlate with mini-mental status examination (MMSE) scores.

MILD COGNITIVE IMPAIRMENT

Another important challenge is to predict the development of Alzheimer's disease in patients with mild cognitive impairment (MCI) in order to treat them early (Scheltens and Korf, 2000). Subjects with MCI have a memory impairment beyond that expected on the basis of age and education, yet they are not demented (Petersen *et al.*, 1999). The diagnosis of MCI is made if the patient meets the following criteria: (1) memory complaints, (2) normal activities of daily living, (3) normal general cognitive function, and (4) abnormal memory for age. As indicated earlier, the entorhinal cortex and hippocampus may be involved before the neocortex in Alzheimer's disease, and massive loss of entorhinal neurons occurs even in very mild cognitive impairment. In an MRI study, Jack *et al.* (2000) identified 129 subjects who met established criteria for normal control subjects, MCI and probable Alzheimer's disease, both at inclusion and at clinical follow-up 3 ± 1 years later. The rates of hippocampal atrophy matched both baseline cognitive status and the change in cognitive status over time in these elderly subjects who lay along the cognitive continuum from normal over MCI to Alzheimer's disease. In the very early stages of Alzheimer's disease, several studies suggest that variants of the apolipoprotein E gene account for the majority of cases of late-onset Alzheimer's disease (Corder *et al.*, 1993; Corder *et al.*, 1994; Roses *et al.*, 1994): people carrying two copies of the E4 allele have a higher risk of Alzheimer's disease. In an rCMRGL PET study, Reiman *et al.* (1996) compared cognitively normal elderly subjects who reported a family history of probable Alzheimer's disease, on the basis of the E4 allele. Only E4 homozygotes had significantly reduced glucose metabolism in the same posterior cingulate, parietal, temporal and prefrontal regions as in previously studied patients with probable Alzheimer's disease. This underlines the role of brain imaging in the early stages of Alzheimer's disease.

VASCULAR DEMENTIA

Vascular factors are recognized increasingly to be important causes of cognitive impairment in the elderly. Even in subjects with MCI without signs of cerebrovascular disease, CT reveals more frequently extensive white-matter abnormalities (Wolf *et al.*, 2000). Two types of vascular disease potentially causing cognitive dysfunction are usually considered. The first is due to subcortical white-matter vascular damage related to microangiopathy; the second is due to multiple small cortical infarcts (multi-infarct dementia) and is related to macroangiopathy. Both can be associated with atrophy.

These white-matter lesions, also called leukoaraiosis, can be patchy or diffuse; they are associated with thickening of deep arterioles and they are nonspecific. Garde *et al.* (2000) carried out a standardized neuropsychological assessment of a cohort of almost 700 subjects born in 1914, at ages 50, 60, 70 and 80 years. Of the 129 subjects tested fully at age 80 years, 68 also underwent MRI scanning. The degree of white-matter changes was related significantly to the decline in performance intelligent quotient on the Wechsler Intelligence Scale (WAIS). However, large studies of elderly populations with serial MRI and neuropsychological testing are scarce.

In multi-infarct dementia, randomly distributed multiple transcortical defects are detected easily by perfusion SPECT or fluorodeoxyglucose (FDG) PET. However, white-matter changes are difficult to assess by these techniques. These limitations do not apply to morphological imaging: lacunar infarcts and deep white-matter lesions are detected readily by CT and MRI, but they are not seen on SPECT or PET. However, these lesions are only epiphenomenona, morphologically characterizing cerebral

microangiopathy. Related neuropsychological deficits are essentially reflected by cortical dysfunction revealed by PET and SPECT (Mori *et al.*, 1999; Sabri *et al.*, 1998) in the absence of cerebral atrophy. If present, atrophy becomes the main determinant of neuropsychological impairment (Sabri *et al.*, 1995). Recently, a relationship between subcortical hyperintensities on MRI, cortical perfusion on SPECT, and cognitive function were studied in 26 patients with vascular dementia (Cohen *et al.*, 2001). The results suggest a complex relationship: subcortical hyperintensities on MRI correlated with frontal lobe perfusion but not with global brain perfusion measured by SPECT. However, frontal lobe perfusion did not correlate reliably with performance on executive function tests.

Using ^{1}H-MRS, cortical metabolic abnormalities through reduction of NAA concentrations secondary to subcortical vascular neuronal loss were also found. Interestingly, in this study decrease of hippocampal NAA was observed specifically in Alzheimer's disease and not in subcortical ischaemic vascular dementia.

FRONTOTEMPORAL LOBAR DEGENERATION

Circumscribed atrophy of the frontal and temporal lobes has been grouped into three prototypical clinical syndromes designated as frontotemporal lobar degeneration (FTLD). FTLD accounts for about one-fifth of primary degenerative dementia cases occurring before age 65 years. A consensus on the diagnostic criteria of FTLD includes functional brain imaging characteristics (Neary *et al.*, 1998).

The most common form of FTLD is frontotemporal dementia, characterized by personality changes, profoundly altered social behaviour, and bilateral atrophy of the frontal and anterior temporal lobes. SPECT, PET, CT and MRI have shown abnormalities, unilaterally or bilaterally, most marked in the anterior (frontal, temporal) part of the brain (Miller *et al.*, 1991; Starkstein *et al.*, 1994). However, on the basis of case studies, Gregory *et al.* (1999) indicated that neuropsychological tests as well as brain imaging may not be sensitive to the very early changes that occur in the ventromedial frontal cortex and that are expressed only though behavioural disorders.

The second syndrome, progressive non-fluent aphasia, is characterized by difficulties with verbal expression, anomia and phonemic errors, despite relative preservation of comprehension; it is associated with atrophy predominating in the left hemisphere. SPECT usually demonstrates a striking reduction in tracer uptake in the left frontal, temporal and parietal regions (Snowden *et al.*, 1996).

Finally, patients with semantic dementia have fluent speech with semantic errors and severely impaired comprehension and naming, together with visual associative agnosia resulting from bilateral atrophy of the inferior and middle temporal gyri. Functional brain imaging shows reduced tracer uptake in the temporal region, bilaterally or markedly asymmetric with a major defect on the left side (Snowden *et al.*, 1996).

DEMENTIA WITH LEWY BODIES

Lewy bodies are found in the subcortical nuclei, limbic cortex and neocortex, and are associated with significant neuronal loss, including extensive disruption of ascending cholinergic and dopaminergic projections. Fluctuating cognitive impairment, visual hallucinations and parkinsonism are core features of dementia with Lewy bodies (DLB) (McKeith *et al.*, 1996). In a recent study (Barber *et al.*, 2001), medial and lateral temporal lobe atrophy on MRI was compared in DLB patients ($n = 26$), Alzheimer's disease patients ($n = 22$) and normal controls ($n = 26$). All patients with dementia had a loss of hippocampal asymmetry compared with the normal controls. Furthermore, hippocampal and parahippocampal volumes were significantly larger in subjects with DLB than in those with Alzheimer's disease. This may help explain differences in the pattern of cognitive deficits between these disorders.

PET studies (Albin *et al.*, 1996; Ishii *et al.*, 1998) showed, in comparison to Alzheimer's disease, a greater reduction in glucose metabolism in the occipital lobe of DLB patients, including the primary visual areas and visual association cortices. In addition, patients with visual hallucinations had hypoperfusion of the occipital cortex and a relatively spared temporoparietal cortex compared with patients without hallucinations (Imamura *et al.*, 2001). SPECT studies have also shown posterior rCBF abnormalities in DLB (Ishii *et al.*, 1999; Defebvre *et al.*, 1999). Specific dopaminergic degeneration was demonstrated in DLB when compared with Alzheimer's disease patients using a SPECT presynaptic ligand iodine-123-carbomethoxy-3 beta (4-iodophenyl) tropane (F-CIT) (Walker *et al.*, 1999). This appears to be a promising tool for this differential diagnosis.

OTHER ORGANIC BRAIN DISEASES

Parkinson's Disease

Morphological changes on MRI are inconsistent, difficult to quantify and common to parkinsonian patients, both with and without dementia (Huber *et al.*, 1989). Several functional imaging studies have shown that dementia in parkinsonism is accompanied by a bilateral reduction in cortical metabolism (Shapiro *et al.*, 1990; Peppard *et al.*, 1990) or perfusion in posterior parietotemporal areas (Spampinato *et al.*, 1991). This metabolic pattern is close to that observed in Alzheimer's disease, from which Parkinson's disease may differ by some involvement of the sensorimotor and visual cortices (Herholz, 1995).

In addition to the dopaminergic system, the cholinergic system could also be involved in the development of the cognitive disorders encountered in Parkinson's disease. Khul *et al.* (1996) showed abnormal cortical cholinergic innervation in parkinsonian patients. The decline was moderate (20%) and localized at the parietal and occipital cortices of non-demented patients, but was more diffuse and severe in parkinsonian patients with dementia.

Steele–Richardson Disease

This is characterized by an atypical parkinsonian syndrome, dementia, and lesions generally localized at the basal ganglia and brainstem. Functional imaging has shown a marked reduction in cortical (predominantly frontal) metabolism and cortico-subcortical circuits involved in motor function, executive function and attention (Salmon *et al.*, 1997).

Involvement of pre and postsynaptic striatal dopaminergic function characterizes this disease. A marked decrease in ^{18}F-Dopa accumulation has been found in the caudate nucleus and putamen (Brooks *et al.*, 1990). Contrary to Parkinson's disease, the number of dopamine D2 receptors is also diminished (Baron *et al.*, 1986). These changes point to a loss of intrinsic striatal neurons and may account for the lack of response to dopa therapy. A study by Pappata *et al.* (1997) suggests that this striatal involvement affects mainly cholinergic neurons, as striatal uptake of ^{11}C-physostigmine is reduced significantly in these patients.

AIDS and Creutzfeldt–Jakob Disease

Brain damage caused by human immunodeficiency virus (HIV) can lead to dementia. Morphological imaging inconsistently shows atrophy or white-matter involvement, which can be present in

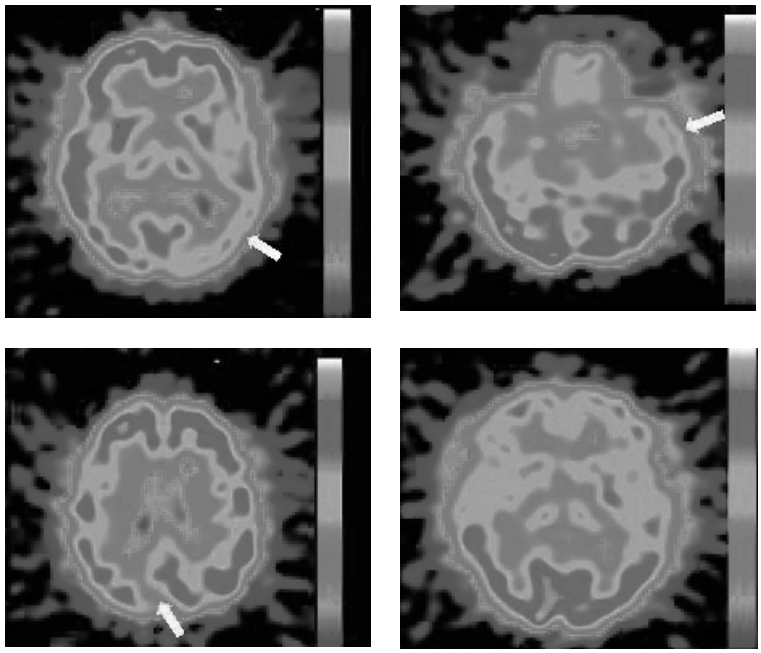

Figure XV-10.3 Perfusion brain SPECTs of four subjects with different pathologies: On the upper right: *Alzheimer disease*: 70 years old woman; MMSE = 19; performance deficit at the following tests; Boston naming test, Token test, verbal fluency and memory recall; Perfusion SPECT: Middle transaxial cut showing left temporo Parietal hypoperfusion. On the upper left: *Mild Cognitive Impairment*: 70 years old woman; MMSE = 28; performance deficit at the following tests; Grober Buschke memory recall; Perfusion SPECT: lower transaxial cut showing left temporal pole hypoperfusion. On the lower right: *Multi-infarct dementia*: 65 years old man; MMSE = 21; performance deficit at the following tests; Benton orientation/praxis/memory recall; Perfusion SPECT: Upper transaxial cut showing a right occipito parietal transcortical hypoperfusion. On the lower left: *Frontotemporal dementia*: 61 years old woman with apathy Irritability & disinhibition; MMSE = 30; performance deficit at the following tasks; attention dual test/capture error sequencing; Perfusion SPECT: Middle transaxial cut showing a diffuse frontotemporal hypoperfusion (See Colour Plate XV-10.3)

combination or alone. The atrophy is mainly subcortical. The signal anomalies initially affect the corpus callosum, the fornix and, later, the white matter. Functional imaging has shown either asymmetric subcortical anomalies or multiple or isolated cortical defects with a variable distribution in patients with a subacute encephalopathy (Kramer and Sanger, 1990). Serial examinations show that the increase in perfusion deficits runs parallel to the clinical deterioration.

Creutzfeldt–Jakob disease is a transmissible spongiform encephalopathy caused by an infectious prion protein. MRI scan may initially be normal or subnormal but subsequently shows severe and rapidly progressive cortical atrophy.

BRAIN IMAGING AND DIFFERENTIAL DIAGNOSIS OF DEMENTIA

A particularly important use of brain imaging is differential diagnosis of dementia (Figure XV-10.3). Using MRI, Barber *et al.* (1999) created a visual rating scale in order to evaluate medial temporal lobe atrophy in 26 patients with DLB, 28 patients with Alzheimer's disease, 24 patients with vascular dementia and 26 control subjects. The results suggest that the absence of medial temporal lobe atrophy had a specificity of 100% (sensitivity 38%) for separating DLB from Alzheimer's disease, and a specificity of 88% for separating vascular dementia from Alzheimer's disease. In another study with SPECT, Talbot *et al.* (1998) prospectively studied 364 patients with dementia (132 Alzheimer's disease, 78 vascular dementia, 24 DLB, 58 frontotemporal dementia, 22 progressive aphasia) for a median of 3 years (range 1–6 years). To evaluate the diagnostic gain of individual brain imaging results (rCBF abnormalities), likelihood ratios were calculated pairwise for disease group comparisons (e.g. disease A *v.* disease B). (Likelihood ratios provide an indication of the degree to which a particular result modifies the pretest odds of one subject having a particular disease to provide a new post-test odds ratio.) A bilateral posterior rCBF abnormality significantly increased the odds of having Alzheimer's disease as opposed to vascular dementia or frontotemporal dementia. 'Patchy' rCBF abnormalities significantly increased the odds of having vascular dementia as opposed to Alzheimer's disease. The technique was, however, less useful for differentiating Alzheimer's disease from DLB.

CONCLUSION

The main message of this chapter is that brain imaging is useful for both positive and differential diagnosis of dementia. Future improvements could result from better standardization of both structural and functional brain imaging methodologies. Brain imaging might also help clinicians to predict the onset of cognitive behavioural disturbances and, possibly, the effectiveness of therapeutic intervention. This approach provides the basis for what has been called cognitive neuropsychiatry (Halligan and David, 2001), which attempts to establish the functional organization of psychiatric disorders within the framework of cognitive neuropsychology.

Neurogenetics of Dementia

Bart Dermaut and Christine Van Broeckhoven

INTRODUCTION

Whereas intensive genetic study has so far failed to convincingly identify genes for psychiatric disorders like schizophrenia or bipolar disorder, the molecular defect of a number of dementia syndromes has been identified unambiguously. Indeed, for rare familial forms of dementia, such as Alzheimer's disease, frontotemporal dementia (FTD), Creutzfeldt–Jakob disease (CJD), and other rare atypical dementias, we are able to pinpoint highly penetrant mutations in genes as the sole cause of the disease. This genetic approach has been successful because of two specific properties of dementia mostly absent in other psychiatric disorders. First, detailed neuropathological study of brains of demented individuals has made possible the classification of dementia syndromes into clinicopathological and biochemical entities amenable for a molecular genetic approach. Second, some of these cognitive disorders or subtypes behave as Mendelian traits, making them suitable for classical positional cloning of disease genes. Although this has led to the identification of the molecular cause of a number of monogenic dementias, genetic study of these diseases remains considerably complicated. First, there is the problem of variable expression, meaning that the same or similar genetic defect can result in different phenotypes. This is particularly well illustrated by the enormous phenotypic heterogeneity observed in inherited tau and prion diseases. Second, the same dementia can be caused by different mutations in different genes. These phenomena are referred to as allelic and genetic heterogeneity and are evident from genetic studies in familial early-onset Alzheimer's disease (EOAD), which can be caused by different mutations in at least three genes. Third, the significant clinical overlap between diseases with totally different neuropathological and molecular diagnoses adds to their clinical diagnostic complexity.

From an academic point of view, the complementary roles of molecular genetics and neuropathology cannot be overestimated. In many cases, important clues to the identification of a disease gene have come from the careful neuropathological and biochemical study of proteins that are present in brain lesions of demented individuals. Historical examples of this approach include the identification of mutations in the amyloid precursor protein gene (*APP*) and prion protein gene (*PRNP*) causing Alzheimer's disease and CJD, respectively. On the other hand, as illustrated by the mutated presenilins in familial EOAD, 'blind' scanning of the whole genome in large families has resulted in the identification of unexpected genetic defects, thereby often providing completely novel insights into the biochemical mechanisms of a disease.

Unfortunately, primary degenerative dementias are presently untreatable and patients therefore benefit little from receiving a correct molecular diagnosis. It is hoped, however, that novel pathogenetic insights obtained from molecular genetic studies of these diseases will finally result in efficient therapeutic strategies.

More recently, for the more frequent occurring late-onset Alzheimer's disease (LOAD) and some other neurodegenerative dementias, common gene polymorphisms and chromosomal loci have been identified that contribute to disease susceptibility. As these gene polymorphisms are common DNA variations, their contribution to the phenotype within the general population is expected to be high. Nevertheless, progress in the field of genetic epidemiology has been slow, and the biochemical significance of the findings is often unclear. This is not surprising as it is likely that these genetic variations will interact with both the environment and other genes. With the enormous amount of frequent genetic variations becoming available through the human genome project and the development of new statistical methods, the area of complex genetics will become increasingly important.

Presently, genetic research is still focused on both the rare monogenic and common complex types of dementia. New chromosomal loci and genes are still being identified for monogenic presenile dementia, and an enormous number of genes are under scrutiny for harbouring variations affecting susceptibility to the common forms of dementia. In this chapter, we try to highlight the major topics in both areas. For reasons of clarity, we have also added the Online Mendelian Inheritance in Man (MIM: http://www.ncbi.nlm.nih.gov/Omim/) numbers of the described genes and phenotypes.

ALZHEIMER'S DISEASE

Alzheimer's disease (MIM 104300) is the most common type of dementia in the elderly. It is characterized by slowly progressive impairment in intellectual function resulting in a state of complete dependency and death after 5–10 years. The definite diagnosis is made at autopsy by the demonstration in brain of extracellular amyloid deposits called neuritic plaques and intracellular neurofibrillary tangles (Mirra *et al.*, 1991). Whereas neuritic plaques are composed mainly of extracellular deposited amyloid peptide (Aβ) fibrils derived from the amyloid precursor protein (APP), hyperphosphorylated tau protein is the main constituent of neurofibrillary tangles. In research settings, an arbitrary cut-off of 65 years is often used to distinguish between the rare EOAD, or presenile type of Alzheimer's disease, and the frequent LOAD, or senile Alzheimer's disease, which are clinically and pathologically highly similar, if not identical. The first genetic evidence suggesting genetic causes of AD came from large, multigenerational families that included many individuals with EOAD (Kennedy *et al.*, 1994; Mirra *et al.*, 1991). Later epidemiological studies of risk in first-degree relatives also revealed a strong familial clustering of the disease. It is estimated that first-degree relatives of AD patients have a 3.5-fold increased risk for developing AD (van Duijn *et al.*, 1991). This relative risk decreases with increasing age at onset of the proband, but

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

even at the age of 80 years the relative risk is 2.6-fold increased for first-degree relatives. The lifetime cumulative risk for first-degree relatives of AD patients was found to be 39%, compared with about 12% in first-degree relatives of controls (Lautenschlager *et al.*, 1996; van Duijn *et al.*, 1993). Although there is substantial evidence for genetic factors in the aetiology of both EOAD and LOAD, the most important genetic breakthroughs have been established by investigation of EOAD families segregating the disease in an autosomal dominant manner.

Molecular Genetics

Chromosomes 21, 14 and 1: APP, PSEN1 and PSEN2

Initial genetic linkage studies targetted mainly chromosome 21 because the brains of almost all middle-aged Down's syndrome patients, who have a trisomy of chromosome 21, contain the neuropathological hallmarks of AD (Mann, 1988; Wisniewski *et al.*, 1985). The underlying hypothesis was that in Down's syndrome patients, AD is caused by overrepresentation of a gene on chromosome 21 as a result of the trisomy 21, while in AD, a mutation in that gene might result in the production of an abnormal protein or the overproduction of a normal protein. In some EOAD families, linkage was found to 21q11.2-21 (St George-Hyslop *et al.*, 1987); around the same time, *APP* (MIM 104760) was characterized and localized to the same chromosomal region (Tanzi *et al.*, 1987) (Figure XV-11.1). Since APP is cleaved endoproteolytically to produce the Aβ peptide, the major component of neuritic plaques in AD brains, *APP* was a strong candidate gene for AD. Moreover, a Glu693Gln mutation in *APP* was found in families suffering from hereditary cerebral haemorrhage with amyloidosis of the Dutch type (HCHWA-D), a rare autosomal dominant disorder found in a few families in the Netherlands (Bakker *et al.*, 1991; Levy *et al.*, 1990). HCHWA-D is characterized by recurrent cerebral haemorrhages caused by excessive deposition of Aβ in the blood vessel walls in the brain (Haan *et al.*, 1991). The discovery of this mutation demonstrated that mutations in *APP* can lead to Aβ deposition and encouraged mutation analysis of *APP* in EOAD families. Sequence analyses of *APP* revealed a Val717Ile mutation in a chromosome-21-linked EOAD family (Goate *et al.*, 1991). To date, 12 different Alzheimer's disease-related *APP* mutations are known (AD mutation database: http://molgen-www.uia.ac.be/ADmutations) (Table XV-11.1). The *APP* Val717Ile mutation was found in multiple EOAD families of different ethnicity, which underlined the causative character of the mutation. *APP* is a housekeeping gene comprising 18 exons encoding a single membrane-spanning protein with a large ectodomain and a small cytoplasmic tail (Tanzi *et al.*, 1987; Konig *et al.*, 1992; Ponte *et al.*, 1988; Sandbrink *et al.*, 1994). All mutations are located in exons 16 and 17 at or near proteolytic cleavage sites involved in the generation of Aβ.

Since *APP* mutations explain the development of EOAD in only a small number of cases, a genome-wide search in families segregating EOAD was started in many laboratories. This led to the discovery of strong linkage evidence of EOAD with markers at chromosome 14q24.3 (Mullan *et al.*, 1992; Schellenberg *et al.*, 1992; St George-Hyslop *et al.*, 1992; Van Broeckhoven *et al.*, 1992). The gene encoding presenilin 1 (*PSEN1*; MIM 104311) was isolated from this region, and missense mutations were identified that cosegregated with EOAD (Figure XV-11.1). To date, 82 different AD mutations have been identified (Table XV-11.1). *PSEN1* contains 13 exons encoding a 467-amino-acid integral membrane protein with six to eight transmembrane domains (Doan *et al.*, 1996; Lehmann *et al.*, 1997; Li and Greenwald, 1998). In contrast to *APP* mutations, the *PSEN1* mutations are scattered over the entire coding region of the gene, with some clustering in exons 5 and 8 encoding the regions that correspond to

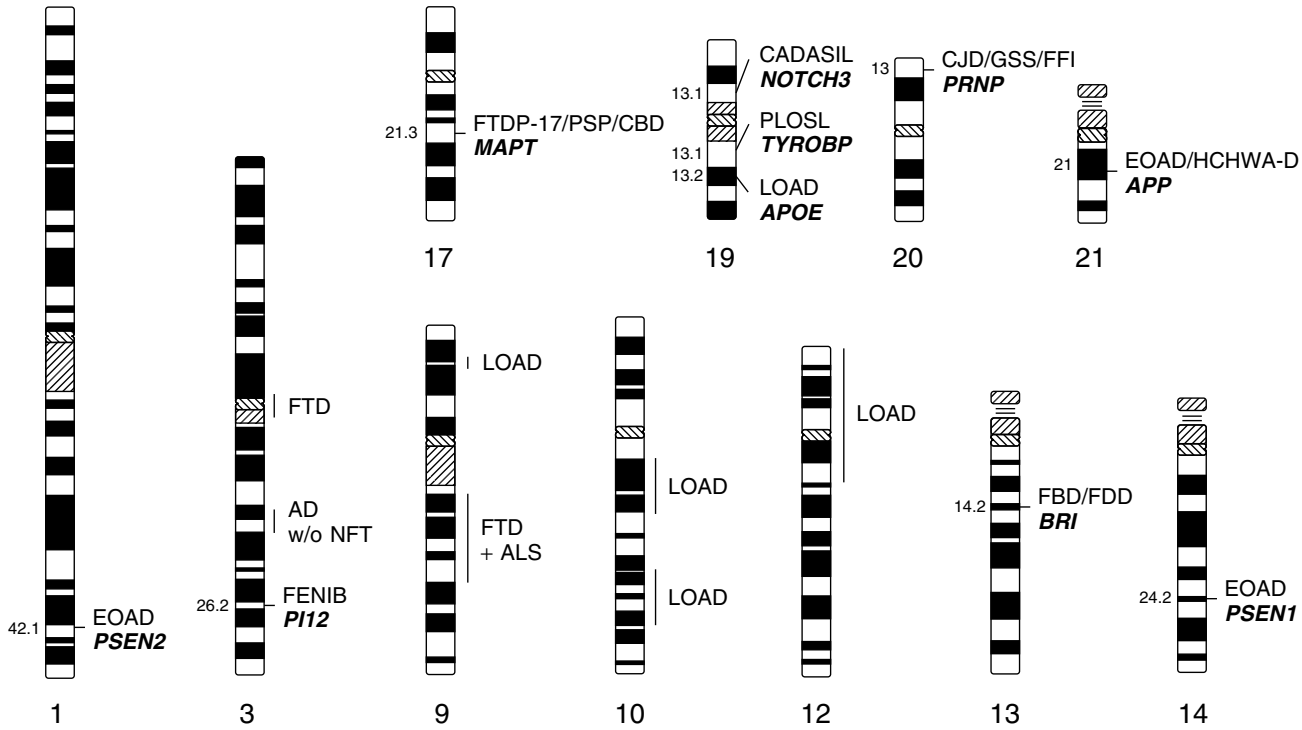

Figure XV-11.1 Human chromosomes with genetic loci that influence different types of dementia syndromes. When known, the responsible gene is highlighted in bold. (AD, Alzheimer's disease)

Table XV-11.1 Monogenic dementias with known molecular defect

Dementia subtype	Main clinical features	Neuropathological features	Mode of inheritance	Mutated gene	Type of mutations	Number of mutations reported
Familial EOAD	Memory impairment, cognitive disturbances, various accompanying features in later stages	Neuritic amyloid plaques (Aβ), neurofibrillary tangles (tau), amyloid angiopathy (Aβ)	A.D.	*APP*	Clustered missense mutations	12
				PSEN1	Mainly missense mutations	82
				PSEN2	Missense mutations	6
FTDP-17	Behavioural, cognitive and motor disturbances (highly variable)	Gliosis, spongiosis, neuronal loss, neurofibrillary tangles (tau), rare Pick bodies (tau)	A.D.	*MAPT*	Clustered missense, silent, intronic mutations	21
Familial prion disease	Cognitive disturbances, ataxia, myoclonus (highly variable)	Gliosis, severe spongiosis, neuronal loss, prion deposits	A.D.	*PRNP*	Missense mutations Octapeptide insertions	22 19
CADASIL	Strokes, migraine, cognitive deterioration	Arteriopathy, osmiophilic deposits near vascular smooth muscle cells	A.D.	*NOTCH3*	Stereotyped missense mutations	25
FBD and FDD	*FBD*: dementia, spastic paraparesis, ataxia *FDD*: dementia, cataracts, deafness, ataxia	Alzheimer's disease-like amyloid plaques (ABri, ADan), neurofibrillary tangles (tau), amyloid angiopathy (ABri, ADan)	A.D.	*BRI*	Stop codon mutation (FBD) and ten nucleotide insertion (FDD) leading to longer precursor protein	2

the second transmembrane domain and the N-terminal part of the sixth hydrophilic loop (Cruts and Van Broeckhoven, 1998). *PSEN2* (MIM 600759) was found based on its homology with *PSEN1* (Levy *et al.*, 1995a). Interestingly, *PSEN2* was located at 1q42.3 (Figure XV-11.1), a region that was genetically linked to AD in the Volga-German group of families who first emigrated from Germany to Russia and later to the USA (Levy *et al.*, 1995b). In these families, the Asn141Ile mutation was identified in *PSEN2*. Now, five additional missense mutations are known (Table XV-11.2).

The majority of *PSEN* mutations are missense mutations giving rise to the substitution of a single amino acid. However, two splicing defects and two genomic deletions have been reported (De Jonghe *et al.*, 1999; Kwok *et al.*, 1997; Perez-Tur *et al.*, 1995; Prihar *et al.*, 1999; Smith *et al.*, 2001). It has been shown in functional studies that all *PSEN* mutations distort APP processing by promoting the secretion of the longer form of the Aβ peptide, suggesting a gain of function mechanism for *PSEN* mutations (Citron *et al.*, 1997).

Table XV-11.2 Genes and chromosomal loci that influence susceptibility to dementia

Dementia subtype	Chromosome	Gene	Risk polymorphism
LOAD	19	*APOE*	*APOE*-ε4 allele
	12	Unknown	Unknown
	10	Unknown	Unknown
	9	Unknown	Unknown
CJD (sporadic, iatrogenic, variant)	20	*PRNP*	*PRNP* -Met129Val
PSP and CBD	17	*MAPT*	*MAPT* spanning haplotype

Chromosome 19: APOE

In LOAD families, no mutations are found in *APP*, *PSEN1* or *PSEN2*. Therefore, a genomic screen was undertaken in a set of LOAD families using the 'affected pedigree members' method in which the segregation patterns of genetic markers are considered only in affected individuals (Pericak-Vance *et al.*, 1991). These analyses supported linkage to 19q13.2. In 1991, the apolipoprotein E (apoE) encoded by *APOE* (MIM 107741) was localized to the lesions in AD brain (Namba *et al.*, 1991). Also, in cerebrospinal fluid (CSF), apoE binds with high avidity to immobilized Aβ (Strittmatter *et al.*, 1993a), and later *APOE* was localized to chromosome 19q13.2 near the candidate region defined by genetic analysis (Figure XV-11.1). Two polymorphisms in the coding region of *APOE* result in three major isoforms of the protein, differing in the presence of a Cys or Arg residue at amino acid positions 112 and 158, respectively. *APOE*-ε3 ($Cys_{112}Arg_{158}$) is the most common isoform, with an allele frequency of 75% in the Caucasian population. The other two common alleles are *APOE*-ε2 ($Cys_{112}Cys_{158}$) and *APOE*-ε4 ($Arg_{112}Arg_{158}$), with frequencies of 10% and 15%, respectively. Genetic association of the *APOE*-ε4 allele was first demonstrated with familial LOAD (Strittmatter *et al.*, 1993a), and later also with sporadic LOAD (Saunders *et al.*, 1993) and EOAD (van Duijn *et al.*, 1994). It was observed that *APOE*-ε4 was associated with a dose-dependent increased risk of developing AD that was confirmed consistently in all studies (Table XV-11.2). Also, the *APOE*-ε2 allele was found to have a protective effect against AD (Corder *et al.*, 1994), but this observation was not confirmed in all studies (van Duijn *et al.*, 1995). In a multicentric meta-analysis, almost a three times increased risk was observed for carriers of one *APOE*-ε4, and a 15 times increased risk was found for homozygote carriers of *APOE*-ε4 (Farrer *et al.*, 1997). There is evidence that the risk associated with *APOE*-ε4 is dose-dependent, as reflected in the age at onset of disease: individuals with two *APOE*-ε4 alleles have an earlier onset than those without an *APOE*-ε4 allele (Corder *et al.*,

1993). Despite the highly consistent association between *APOE*-ε4 and AD in Caucasian populations, this association seems to be absent in populations of African origin, where the *APOE*-ε4 frequency is relatively high (Kalaria *et al.*, 1997). The reasons for these discrepant findings are still unclear, although a difference in linkage disequilibrium patterns between African populations and evolutionarily more recent Caucasian populations might offer a clue (de Knijff and van Duijn, 1998). More recently, several polymorphisms in the promoter region of *APOE* were reported to be associated with AD independently of *APOE* isoforms, suggesting that apoE expression levels might be important in the development of AD (Artiga *et al.*, 1998a; Artiga *et al.*, 1998b; Bullido *et al.*, 1998; Lambert *et al.*, 1998a; Lambert *et al.*, 1998b). However, this was not confirmed in all studies (Roks *et al.*, 1999). On the biochemical level, it was demonstrated that the apoE-ε4 isoform binds Aβ much faster than the apoE-ε3 isoform (Strittmatter *et al.*, 1993b). Nevertheless, the exact mechanism by which apoE isoforms influence the development of AD remains unknown.

Chromosomes 9, 10 and 12

In a complete genomic screen using different linkage methods in families affected with LOAD, possible or suggestive linkage was detected on chromosomes 4, 6, 12 and 20, with the strongest evidence for markers in the pericentric region of chromosome 12 (Pericak-Vance *et al.*, 1997) (Figure XV-11.1). Using parametric linkage analysis, the presence of an AD susceptibility locus on chromosome 12 was confirmed in an independent set of families with LOAD (Rogaeva *et al.*, 1998). Although the precise location of the gene could not be determined, it included the previously reported region. In the first stage of a full genome scan in 292 affected sibling pairs (ASPs) with LOAD, only moderate evidence for a somewhat overlapping region on 12p was detected (Wu *et al.*, 1998), while the highest peaks were on chromosomes 1, 9, 10 and 19 (Kehoe *et al.*, 1999). In the second stage using 429 ASPs, a multipoint lod score of 3.83 was found near D10S1225 (Myers *et al.*, 2000) (Figure XV-11.1). Interestingly, in an independent set of LOAD families, Aβ42 plasma levels again showed strongest evidence for linkage at the same marker (Ertekin-Taner *et al.*, 2000), while another study of 435 multiplex AD families, partially overlapping with the ASP sample, found linkage with AD more downstream at D10S583 (Bertram *et al.*, 2000) (Figure XV-11.1). In another study using 730 ASPs, strongest evidence was found for a marker on chromosome 9p22.1 (Pericak-Vance *et al.*, 2000) (Figure XV-11.1). The chromosome 9, 10 and 12 AD genes remain to be identified.

Other Candidate Genes

Numerous genes have been reported to affect genetic susceptibility to AD. Although there is substantial functional evidence for an involvement in AD for most of these genes, initial positive genetic associations are often not replicated in independent populations (Prince *et al.*, 2001; Emahazion *et al.*, 2001). One gene that has recently attracted the attention of many researchers is the gene encoding α2-macroglobulin (α2m), *A2M*, which is located within the putative chromosome 12 AD locus. α2m is an abundant panprotease inhibitor (Borth, 1992) and, like apoE, a major ligand for the lipoprotein-related receptor protein (Strickland *et al.*, 1990). Moreover, α2m has been implicated in the binding (Hughes *et al.*, 1998), degradation (Qiu *et al.*, 1996) and clearance (Narita *et al.*, 1997) of the Aβ protein. Two polymorphic loci in *A2M* have been reported to increase the risk for AD (Blacker *et al.*, 1998; Liao *et al.*, 1998), but subsequent replication studies on both polymorphisms were inconsistent. A meta-analysis of all published case–control studies, including our own results in the Dutch population, showed no demonstrable contribution of *A2M* to AD (Koster *et al.*, 2000).

PSEN1, which causes autosomal dominant EOAD when mutated, has also been investigated as an AD susceptibility gene. A genetic association between LOAD and a polymorphism in intron 8 of *PSEN1* was reported, with a two-fold increased risk for the AA genotype (Wragg *et al.*, 1996). This finding was replicated in some other LOAD populations, while others showed no association. This can be explained if the *PSEN1* intron 8 polymorphism is not functionally relevant but is genetically close to another, biologically functional polymorphism. Recently, we performed an association study of *PSEN1* in a population-based series of EOAD patients, suggesting that a functional polymorphism in the promoter of *PSEN1* might contribute to the genetic risk of EOAD (van Duijn *et al.*, 1999; Theuns *et al.*, 2000). Interestingly, our results were replicated in an independent AD sample, where the effect was strongest in EOAD cases (Lambert *et al.*, 2001). However, in a Dutch population-based sample of LOAD, we were unable to demonstrate association with the *PSEN1* promoter (Dermaut *et al.*, 2001a). It is important to realize that since the identification of *APOE*, genetic association studies in AD have generally yielded no conclusive results. As such, *APOE* remains the only established genetic risk factor in AD. Without denying the complex nature of a multifactorial disease, empirical experience with genetic association studies in AD over the past 10 years raises questions on the utility of this strategy in unravelling the genetic components of AD (Emahazion *et al.*, 2001).

Genotype–Phenotype Correlations in Familial Early-Onset Alzheimer's Disease

A recent study compared age at onset and age at death in 90 subjects with dominantly inherited EOAD caused by *PSEN1*, *PSEN2* and *APP* mutations (Lippa *et al.*, 2000). Although highly variable in each group, it was found that both age at onset and death were significantly earlier in *PSEN1* and *APP* mutation carriers than in the *PSEN2* group. Mean ages at onset were 44 ± 8 years in the *PSEN1* group, 59 ± 7 years in the *PSEN2* group, and 49 ± 7 years in *APP* mutation carriers, with a similar mean disease duration of about 10 years in the three groups. There is evidence that *APOE* genotype modulates age at onset in some but not all *APP* families. In one well-studied family, the age at onset of individuals with a mutation who are *APOE*-ε3ε3 homozygous is 55 years, whereas *APOE*-ε4ε4 homozygotes have an onset at 45 years and *APOE*-ε2ε3 heterozygotes have an onset of 60 years (Alzheimer's Disease Collaborative Group, 1993). In *PSEN1* families, the *APOE* genotype does not seem to modulate age at onset (Van Broeckhoven *et al.*, 1994).

A number of neurological symptoms can accompany *APP*- and *PSEN*-related dementia syndromes in later stages of the disease course. These include myoclonus, epileptic seizures, pyramidal signs, extrapyramidal signs, cerebellar signs and ataxia (Fox *et al.*, 1997; Haltia *et al.*, 1994; Kennedy *et al.*, 1995; Lampe *et al.*, 1994; Martin *et al.*, 1991). However, these features are not unique to familial EOAD, as they are also observed in other inherited dementias and even typical LOAD cases (McKhann *et al.*, 1984). Therefore, accompanying neurological features generally do not allow a reliable prediction on which causal EOAD gene is mutated. Recently, however, it has been suggested that a subset of *PSEN1* mutations leads to 'variant' AD, presenting with spastic paraparesis and so called 'cotton-wool plaques' in the brain (Houlden *et al.*, 2000). The first report concerned a Finnish pedigree in which a 4.6-kb genomic deletion containing exon 9 of *PSEN1* leads to this EOAD subtype (Crook *et al.*, 1998; Prihar *et al.*, 1999). It was suggested that such cases with variant AD, also seen with other *PSEN1* mutations, represent an aggressive subtype of EOAD,

since mutations causing this condition lead to exceptionally high amyloid concentrations in *in vitro* experiments (Houlden *et al.*, 2000).

At the neuropathological level, amyloid deposition in the cerebral blood vessel walls, called cerebral amyloid angiopathy (CAA), has received much attention. CAA is found in 90% of autopsied AD brains, but its severity and quantity are highly variable (Glenner *et al.*, 1981; Yamada, 2000). CAA is classically considered an important cause of cerebral haemorrhage, and is a prevailing feature in carriers of mutations affecting codons 692, 693 and 694 of *APP*, which are located at the α-secretase site within the coding region of the Aβ peptide. While patients carrying Dutch APP (Glu693Gln) suffer from recurrent cerebral haemorrhages (Van Broeckhoven *et al.*, 1990), Flemish APP (Ala692Gly) is associated with both AD and cerebral haemorrhages (Hendriks *et al.*, 1992; Roks *et al.*, 2000). Iowa APP (Asp694Asn) mainly presents as AD without obvious stroke-related events, although small haemorrhagic lesions are demonstrable by magnetic resonance imaging (MRI) and at neuropathological examination (Grabowski *et al.*, 2001).

Interestingly, some *PSEN* mutations also present with a comparably severe CAA but mostly in the absence of haemorrhages or infarcts. It is noteworthy that a recent systematic neuropathological study of *PSEN1*-related EOAD showed a strong correlation between CAA and *PSEN1* mutation codon position (Mann *et al.*, 2001). It was demonstrated that a severe degree of CAA was much more frequent among cases with a *PSEN1* mutation occurring after codon 200. Consistent with these findings, we have described a Belgian EOAD pedigree with unusual severe CAA segregating a novel *PSEN1* mutation at codon 282 (Leu282Val) (Dermaut *et al.*, 2001b). Immunohistochemical study of the brain of a *PSEN1* Leu282Val carrier revealed that the CAA lesions were capable of instigating a strong local dystrophic and inflammatory reaction, similar to the neuritic plaques that are classically considered the pathogenic amyloid lesion in AD brains.

Population Attribution

Several studies have estimated the genetic contribution of *PSEN* and *APP* mutations to EOAD. The estimated frequencies of *APP* and *PSEN* mutations to autosomal dominant EOAD depend largely on the ascertainment strategy of families. In families with a very early onset of disease that are documented thoroughly for use in genetic linkage studies or genetic counselling, mutation frequencies are clearly higher. In a French study, it was estimated that about 71% of all autosomal dominant EOAD families were explained by mutations in *APP*, *PSEN1* or *PSEN2* (Campion *et al.*, 1999). However, in a more systematic population-based sample of autosomal dominant EOAD in the Netherlands, we showed that only 20% could be explained by mutations in *APP*, *PSEN1* or *PSEN2* (Cruts *et al.*, 1998). In the same Dutch EOAD population, including both sporadic and familial cases, mutation frequencies were 0.5% for *APP*, 6% for *PSEN1* and 1% for *PSEN2*. Since the fraction of EOAD in the total AD population is very small (<1%) (Ott *et al.*, 1995), the contribution of the three dominant genes together to AD in general is probably less than 0.1%. Moreover, other dominant EOAD genes are expected, since in an important percentage of familial EOAD cases the genetic cause is unknown, including large, well-documented autosomal dominant pedigrees with neuropathological confirmation.

At the level of the population, *APOE* seems to be a more important determinant of AD. Although the relative risk associated with carriership of one *APOE*-ε4 allele is increased only moderately, the proportion of patients with dementia that is attributable to the *APOE*-ε4 allele was estimated to be 20% (Slooter *et al.*, 1998). This substantial contribution to the occurrence of AD in the general population is explained by the large amount of heterozygote carriers of the *APOE*-ε4 allele ($\sim$25% in the Caucasian population). Because of the rarity of the homozygous *APOE*-ε4ε4 genotype (<2%), the contribution of this genotype to AD in the population is limited, despite the high relative risk associated with this genotype.

FRONTOTEMPORAL DEMENTIA

Between 1892 and 1906, Arnold Pick described several patients with frontal and temporal atrophy presenting with language and/or behavioural disturbances. The term 'Pick's disease' (MIM 172700) has since been used to classify such cases. However, the clinical and pathologic heterogeneity of these focal non-Alzheimer's dementias has led historically to a proliferation of names. In 1994, the Lund and Manchester Groups published a consensus statement and introduced the term 'frontotemporal dementia' (FTD), along with its clinical and neuropathological criteria. Pick's disease is now considered to be a subtype of FTD that is defined neuropathologically by the presence of intraneuronal inclusion bodies (Pick bodies) and ballooned neurons (Pick cells), the microscopic lesions originally described by Aloïs Alzheimer in 1911 (Alzheimer, 1911). The most common type of FTD neuropathology is characterized by neuronal loss and spongiform change, together with mild or moderately severe gliosis in the outer cortical layers (Lund and Manchester Groups, 1994). In another type, spinal motor neuron degeneration is an additional feature. In a recent Dutch population-based study, the approximate prevalence of FTD varied between 1.2 of 10^6 in the age group 30–40 years and 28.0 of 10^6 in the age group 60–70 years (Stevens *et al.*, 1998). It is estimated that FTD comprises 3–12% of all demented patients (Brun, 1987; Giannakopoulos *et al.*, 1995; Knopman *et al.*, 1990) and may account for up to one-quarter of patients presenting before the age of 65 with dementia due to primary cerebral atrophy (Brun, 1987; Neary *et al.*, 1988). A positive family history for dementia is found in 38–50% of FTD patients (Knopman *et al.*, 1990; Neary *et al.*, 1988; Stevens *et al.*, 1998), and in the majority of these familial cases the disease is transmitted as an autosomal dominant trait.

Molecular Genetics

Chromosome 17: MAPT

In 1939, autosomal dominant presenile dementia was described in a Dutch family with prominent behavioural disturbances, language problems and mild memory impairment (Sanders *et al.*, 1939). This was the first description of the familial form of FTD. Between 1994 and 1996, several families with disinhibition-dementia-parkinsonism-amyotrophy complex, familial progressive subcortical gliosis and pallidopontonigral degeneration were linked to a locus on chromosome 17q21-22 (Petersen *et al.*, 1995; Wijker *et al.*, 1996; Wilhelmsen *et al.*, 1994) (Figure XV-11.1). In 1997, the original Dutch family (now known as Dutch family 2) was also assigned to this locus (Heutink *et al.*, 1997). By then, definite or probable linkage was established for 13 families with early-onset FTD, and in a consensus conference the clinical and morphological phenotypes of these families were compared (Foster *et al.*, 1997). Although the clinical phenotype of these families is highly variable, the term 'frontotemporal dementia and parkinsonism linked to chromosome 17' (FTDP-17) (MIM 600274) was adopted to emphasize the predominant symptoms of these families. Macroscopic examination of these FTDP-17 brains reveals severe frontotemporal atrophy as a consistent pathological feature, while involvement of the medial temporal lobe, amygdala, basal ganglia and substantia nigra is variable. However, in nearly all FTDP-17 affected brains, there is a pathological accumulation of the microtubule-associated protein tau, hence FTDP-17 is

often classified as a 'tauopathy'. Tau is involved in stabilizing microtubules, which are essential for cell shape, support and intracellular transport. As the gene encoding tau (*MAPT*; MIM 157140) maps within the FTDP-17 locus (Neve *et al.*, 1986), *MAPT* became the obvious candidate gene to screen for pathological mutations; and in 1998, the first *MAPT* mutations were reported (Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Spillantini *et al.*, 1998).

MAPT contains a total of 15 exons, with the major tau protein isoforms being encoded by 11 of these (Andreadis *et al.*, 1992). The gene undergoes complex alternative splicing, resulting in six different tau isoforms (Goedert *et al.*, 1989). Exons 9 to 13 encode four microtubule-binding motifs, and alternative splicing of exon 10 generates tau protein with either three or four microtubule-binding repeats. Presently, around 20 different mutations in *MAPT* have been identified in at least 50 known pedigrees worldwide (Reed *et al.*, 2001) (Table XV-11.1). All mutations are located in the carboxy-terminus of the protein, and include missense, silent and intronic variations as well as a codon deletion. They are all clustered in or near the microtubule-binding domains, and they affect microtubule-binding properties of tau in some cases by altering the three to four microtubule-binding repeats ratio resulting from distorted alternative splicing of exon 10.

MAPT: A Susceptibility Gene for Progressive Supranuclear Palsy and Corticobasal Degeneration

Progressive supranuclear palsy (PSP; MIM 601104) and corticobasal degeneration (CBD) are sporadic atypical parkinsonian syndromes that are often clinically confused with each other (Litvan *et al.*, 1999). These disorders share a rapid disease progression and parkinsonism with poor response to dopaminergic therapy, and display associated signs, such as ocular abnormalities (supranuclear gaze palsy), pyramidal signs and cognitive involvement often resembling FTD. Neuropathologically, both disorders are associated with tau inclusions in neurons and glia and are thus, like FTDP-17, classified as primary tauopathies (Dickson, 1999). Both PSP and CBD have similar biochemical alterations in the tau protein, with the abnormal tau containing predominantly four repeat tau. However, microscopically, the tau lesions appear different for the two disorders: while PSP is characterized by the presence of globose shaped neurofibrillary tangles in affected neurons, in CBD mainly fine filamentous tau inclusions are seen.

A genetic association between an intronic dinucleotide polymorphism in *MAPT* and PSP was reported (Conrad *et al.*, 1997). Later, it was shown in several studies that homozygosity of a common haplotype spanning the whole *MAPT* gene was significantly overrepresented in PSP patients (Baker *et al.*, 1999; Higgins *et al.*, 2000), and recently these results have been extended to CBD (Houlden *et al.*, 2001) (Table XV-11.2). The causal variation explaining this association is still unknown. These results suggest that PSP and CBD share a similar genetic cause. It is of interest that familial atypical PSP has been reported to be caused by homozygosity of an *MAPT* deletion at codon 296 located in the second tubulin-binding domain of the tau protein (Pastor *et al.*, 2001). No association between the extended *MAPT* haplotype was observed in a sample of patients with Pick's disease, a primary tauopathy in which predominantly three repeat tau accumulates in Pick bodies (Russ *et al.*, 2001).

Other Familial Frontotemporal Dementia Loci

A Danish FTD family lacking distinctive neuropathological features was linked to the centromeric region of chromosome 3 (MIM 600795) (Brown *et al.*, 1995) (Figure XV-11.1). Since this pedigree shows anticipation, an unstable trinucleotide expansion has been suggested as the genetic cause of FTD in this family (Ashworth *et al.*, 1999). Another family with clinical AD and neuritic plaques but no tangles (MIM 604154) was also mapped to a locus on chromosome 3 that was about 40 centimorgans (cM) more downstream from the marker, giving the highest lod score in the Danish FTD pedigree (MIM 604154) (Poduslo *et al.*, 1999) (Figure XV-11.1). The families are probably phenotypically and genetically distinct.

The combination of amyotrophic lateral sclerosis (ALS) and FTD is well known (Hudson, 1981; Neary *et al.*, 1990). Moreover, the presence of amyotrophy is a supportive diagnostic feature in the Lund and Manchester criteria for FTD (Lund and Manchester Groups, 1994). In a set of families in which people develop both ALS and FTD, linkage was found with markers on 9q21-22 (MIM 105550) (Hosler *et al.*, 2000) (Figure XV-11.1). This locus is distinct from the juvenile ALS locus on 9q34 (MIM 602433).

Genotype–Phenotype Correlations in FTDP-17

The principal clinical features in FTDP-17 families consist of behavioural, cognitive and motor disturbances, albeit with substantial variability within and between families (Foster *et al.*, 1997). In typical FTD, the disease is characterized by behavioural and personality changes involving disinhibition, stereotypy, antisocial acts and language disorders, leading to apathy, mutism and late neurological (frontal release or extrapyramidal) signs (Neary and Snowden, 1996). However, the spectrum of disease extends wider and comprises cases where severe parkinsonism or amyotrophy is the major disabling feature (Lynch *et al.*, 1994; Wszolek *et al.*, 1992; Spillantini *et al.*, 1997). The duration of disease in FTDP-17 families is highly variable; it usually lasts for 10 years, but it can be as short as 3 years and as long as 35 years (Foster *et al.*, 1997). In terms of duration and progression, the parkinsonism seen in FTDP-17 is generally more aggressive than that observed in Parkinson's disease but is similar to that in other extrapyramidal tauopathies, such as PSP and CBD, diagnoses that are also found within FTDP-17 families. This type of parkinsonism is also poorly responsive to dopaminergic therapy (Reed *et al.*, 2001).

Population Attribution

Several investigators have studied the contribution of *MAPT* mutations to the occurrence of FTD, and estimates vary widely among studies (Houlden *et al.*, 1999; Poorkaj *et al.*, 2001; Rizzu *et al.*, 1999). However, the percentage of *MAPT* mutations is consistently higher among FTD cases with a positive family history (10.5–43.0%) and tau-related neuropathological features (13.6–33.0%) compared with total FTD (5.9–17.8%), including both sporadic and familial patients with or without tau neuropathology. So far, no *MAPT* mutations have been detected in sporadic FTD patients, and in one study it was estimated that the occurrence of *MAPT* mutations in dementia in general is extremely rare (<0.2%) (Houlden *et al.*, 1999). In all studies, *MAPT* Pro301Leu was the most frequent mutation. It is of interest that for some FTDP-17 families, including one family with conclusive linkage to 17q21-22, no *MAPT* mutations have been found (Bird *et al.*, 1996; Froelich *et al.*, 1997; Heutink *et al.*, 1997; Lendon *et al.*, 1998), suggesting either the presence of another FTD gene on 17q21-22 or the existence of other unidentified *MAPT* mutations. Moreover, the relatively low *MAPT* mutation frequency in familial FTD, and the fact that 64% of FTD patients do not have tau pathology as shown by immunohistochemistry (Mann *et al.*, 2000), suggest that only a minority of FTD cases can be classified as tauopathies. Therefore, other FTD genes, as already suggested by the FTD loci on chromosomes 3 and 9, are to be expected.

PRION DISEASE

Transmissible spongiform encephalopathies (TSE) are subacute or chronic neurodegenerative disorders of humans and animals that are characterized neuropathologically by the classical triad of spongiosis, neuronal loss and reactive gliosis. In 1982, it was found that a proteinaceous infectious particle devoid of nucleic acid (prion) was the disease-causing agent of scrapie, a TSE of sheep and goats (Prusiner, 1982). In humans, around 85% of TSEs or prion diseases are sporadic and described clinically as CJD (MIM 123400). Familial prion disease, iatrogenic CJD and the bovine spongiform encephalopathy (BSE)-related variant CJD account for the remainder. Human prion disease has an estimated yearly incidence of 1/1 000 000/year (Haywood, 1997). The core clinical syndrome of classical sporadic CJD is a rapidly progressive (disease course of <6 months), generalized early-onset dementia, usually accompanied by myoclonus and periodic synchronized discharges in the electroencephalogram (EEG). More recently, it was shown that the presence of the 14-3-3 protein in the CSF significantly increases diagnostic accuracy (Zerr *et al.*, 2000).

Molecular Genetics

Chromosome 20: PRNP

Prion diseases are inherited in about 10% of cases and have been described under different names, including CJD, Gerstmann–Sträussler–Scheinker syndrome (GSS; MIM 137440) and fatal familial insomnia (FFI; MIM 600072). In 1989, the first disease-causing mutations in the gene encoding the prion protein (*PRNP*; MIM 176640) on chromosome 20 were described (Figure XV-11.1). The first report involved an insertion in *PRNP* (Owen *et al.*, 1989), shown later to comprise 144 bp encoding six extra octapeptide repeats in addition to the five present in normal prion protein (Owen *et al.*, 1990). The report of this insertion was followed quickly by several missense mutations (Hsiao *et al.*, 1989; Doh-ura *et al.*, 1989). Presently, more than 20 pathogenic *PRNP* mutations have been reported that can be subdivided into two groups: (1) point mutations within coding sequence, resulting in amino acid substitutions in the prion protein or, in one case, production of a stop codon resulting in truncated prion protein; (2) insertions encoding additional copies of an octapepetide repeat present in tandem array of five copies in the normal protein (Collinge, 1997) (Table XV-11.1). All inherited prion diseases are caused by *PRNP* mutations, suggesting no locus heterogeneity for this condition.

Genetic Susceptibility to Sporadic and Acquired Prion Diseases

In sporadic and acquired CJD, no *PRNP* mutations have been observed. However, homozygosity for a common *PRNP* polymorphism at codon 129, where either Met or Val can be encoded, is a key determinant in the genetic susceptibility in sporadic (Palmer *et al.*, 1991) and iatrogenic CJD (Collinge *et al.*, 1991) (Table XV-11.2). Also, all cases with the BSE-related variant CJD have been homozygous for the Met allele (Collinge *et al.*, 1996). In a recent multicentric study including 749 sporadic CJD patients, it was shown that the Val homozygous genotype is significantly more frequent in patients younger than 49 years compared with those aged 50 years and over (Alperovitch *et al.*, 1999). These Val homozygous patients are generally younger, have an atypical clinicopathological phenotype, and lack the typical EEG findings (Parchi *et al.*, 1996).

Genotype–Phenotype Correlations in Inherited Prion Disease

Generally, phenotypic expression of inherited prion disease is highly variable. However, symptoms, disease course and neuropathological findings usually fall within a broad spectrum defined by classical CJD (with dementia, a rapid course, and marked spongiform changes) and GSS (with cerebellar ataxia, a slow course, and multicentric amyloid plaques) at the extremes. Familial prion diseases tend to have an earlier age at onset and a more protracted course than sporadic CJD. Also, the typical EEG findings are often missing and the 14-3-3 protein in CSF is detected in only about one-half of the cases (Zerr *et al.*, 2000). It is important to note that even within the same family, the disease can present as, or mimick conditions like, EOAD, FTD, multiple sclerosis, CBD, GSS or CJD (Mallucci *et al.*, 1999). With the exception of FFI, most *PRNP* missense mutations are associated with CJD. The *PRNP* Glu200Lys is the most frequent cause of hereditary CJD, accounting for >70% of the families worldwide (Lee *et al.*, 1999). Unlike most inherited prion diseases, these cases present clinically with a rapidly progressive dementia (<12 months) with myoclonus and typical periodic sharp wave complexes on EEG reminiscent of sporadic CJD (Brown *et al.*, 1992). Prevalence of this mutation and hence CJD is particularly high in Slovakia, Chile and Italy, and among populations of Libyan and Tunisian Jews. Recent haplotype analysis suggests that at least four independent mutational events are responsible for the current geographic distribution of Glu200Lys related CJD (Lee *et al.*, 1999). The classical GSS presentation, on the other hand, is a chronic cerebellar ataxia accompanied by pyramidal features, with dementia occurring later. Neuropathologically, the disease is characterized by the presence of multicentric amyloid plaques. The first *PRNP* missense mutation (Pro102Leu) reported was described in two GSS families (Hsiao *et al.*, 1989). Other missense mutations also led to a GSS phenotype (Prusiner, 1993). Another *PRNP* mutation (Asp178Asn) is of particular interest because its phenotypic expression is modulated by the codon 129 polymorphism. When inherited together with a Met allele on the same haplotype, Asp178Asn results in FFI, a rapidly progressive disease characterized clinically by untreatable insomnia, dysautonomia, motor signs and prominent atrophy of the thalamic nuclei. However, when coupled with Val at codon 129, Asp178Asn results in familial CJD (Goldfarb *et al.*, 1992). The stop codon 145 mutation results in a vascular variant of prion disease with severe CAA (Ghetti *et al.*, 1996). Clinically, the patient with this mutation was diagnosed as having AD.

PRNP insertions of extra copies of an octapeptide coding repeat (normal = 5) are the second major type of *PRNP* mutations. These tend to give rise to a form of CJD with an earlier onset and a relatively slow progression (>1 year) (Goldfarb *et al.*, 1991). Interestingly, there seems to be a relationship between the number of inserted repeats and the disease presentation. Although exceptions can be found, the majority of patients with long insertions of more than four extra repeats display a long disease duration ranging between 2 and 18 years, whereas CJD associated with shorter insertions usually mimics the classical sporadic CJD course (Capellari *et al.*, 1997). Also, elongated prion protein deposits in the molecular layer of the cerebellum are a typical feature in *PRNP* insertion carriers. It was demonstrated that these elongated prion protein deposits are associated with four to seven extra repeats, whereas the larger plaques are present only in patients carrying eight or nine octapeptide repeats (Vital *et al.*, 1998).

OTHER MENDELIAN EARLY-ONSET DEMENTIAS

Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL; MIM 125310) is an inherited stroke syndrome that leads to dementia. The key features of the disorder are recurrent subcortical ischaemic events (85%), dementia

(40%), migraine with aura (20–30%), mood disturbances (20%) and diffuse white-matter abnormalities on neuroimaging (Bousser and Tournier-Lasserve 2001). CADASIL is characterized by an arteriopathy that affects mainly the small cerebral arteries and by prominent alterations of the vascular smooth muscle cells that ultimately disappear. Ultrastructural examination shows granular osmiophilic deposits located close to the membrane of the vascular smooth muscle cells in both cerebral and peripheral arteries, including skin arterioles (Ruchoux *et al.*, 1995). The disease was mapped to chromosome 19 in two families (Tournier-Lasserve *et al.*, 1993), and subsequent linkage analysis of 13 additional pedigrees revealed genetic homogeneity of the condition and allowed refinement of the locus to a 2 cM interval on 19p13.1 (Ducros *et al.*, 1996) (Figure XV-11.1). In 1996, it was found that CADASIL is caused by highly stereotyped missense mutations in the gene encoding the Notch3 receptor (*NOTCH3*; MIM 600276), predicted to result in either the gain or loss of a cysteine residue within one of the 34 epidermal growth factor repeats of the extracellular domain of the Notch3 receptor (Joutel *et al.*, 1996). It has been shown that in CADASIL brains, there is a dramatic and selective accumulation of the extracellular domain of the Notch3 receptor at the cytoplasmic membrane of the smooth muscle cells but not within the granular osmiophilic material (Joutel *et al.*, 2000a). Worldwide, more than 400 families have been reported since 1993, and a sporadic case with a *NOTCH3* mutation has been described suggesting that CADASIL might be more frequent than anticipated (Joutel *et al.*, 2000b) (Table XV-11.1).

Familial British Dementia and Familial Danish Dementia

Familial British dementia (FBD; MIM 176500), also called Worster-Drought syndrome, was first described in 1933 as a familial presenile dementia with spastic paraparesis and cerebellar ataxia (Worster-Drought *et al.*, 1933). The disease is transmitted as an autosomal dominant trait in a large family, and is characterized neuropathologically by the presence of prominent CAA and Alzheimer's disease-like neuritic and non-neuritic plaques and neurofibrillary tangles. By immunohistochemistry, however, the amyloid deposited is negative for antibodies directed to the classical β-amyloid of AD (Plant *et al.*, 1990). On MRI, the disease is manifest as deep white-matter lesions and lacunar infarcts (Mead *et al.*, 2000).

In 1999, a point mutation at the stop codon of a novel gene, *BRI* (MIM 603904), located on chromosome 13 was reported to cause FBD (Vidal *et al.*, 1999) (Figure XV-11.1). This mutation generates a longer open reading frame, resulting in a larger precursor protein of which the release of the 34 carboxy-terminal amino acids generates the British amyloid fibril ABri that is deposited in FBD brains. Another *BRI* mutation causes familial Danish dementia (FDD; MIM 117300), also known as heredopathia ophthalmo-oto-encephalica, characterized by cataracts, deafness, progressive ataxia, dementia and Alzheimer's disease-like neuropathology similar to FBD (Vidal *et al.*, 2000a). The FDD mutation is a ten-nucleotide duplication producing a frame shift in the *BRI* sequence, again generating a larger-than-normal precursor protein, of which the amyloid subunit (designated Danish amyloid or ADan) comprises the last 34 carboxy-terminal amino acids. By comparing FBD and FDD with AD, it is clear that different types of amyloid peptides can trigger similar neuropathological changes, leading to neuronal loss and dementia, suggesting that amyloid peptides are the primary event in the neurodegenerative process (Vidal *et al.*, 2000b).

Familial Encephalopathy with Neuroserpin Inclusion Bodies

In 1999, two Caucasian families living in the USA with autosomal dominant early-onset dementia were described (Davis *et al.*, 1999). In one family, the disease presented in the fifth decade with cognitive decline, including deficits in attention and concentration and impaired visuospatial skills. Memory was also impaired, albeit to a lesser extent than in AD. In the other family with an earlier onset around the second and third decades of life, the disease presented with both epilepsy and cognitive decline (Yerby *et al.*, 1986). The principal neuropathological finding in both families was the presence of eosinophilic neuronal inclusions, termed Collins bodies, in the cerebral cortex and many subcortical nuclei (Davis *et al.*, 1999). These inclusions were different from other intraneuronal inclusions, such as Pick bodies, Lewy bodies and Lafora bodies, and were composed primarily of a single protein, identified as neuroserpin. The disease was therefore called familial encephalopathy with neuroserpin inclusion bodies (FENIB; MIM 604218); in each family, a causative missense mutation in the gene encoding neuroserpin (*PI12*; MIM 602445) at 3q26 was identified (Figure XV-11.1; Table XV-11.1). However, in a French study, no mutations were found in a series of familial early-onset dementia, suggesting that *PI12* mutations are a rare cause of inherited dementia (French Alzheimer's Disease and Fronto-Temporal Dementia Genetics Study Groups, 2000).

Presenile Dementia with Bone Cysts

Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOSL; MIM 221770), also called Nasu–Hakola disease or presenile dementia with bone cysts, is a rare recessive disorder characterized by bone cysts restricted to ankles and wrists, followed by a combination of psychotic symptoms and progressing rapidly to presenile dementia of the FTD type. There is a long period between the early skeletal and the neuropsychiatric symptoms, which can be as long as 20 years. Most patients have been diagnosed in Finland and Japan, with an estimated population prevalence in Finland of $2/10^6$. Neuropathologically, the disease is characterized by frontally accentuated loss of myelin, astrocytic gliosis, calcifications and atrophy of the basal ganglia, atrophy of the corpus callosum, and thick-walled or obliterated small arterioles and capillaries. In 1998, the disease was mapped to 19q13 (Pekkarinen *et al.*, 1998), and recently two different loss-of-function mutations in the gene encoding TYRO protein tyrosine kinase binding protein (*TYROBP*; MIM 604142) were identified (Paloneva *et al.*, 2000) (Figure XV-11.1; Table XV-11.1). However, the molecular and cellular pathogenesis remains unknown.

GENETIC COUNSELLING AND TESTING

As described above, dementia in both its late-onset and early-onset forms is a disorder with a high genetic contribution. Therefore, asymptomatic relatives of demented patients often seek genetic advice about their own and their children's risks. Alternatively, molecular genetic testing is sometimes requested by clinicians as a differential diagnostic tool in patients presenting with cognitive symptoms. Regardless of the purpose (prediction or diagnosis), molecular genetic testing should not be performed without a thorough pedigree analysis, including careful determination of the age at onset of dementia in the affected family members.

Autosomal Dominant Dementia

When the dementia has an early onset and is clearly familial, pedigree analysis might reveal an inheritance pattern that is consistent with autosomal dominant transmission. However, in the absence of molecular genetic confirmation, counselling is often uncomfortable because of problems of insufficient family information, diagnostic uncertainty, and the possible confounding by phenocopies.

Therefore, molecular genetic screening might be requested in order to alter an individual's a priori risk of 50% to almost zero (mutation absent) or 100% (mutation present). Depending on the clinical or pathological diagnosis, genetic screening in an affected individual of the most frequently mutated familial dementia genes can be performed. At present, these include *APP*, *PSEN1*, *PSEN2*, *MAPT* and *PRNP*. If AD is the suspected diagnosis, then *APP*, *PSEN1* and *PSEN2* are the main candidates for screening. However, it is important to realize that a considerable proportion of autosomal dominant EOAD is not explained by any of these AD genes (see above). In such cases, but also justified by the high amount of genetic and phenotypic heterogeneity in familial dementia, screening of *MAPT* or *PRNP* should be considered. It is of interest in this context that in a recent study, *PRNP* mutations were found in three out of 16 familial early-onset dementia patients (19%), while *APP*, *PSEN1* and *PSEN2* together accounted for 37% of the cases (Finckh *et al.*, 2000). In this study, none of the *PRNP* mutation carriers were expected clinically to have inherited prion disease. Unfortunately, systematic studies on the relative contribution of *APP*, *PSEN1*, *PSEN2*, *MAPT* and *PRNP* mutations in familial early-onset dementia are presently unavailable. In case a causative mutation is found, presymptomatic predictive testing can be offered to at-risk family members. Presymptomatic testing for Huntington's disease is considered the paradigm for predictive testing in genetic disorders of adulthood and has shown the psychological importance of pretest and post-test genetic counselling (Meiser and Dunn, 2000; Wiggins *et al.*, 1992). Given the complex nature of such counselling, this should preferentially be carried out in a medical genetics centre by a multidisciplinary team.

A major problem contributing to the complexity of genetic counselling of familial dementia is the interpretation of a mutation as being causative or not causative. Clues to the causative nature of a mutation come from different angles, including location in a functionally important region of the protein, evidence of cosegregation of the mutation in the family, absence of the mutation in a large series of controls, and *in vitro* functional evidence that the mutation is pathogenic. An illustrative example of misinterpreting the pathogenic character of a mutation is the *PSEN1* Glu318Gly missense substitution. This mutation was reported by several investigators and interpreted as a causative mutation (Cruts *et al.*, 1998; Forsell *et al.*, 1998; Sandbrink *et al.*, 1996). However, we demonstrated later that the Glu318Gly carrier frequencies were similar in elderly nondemented controls (9/256; 4.1%) and demented individuals (13/390; 3.3%) and that this substitution had no *in vitro* effect on APP processing (Dermaut *et al.*, 1999). This study therefore demonstrated that *PSEN1* Glu318Gly is a rare benign polymorphism rather than a causative mutation, and emphasizes the need to be careful when assigning a pathological nature to *PSEN1* mutations, especially when they are reported in isolated cases or in the absence of conclusive evidence for cosegregation with the disease. In a presymptomatic testing programme, the burden of an incorrect molecular diagnosis should be prevented by all means.

Some authors have advocated genetic testing as a diagnostic tool in familial forms of dementia and emphasized its use in excluding the presence of treatable forms of dementia (Finckh *et al.*, 2000). However, given the low prevalence rates of autosomal dementias, the sometimes complex interpretation of genetic variations, and the untreatable character of these diseases, genetic testing is presently of limited use in clinical practice (Croes *et al.*, 2000).

Common Forms of Dementia

The identification of causative mutations for autosomal dominant dementia has probably overinflated the public's perception of the role of genes in causing the far more common forms of dementia like LOAD. Presently, only *APOE* is known to affect susceptibility to LOAD. However, as many people with *APOE*-ε4 alleles will never get AD and, conversely, many AD patients do not have *APOE*-ε4 alleles, the predictive value of *APOE* genotyping in asymptomatic individuals is of limited value (McConnell *et al.*, 1998). Therefore, genetic counselling can be performed only in the broadest terms. In general, it is probably safe to say that the risk for first-degree relatives of typical LOAD patients is three- to fourfold increased, resulting in an absolute risk of between one in five and one in six (Liddell *et al.*, 2001).

APOE genotyping has also been advocated by some as a diagnostic test. Although it was shown that *APOE* genotyping might increase diagnostic certainty when applied to people already diagnosed clinically with probable AD (Mayeux *et al.*, 1998), *APOE* genotyping alone can never establish a diagnosis of AD. As currently a patient's prognosis and treatment would not change based on the increased likelihood that the dementia is caused by AD or another cause of dementia, the use of *APOE* genotyping as a diagnostic tool should not be encouraged (McConnell *et al.*, 1998).

Gene–Environment Interactions in Cognitive Disorders

Kala M. Mehta and Kristine Yaffe

Gene–environment interactions are critical to understanding complex chronic disease processes, such as those involved in cognitive disorders. Genetic factors may increase the likelihood of a cognitive disorder developing. Environmental factors may also increase the risk of developing a cognitive disorder. However, neither genes nor environmental factors alone are sufficient to explain the development of these disorders. More likely, genes and environment interact to confer risk, e.g., an environmental factor may affect genetic predisposition by altering the time of onset, progression or the severity of disease. By studying gene–environment interactions, further advances can be made regarding the aetiology and possible treatment of cognitive disorders.

PREVALENCE OF COGNITIVE DISORDERS AND DEMENTIA

Cognitive disorders in the elderly range from mild cognitive deficits to severe dementia (Petersen, 2000). Worldwide incidence of dementia increases steeply with age: for people aged 60–64 years, the incidence is 0.8–4.0 per 1000 person-years, but in people over 95 years, it is 50–136 per 1000 person-years (Fratiglioni *et al.*, 1999). The most common forms of dementia are Alzheimer's disease and vascular dementia, accounting for 50–70% and 20–30% of all dementia patients, respectively (Plassman and Breitner, 1996).

Most of the research concerning the aetiology, genetics and environmental risk factors in cognitive disorders in the elderly has focused on Alzheimer's disease (Mayeux, 1998). Alzheimer's disease has two patterns of inheritance: familial and sporadic. The familial form tends to be inherited via autosomal dominance, can have a more severe course, and typically has an onset before age 65 years. This form of Alzheimer's disease accounts for less than 5% of all cases. The sporadic form of Alzheimer's disease tends to have a more diverse genetic aetiology, with a more gradual course, and often has an onset after age 65 years (National Institute on Aging National Institutes of Health, 1999). The past decade has seen tremendous advances in the genetics of both forms of Alzheimer's disease.

REVIEW OF ALZHEIMER'S DISEASE MOLECULAR BIOLOGY AND GENETICS

Senile plaques and neurofibrillary tangles are the two pathological brain lesions found in Alzheimer's disease. Neurofibrillary tangles are comprised of microtubule-associated proteins, tau. Hyperphosphorylation of tau by kinases leads to disassociation of microtubules and subsequent aggregation into filaments. The senile plaques consist of extracellular deposits of amyloid β protein (Aβ). Aβ comes in two forms, Aβ_{40} and Aβ_{42}, the latter of which is more hydrophobic and prone to aggregation. A higher ratio of Aβ_{42}/Aβ_{40} is thought to lead to greater plaque deposition. Aβ is derived from the amyloid precursor protein (APP). APP is a single transmembrane polypeptide, common to neurons and other cells such as astrocytes, microglia, endothelial and smooth-muscle cells. Aβ is formed when APP is cleaved sequentially by secretases. When APP is cleaved by a β-secretase, a 99-residue fragment is formed. The 99-residue fragment can be cleaved by a γ-secretase resulting in either Aβ_{40} or Aβ_{42} (Selkoe, 2001). At least three known autosomal dominant gene mutations are involved in Alzheimer's disease: APP on chromosome 21, Presenilin-1 (PSEN1) on chromosome 14, and Presenilin 2 (PSEN2) on chromosome 1 (Table XV-12.1). APP, PSEN1 and PSEN2 all alter APP processing, producing more Aβ_{42} than Aβ_{40} (Hardy, 1997).

Apolipoprotein E allele ε4 (APOE-ε4) on chromosome 19 is a genetic risk factor for the sporadic form of Alzheimer's disease. The APOE locus has three common alleles, ε2, ε3 and ε4. The ε4 allele has consistently been found to predispose individuals to Alzheimer's disease, with increasing allele-dose risk per ε4 allele (Corder *et al.*, 1993; Saunders *et al.*, 1993; Strittmatter *et al.*, 1993). It is different from the three familial gene mutations in that it increases the likelihood that a person will develop Alzheimer's disease in people aged over 65 years, but it is not conveyed by a dominant pattern of inheritance. APOE contributes approximately 50–70% to sporadic Alzheimer's disease risk; other susceptibility genes or environmental factors may account for the remainder (Pericak-Vance *et al.*, 2000). APOE may also increase the risk of developing other cognitive disorders, such as preclinical cognitive impairment (Hyman *et al.*, 1996; Yaffe *et al.*, 1997), vascular dementia (Skoog *et al.*, 1998), and dementia associated with neuromuscular diseases (Bedlack *et al.*, 2000). There are two main hypotheses for APOE ε4's effects on the increased risk of developing Alzheimer's disease: either ε4 increases the aggregation of Aβ into fibrils found in plaques, or APOE-ε4 helps with

Table XV-12.1 Genetic factors involved in Alzheimer's disease

Factor	Chromosome
Autosomal dominant genes	
β-Amyloid precursor protein	21
Presenilin-1	14
Presenilin-2	1
Genetic risk factors	
Apolipoprotein E allele ε4	19
Alpha-2-macroglobulin	12
Low-density lipoprotein-related protein 1	12

deposition or clearance of Aβ (probably Aβ_{40}). Both of these pathways could result in increased numbers of senile plaques.

Other recent genetic factors that may be involved in sporadic Alzheimer's disease include alpha-2 macroglobulin (A2M), a potent pan-protease inhibitor, and low-density lipoprotein-related protein 1 (LRP-1), a multifunctional receptor. A2M may also be associated with the accumulation of Aβ in senile plaques. As LRP-1 is a multifunctional receptor and binds three important Alzheimer's disease-related proteins (APOE, APP and A2M), it may increase the risk by a common neurogenetic pathway affecting senile plaque deposition or other molecular processes involved in Alzheimer's disease.

ENVIRONMENTAL FACTORS ASSOCIATED WITH THE RISK OF ALZHEIMER'S DISEASE AND EXAMPLES OF GENE–ENVIRONMENT INTERACTIONS

Identifying environmental risk factors and how they are involved in the risk of developing Alzheimer's disease is important because this could lead to interventions and possibly a reduction in disease prevalence. Most of the environmental factors that are associated with the risk of developing Alzheimer's disease can be categorized into three subgroups: medications or supplements, atherosclerotic risk factors or lifestyle factors (Table XV-12.2). A hypothetical scenario of how genes and environmental factors may act together to confer earlier cognitive impairment is depicted in Figure XV-12.1. Since the sporadic form of Alzheimer's disease affects far more people than the familial form, and the APOE-ε4 allele is a genetic risk factor for the sporadic form of Alzheimer's disease, much of the research has focused on APOE-ε4–environment interaction.

Medications or Supplements

Based on observational studies and biological plausibility, several medications and supplements have been investigated as having an effect on the risk of developing Alzheimer's disease. The three most studied medications are oestrogen, anti-inflammatory agents, and antioxidants.

Oestrogen supplementation may be an important contributor to cognitive health. Several potential mechanisms of action have been suggested (Yaffe *et al.*, 1998). Oestrogen may affect Aβ deposition through neurotransmitter modulation, specifically acetylcholine, serotonin and monoamine oxidase. Alternatively, oestrogen may have a direct effect on neurons through either synaptic regulation or dendritic sprouting, or oestrogen may have a positive effect on cognition via a positive effect on lipids. Some studies on oestrogen in nondemented elderly women support the idea that oestrogen improves cognition (Jacobs *et al.*, 1998), but other studies have not shown this effect (Barrett-Connor and Kritz-Silverstein, 1993). A recent multicentre trial in community-dwelling women suggests that using a selective oestrogen receptor modulator, raloxifene, has no positive or negative effect on cognitive function over 3 years (Yaffe *et al.*, 2001b). Oestrogen has also been studied as a potential treatment for Alzheimer's disease, with some trials, mostly uncontrolled, showing a beneficial effect (Honjo *et al.*, 1989; Asthana *et al.*, 1999; Ohkura *et al.*, 1994; Ohkura *et al.*, 1995), but more recent controlled trials not showing a positive effect of oestrogen on Alzheimer's disease (Wang *et al.*, 2000; Mulnard *et al.*, 2000; Henderson *et al.*, 2000). Observational studies of oestrogen as a potential preventive agent for Alzheimer's disease have mostly reported that oestrogen does decrease the risk of developing Alzheimer's disease (Kawas *et al.*, 1997; Tang *et al.*, 1996a; Paganini-Hill and Henderson, 1994), but there are some exceptions (Brenner *et al.*, 1994; Graves *et al.*, 1990b). Results from four ongoing primary prevention trials will extend the understanding of whether oestrogen may be used for the prevention of Alzheimer's disease.

A recent study of over 2700 women found that the effect of current oestrogen use on cognitive decline varies by APOE-ε4 allele status (Yaffe *et al.*, 2000). Women who did not have an ε4 allele had

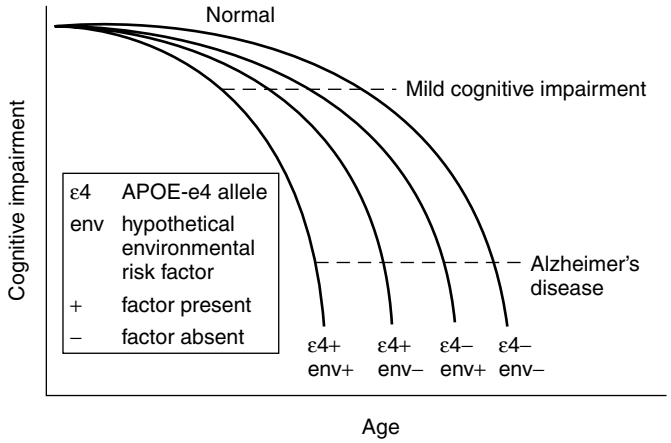

Figure XV-12.1 Trajectory of cognitive impairment by APOE-ε4 allele status, a hypothetical environmental risk factor and age

Table XV-12.2 Environmental risk factors associated with Alzheimer's disease

	Strength of evidence[†]	Gene Interaction
Medication and supplements		
Oestrogen replacement	Decrease risk (+)	(+)
Anti-inflammatory agents (e.g., NSAIDs)	Decrease risk (++)	
Antioxidants (e.g., vitamin E)	Decrease risk (+)	
Atherosclerotic risk factors		
Hypertension	Increase risk (+)	(+)
Lipids	Increase risk (+/−)	(+/−)
Diabetes	Increase risk (+/−)	(+/−)
Homocysteine	Increase frequency	
Lifestyle factors		
Smoking	Increase risk (+)	(+/−)
Moderate alcohol consumption	Decrease risk (+)	(+/−)
Physical activity	Decrease risk (+)	(+)
< 8 years of education	Increase risk (+++)	
Intellectual activity	Decrease risk (+/−)	
Moderate or severe head injury	Increase risk (++)	(+)

NSAID, non-steroidal anti-inflammatory drug.

[†] *Convincing* (+++): epidemiological studies show consistent associations, with little or no evidence to the contrary.
Probable (++): epidemiological studies showing associations are either not so consistent, with a number and/or proportion of studies not supporting the association, or else the number or type of studies is not extensive enough to make a more definite judgement; mechanistic and laboratory evidence are usually supportive or strongly supportive.
Possible (+): epidemiological studies are generally supportive, but are limited in quantity, quality or consistency. There may or may not be supportive mechanistic or laboratory evidence. Alternatively, there are few or no epidemiological data, but strongly supportive evidence from other disciplines.
Insufficient (+/−): there are only a few studies, which are generally consistent, but really do no more than hint at a possible relationship; often, more well-designed research is needed.

a 40% lower risk of developing cognitive impairment associated with oestrogen use, whereas women who were $\varepsilon 4$ positive did not obtain a protective effect from oestrogen (Figure XV-12.2). This study supports the hypothesis that the environmental factor (oestrogen replacement) affects risk of cognitive impairment and that it varies by genetic profile (APOE). Since the $\varepsilon 4$-positive women in this study had greater internal carotid wall thickness than $\varepsilon 4$-negative women, and this varied by oestrogen use as well, a potential mechanism of oestrogen's effect on cognitive impairment could be via carotid atherosclerosis.

Inflammation may be related to Alzheimer's disease pathology either as a primary or secondary process, since Aβ plaques are associated with inflammation with resultant increases in cytokines, such as interleukin 1β, interleukin-6 and tumour necrosis factor. Anti-inflammatory agents potentially could decrease Alzheimer's disease severity by altering the disease's inflammatory response. A meta-analysis of 17 observational studies found that non-steroidal anti-inflammatory drugs (NSAIDs) may decrease the development of Alzheimer's disease by 30–50% (McGeer *et al.*, 1996). Few studies have investigated the NSAIDs–gene interaction on cognitive decline or Alzheimer's disease. One study showed a decreased occurrence of Alzheimer's disease associated with NSAIDs in people with and without APOE-$\varepsilon 4$ (Anthony *et al.*, 2000). Further work on the interaction between the APOE-$\varepsilon 4$ allele and anti-inflammatory agents is needed. A form of NSAID that selectively binds the cyclooxygenase-2 (COX-2) receptor is of particular interest. Because COX-2 inhibitors bind receptors more selectively and cause fewer side effects than other NSAIDs, they may be useful for treating or preventing Alzheimer's disease (McGeer, 2000). An ongoing primary prevention trial will compare an NSAID (ibuprofen), a COX-2-selective agent (celecoxib) and placebo in 2625 older dementia-free subjects with a family history of Alzheimer's disease. The results of this trial will further the understanding of the effect of NSAIDs on the prevention of Alzheimer's disease.

Antioxidants, such as vitamins E and C, have various health benefits and may be beneficial to cognitive health. Vitamin E may prevent or help treat Alzheimer's disease by reducing oxidative stress (Smith *et al.*, 2000). Some observational studies have investigated the association between high doses of vitamin E and the risk of developing Alzheimer's disease, showing a lower incidence of Alzheimer's disease in vitamin E users (Morris *et al.*, 1998). One clinical trial investigated the effects of alpha-tocopherol (vitamin E, 2000 IU per day), a selective monoamine oxidase inhibitor (selegiline, 10 mg per day), and a placebo in patients with moderate to severe Alzheimer's disease (Sano *et al.*, 1997). Both vitamin E and selegiline were associated with fewer adverse outcomes, such as nursing home placement, compared with the placebo, but there were no differences on cognitive test scores. Although preliminary basic science studies have suggested differential oxidative effects by APOE allele type (Ramassamy *et al.*, 2001; Veinbergs *et al.*, 2000), no population-based studies have investigated the effects of vitamin E or other antioxidants according to the APOE allele.

Summary

Oestrogen, NSAIDs and antioxidants potentially decrease the risk of developing Alzheimer's disease. The oestrogen use–Alzheimer's disease relationship varies by APOE-$\varepsilon 4$ presence, suggesting an interaction. Whether an interaction exists between NSAIDs or antioxidants and APOE-$\varepsilon 4$ remains to be investigated.

Atherosclerotic Risk Factors

Atherosclerotic risk factors, such as hypertension and diabetes mellitus, are known to be associated with vascular disease, such as coronary artery disease, stroke and vascular dementia. Vascular pathology often coexists with Alzheimer's disease pathology, so the relationship between atherosclerotic risk factors and Alzheimer's disease is of growing interest. It is clear that atherosclerotic risk factors play a large role in both diseases and therefore are important in preserving cognitive health.

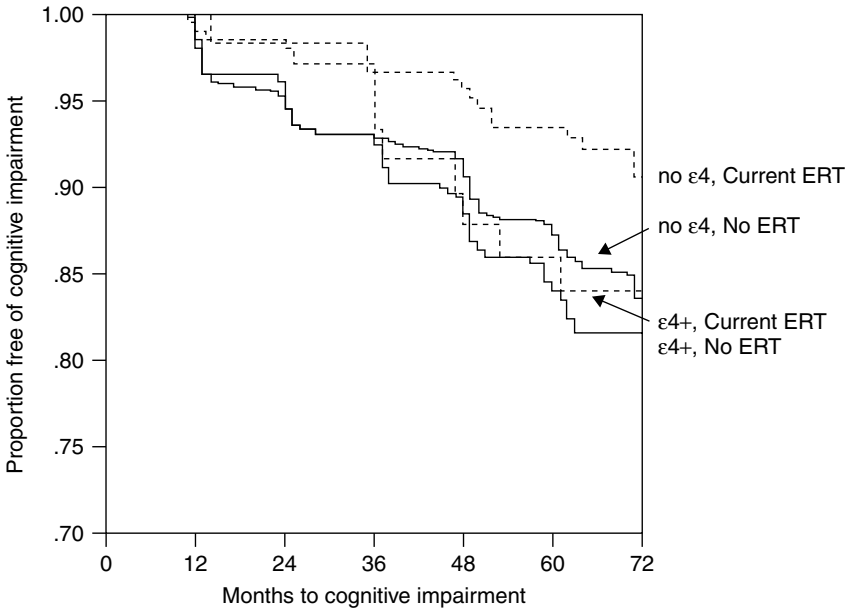

Figure XV-12.2 Time to cognitive impairment (modified mini-mental score <80) according to APOE-$\varepsilon 4$ status and baseline oestrogen use after adjusting for age, education, race and stroke history. Reproduced from Yaffe, K., Haan, M., Byers, A., Tangen, C. and Kuller, L., 2000. Estrogen use, APOE, and cognitive decline: evidence of gene–environment interaction. *Neurology*, 54, 1949–1954 Figure 1 by permission of Lippincott Williams & Wilkins

Elevated systolic blood pressure (SBP) and diastolic blood pressure (DBP) are known risk factors for stroke and are associated with central nervous system vascular changes, such as small-vessel disease and white-matter hyperintensities seen on brain imaging (Schoenberg, 1979; Ketonen, 1998). The hypertension–Alzheimer's disease relationship is less well understood. Several longitudinal studies suggest that SBP and DBP are correlated negatively with cognition after a 12–15-year follow-up (Elias *et al.*, 1993; Skoog *et al.*, 1996) and a 25-year follow-up (Launer *et al.*, 1995). It is possible that a J-shaped relation exists between blood pressure and Alzheimer's disease, similar to coronary artery disease, in which low blood pressure increases the risk of Alzheimer's disease slightly and high blood pressure increases the risk much more, relative to pressures within the normal range. In one study, people with either the APOE-ε4 allele or with low ankle–arm blood pressure declined about three times as much as people with neither risk factor, whereas people with both low ankle–arm blood pressure and the ε4 allele were eight times as likely to decline, suggesting a gene–atherosclerosis risk factor interaction (Haan *et al.*, 1999).

Since APOE-ε4 increases susceptibility for Alzheimer's disease and is related directly to lipid metabolism (increases in serum total cholesterol and low-density lipoproteins), serum lipid levels may be associated with Alzheimer's disease. The few studies on the relationship between total cholesterol levels and Alzheimer's disease are inconclusive. Both high total cholesterol (Evans *et al.*, 2000; Notkola *et al.*, 1998) and high intake of fat (Kalmijn *et al.*, 1997) were associated with Alzheimer's disease in some studies but not in others (Breteler, 2000). APOE-ε4 may modify the relationship between total cholesterol and Alzheimer's disease risk, as suggested in two studies where total cholesterol levels were found to be higher in Caucasian people with the ε4 allele (Jarvik *et al.*, 1995) and Chinese people with the ε4 allele (Liu *et al.*, 1999). In African-American and in Finnish cohorts, increased total cholesterol, independent of ε4 allele, was associated with increased Alzheimer's disease risk, suggesting an alternative mechanism (Evans *et al.*, 2000; Notkola *et al.*, 1998). Further studies in diverse racial groups are needed to increase the understanding of APOE-ε4 and total cholesterol. As the LRP receptor also binds to cholesterol, further investigation of APOE-ε4, cholesterol and LRP receptor is warranted.

Studies are conflicting regarding diabetes and Alzheimer's disease. One case–control and several longitudinal studies have shown a positive association between diabetes mellitus and cognitive impairment, with up to a two-fold increased risk of developing Alzheimer's disease (Leibson *et al.*, 1997; Ott *et al.*, 1999) or cognitive impairment (Gregg *et al.*, 2000). Several other studies have shown an inverse association between diabetes and risk of Alzheimer's disease (Bucht *et al.*, 1983; Launer *et al.*, 1995; Landin *et al.*, 1993). Studies vary regarding the relationship between diabetes, APOE-ε4 and Alzheimer's disease. In one study, diabetics with dementia had low frequency of the ε4 allele as compared with non-diabetics with dementia (Nielson *et al.*, 1996). In another study, participants who had an ε4 allele and diabetes mellitus declined 1.7 times more on cognitive tests than participants with neither risk factor. However, people with ε4 alone or diabetes alone declined three times and two times worse, respectively (Haan *et al.*, 1999). This suggests that diabetes may increase the risk of Alzheimer's disease in people who do not have a strong genetic disposition, or that an increased risk of Alzheimer's disease cannot be detected in people with diabetes and ε4 due to inadequate sensitivity of instruments. Further studies are needed to elucidate whether diabetes is associated with the risk of developing Alzheimer's disease, and, if so, whether it is modified by APOE-ε4 status.

Hyperhomocysteinaemia increases the likelihood of cardiovascular, peripheral vascular and cerebrovascular disease (Refsum *et al.*, 1998). Higher levels of homocysteine have been found more frequently in Alzheimer's disease patients compared with controls (Clarke *et al.*, 1998), and were associated inversely with cognitive function (Kalmijn *et al.*, 1999). More work on homocysteine is needed to determine its association with Alzheimer's disease and its interaction with APOE-ε4 and other genetic markers.

Most of the published gene–environment studies have focused on APOE-ε4. However, other genetic factors, such as presenilins, alpha-2 macroglobulin and the low-density lipoprotein-related protein 1 receptor, may interact with atherosclerotic risk factors and further study is needed.

Summary

Atherosclerotic risk factors such as hypertension, total cholesterol and diabetes increase the risk of cognitive impairment and may also be similarly associated with developing Alzheimer's disease. Hypertension has the strongest evidence for a gene–environment interaction with APOE-ε4. Results differ as to whether a gene–environment interaction exists between either cholesterol or diabetes and APOE-ε4. Further studies on atherosclerotic risk factor–gene interactions are warranted.

Lifestyle Factors

Several early studies suggested that smoking is a protective factor for cognitive impairment (Letenneur *et al.*, 1994) and Alzheimer's disease (van Duijn and Hofman, 1991; van Duijn *et al.*, 1995; Brenner *et al.*, 1993; Lee, 1994; Graves *et al.*, 1991). More recent studies with stronger methodology suggest that smoking either has no effect (Doll *et al.*, 2000) or increases the risk of Alzheimer's disease (Launer *et al.*, 1999). Indeed, several mechanisms might explain an association between smoking and a greater likelihood of cognitive decline (Lee, 1994). Smoking is a well-known risk factor for cerebrovascular disease, and smoking may be directly neurotoxic and cause oxidative damage to neurons (Linert *et al.*, 1999). Finally, smoking may promote the deposition of APP into amyloid (Plaschke *et al.*, 1997). Few studies have examined the effects of smoking on cognitive decline by APOE-ε4 status. One study found up to a 75% reduction in risk in smokers with an ε4 allele, consistent with the early reports of a protective effect (van Duijn *et al.*, 1995). More recent population-based studies have reported the opposite, suggesting that smokers who do not have the ε4 allele are up to four times as likely to get Alzheimer's disease compared with nonsmokers, whereas smokers with the ε4 allele are not at any greater risk than nonsmokers with ε4 (Ott *et al.*, 1998; Merchant *et al.*, 1999). In contrast, smokers with ε4 are at significantly greater risk of coronary heart disease compared with nonsmokers with ε4. (Humphries *et al.*, 2001) The modification of APOE-ε4–Alzheimer's disease risk by smoking may be due to selection bias, such that participants who were smokers and had ε4 were more likely to die. Two alternative explanations are that the increased risk of Alzheimer's disease cannot be detected in smokers with an ε4 allele due to inadequate sensitivity of instruments, or that smoking may act through a vascular mechanism on Alzheimer's disease risk, independent of the APOE-ε4-related vascular mechanisms.

A longitudinal study on moderate alcohol consumption and risk of Alzheimer's disease was conducted in Bordeaux, France (Orgogozo *et al.*, 1997). Moderate wine consumption lowered the risk of Alzheimer's disease by 75% compared with nondrinkers, but other studies have not confirmed this finding (Graves *et al.*, 1991; Elwood *et al.*, 1999). Smoking may have confounded the alcohol–Alzheimer's disease relation in the French study (Hebert *et al.*, 1992; Leibovici *et al.*, 1999), or the result may have been obtained due to the sampling strategy. Alcohol consumption may act through several mechanisms to affect the risk of Alzheimer's disease, such

as reducing cardiovascular risk factors, inhibiting platelet aggregation, altering serum lipid profile, or directly affecting acetylcholine release, in turn facilitating learning and memory. The association between moderate alcohol consumption and Alzheimer's disease may be mediated by APOE allele status, as suggested by one study in which the protective effect of alcohol was stronger in people with the ε4 allele (Carmelli *et al.*, 1999). Another study found the opposite, i.e., that people who drank moderately and had the ε4 allele had a lower risk of Alzheimer's disease compared with moderate drinkers without the ε4 allele (Dufouil *et al.*, 2000). These conflicting results highlight the need for more investigation of alcohol consumption, APOE and Alzheimer's disease.

Physical activity has several positive health benefits, including lowering the risk for coronary artery disease, stroke and diabetes. For Alzheimer's disease, physical activity has shown a positive effect in some studies but not others (Yaffe *et al.*, 2001a; Laurin *et al.*, 2001; Schuit *et al.*, 2001; Broe *et al.*, 1998). The one study that has examined physical activity by APOE-ε4 status suggests that people with both ε4 and who perform less than 1 hour of physical activity per week have an increased risk of cognitive decline as compared with people who have ε4 and who engage in more than 1 hour of physical activity per week, suggesting that physical activity may modify the risk of APOE-ε4 on cognitive decline (Schuit *et al.*, 2001). It remains to be seen whether the positive effects of physical activity on cognitive health are replicated, and whether physical activity interacts with other genetic risk factors.

Low educational level is an established risk factor for Alzheimer's disease (Katzman, 1993). Specifically, less than 8 years of education is associated with at least double the increased risk of Alzheimer's disease in Western societies. Potential explanations for the education–Alzheimer's disease relationship include: (1) education is a proxy marker for better socioeconomic, nutrition or housing status, which in turn are associated with decreased risk of Alzheimer's disease; (2) people with higher education might have more brain capacity, which buffers them against later cognitive decline; (3) education and intellectual stimulation could promote brain development, neuronal connectivity, or increased cerebral blood flow (Deary and Caryl, 1997; Stern *et al.*, 1995; Friedland, 1994). Studies indicate that higher performance on intelligence tests is associated inversely with Alzheimer's disease. In one study, army recruits' intelligence scores were measured on the Army General Classification Test early in life and their scores used to predict cognitive function in late life (Plassman *et al.*, 1995). Similarly, in a study of nuns, linguistic ability early in life was inversely proportional to severity of Alzheimer's disease pathology in the neocortex (Snowdon *et al.*, 2000). Whether the effect of intellect or education on Alzheimer's disease varies by APOE status or other genes warrants further investigation.

Head injury has been studied as one of the environmental risks of developing Alzheimer's disease (Mortimer *et al.*, 1985). Insults to the rodent brain may potentiate beta-amyloid neurotoxicity (Smith *et al.*, 1998). In humans, amyloid deposition subsequent to head trauma may represent a milder version of the diffuse Aβ plaques seen in boxers (Clinton *et al.*, 1991). Epidemiological studies conducted to investigate the head injury–Alzheimer's disease relation have had conflicting results. Some studies report up to a ten-fold increased risk of Alzheimer's disease associated with head injury (Mortimer *et al.*, 1991; Graves *et al.*, 1990a; Molgaard *et al.*, 1990; Rasmusson *et al.*, 1995; Mayeux *et al.*, 1993), but other studies show no association between head injury and Alzheimer's disease (Brayne, 1991; Chandra *et al.*, 1987; Chandra *et al.*, 1989; Salib and Hillier, 1997; van Duijn and Hofman, 1992). Factors that underlie these discrepant results include study design, criteria of both head trauma and Alzheimer's disease, and differential survival in head injured and non-injured groups. People with a history of head trauma had earlier symptom onset of Alzheimer's disease compared with people without head trauma in two studies (Nemetz *et al.*, 1999; Schofield *et al.*, 1997). With respect to the APOE–head injury relationship, some studies indicate an additive relation (Katzman *et al.*, 1996), others a synergistic relation (Tang *et al.*, 1996b), and others no relation at all (Mehta *et al.*, 1999). The differences in the studies on gene–head trauma interaction may be explained by reporting bias or by varying degrees of head trauma severity. In one study using documented military head injuries (Plassman *et al.*, 2000), mild head injury was not associated with Alzheimer's disease, whereas moderate head injury doubled the risk and severe head injury quadrupled the risk when compared with non-head-injured individuals. With respect to APOE-ε4, people with any degree of head injury and who were homozygous for the ε4 allele had four times the risk, ε4 heterozygotes had 1.5 times the risk, and no ε4 alleles had no increased risk, compared with people with neither risk factor. These findings, coupled with prior reports, suggest that moderate or severe head injury, but not mild head injury, increases the risk of developing Alzheimer's disease, especially in people with APOE-ε4.

Summary

Lifestyle factors such as having fewer than 8 years of education or a history of moderate head injury sharply increases the risk of developing Alzheimer's disease. Smoking slightly increases the risk of developing Alzheimer's disease, whereas moderate alcohol consumption and physical activity seem to decrease the risk of developing Alzheimer's disease. Moderate to severe head injury has the strongest evidence of a gene–lifestyle factor interaction, followed by preliminary evidence of a physical activity–gene interaction. Whether a lifestyle factor–gene interaction exists for either moderate alcohol consumption or smoking will require further study, as the evidence thus far differs. Similarly, the association of education or intellectual activity and genes on Alzheimer's disease warrants further investigation.

INCIDENCE AND PREVALENCE OF ALZHEIMER'S DISEASE BY ETHNICITY AND APOE-ε4 ALLELE STATUS

The incidence and prevalence of Alzheimer's disease are not consistent across different ethnic groups. Potential explanations for this variation could be due to study methodology, presence of environmental risk factors, or variance in susceptibility allele frequency. Studies in Caucasians indicate a gene–dose risk of ε4 allele presence on the risk of Alzheimer's disease with approximately a three-fold increased risk for heterozygous ε4 allele and a 15-fold increase for homozygous ε4 alleles (ε4/ε4) (Farrer *et al.*, 1997). In Japanese people, gene–dose risk is more robust, with up to a 43-fold increase for ε4/ε4 (Yoshizawa *et al.*, 1994). However, in Hispanic and African-American people, the gene–dose risk is weaker, despite similar cumulative incidence and familial aggregation across racial groups (Tang *et al.*, 1998; Devi *et al.*, 2000), suggesting either environmental determinants or other genetic determinants of Alzheimer's disease risk in these groups. Two recent cross-cultural studies comparing ethnic Japanese people in Japan, Hawaii and Washington state and ethnic African people in Yoruba and America show that the proportion of Alzheimer's disease to vascular dementia in each ethnic group decreases according to westernization (Shadlen *et al.*, 2000; Hendrie *et al.*, 2001). Although a likely explanation for this shift is the increasing vascular risk factors present in Western lifestyles, unidentified genetic causes could also play a role through genetic drift. Further studies to investigate the complex interaction between genetic predisposition and environmental triggers are necessary to explain the differences found in different ethnic groups.

Monozygotic and dizygotic twin pairs have been used to study gene–environment influences in Alzheimer's disease. Some studies have quantified the genetic contribution to Alzheimer's disease in twins, suggesting that hereditary factors may contribute approximately 60–80% of Alzheimer's disease risk (Bergem *et al.*, 1997; Gatz *et al.*, 1997). Others suggest that genes contribute 37% and common environmental factors contribute 35% of the risk (Meyer and Breitner, 1998). The first two studies suggest that genetics strongly influence the risk of developing Alzheimer's disease, with a simple heritability of about 0.83–0.84. The latter study, which has a simple heritability of 0.28, suggests the opposite, i.e., that genes and environment contribute almost equally to developing Alzheimer's disease. As the first two studies had longer follow-ups than the latter study, further studies in twins with long follow-up times and that examine multiple environmental risk factors are needed.

SUMMARY

The elucidation of genetic risk factors, environmental risk factors, and gene–environment interactions that put people at either substantially higher or lower risk for developing cognitive disorders may lead to efforts that can preserve cognitive health. For example, as individuals with $\varepsilon 4$ are at greater risk for developing Alzheimer's disease, interventions to preserve cognitive health in these patients could include increasing physical activity, smoking cessation or maintaining a low to moderate level of alcohol intake, as well as administration of currently available therapeutic agents.

Future studies may examine potentially protective agents and evaluate their potential harms. For example, if vitamin E is determined to have a protective effect against developing cognitive decline and has low side effects, then providing vitamin E supplements and public education for elderly people or those at risk could lower the prevalence of Alzheimer's disease. Whether this is true for people with the $\varepsilon 4$ allele remains to be seen. As knowledge of protective agents increases, clinical practice guidelines will change to include safe and effective protective strategies.

Gene–environment interactions will also need to be studied in non-Alzheimer's disease cognitive disorders, such as preclinical cognitive impairment and vascular dementia. More specifically, APOE and the other genetic risk factors under investigation for Alzheimer's disease may play a role in both mild cognitive impairment and vascular dementia. Future studies addressing gene–environment interactions in cognitive disorders will need to call on closer collaboration between interdisciplinary researchers. Molecular biologists and geneticists investigating genes will have to work more closely with clinical researchers and epidemiologists studying environmental risk factors. In addition, statisticians will need to be involved in modelling gene–environment interactions in cognitive disorders, to aid in predicting an individual's likelihood of disease. The complex nature of cognitive disorders will require innovative and collaborative research involving gene–environment interactions before cures for these diseases are found.

Review of Gender Issues and Oestrogen Replacement in Common Cognitive Disorders

John Stirling Meyer and Yan-Sheng Li

INTRODUCTION

Differences in brain structure and function between men and women are believed to result from gender differences in exposure to sex hormones during foetal life. Although there are no significant sex differences in global cognitive functioning, some gender differences in specific cognitive abilities have been reported. For example, men excel in spatial orientation and some quantitative abilities, particularly in gross motor strength, whereas women excel in verbal abilities, perceptual speed and accuracy, and fine motor skills. Gender differences also exist for cognitive disorders, particularly for dementia of Alzheimer type (DAT) and vascular dementia (VAD). Generally, women have a higher prevalence and incidence of DAT, while men have a higher prevalence of VAD, with symptoms beginning at a younger age (Jorm *et al.*, 1987; Jorm and Jolley, 1998; Fratiglioni *et al.*, 1997; Fratiglioni *et al.*, 2000; Lobo *et al.*, 2000).

GENDER DIFFERENCES IN ALZHEIMER'S DISEASE

Clinical and Epidemiological Studies

Epidemiological investigations from northern America, Europe and Asia have reported gender differences in the prevalence rates of DAT, especially older women exhibiting higher prevalence rates with female to male ratios between 1.5 : 1 and 3 : 1 (Jorm *et al.*, 1987; Lobo *et al.*, 2000; Skoog *et al.*, 1993; Hofman *et al.*, 1991; Zhang *et al.*, 1990). With regard to age-specific prevalence rates, combining the results of 22 prevalence studies between 1945 and 1985, no age-adjusted gender differences for prevalence of dementia were found, but analysis of the type of dementia showed higher rates of DAT for women (Jorm *et al.*, 1987). The Framingham Study displayed higher age-specific prevalences for both dementia and DAT in women older than 75 years (Bachman *et al.*, 1993).

A longitudinal study of 987 subjects aged 75 years or older in Stockholm indicated that women had higher incidence rates than men for both dementia and DAT (Fratiglioni *et al.*, 1997). A meta-analysis study demonstrated modest gender differences for DAT incidence rates, and the odds ratio for women developing DAT relative to men was 1.56 (Gao *et al.*, 1998). Collaborative studies confirm that in Europe, women have higher prevalence and incidence rates of DAT than men in all age ranges (Lobo *et al.*, 2000; Fratiglioni *et al.*, 2000). Gender differences in prevalence rates are thought to be attributed to different incidence and survival rates between the two sexes, since women survive longer than men with similar severities of dementia (Jorm *et al.*, 1987; Jagger *et al.*, 2000; Morrison and Tweedy, 2000).

Gender differences in DAT have also been noted by neuropsychological studies, such as women with DAT manifesting greater deficits on semantic memory but not on letter fluency or word recognition. These differences present even when the effects of age, education, duration of illness, and level of global impairment are controlled (McPherson *et al.*, 1999). A meta-analytic study showed that the sexual dimorphic character in DAT risk is 1.5 times greater in individuals with apolipoprotein E (*APOE*) genotype E3/E4 than in those with E3/E3 (Farrer *et al.*, 1997).

Effects of Oestrogen Replacement Therapy

Early cross-sectional and case–control studies suggested that oestrogen replacement therapy (ORT) was associated with improved cognitive performance and lower risk for dementia (Paganini-Hill and Henderson, 1994; Mortel and Meyer, 1995; Brenner *et al.*, 1994; Henderson, 1997). One prospective study reported that among 727 women, history of ORT use was associated with higher cognitive function at baseline and less cognitive decline during a mean 2.5 years of follow-up, and the beneficial effect of oestrogen on cognition was independent of age, education, ethnicity and *APOE* genotype (Jacobs *et al.*, 1998). Furthermore, both a community-based study in northern Manhattan and the Baltimore Longitudinal Study of Aging showed that oestrogen users had reduced risk for development of DAT compared with non-users (Kawas *et al.*, 1997; Tang *et al.*, 1996). Another cross-sectional study found that among 2338 non-demented women aged 65 years or older, absence of ORT was associated with lower scores on the modified mini-mental status examination (MMSE) (Steffens *et al.*, 1999).

However, not all recently published results support the conclusion that ORT is beneficial for postmenopausal women. The results of both the Rancho Bernardo Study and the Study of Osteoporotic Fractures showed similar patterns of cognitive declines between women with and without ORT (Barrett-Connor and Kritz-Silverstein, 1999; Mattews *et al.*, 1999), and higher endogenous oestrogen levels were not associated with significantly better performance on any cognitive function test. Results from the Alzheimer Disease Cooperation Study, which followed 120 DAT subjects of mild to moderate severity with or without ORT for 15 months, showed no differences in secondary outcomes, and patients with ORT even showed accelerated changes on the clinical dementia rating scale. Furthermore, the benefit of low-dosage oestrogen on the scores of MMSE after brief exposure (2 months) was not sustained (Mulnard *et al.*, 2000).

Some investigators argue that serum total oestrogen and oestradiol levels may not be the best measurements of their biological activities, whereas bioavailable oestrogens cross the blood–brain barrier more readily and should be correlated better with cognitive

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

function. A prospective study showed that at baseline, there were no associations between serum bioavailable hormones and cognitive function, while after 6 years follow-up, women with high concentrations of serum bioavailable oestrogen were less likely to develop cognitive impairment (Yaffe *et al.*, 2000).

Although several observational studies showed that ORT had beneficial effects on paragraph recall and verbal recall tests, some large longitudinal studies and some randomized trials showed inconsistent results. In the Nurses' Health Study, 2138 female nurses aged 70–78 years were evaluated; the results showed that after confound adjustment, neither current nor long-term hormone users demonstrated better performance on general cognitive status or immediate and delayed recall. However, on the test of verbal fluency, current users scored significantly better than never-users, and current users had a 30% decrease in their risk of a low score on the test of verbal fluency (Grodstein *et al.*, 2000). These results suggest that although oestrogen use may provide little benefit on overall cognitive function, there may be certain specific benefits, such as on verbal fluency.

A meta-analysis study collected 27 peer-reviewed articles from 1966 to 1997 and showed that the odds ratio for development of dementia was 0.71 among ORT users (Yaffe *et al.*, 1998). However, different designs and multiple outcome measures used in these studies precluded quantitative summary of the data, since the largest and most methodologically sound observations in non-demented populations showed little or no benefit of ORT for prevention of dementia.

Observational studies of the association of ORT with cognitive performance are susceptible to confounds, such as age, education and depression. Women who choose to take oestrogen generally are younger, are less depressed, have more years of education, and follow a healthier lifestyle than those who do not take oestrogen. Another possible factor in results is whether oestrogen was administrated intermittently or continuously. Based on the weakness of the evidence and potential adverse effects of ORT (breast cancer, endometrial cancer, uterine bleeding, pulmonary and venous thrombosis, gallbladder disease) (Morrison and Tweedy, 2000; Yaffe *et al.*, 1998), ORT has not been recommended universally among women for prevention of DAT.

The influences of oestrogen on cognition have been difficult to establish. It is presently unclear whether the effects of oestrogen on cognition refer to the immediate postmenopausal period, effects on cognition in later life, the ability of oestrogen to prevent cognitive decline and onset of DAT, or the effects on cognitive performance in women with established DAT (Shaywitz and Shaywitz, 2000).

Several important conclusions can be drawn from recently published investigations. First, it is apparent that the questions that now need to be addressed are much more refined than simply asking whether oestrogen improves cognition. Future studies need to investigate effects on particular cognitive functions (e.g. memory, reading, attention) of specific oestrogen types when prescribed under particular conditions (dosage, frequency) to well-defined groups of women. Second, there is no simple translation from laboratory experiments to clinical application. Hypotheses, no matter how compelling the results on which they are based, remain provisional suppositions that must be proven before they can be transformed into clinical practice (Yaffe *et al.*, 2000).

Biological Basis for Gender Differences in Alzheimer's Disease

Oestrogen is present in the brain and plasma at low concentrations, ranging from 10^{-7} to 10^{-12} M, after being synthesized by the liver and ovary. Inside the brain, cytochrome P450 aromatase from glial cells converts testosterone to oestrogen. Among postmenopausal women without oestrogen replacement, the age- and obesity-adjusted levels for oestradiol and oestrone are $12\,\mathrm{pg\,ml^{-1}}$ and $38\,\mathrm{pg\,ml^{-1}}$, respectively, while age-matched non-smoking men have oestradiol and oestrone levels of $39\,\mathrm{pg\,ml^{-1}}$ and $48\,\mathrm{pg\,ml^{-1}}$, respectively. There are two kinds of oestrogen receptors, ERα and ERβ (Kuiper *et al.*, 1996). The receptors are distributed in the CA1 region of the hippocampus, hypothalamus, preoptic area, anterior pituitary, and several other brain regions.

Oestrogen has multiple genomic and non-genomic mediated functions. It can regulate neurotransmitter systems, modulate neurite and synapse reorganization, enhance cerebral blood flow (CBF), upregulate antiapoptotic proteins in the bcl-2 family, act as an antioxidant, and modulate lipid metabolism. In addition to these favourable effects, it also exerts a neuroprotective function among neurons against ischaemic injuries, which are now considered to be more common in DAT than believed previously. Oestrogen and nerve growth factor (NGF) receptors colocalize in neurons in the cerebral cortex and hippocampus. Oestrogen enhances NGF receptor expression; conversely, NGF increases the binding of oestrogen to the same neuron. So, each type of molecule may amplify the other's growth responses. Furthermore, oestrogen has been found to modulate the expression of the *APOE* in rodent tissues and theoretically can reduce the risk of Alzheimer's disease in humans via *APOE* alteration (Dubal *et al.*, 1999).

Modulation of Neurotransmitter Systems

Oestradiol was found to increase choline acetyltransferase activity in the forebrains of oophorectomized rats. Later studies showed that oestrogen also increased potassium-stimulated acetylcholine release in certain brain regions, and prolonged survival of cholinergic neurons (Gibbs *et al.*, 1997). Effects of oestrogen on cholinergic neurons may be in synergy with neurotropic factors (Toren-Allerand *et al.*, 1992). In rats, oestradiol induces serotonin receptors in regions involved in cognition, such as the frontal lobe, cingulate gyrus and nucleus accumbens. Oestrogen affects the dopamine transport system by modulating presynaptic dopamine uptake, turnover and release and D_2 receptor affinity.

Direct Effects on Neurons

Electrophysiological and biochemical studies indicate that oestrogen has rapid effects on membrane excitability of neurons and rapid modulation of presynaptic neuronal events. Moreover, some effects are related not to neuronal communication but rather to morphology, membrane permeability and cell–cell interactions. Oestrogen regulates synaptic plasticity by stimulating axonal sprouting and dendritic spine formation in the hippocampus (McEwen and Woolley, 1994). Oestrogen modulates growth proteins specifically associated with axonal elongation, enhances the outgrowth of nerve processes in cultured neurons, and enhances long-term potentiation (Warren *et al.*, 1995). The effects of oestrogen on morphological plasticity and physiological and cognitive processes in the brain are believed to occur, at least in part, via post-transcriptional regulation of *N*-methyl-D-aspartate (NMDA) receptors, which are important for learning, memory and pattern recognition (Gazzaley *et al.*, 1996). Oestrogen replacement induces a 30% rise in both NMDA receptors and spines in the hippocampus of ovariectomized female rats.

Oestrogen as a Neuroprotectant

Oestrogen protects rodent neurons against oxidative stress, excitotoxins and β-amyloid-induced toxicity. Oestrogen increases cultured hippocampal neurons expression of Bcl-x_L and decreases both the caspase-mediated proteolysis and cell death induced by β-amyloid (Pike, 1999). *In vitro*, oestradiol promotes the breakdown of the amyloid precursor protein to fragments less likely to

accumulate as the β-amyloid peptide; it also attenuates oxidative impairment of synaptic Na^+/K^+ ATPase activity, glucose transport, and glutamate transport induced by amyloid β-peptide and iron (Jaffe *et al.*, 1994; Keller *et al.*, 1997).

In DAT brains, hippocampal subfields such as CA3 exhibiting oestrogen receptor and Bcl-x colocalization are relatively resistant to neurodegeneration. As inflammatory mechanisms are implicated in neuritic plaque formation, and anti-inflammatory agents may protect against DAT, oestrogen has the potential to modify some aspects of the inflammatory response (Bauer *et al.*, 1992).

GENDER DIFFERENCES IN VASCULAR DEMENTIA

Clinical and Epidemiological Studies

The prevalence and incidence of VAD have not been studied as comprehensively as DAT because of large variations in subtypes in the heterogeneous population samples investigated as well as problems with clinical criteria. However, it is known that VAD is more common in men than in women (Jorm and Jolley, 1998; Nyenhuis and Gorelick, 1998). In Europe, under age 85 years, the prevalence of VAD has been reported to be higher among men compared with women; after age 85 years, prevalence in women becomes higher, despite increasing incidence rates with age, but without gender differences (Lobo *et al.*, 2000; Fratiglioni *et al.*, 2000).

Most vascular risk factors for VAD correlate with heightened risk from stroke. Gender differences have long been recognized for stroke. Overall incidence of strokes is uniformly higher in men than in women in all countries, and incidence increases with age in both sexes despite decreases in the male to female ratio. Strokes of embolic origin are the only type to occur more commonly in women than in men. Women demonstrate strikingly less cerebral atherosclerosis relative to men until age 65 years. Women who use oral contraceptives have increased risk for ischaemic stroke, particularly when associated with additional risk factors, such as hypertension, smoking and migraine. Women with stroke have lower mortality compared with men (Holroyd-Leduc *et al.*, 2000).

The value of exogenous hormone replacement in improving risk and outcome is unclear. Although several reports suggest protection from fatal strokes by ORT, some clinical studies did not report significant protection against stroke by ORT. A case–control study compared ORT on the risk of stroke among 1422 stroke patients and 3171 controls aged 45–64 years. The results showed no differences between ORT users' and non-users' brains in non-fatal haemorrhagic and ischaemic stroke. Moreover, a significantly increased incidence of transient ischaemic attack was found in users of oestrogen and progestin (Pedersen *et al.*, 1997). The prospective Cardiovascular Health Study compared the relationship between history of ORT use and magnetic resonance imaging (MRI)-demonstrated cerebral infarcts, white-matter lesions and atrophy among 2133 women aged 65 years or older. The study showed no difference in prevalence of MRI-demonstrated infarcts between current or past ORT users and non-users (Luoto *et al.*, 2000).

The Heart and Oestrogen/Progestin Replacement Study was the first randomized, double-blind, placebo-controlled study to evaluate the outcome of hormone therapy on subsequent cardiac events in 2763 postmenopausal women with established coronary heart disease. The results were surprising as there were no significant differences between the treatment and placebo groups, despite a net 11% reduction on low-density-lipoprotein (LDL) cholesterol and a net 10% increase in high-density-lipoprotein (HDL) cholesterol after 1 year follow-up (Wells and Herrington, 1999). So, the use of oestrogen for secondary prevention of heart disease is more complex than was believed initially.

Possible Mechanisms for Gender Differences in Vascular Dementia

Endogenous oestrogen exerts profoundly protective actions against cerebral ischaemia by several genomic and non-genomic mechanisms, including central nervous system vasodilation with improved cerebral perfusion, reduction of injury responses of arterial smooth muscle, inhibition of platelet aggregation and lipid peroxidation, and modulation of expression of Bcl-2.

Effects on Blood Vessels

The effect of oestrogen on blood vessels is multiple, but the net effect is a promotion of vasodilation. Improved cerebral perfusion and increased cerebral vasodilatory responses by oestrogen have been shown by xenon inhalation contrast computerized tomography (CT), single positron emission computerized tomography (SPECT), positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) (Kastrup *et al.*, 1999). Oestrogen increases the expression of prostacyclin synthesis and nitric oxide synthase (NOS). In physiological concentrations, oestrogen stimulates the opening of calcium-activated potassium channels through a nitric oxide- and cyclic guanosine monophosphate (cGMP)-dependent pathway, thus relaxing smooth muscle. Blocking calcium mobilization, modulating the cyclic adenosine monophosphate (cAMP) signalling cascade, and reducing L-type and T-type calcium channel peak currents are non-genomic actions of oestrogen on vascular smooth muscle. Oestrogen reduces the sensitivity of blood vessels to endothelin, noradrenaline and thromboxane. It reduces arterial cholesterol ester influx and lipoprotein-induced smooth muscle proliferation, and prevents neointimal thickening after vascular injuries and atherogenesis over time. Oestrogen also elaborates growth factors, decreases collagen and elastin production, and inhibits foam cell formation (Wild, 1996).

Effect on Endothelium

Oestrogen has considerable beneficial functions on vascular endothelium. Oestrogen binding to membrane-sited ERα can activate NOS and cause a rapid release of nitric oxide through the tyrosine kinase pathway or the mitogen-activated protein kinase signalling pathway (Caulin-Glaser *et al.*, 1997). It can inhibit endothelial expression of adhesion molecules, thus inhibiting platelet aggregation. The rapid re-endothelialization induced by oestrogen after vascular injury may be due, in part, to increased local expression of vascular endothelial growth factor.

Effects on Metabolism

Oestrogen increases pancreatic insulin secretion and improves insulin sensitivity. It also inhibits aberrant lipid effects contributing to atherosclerosis by acting at the liver and arterial walls. The net effects of oestrogen on lipoprotein lipid metabolism are increased HDL cholesterol and triglyceride concentrations and reduced LDL cholesterol and lipoprotein A (Lp(a)) levels (Mendelsohn and Karas, 1999).

Effects on Coagulation and Fibrinolysis

Oestrogen regulates the hepatic expression of the genes for several proteins involved in coagulation and fibrinolysis of the blood. It decreases plasma concentrations of fibrinogen, antithrombin III, plasminogen-activator inhibitor type I, factor VII and protein S. Long-term use of oestrogen is associated with decreased plasma concentrations of renin, angiotensin-converting enzyme and endothelin-1 (Mendelsohn and Karas, 1999).

Effects on Experimental Stroke

Oestrogen blunts cerebral ischaemic excitotoxic cascades by reducing NMDA-induced calcium influx and promoting γ-aminobutyric acid A ($GABA_a$) receptor-mediated activity. Oestrogen can alter GABA conduction, induce synaptosomal and hippocampal GABA release, upregulate $GABA_a$ receptor numbers, increase GABA agonist binding, and alter glutamic acid decarboxylase mRNA (Hurn and Macrae, 2000).

GENDER ISSUES IN OTHER COGNITIVE DISORDERS

Age-Related Cognitive Decline

It is believed that age-related degenerative processes affect only certain domains of cognitive functioning, such as encoding and retrieval of new information. In a study concerned with predictors of cognitive change in adults with memory loss, older women were found to have more rapidly declining visual-spatial abilities than older men (Small *et al.*, 1995). In the Italian Longitudinal Study on Aging, women had higher prevalence rates in all age groups for both cognitive impairment but no dementia and age-related cognitive decline (Di Carlo *et al.*, 2000).

Pseudodementia of Depression

It is estimated that in all age ranges, the prevalence rates ratio for depression in women versus men is about 1.9 : 1 to 5 : 1, with an incidence rate ratio of 2 : 1. Lifetime prevalence of depressive disorders is 21% in women and 13% in men. A recent study reported that depressive symptoms in older women were associated with impaired cognitive function with greater cognitive declines at baseline, as well as greater risk of clinically evident cognitive deterioration (Sherwin, 1988). Depression in the elderly is associated with cognitive problems, and about 30% of patients with DAT or VAD have depressive symptoms (Li *et al.*, 2001). Whether depressive disorders are associated with accentuated cognitive decline or the development of dementia or mild cognitive impairment is controversial.

GENDER ISSUES IN DEMENTIA DUE TO OTHER GENERAL MEDICAL CONDITIONS

Dementia due to Head Trauma

In the USA, there is an incidence of over 2 000 000 head injuries per year that are sufficiently serious to require hospitalization, with 30 000–50 000 per year suffering serious intellectual dysfunction. Incidence of post-traumatic dementia is difficult to estimate, but among those with a history of post-traumatic amnesia exceeding 3 weeks, some degree of permanent measurable cognitive deficit is the rule. In some cases, substantial post-traumatic amnesia and residual intellectual deficit may follow head injury without a history of loss of consciousness. Traumatic brain injury occurs twice as often in men as in women. Between the ages of 12 to 24 years, men are involved four times as often as women in cases suffering injury from a motor vehicle accident. Traumatic head injury, particularly from boxing (dementia pugilistica), is a risk factor for DAT.

Dementia due to HIV Infection

Cognitive, motor and behavioural functional changes are the most frequent neurological complications of human immunodeficiency virus (HIV) infection. The principle risk factors for HIV infection include homosexual activities and intravenous administration of illicit drugs with contaminated needles. A total of 72% of patients are homosexual or bisexual men. Direct invasion of the brain has been shown to be causative in the majority of HIV dementia cases.

Dementia due to other Neurodegenerative Diseases

About 20–30% of patients with a clinical diagnosis of DAT were found to meet neuropathological criteria for a diagnosis of Lewy body dementia (LBD), making LBD the second most common cause of neurodegenerative dementia after DAT. Although gender distribution in LBD has not been addressed in the literature, more men than women seem to be affected, with a male to female ratio of 3 : 2, similar to the distribution for Parkinson's disease (Cercy and Bylsma, 1997). Of patients with Parkinson's disease, 10–80% have mild problems in language, visual-spatial function and executive functions, with an incidence rate of about 2.27% at 65 years and 13.6% at 80 years. There is no comprehensive study investigating gender differences in Parkinson's disease-related cognitive disorders, although men with Parkinson's disease have a higher risk for mortality than do women.

Alcohol-Associated Dementia

Over 75% of men and 50% of women in western countries drink alcoholic beverages more than occasionally. Alcohol abuse is usually associated with deterioration of memory, abstract thinking, judgement and personality. Dementia occurs in 10% of all alcoholics and 45% of alcoholics over age 65 years. The role of alcohol in alcohol-associated dementia has been considered secondary to other conditions such as Wernicke–Korsakoff syndrome (WKS), alcoholic pellagra, alcoholic neurotoxicity, Marchiafava–Bignami disease and hepatic encephalopathy. Although the incidence ratio of WKS in men versus women is 1.7 : 1, dementia appears earlier and with less consumption of alcohol among women than men.

Vascular Headache Related to Cognitive Changes

Epidemiological studies demonstrate that women have two to three times the prevalence for migraine than men. Migraine is often associated with temporary cognitive impairments, especially during the time of headache attack with or without aura. Most common cognitive impairments include deficits of attention, concentration, and verbal and visual-spatial memory. A longitudinal study demonstrated that there are temporary or transient global cognitive declines at the time of the headache measured by MMSE and cognitive capacity screening examinations. Female gender and younger age were associated with maximal cognitive decline (Meyer *et al.*, 2000).

Pharmacological Treatment of Dementia, with the Emphasis on Dementia of the Alzheimer Type

P.P. De Deyn

INTRODUCTION

In this chapter, we will focus on the pharmacological treatment possibilities of dementia. Major advances were achieved during the 1990s in the field of Alzheimer's disease, which will therefore be the main topic of this chapter. Nevertheless, whenever applicable, we will also refer to other dementias, such as vascular dementia, mixed dementia, and diffuse Lewy body disease (DLBD). We will not give a review of all treatment strategies or substances investigated, or present guidelines as formulated by some authors (e.g. Doody *et al.*, 2001b), but we will focus mainly on agents with proven efficacy that are currently available for the treatment of cognitive and non-cognitive symptomatology of dementia.

Dementia of the Alzheimer type (DAT) is the most frequent type of dementia, accounting for 60% of cases. The prevalence of DAT has been estimated to be about 10% among people aged 65 years or more, and 40% among people aged 85 years or more (Evans *et al.*, 1989). DAT is, by its prevalence and nature, an important burden on the life of older people, their immediate family and the community.

The clinical-diagnostic criteria for DAT are defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 1994). The symptoms are presented in Table XV-14.1. There are two groups of symptoms: the impairment of cognitive functioning of which memory impairment is the hallmark in DAT, and the behavioural and psychological symptoms associated with dementia (BPSD) (Finkel *et al.*, 1996). A complete medical treatment of DAT should therefore consist of treatment of both groups of symptoms whenever needed.

Table XV-14.1 Symptoms of DAT

(a) Symptoms of cognitive impairment
Memory impairment
One or more of the following cognitive disturbances:
– aphasia
– apraxia
– agnosia
– disturbance in executive functioning
Cognitive deficits cause significant impairment in social or occupational functioning
Consciousness is preserved
(b) Behavioural and psychological symptoms
Aggression and violence
Agitation
Hallucinations and delusions
Sleeplessness
Pacing and wandering
Depression
Anxiety
Inappropriate sexual behaviour

Figure XV-14.1 shows the hypothetical cascade of events leading to the formation of senile plaques and the development of DAT. The brains of patients with DAT contain a number of structural alterations, including senile plaques, neurofibrillary tangles and cell death. Among a number of deficits of neurotransmission, the most important are cholinergic and noradrenergic (Davis *et al.*, 1982; Rossor and Iversen, 1986). Deficient cerebral glucose consumption and pyruvate dehydrogenase activity are some of the metabolic derangements observed in DAT.

OVERVIEW OF TREATMENT STRATEGIES

Treatment Strategies Based on Knowledge of Aetiology and Pathogenic Mechanisms of Dementia of the Alzheimer Type

These treatment strategies should consist of preventing abnormal β-amyloid production and/or deposition, antagonizing β-amyloid neurotoxicity, and antagonizing inflammatory mechanisms. The β-amyloid protein is deposited as insoluble amyloid fibrils in the brains of patients with DAT. This deposition plays an important role in the pathogenesis of DAT. β-Amyloid protein is produced from its precursor, β-amyloid precursor protein, through enzymatic cleavage by secretase enzymes. γ-Secretase is of particular interest since it is responsible for production of the β-amyloid protein carboxyl terminus, whose length influences the pathogenicity of the protein (Cordell *et al.*, 1998). Currently, research is ongoing into a novel therapy using γ-secretase inhibitors to reduce amyloid deposition. Their effects were confirmed in an *in vivo* situation using transgenic animal models (Felsenstein, 1998). This class of drugs may become the next generation of agents for treatment of DAT.

Interaction with neuronal cell death has been the subject of earlier research, with studies being carried out on the efficacy of neuroprotectants, mainly drugs acting against oxidative stress, which occurs as a result of action by oxygenized free radicals. However, no clear-cut benefits have resulted so far from experimental data with selegiline and/or α-tocopherol (Freedman *et al.*, 1998; Sano *et al.*, 1997). The selective irreversible inhibitor of monoamine

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

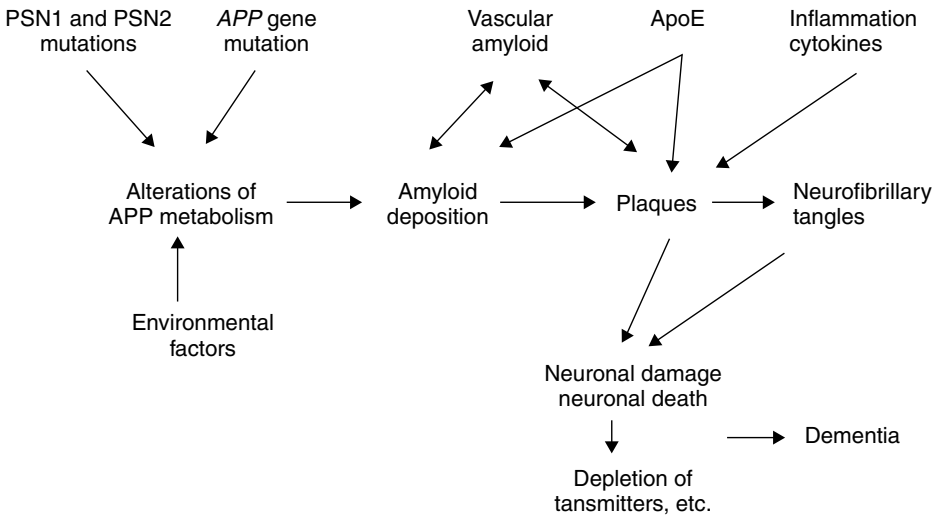

Figure XV-14.1 Hypothetical model of amyloid-related cascade of events leading to the formation of Alzheimer's disease plaques and the development of dementia. (APP, amyloid precursor protein; PSN1, presenilin 1; PSN2, presenilin 2)

oxidase B (MAO-B), selegiline, has been investigated for its presumed beneficial effects on the cognitive symptoms in DAT. While preliminary studies with short-term treatment had suggested promising results, long-term treatment could not confirm this (Schneider *et al.*, 1991; Koivisto *et al.*, 1995). α-Tocopherol interacts with the cellular membrane and is a free-radical scavenger. Sano *et al.* (1997) showed that α-tocopherol alone and in combination with selegiline could slow down the functional deterioration of patients with DAT, but that it had no effect on the outcome of cognitive parameters.

Ginkgo biloba, an extract of the ginkgo biloba tree, has been used widely for the treatment of memory disorders for many years, despite proof of efficacy. The flavonoids, terpenoids and organic acids probably have an antioxidative effect. In a 52-week, double-blind, randomized, placebo-controlled trial with ginkgo biloba in patients with mild to severe DAT and vascular dementia, the active treatment group had an Alzheimer's disease assessment scale-cognitive subscale (ADAS-cog) score slightly better than the placebo group (1.4). However, no difference was seen in the clinical global impression of change evaluation (CGIC) (Le Bars *et al.*, 1997).

Symptomatic Treatment of Core Symptomatology

While not healing the disease and probably not slowing the pathogenic process, symptomatic treatment may contribute during a limited time period to slowing down the evolution of the symptoms. This mode of action is currently the most used method and consists mainly of neurotransmitter replacement therapy. In theory, this can be accomplished by increasing the synthesis and/or release of neurotransmitter, inhibiting the neurotransmitter breakdown, or directly administering receptor agonists. Cholineacetyltransferase (ChAT) is the neurotransmitter marker whose decline best parallels the severity of neuronal loss, density of senile plaques, and impairment on cognitive tests in DAT (Davis *et al.*, 1982). Drugs originally aiming to improve cognitive functioning in dementia were based on acetylcholine replacement treatment strategies by inhibition of acetylcholinesterase. Later, some of these substances were also shown to improve activities of daily living and finally BPSD. A series of psychotropic agents has been tested for control of BPSD. Recently, major progress has been made in the development of efficacious and safe novel antipsychotic agents in this indication.

Outcome Parameters for the Evaluation of Novel Antidementia Agents

Cognitive Symptomatology

To establish the effectiveness of new drugs, we have to evaluate the effect of the drug on the symptoms. This is done in double-blind, placebo-controlled studies. Evaluation is performed by applying a number of instruments developed for this research. The ADAS-cog is used to assess in a longitudinal way the evolution of cognitive function in patients with DAT (Rosen *et al.*, 1984). The ADAS is a comprehensive assessment battery used widely in clinical investigations of DAT. It comprises two components: the cognitive and non-cognitive subscales. The cognitive subscale is the most objective portion of the ADAS, since it relies solely on the patient's ability to perform specific tasks during the administration of the tests, and it captures the cardinal symptoms of DAT. The cognitive abilities evaluated in this subscale consist of memory, language and praxis. Scores on the ADAS-cog can range from 0 to 70 points, with higher scores indicating a greater degree of impairment. Normal elderly subjects score an average of 0–10 points on this subscale, whereas a sample of untreated patients with mild to moderate DAT score between 15 and 25 points. The average rate of decline over a 12-month period for untreated Alzheimer's disease patients is reported to be 6.8 points, while normal elderly subjects do not change significantly over this same period of time.

Global Symptomatology

Another measure used in the double-blind studies is the clinician interview-based impression of change (CIBIC) or its more recent variant, the clinician interview-based impression of change-plus (CIBIC-plus), both developed from the CGIC (Guy, 1976; Schneider *et al.*, 1997).

The CIBIC is an assessment of the patient's status by a semi-structured interview and provides a global rating score that reflects patient function in four areas: general, cognitive, behaviour, and activities of daily living. Using the results from baseline for reference, the rater then interviews the patient and caregiver

at specified times during the study to obtain an impression of change. After the interview, a seven-point scale is used for scoring, from very much improved to very much worse, as compared with baseline results. Another measure to estimate the caregiver's impression of change is the final comprehensive consensus assessment (FCCA) (Knapp *et al.*, 1994).

Behavioural and Psychological Symptomatology

A variety of reliable and sensitive scales have been applied in order to demonstrate clinical efficacy and safety of pharmacological agents in the treatment of BPSD (De Deyn and Wirshing, 2001).

The behavior pathology in Alzheimer's disease rating scale BEHAVE-AD is a 25-item scale that measures behavioural symptoms in a total of seven clusters: paranoid and delusional ideation, hallucinations, activity symptoms, aggressiveness, diurnal rhythm symptoms, affective symptoms and anxieties and phobias (Reisberg *et al.*, 1987). All items are scored on a four-point scale of increasing severity. The BEHAVE-AD global score is a measure of behaviour deemed to be disturbing or dangerous to the patient or to those in their environment.

The Cohen-Mansfield agitation inventory (CMAI) is a rating scale used in nursing homes to assess a total of 29 agitated behaviours on a seven-point scale of increasing frequency (Cohen-Mansfield *et al.*, 1989). The cluster scores include physical, verbal and total aggression, and physical, verbal and total nonaggressive scores. CGIC ratings by the investigator measure behavioural symptoms on a seven-point scale of increasing severity.

The neuropsychiatric inventory (NPI) scores a wide range of psychopathology and may help distinguish between different causes of dementia. It also records severity and frequency separately. The behavioural disturbances assessed by the NPI (Cummings *et al.*, 1994; Cummings, 1997) are delusions, hallucinations, agitation, dysphoria, anxiety, apathy, irritability, euphoria, disinhibition, aberrant motor behaviour, night-time behaviour disturbances, and appetite and eating abnormalities.

Cognitive Enhancers Based on Acetylcholinesterase Inhibitory Action Mechanisms

Five cholinesterase inhibitors have been marketed: tacrine, donepezil, rivastigmine, metrifonate and galantamine. At the time of writing, four are still available, one of which, tacrine, sees its use decreasing steadily. We will describe these products and discuss the findings from studies as well as the pros and cons of treating patients with these products.

Tacrine

Tacrine (tetrahydroaminoacridine) was the first drug to become available for the treatment of cognitive impairment in patients with DAT. Tacrine was compared with placebo in a 30-week, randomized, double-blind, controlled trial with four doses of tacrine (40 mg per day, 80 mg per day, 120 mg per day and 160 mg per day) (Knapp *et al.*, 1994). The patients receiving the highest-dose regimen fared better for the three primary outcome measures (ADAS-cog, CIBIC and FCCA) and for five of the eight secondary measures (Table XV-14.2). Placebo patients declined on the ADAS-cog by an average of 2.0 points compared with a mean improvement of 2.1 points for the patients receiving 160 mg per day of tacrine. Forty-two per cent of patients receiving 160 mg per day of tacrine were rated improved on the CIBIC compared with 18% of patients receiving placebo. Forty-two per cent of patients receiving 160 mg per day of tacrine were rated improved on the FCCA as compared with 16% of placebo patients. However, the evaluated patients represented only about 30% of the patients who had been part of the 160-mg per day tacrine group, the remainder being unable to complete the 30-week treatment period. The lower-dose groups also showed a significant proportion of drop-outs because of lack of efficacy, not-drug-related adverse events, and side effects. Treatment with tacrine was related with substantial side effects: elevation of transaminases, even in the lowest-dose group, requiring interruption and even suspension of tacrine treatment, and cholinergic side effects, especially gastrointestinal effects, such as nausea, vomiting, diarrhoea, anorexia, dyspepsia, abdominal pain and weight loss. Not all patients taking the higher doses showed improvement. This suggests that there must be subpopulations of patients who are responsive and others who are unresponsive to tacrine (and, to a wider extent, to cholinesterase inhibitors). Although apolipoprotein E (apoE) 4 is thought to be a prognostic factor of poor response to therapy with acetylcholinesterase inhibitors in DAT patients (Poirier *et al.*, 1995), a recently published study failed to show an influence of apoE genotype on the efficacy of galantamine in patients with DAT (Aerssens *et al.*, 2001). Gender is likely to be a more powerful determinant of outcome of anticholinesterase treatment than apoE genotype (MacGowan *et al.*, 1998). Indeed, female patients are more likely to fail to improve with tacrine (Farlow *et al.*, 1998; MacGowan *et al.*, 1998). Further prospective studies are needed to confirm these observations.

Tacrine also showed a more practical inconvenience, since it requires a time interval between food administration, and drug administration, and it has to be administered four times daily. The study patients were observed further in an unblinded open-label period to evaluate whether there was a long-lasting effect,

Table XV-14.2 Cholinesterase inhibitors: changes in ADAS-cog for the highest-dose patients versus placebo patients in double-blind, placebo-controlled randomized clinical trials

Drug	Reference	*N* patients with highest dose	Maximum daily dose (mg)	Duration (weeks)	ADAS-cog: difference from placebo
Tacrine	Farlow *et al.*, 1992	37	80	12	3.8
	Knapp *et al.*, 1994	64	160	30	4.1
Donepezil	Rogers and Friedhoff, 1996	34	5	12	3.2
	Rogers *et al.*, 1998	152	5	24 + 6	2.5*
		150	10	24 + 6	2.9*
Rivastigmine	Corey-Bloom *et al.*, 1998	145	6–12	26	4.9
Metrifonate	Cummings *et al.*, 1998	111	30–60	12	3.2
	Morris *et al.*, 1998	250	30–60	26	2.8
Galantamine	Tariot *et al.*, 2000	253	24	22	3.6
	Raskind *et al.*, 2000	197	32	26	3.4*
	Wilcock *et al.*, 2000	218	32	26	4.1

* Intent-to-treat analysis

especially on nursing-home placement and mortality. This study showed that patients treated with tacrine in doses of more than 80 mg per day had a decreased chance of admission to nursing home (Knopman *et al.*, 1996). However, there might be some difficulties with the interpretation of these results: since the study was neither randomized nor blinded after the first 30 weeks, it cannot be proven that there was a causal relationship between higher-dose treatment and more favourable outcomes.

Donepezil

Donepezil was the second cholinesterase inhibitor to become available for the treatment of cognitive dysfunction in DAT. The efficacy and safety of this agent was demonstrated initially in a randomized, double-blind, placebo-controlled trial involving 161 patients randomized to a once-daily treatment with either donepezil (1, 3 or 5 mg) or placebo during a 12-week study period, followed by a 2-week single-blind placebo wash-out (Rogers and Friedhoff, 1996). The primary efficacy parameters were the ADAS-cog and the CGIC. Improvements in ADAS-cog at week 12 were significant for the 3-mg per day ($P < 0.05$) and the 5-mg per day ($P < 0.01$) dose regimen as compared with placebo. The short treatment duration complicated the interpretation of CGIC results since the majority of patients were scored as being unchanged. The proportion of treatment failures was, however, significantly lower for the patients receiving the 5-mg per day dose regimen. The most frequent adverse events at the 5-mg per day dosage were nausea and vomiting (10% versus 5% for placebo). The use of donepezil was not associated with hepatotoxicity.

A second trial of similar design compared donepezil 5 mg per day and 10 mg per day with placebo during a 24-week treatment period (Rogers *et al.*, 1998). There was a significant dose-dependent improvement on ADAS-cog score, with 2.49 points for 5 mg per day and 2.88 for 10 mg per day, as well as a dose-dependent improvement on CIBIC-plus of 0.36 points for the low-dose group and 0.44 points for the 10-mg dose regimen as compared with the results of patients in the placebo group. Drop-out rates were 7% for placebo, 6% for 5 mg per day donepezil and 16% for 10 mg per day donepezil. As in the prior study, the most frequently observed side effects were of a cholinergic nature, and there was no hepatotoxicity. Donepezil is given as a once-daily administration, which is a favourable dosing regimen, especially in this patient population.

Longer treatment duration data are only provided by two open-label studies (Rogers *et al.*, 2000; Doody *et al.*, 2001a). A rather limited number of DAT patients ($n = 133$) were included and followed up for a period of 240 weeks in a US multicentre, open-label study (Rogers *et al.*, 2000). All patients were treated with 3, 5, 7 or 10 mg donepezil per day. During the first 6–9 months of the study, mean ADAS-cog scores showed evidence of improvement from baseline. Thereafter, the revealed decline was less than that estimated if this cohort of patients had not been treated (Rogers *et al.*, 2000). A much larger cohort of DAT patients ($n = 736$) was included in a multicentre, open-label extension study of several double-blind, placebo-controlled clinical trials (Doody *et al.*, 2001a). After a 3–6-week placebo wash-out, all patients were treated with 5 or 10 mg donepezil per day for up to 144 weeks. In contrast to the 3-week placebo wash-out patient group, all donepezil-associated benefits were lost after a 6-week wash-out period, and ADAS-cog scores declined below original baseline values for all patient groups. Although scores improved relative to the new open-label study baseline values, these patients remained below the original baseline values.

Rivastigmine

Rivastigmine is a pseudoirreversible cholinesterase inhibitor that binds to the enzyme but dissociates slowly, providing a much longer cholinesterase inhibition in the brain (about 10 h) than its plasma half-life (Anand and Gharabawi, 1996). Its efficacy and safety were assessed in the ADENA (Alzheimer's disease with ENA 713) project, which consisted of a real phase III study of mild to moderate DAT patients with admission of associated pathology. The study duration was 26 weeks, and participants received either rivastigmine 3–12 mg per day in two daily doses or placebo (Corey-Bloom *et al.*, 1998). The outcome parameters were ADAS-cog and CIBIC-plus. To evaluate the effect on activities of daily living, the progressive deterioration scale was used. Patients receiving rivastigmine showed significant improvements on ADAS-cog, CIBIC-plus and the progressive deterioration scale as compared with patients receiving placebo (see also Table XV-14.2). Side effects were again due to the cholinergic effects of the drug, and no liver abnormalities were observed. Patients who participated in this 26-week phase III trial and who returned for an assessment from week 26 onwards received open-label treatment for an additional period of 26 weeks (Farlow *et al.*, 2000). Patients were assigned randomly to receive treatment with rivastigmine 1–4 mg per day, rivastigmine 6–12 mg per day or placebo for the 26-week, open-label treatment. A greater percentage of patients from the original 6–12-mg per day group who received 12 mg per day during weeks 32–52 demonstrated improvement at week 52 from baseline in ADAS-cog scores compared with the original placebo-treated patients. This failure to 'catch up' in the group starting treatment later would be considered as an indication of disease-modifying effect of treatment. However, we must be cautious with this interpretation based on data of studies with the above-described design given, among other things, a potential bias and selection of patients who could tolerate rivastigmine for the open extension phase and the lack of randomization to treatment for the 52 treatment weeks at week 1. To our knowledge, there are no conclusive data available with regard to potential disease-modifying effects of acetylcholinesterase inhibitors.

Although not the focus of this chapter, we would like to refer to a recent paper indicating the beneficial effect of the acetylcholinesterase inhibitor rivastigmine on DLBD (McKeith *et al.*, 2000). In this paper, the authors demonstrated that rivastigmine 6–12 mg daily produces statistically and clinically significant behavioural effects in patients with Lewy body dementia, as demonstrated on the NPI-4 (a four-item subscore of the NPI, calculated as the sum of scores for delusions, hallucinations, apathy and depression, previously identified as the main Lewy body dementia cluster).

Metrifonate

Metrifonate is a drug that has been used for many years in the treatment of schistosomiasis. Since it is an acetylcholinesterase inhibitor, it was considered a possible DAT drug. It is unique among the cholinesterase inhibitors used in DAT since it binds irreversibly with cholinesterase. Its efficacy and safety were demonstrated recently in two large double-blind trials. The first trial evaluated patients after a treatment period of 12 weeks (Cummings *et al.*, 1998). Patients received placebo or one of three loading doses of metrifonate for 2 weeks, followed by one of three maintenance doses (0.2 mg kg^{-1} per day (10–20 mg per day), 0.3 mg kg^{-1} per day (15–25 mg per day) or 0.65 mg kg^{-1} per day (30–60 mg per day)) for 10 weeks. Metrifonate significantly improved cognitive ability, as assessed by the ADAS-cog (see Table XV-14.2). The CIBIC-plus results showed improved global functions. The agent was well tolerated, with 89% of the high-dose metrifonate group completing the study. Adverse events related to metrifonate included abdominal pain, diarrhoea, flatulence, nausea and leg cramps.

The second study observed patients for a 26-week double-blind treatment period, consisting of a 2-week loading dose phase (2 mg kg^{-1} per day or placebo) and a 24-week maintenance dose phase (0.65 mg kg^{-1} per day or placebo), followed by an 8-week follow-up period (Morris *et al.*, 1998). The efficacy outcome on the ADAS-cog was clinically significant, with a difference of 2.86

points (see Table XV-14.2). The difference for the mean CIBIC-plus score was also significant at 26 weeks. The study also showed beneficial effects on behaviour (Morris *et al.*, 1998).

Metrifonate was well tolerated in this trial, with an adverse-events-related discontinuation rate of 12% for metrifonate-treated patients. Most adverse events were of cholinergic nature. No hepatotoxicity was observed. Metrifonate was given in a once-daily dosing regimen. Unfortunately, a myasthenia-like syndrome has been reported recently as a side effect of metrifonate, and consequently the product has been withdrawn from the market.

In a post hoc analysis of pooled NPI data from two double-blind, placebo-controlled studies of metrifonate in DAT patients, an overall reduction of 15% on total NPI scores was revealed when compared with placebo (Cummings *et al.*, 2001). Metrifonate reduced or stabilized neuropsychiatric disturbances in 60% of symptomatic patients (Cummings *et al.*, 2001).

Galantamine

Galantamine is the most recently introduced antidementia agent. It is a competitive acetylcholinesterase inhibitor that also allosterically modulates nicotinergic acetylcholine receptors (Bores *et al.*, 1996; Albuquerque *et al.*, 1997). It is speculated that the latter mechanism of action may produce neuroprotective effects and may therefore slow down the disease progression. The efficacy and safety profile of galantamine has been the focus of several large phase III, placebo-controlled, randomized clinical trials. Efficacy measures included not only cognitive parameters but also activity of daily living and behavioural outcome measures.

A 5-month, randomized clinical trial testing galantamine 8, 16 or 24 mg per day versus placebo was performed in patients with mild to moderate Alzheimer's disease (Tariot *et al.*, 2000). It was concluded that galantamine 16 and 24 mg per day significantly benefits the cognitive (ADAS-cog), functional (Alzheimer's disease cooperative study activities of daily living inventory (ADAS/ADL)) and behavioural symptoms (NPI) of Alzheimer's disease as compared with placebo.

Raskind *et al.* (2000) reported on efficacy of galantamine over a 6-month treatment period followed by a 6-month extension. At 6 months, galantamine administered at either 24 or 32 mg per day significantly improved cognition and global function. Galantamine significantly improved cognitive function relative to placebo; the treatment effects were 3.9 points (lower dose) and 3.8 points (higher dose) on the ADAS-cog at month 6. Also, CIBIC-plus scores were significantly better in the active treatment groups. Moreover, cognitive and daily function were maintained for 12 months with the 24-mg per day dose. The most common adverse events, which were predominantly gastrointestinal, decreased in frequency during long-term treatment.

The last published phase III trial on galantamine in Alzheimer's disease considered 653 subjects with mild to moderate Alzheimer's disease. Patients assigned randomly to galantamine had their daily dose escalated over 3–4 weeks to maintenance doses of 24 or 32 mg in a twice-daily-dosing regimen. At 6 months, patients who received galantamine had a significantly better outcome on the 11-item subscale of the ADAS-cog than placebo-treated individuals (mean treatment effect of 2.9 points for the lower dosage, and 3.1 points for the higher dose) (Wilcock *et al.*, 2000). Also, at 6 months, patients on galantamine had a better outcome on the CIBIC-plus and had significantly better scores on the disability assessment for dementia scale than patients in the placebo group. ApoE genotype, however, had no effect on the efficacy of galantamine. Galantamine was tolerated well by most patients. The completion rates for the two galantamine groups were comparable to those reported for other cholinesterase inhibitors. More adverse events were reported with the higher dose, and more patients who received the higher dose discontinued treatment as a result of adverse events. The most common adverse event in the galantamine groups was nausea, which was mild for most patients and lasted a median of 5–6 days.

The effects of galantamine on cognitive, functional and behavioural symptomatology in vascular dementia have been studied recently. These promising data have not yet been the focus of international peer-reviewed publications.

Psychopharmacological Agents with Proven Efficacy on the Behavioural and Psychological Symptoms of Dementia

Until recently, the main focus of pharmacological research related to dementia was on the improvement of cognitive functioning. However, BPSD are among the most predominant and pervasive features of dementia and increasingly form a target for therapeutic intervention in this cognitively impaired population (Reisberg *et al.*, 1986; Reisberg *et al.*, 1987; American Psychiatric Association, 1994; Jost and Grossberg, 1996). Aggression and other behavioural symptoms of dementia (e.g. agitation, purposeless activity, wandering, pacing, psychotic symptoms) are important features of the illness and have a severe impact on the quality of life of patients and caregivers, thus complicating effective medical management (Reisberg *et al.*, 1987; Tariot *et al.*, 1994; Tariot *et al.*, 1995; Reisberg, 1992; Eastly and Wilcock, 1997). Behavioural symptoms have been described as the primary predictor of caregiver burden (Coen *et al.*, 1997; Donaldson *et al.*, 1997; McKhann *et al.*, 1984). In fact, the behavioural symptoms of dementia (in particular, aggression and agitation) may be the most common reason for patients being admitted to hospital or residential care (Ferris *et al.*, 1987).

A variety of pharmacological agents have been evaluated for the treatment of BPSD, including cholinergic agents, anticonvulsants, antidepressants, anxiolytics, hormonal preparations and neuroleptic drugs. Unfortunately, the reports often rely on anecdotal observations and/or open-label clinical trials (Porsteinsson *et al.*, 1997; Mintzer *et al.*, 1998). Neuroleptics have been studied more intensively than other agents. Although available evidence supports the efficacy of the conventional neuroleptics, side effects, including the risk of irreversible movement disorders, extrapyramidal symptoms (EPS), anticholinergic effects and adverse drug interactions, are particularly problematic in this elderly patient population (Stoppe *et al.*, 1999, Schneider *et al.*, 1990). Therefore, special efforts have been made to determine the efficacy and safety profile of some novel antipsychotic agents in the treatment of BPSD. Two atypical antipsychotic agents, risperidone and olanzapine, have been investigated in placebo-controlled, randomized clinical trials.

The utility of risperidone, a selective dopamine D_2 and serotonin $5\text{-}HT_{2A}$ receptor antagonist, in elderly patients with dementia and behavioural symptoms has been evaluated in two multicentre, placebo-controlled, double-blind clinical trials (Katz *et al.*, 1999; De Deyn *et al.*, 1999). The primary objective of both studies was to compare the efficacy and tolerability of risperidone with those of placebo in the treatment of behavioural symptoms in patients with dementia. The secondary objective of the latter trial (De Deyn *et al.*, 1999) was to compare the tolerability (particularly with regard to EPS) and the general safety of risperidone with those of haloperidol.

The European-Canadian study (De Deyn *et al.*, 1999) compared the effects of risperidone with those of placebo (efficacy and tolerability) and haloperidol (tolerability). This 13-week double-blind study involved 344 institutionalized elderly patients who had severe dementia (67% Alzheimer's disease, 26% vascular dementia, 7% mixed dementia), assigned randomly to receive either placebo or flexible doses (0.5–4 mg per day) of risperidone or haloperidol. Behavioural symptoms were assessed using the BEHAVE-AD, the CMAI and the clinical global impression (CGI) scale (Guy *et al.*, 1976, Reisberg *et al.*, 1987; Cohen-Mansfield *et al.*, 1989). Tolerability assessments included extrapyramidal symptom rating scale (ESRS) scores.

The Katz *et al.* (1999) trial was a USA-based study in which the effects of fixed doses of risperidone (0.5 mg per day, 1 mg per day, 2 mg per day) were compared with those of placebo. The study involved 625 institutionalized elderly patients with severe dementia (73% Alzheimer's disease, 15% vascular dementia, 12% mixed dementia).

In the flexible-dose regimen European-Canadian trial, the mean dose at endpoint was 1.1 mg per day in the risperidone group and 1.2 mg per day in the haloperidol group. The risperidone group showed significantly greater improvement in the mean BEHAVE-AD total score at week 12 than did the placebo group (completer analysis). The therapeutic effect was most evident for aggressive symptoms. Risperidone was associated with a significantly greater improvement than placebo in the BEHAVE-AD aggression cluster and CMAI aggressiveness scores (total, physical and verbal cluster) at both endpoint (intention-to-treat analysis) and week 12 (completer analysis). The superior effect of risperidone was seen as early as week 2 of treatment and was maintained over the next 10 weeks. Baseline scores for the paranoid and delusional ideation and hallucinations clusters were quite low, and thus there were no significant treatment-related changes in this parameter during the trial. Patients receiving risperidone also exhibited significantly greater global improvement (CGI severity rating) than placebo-treated patients at both week 12 and endpoint. A subanalysis was also performed, excluding patients with vascular dementia. The results (mean shifts on BEHAVE-AD and CMAI scores) were consistent with those observed in the mixed group of dementia patients. At endpoint and week 12, there were significantly greater improvements with risperidone than placebo on BEHAVE-AD aggressiveness score and CMAI total aggressiveness scores.

Significantly greater improvements were noted for haloperidol than placebo on BEHAVE-AD total and aggression cluster scores at endpoint. There were significantly greater improvements with risperidone than haloperidol on the BEHAVE-AD aggressiveness score and the CMAI total and verbal aggressive scores at week 12.

The severity of EPS (as measured by the ESRS total score) at endpoint was not significantly different between the risperidone and placebo groups, while EPS associated with haloperidol was significantly greater than with risperidone. There was no significant difference between the risperidone and placebo groups with respect to the change in mini-mental state examination (MMSE) score during the study. However, the decline in MMSE scores with haloperidol was greater than that with placebo, suggesting that haloperidol led to cognitive toxicity. There were no consistent changes or clinically relevant abnormalities in vital signs (blood pressure, heart rate), laboratory safety parameters, body weight or electrocardiogram.

In the USA trial (Katz *et al.*, 1999), treatment responses (defined post hoc as a 50% or greater reduction in BEHAVE-AD total score) occurred in more patients receiving risperidone 1 or 2 mg per day compared with those receiving placebo. At endpoint, patients receiving risperidone (1 or 2 mg per day) improved significantly more than placebo-treated individuals, as assessed by the BEHAVE-AD total score and the psychosis and aggressiveness scores. Effects of treatment on the CMAI score paralleled those on the BEHAVE-AD total score: patients receiving 1 or 2 mg per day of risperidone exhibited significantly greater improvements than did placebo-treated patients at week 12 and endpoint, according to the verbal, physical and total aggression scales of the CMAI. At the highest dose of risperidone (2 mg per day), there were significant increases in scores on the parkinsonism total and hypokinesia scales compared with placebo. Other dose-related events included mild somnolence and peripheral oedema.

Open-label follow-up studies to the above-mentioned phase III trials, involving a total of 413 patients, demonstrated sustained efficacy and safety of risperidone administered at approximately 1 mg per day in the treatment of BPSD. Jeste *et al.* (2000) reported the follow-up data from the patients enrolled after ending the Katz *et al.* (1999) trial. A total of 330 patients with Alzheimer's disease, vascular dementia or mixed dementia were enrolled in a 1-year, open-label study. The mean modal risperidone dose was 0.96 mg per day. The 1-year cumulative incidence of persistent emergent tardive dyskinesia among the 255 patients without dyskinesia at baseline was 2.6%. Patients with dyskinetic symptoms at baseline experienced significant reductions in the severity of dyskinesia. Patients who received 0.75–1.5 mg per day of risperidone showed a significant improvement in psychopathologic symptoms over the 1-year period. Although there was no control group, the observed incidence of persistent tardive dyskinesia with risperidone seems much lower than that seen in elderly patients treated with conventional neuroleptics, where yearly incidence rates up to 26% have been reported (Jeste *et al.*, 1995).

The second novel antipsychotic agent evaluated in a phase III trial involving a rather homogeneous population suffering from Alzheimer's disease is olanzapine. Street *et al.* (2000) conducted a multicentre, double-blind, placebo-controlled 6-week study in 206 elderly US nursing-home residents with DAT who exhibited psychotic and/or behavioural symptoms. Patients were assigned randomly to placebo or a fixed dose of 5, 10 or 15 mg per day of olanzapine. The primary efficacy measure was the sum of the agitation/aggression, hallucinations and delusions items (core total) of the NPI-nursing-home version. Low doses of olanzapine (5 and 10 mg per day) produced significant improvement compared with placebo, while 15 mg per day failed to do so. The occupational disruptiveness score, reflecting the impact of the patient's psychosis and behavioural disturbances on the caregiver, was reduced significantly in the 5-mg per day olanzapine group compared with placebo. Somnolence was significantly more common among patients receiving olanzapine (25.0–35.8%), and gait disturbance occurred in those receiving 5 or 15 mg per day (19.6% and 17.0%, respectively). No significant cognitive impairment, increase in EPS, or central anticholinergic effects were found at any olanzapine dose relative to placebo.

CONCLUSION

This chapter has focused on the growing number of possibilities for treatment of cognitive and behavioural symptoms in patients with DAT. Currently available drugs are more efficacious and show fewer side effects than first-generation drugs. However, the availability of these drugs may never justify treatment of memory problems without relying on a clear diagnosis.

The treatment presently available is a symptomatic treatment that does not modify the course of the disease significantly. Causal treatment is the subject of biochemical and animal studies. Once such disease-modifying treatment becomes available, a combination of this with symptomatic treatment of the cognitive and behavioural dysfunctions will possibly yield more important and longer lasting beneficial results.

Animal Model of Substance Abuse and Dependence

Toni S. Shippenberg

INTRODUCTION

In 1968, the term 'substance dependence' replaced 'addiction' in the nomenclature of the World Health Organization and the American Psychiatric Association. Defined as a cluster of cognitive, behavioural and physiological symptoms indicative of an individual continuing substance use despite significant substance-related problems, this term is the accepted diagnostic term for compulsive use of a psychoactive substance (Table XVI-1.1). When defined as described, it is analogous to the term addiction. However, this term should not be confused with physical or psychic dependence, conditions in which the cessation or reduction of drug usage results in a withdrawal syndrome. Withdrawal and tolerance often are associated with compulsive drug use and are criteria used to define substance dependence. However, the diagnosis of dependence is based on the presence of a constellation of symptoms, and dependence can occur in the absence of either. Importantly, although individuals suffering from chronic pain may develop tolerance to the analgesic effects of an opiate and experience withdrawal symptoms, they do not exhibit compulsive drug-seeking behaviour.

Like substance abuse, substance dependence is defined as a maladaptive pattern of substance use that leads to clinically significant impairment or distress. However, the criteria for abuse do not include tolerance, withdrawal or a pattern of compulsive use but instead are based upon the adverse social consequences of drug use. Although a diagnosis of substance abuse is most often seen in individuals who have recently initiated drug use, not all individuals exhibiting substance abuse will progress to dependence. The identification of those factors that prevent the escalation of abuse to dependence in these individuals is an important focus in addiction research.

The concept of reinforcement has provided the cornerstone for current theories and animal models of substance abuse and addiction. A reinforcer is defined operationally as 'any event that increases the probability of a response' and often is used interchangeably with 'reward'. In general, drugs function as positive or conditioned reinforcers by virtue of their rewarding effects, and reward often connotes additional attributes of a drug (e.g. pleasure) that cannot be defined operationally.

In this chapter, animal models currently used to examine the neurobiological basis of substance dependence and the role of reinforcement processes in its initiation, maintenance and reinstatement are reviewed. The models are then evaluated with respect to the criteria of reliability, predictability and face validity. Limitations of these models that should be considered when interpreting data are also discussed.

Table XVI-1.1 Criteria for substance dependence. A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period

Criteria	Definition
1	Tolerance, as defined by either: (a) need for markedly increased amounts of the substance to achieve intoxication or desired effect (b) markedly diminished effect with continued use of the same amount of substance
2	Withdrawal as manifested by either: (a) characteristic withdrawal syndrome for the substance or (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
3	Substance is often taken in larger amounts or over a longer period than was intended
4	A persistent desire or unsuccessful efforts to cut down or control substance use
5	A great deal of time spent in activities necessary to obtain the substance, use the substance or recover from its effects
6	Important social, occupational or recreational activities are given up or reduced because of substance use
7	Substance use is continued despite knowledge of having a persistent or psychological problem that is likely to have been caused or exacerbated by the substance.

CRITERIA FOR EVALUATING ANIMAL MODELS OF SUBSTANCE DEPENDENCE

The use of animal models in scientific research is based on the premise that there is homology among the physiology and behaviour of various species and, hence, extrapolations can be made from experimental animals to humans. Three criteria are typically used to evaluate the strength of a particular model: reliability, predictability and face validity. Reliability refers to the consistency and stability with which the variable is observed. An animal model should permit objective measurement of the variable of interest (e.g. reinforcing efficacy) and within-subject variability should be low. In addition, the phenomenon measured as well as manipulations that affect its development and/or expression should be reproducible. As discussed by Markou *et al.* (1993), the only meaningful criterion for evaluating an animal model concerns the ability of the model to accurately predict the modelled phenomenon (e.g. human condition) based on the behaviour of the model system (e.g. predictive validity). Predictive validity has often referred solely to the ability of a model to identify pharmacological agents with potential therapeutic value in humans. However, this definition does not take into account important ways in which a model can predict a particular behaviour. Although construct validity may be considered relevant to animal models, the process of

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

construct validation can also be viewed as analogous to processes of model development, scientific investigation and hypothesis testing (Cronbach and Meehl, 1955; Ebel, 1961). Therefore, this chapter focuses upon predictability and face validity only.

Predictability refers to the ability of a model to identify effects of drugs (e.g. reinforcement, withdrawal) that are observed in human subjects, as well as pharmacological agents with potential therapeutic value. Face validity is evaluated with respect to the ability of a particular animal model to satisfy the DSM IV (American Psychological Association, 2000) criteria used for the diagnosis of substance dependence and abuse in humans (see Table XVI-1.1). In this regard, it should be noted that drug addiction, in humans, has been characterized as occurring in stages (e.g. initiation, maintenance and reinstatement). Furthermore, therapies effective in one stage of the addiction cycle may be ineffective in another. Therefore, the ability of a particular experimental paradigm to model these various stages should be considered.

ANIMAL MODELS OF THE POSITIVE REINFORCING EFFECTS OF DRUGS

A characteristic effect of drugs of abuse is their ability to function as positive reinforcing stimuli. This action has provided the framework for currently used animal models of substance dependence. Early models of drug reinforcement used operant paradigms in nonhuman primates; however, many of these same paradigms now are utilized in rodents. The use of these rodent models, together with molecular biological techniques as well as *in vivo* techniques for the quantification of neurotransmitter dynamics, has provided important insights regarding the neurobiology of addiction (Berke and Hyman, 2000; Hiroi *et al.*, 1997; Weiss *et al.*, 2000).

Operant Intravenous Drug Self-Administration

Experimental animals readily self-administer drugs of abuse via the intravenous route and, in general, drugs that are self-administered correspond to those that have high abuse potential in humans (Brady and Lukas, 1984; Fischman, 1989). Indeed, this relationship is so strong that intravenous drug self-administration is considered an animal model predictive of abuse potential. However, not all drugs abused by humans are self-administered by experimental animals (e.g. hallucinogens).

For intravenous self-administration studies, a chronic indwelling catheter is surgically implanted into a vein to permit drug infusion. During self-administration sessions, the subject acquires a drug infusion by performing a discrete response (e.g. pressing a lever or emitting a nose poke through a hole on an operant panel). The number and pattern of responding required for each infusion is determined by the schedule of reinforcement imposed by the experimenter. Drug availability usually is signalled by an environmental stimulus (e.g. light or tone). The number of infusions obtained for a given drug dose or the rate of responding during a session is typically assessed. Self-administration sessions are continued until animals exhibit stable rates of responding. Test sessions examining responding in response to other doses, test drugs or pharmacological manipulations are then conducted. From comparisons of dose–effect curves, the relative efficacies and potencies of drugs in maintaining self-administration can be determined. Alternatively, the number of sessions required to achieve stable rates of self-administration or the number of animals acquiring self-administration across sessions can be used to examine the influence of pharmacological or genetic manipulations on the acquisition of self-administration.

Factors affecting the amount of drug self-administered as well as the pattern and rate of responding include the schedule of reinforcement imposed, session duration (e.g. limited versus unlimited drug access), the presence of stimuli that predict drug availability, the drug itself, and the rate of drug infusion. Furthermore, there are species- and strain-related differences in the degree to which a drug is self-administered (Kuzmin and Johansson, 2000). In addition to the intravenous route of administration, the intragastric or oral route can be employed (see below).

Fixed-Ratio Schedule

In simple fixed-ratio schedules, the number of responses required for infusion of a drug is set at a fixed number. In rodents, these schedules generally will not maintain stable responding below a certain unit dose and, within the range of doses that do maintain stable responding, self-administration rate is inversely related to dose. Within the range of doses that maintain stable responding, animals increase their self-administration rate as the unit dose is decreased, apparently compensating for decreases in the unit dose. Conversely, animals reduce their rate of self-administration as the unit dose is increased, resulting in a characteristic inverted U-shaped dose–response curve (Figure XVI-1.1a; Brady and Lukas, 1984).

Fixed-Interval Schedules

In a fixed-interval schedule, the frequency of injections is determined primarily by the interval schedule imposed and not by the response rate (Corrigal and Koen, 1989). Therefore, the use of these different schedules can provide information regarding both the reinforcing effects of a drug and potential nonspecific motor effects that can confound data interpretation.

Progressive-Ratio Schedules

Under these schedules, the response requirements for successive drug infusions increase with sequential injections according to

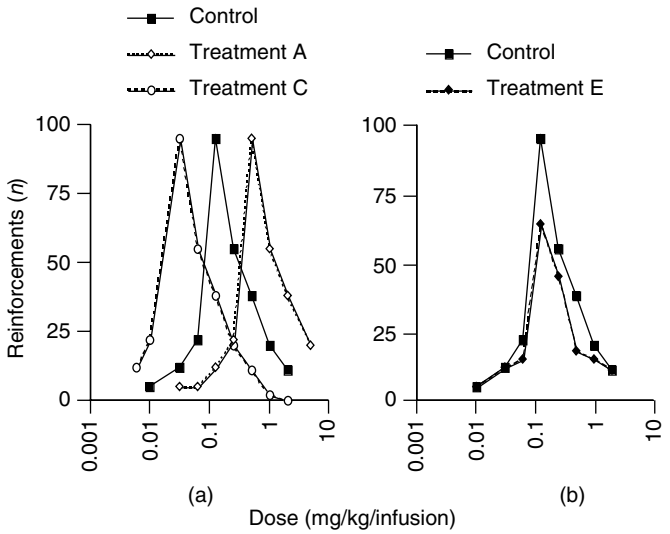

Figure XVI-1.1 Hypothetical data showing rates of responding for unit doses of drug under an FR schedule and the interactions between unit dose and pharmacological manipulation. (a) Response rates increase across low to moderate drug doses and then decrease across higher doses resulting in an inverted U-shaped function. Treatments can result in shifts to the left or right of the dose–response curve as well as upward or downward shifts (b). The failure to assess the effects of a particular treatment on multiple doses of a drug could lead to erroneous conclusions about the ability of a treatment to influence drug taking as well as the mechanisms mediating the treatment–drug interaction

some predetermined progression. The *breakpoint*, defined as the response requirement at which the subject ceases responding, is then determined. The breakpoint, defined as the largest ratio requirement that the subject completes (Hodos, 1961) or as the number of ratios completed by the subject per session (Depoortere *et al.*, 1993), represents the maximum work a subject will perform to receive an infusion of a drug and can be used to determine the reinforcing efficacy of drugs both within and across pharmacological classes as well as the neural basis of reinforcement (Griffiths *et al.*, 1978; Ranaldi and Roberts, 1996; for review see Stafford *et al.*, 1998).

Drug craving has been conceptualized as the incentive motivation to self-administer a drug that has been previously consumed. Therefore, this schedule can provide an animal model of drug craving. Since, however, the breakpoint reflects both the unconditioned (reinforcing) and conditioned incentive effects of drugs, it typically does not allow for the assessment of drug seeking in the absence of drug administration. Hence, the unconditioned effects of a drug (e.g. sedation, activation) can affect the dependent variable. This potential confound can, however, be minimized when the ratio progression is increased across rather than within sessions and/or when performance of the first ratio schedule presented during a trial is evaluated.

Multiple Schedules

Clinical definitions of substance dependence typically refer to the disruptive effects of drug use on non-drug-related activities. The use of multiple schedules of reinforcement enables the application of concepts of behavioural economics (e.g. commodities, consumption, price and demand) to operant behaviour. It also can provide a control for nonselective effects of drug reinforcement. In these procedures, self-administration of a drug is incorporated into a multiple component schedule with other reinforcers (e.g. other drugs, sucrose or water). Behaviour maintained by alternate presentation of natural reinforcers (e.g. food, water) and drugs of abuse in the same session and with the same reinforcement requirements has been reported for several species. Using these procedures, several groups have shown that the contingencies for concurrent reinforcers can affect behaviour asymmetrically and that the response requirement for reinforcers can affect drug self-administration (for review see Bickel *et al.*, 1995; Carroll *et al.*, 1989; Elsmore *et al.*, 1980). It is also apparent that drugs can substitute for, be complementary to, or be independent from, the 'price' of one another and that their effects can be interpreted in economic terms. In addition to evaluating the selectivity of manipulations that apparently reduce the reinforcing efficacy of a drug, these procedures can provide information regarding those factors affecting 'loss of control', as well as the effectiveness of behavioural and/or pharmacological interventions (Bickel *et al.*, 1995).

Second-Order Schedules

Under a second-order schedule, completion of an individual component (or part) of the schedule produces the terminal event (drug infusion) according to another overall schedule (Katz and Goldberg, 1991). Typically, completion of a unit schedule results in the presentation of a brief stimulus, and completion of the overall schedule results in the delivery of the stimulus and the drug. Second-order schedules have the advantage that they maintain high rates of responding and extended sequences of behaviour before any drug infusion occurs. Therefore, acute drug effects on response rates are minimized. High response rates are maintained even for doses that decrease rates when several injections are self-administered during a session. In addition, this schedule requires extended sequences of behaviour, thus, modelling the human condition in which drug taking is preceded by a series of behaviours (e.g. procurement, preparation). Second-order schedules of reinforcement can, when analysed appropriately, separate responses emitted for a drug from those affected by the drug and also enable assessment of the role of stimuli associated with drug administration upon responding. In contrast to the schedules described above that provide a measure of 'drug taking', by examining responding during the interval prior to any drug infusions, a measure of 'drug seeking' is obtained (Alderson *et al.*, 2000; Arroyo *et al.*, 1998). Furthermore, this measure, in contrast to others, is not obtained under extinction conditions (see below).

Oral Drug Self-Administration

Another approach to studying the motivation to consume a drug is to measure the volume consumed when a drinking bottle is available in the home cage. Typically the subject is offered a choice between a drug solution and alternative solutions, one of which is often water. The position of the solutions is random and alternated across self-administration session to avoid potential confounds of position bias. The proportion of drug intake relative to total intake is calculated as a preference ratio. Alcohol is most often studied with these procedures. However, similar studies have been done with cocaine (Jentsch *et al.*, 1998). This procedure has been used to characterize genotype-dependent differences in drug preference, most often alcohol preference (Li, 2000), and the effects of pharmacological treatments on drug intake and preference.

Using operant procedures, the reinforcing effects of drugs can be directly assessed by having animals work to obtain oral consumption of a drug. In this approach the effort to obtain the substance can be separated from the consummatory response (e.g. drinking) and intake can be easily charted over time. In addition, different schedules of reinforcement can be used to change baseline parameters. For operant self-administration of alcohol, rats can be trained to lever press for alcohol using a variety of techniques all designed to overcome the aversive taste and after-effects of initial exposure to alcohol. One approach involves using a sweetened solution fading procedure (Samson, 1986; Samson *et al.*, 1999). Alcohol concentrations are increased from 5% to 8% to a final concentration of 10% over time, with each concentration mixed first with saccharin or sucrose and then presented alone. Typically, rats are allowed to respond for 10% alcohol versus water for 4–6 weeks until stable self-administration is achieved. Using this approach, animals can be trained to lever press for concentrations of alcohol up to 40% (Samson, 1986). The animals will perform on fixed-ratio schedules and progressive-ratio schedules and obtain significant blood alcohol levels in a 30 min session (Samson *et al.*, 1999). Similar procedures have been applied to other drugs of abuse (Macenski and Meisch, 1998; Meisch *et al.*, 1992; Stewart *et al.*, 1994).

Evaluation of Self-Administration Techniques

Drug self-administration techniques have both reliability and predictive validity. The dependent variable provides a measure of the motivation to obtain drugs (e.g. the amount of work an animal will perform to obtain drug) and has demonstrated that drugs function as powerful reinforcers. Responding maintained by drugs as reinforcers is stable across sessions and can be altered predictably by neurotransmitter antagonists. Intravenous drug self-administration also has predictive validity in that drugs having high reinforcement potential in experimental animals have reinforcing effects in humans as measured by both operant and subjective reports (Fischman, 1989; Johanson and Balster, 1978; Schuster and Thompson, 1969).

Drug self-administration can vary as a function of the dose available as well as the species or strain tested. It is influenced by the

presence of alternate reinforcers, environmental stimuli that signal drug infusions, post-reinforcement interval, and prior history of the subject (Carroll *et al.*, 1981; Comer *et al.*, 1996; Glowa and Williams, 1992; Nader and Woolverton, 1992). These variables should be considered when interpreting self-administration studies.

Self-administration under a fixed ratio schedule of reinforcement typically results in an inverted U-shaped curve. Since both leftward and rightward shifts in the dose–effect function will decrease self-administration of some unit doses but simultaneously increase self-administration of other doses (Figure XVI-1.1b,c), construction of full dose–effect functions is essential. Without this data, it is unclear as to whether a particular pharmacological manipulation results in a shift of the dose–response function to the left or to the right or is unique to the dose tested. Since a given pretreatment may decrease self-administration by having nonspecific effects on behaviour (e.g. sedation), the influence of a pretreatment on non-drug reinforcers should be assessed regardless of the schedule employed.

The duration of drug access as well as the inter-infusion interval should also be considered when attempting to model the human condition. An important feature of unlimited-access cocaine self-administration paradigms is that they provide an animal model of the 'binge' abstinence patterns of cocaine use seen in humans (Fitch and Roberts, 1993; Gawin, 1991). As such, unlimited-access conditions can also enable examination of the variables controlling reinstatement of drug use following a period of abstinence. Even when limited-access conditions are imposed, dramatic differences in cocaine self-administration are seen depending upon whether self-administration sessions are 1 or 6 hours in duration (Ahmed and Koob, 1998). In a recent study, rats with 1-hour access to cocaine exhibited lower intake that remained stable for several weeks as compared to rats with longer access (e.g. 6-hour sessions), which exhibited a progressive increase in intake over the same number of sessions. Interestingly, after a period of abstinence the short-access animals resumed stable intake whereas the rate of escalation of intake of the longer-access animals was greater than that observed previously.

Brain Stimulation Reward Thresholds

Electrical self-stimulation of certain brain areas is rewarding for animals and humans as demonstrated by the fact that subjects will readily self-administer the stimulation (Olds and Milner, 1954). The high reward value of intracranial self-stimulation (ICSS) has led to the hypothesis that ICSS directly activates neuronal circuits that are activated by conventional reinforcers (e.g. food, water, sex) and that are modulated by drugs of abuse. Although ICSS is an operant procedure, it differs significantly from drug self-administration in that subjects work to directly stimulate presumed reinforcement circuits in the brain, and the effects of test drugs on ICSS are determined. Various drugs of abuse decrease thresholds for ICSS, and there is a good correspondence between the ability of drugs to decrease ICSS thresholds and their abuse liability (Kornetsky and Esposito, 1979). More recently, ICSS has been used in conjunction with *in vivo* voltammetry, a technique that permits rapid determination of changes in neurotransmitter release in discrete regions of the brain, to examine the neurochemical basis of reward (Garris *et al.*, 1999).

Many ICSS procedures have been developed (for review see Gallistel, 1983; Stellar and Stellar, 1985). Two, however, provide a measure of stimulation thresholds that are not confounded by influences on motor and performance capability. These are the rate-frequency curve-shift procedure, and the discrete-trial, current-intensity procedure (Markou and Koob, 1993; Miliaressis *et al.*, 1986).

Rate-Frequency Procedure

In the rate-frequency procedures, a frequency threshold measure is obtained by the generation of a stimulation input–output function (Gallistel, 1983; Miliaressis *et al.*, 1986). Rate-frequency curves are collected by allowing the rats to press a lever for a series of pulse frequency stimuli delivered through an electrode in a rewarding brain site (e.g. medial forebrain bundle). A runway apparatus also can be used with running speed as the dependent measure. Frequencies can be presented in an ascending, descending or random order or in alternating descending and ascending series. The locus of rise, defined as the frequency at which the function rises from zero to an arbitrary criterion-of-performance level, is determined and provides a measure of ICSS reward threshold (Gallistel, 1983). The behavioural maximum measure is the asymptotic maximal response rate, and changes in this variable are thought to reflect motor or performance effects. Changes in the reward efficacy of stimulation (i.e. intensity manipulations) shift the rate-frequency functions laterally, resulting in marked changes in the locus of rise value. However, they do not alter the asymptote or the shape of the function. In contrast, performance manipulations or changes in motivation (as may occur after priming), alter the value of the behavioural maximum and the shape of the function.

Discrete-Trials Procedure

In the discrete-trials procedure the current-intensity threshold is determined (Kornetsky and Esposito, 1979; Markou and Koob, 1993). This procedure consists of a series of discrete trials in which the subject is expected to emit a single response to receive the electrical stimulus, the current-intensity of which is varied between trials. At the start of each trial, rats receive a non-contingent, experimenter-administered electrical stimulus and then must turn a wheel manipulandum to obtain a contingent stimulus identical to the previously delivered non-contingent stimulus (positive reinforcer). The threshold value is defined as the midpoint between the current-intensity level at which the animal makes two or more positive responses out of the three stimulus presentations and the level at which the animal makes less than two positive responses at two consecutive intensities. Response latency is defined as the time that elapses between the delivery of the non-contingent electrical stimulus and the animal's response on the wheel. Manipulations that increase the reward value of stimulation lower thresholds whereas increases in threshold are indicative of decreases in reward value (Bespalov *et al.*, 1999; Panagis *et al.*, 2000). Increases in response latency can be interpreted as a motor or performance deficit. Since, however, the discrete-trials threshold procedure is designed to minimize behavioural response requirements, it is less sensitive to manipulations that produce motor and performance deficits (Markou and Koob, 1993).

Evaluation of ICSS

ICSS permits direct assessment of the effects of drugs on reward circuits in the brain and, as such, eliminates the influences of consummatory-like behaviours on responding. Since electrodes can be placed in various structures, it permits mapping of those brain areas mediating the rewarding effects of drugs. It can also be used to examine the neuroanatomical basis of drug withdrawal and relapse (Vorel *et al.*, 2001).

Many of the same limitations described above apply to ICSS studies. In addition, it should be noted that ICSS can be elicited in many brain regions and certain brain areas support higher rates of stimulation reward than others. In addition, stimulation of particular brain regions may activate different circuits.

ANIMAL MODELS OF THE CONDITIONED REINFORCING EFFECTS OF DRUGS

Drug-seeking behaviour in humans is maintained not only by the primary reinforcing effects of a drug but also by environmental stimuli that have signalled drug use (O'Brien *et al.*, 1977, 1992). Through the processes of classical conditioning, these stimuli can then function as conditioned reinforcers that maintain drug-seeking behaviour and exacerbate craving and/or withdrawal (O'Brien *et al.*, 1992; Wikler and Pescor, 1967).

Conditioned Place Preference

The conditioned place preference paradigm is a classical conditioning procedure that has been used to model the conditioned reinforcing (or aversive) effects of drugs in experimental animals. In this paradigm, administration of a drug (the unconditioned stimulus, UCS) is paired with one distinct environment and administration of placebo with another. After several environmental pairings, non-injected animals are allowed access to both environments and the time spent in each is measured. The animal's choice to spend more time in either environment provides a direct measure of the conditioned reinforcing effect of a drug.

The apparatus used in conditioning experiments consists of two or three environments that are differentiated from each other on the basis of visual, tactile and/or olfactory cues. The distinctiveness of the environments is essential for the development of conditioning. In the unbiased design, the environments are manipulated so that animals differentiate one from the other but do not exhibit an innate preference for either of the place cues. Pairing of drug with a particular environment is counterbalanced and change in the time spent in the drug-paired environment can be directly attributed to the conditioned reinforcing effects of a drug. Control groups, which receive saline in each of the environments, are run to ensure the unbiased nature of the conditioning procedure. In contrast, however, to the biased procedure (see below), a preconditioning phase, to assess pretest preferences, is not necessary, thus preventing the potential confound of latent inhibition (Lubow, 1989) and decreasing the time necessary for a particular experiment.

In the biased design, animals exhibit a preference for one of the place cues prior to the commencement of conditioning. A preconditioning phase, in which animals are allowed access to both environments, is necessary to determine the innate preference of each animal. The drug then is paired with the preferred or non-preferred environment depending upon whether the drug is assumed to produce aversive or positive reinforcing effects, respectively. The difference in time spent in a particular environment during the preconditioning and conditioning phases is then used to determine drug effect. Although this design is used often, data interpretation can be problematic since place preferences may indicate either incentive motivational effects of a drug or a decrease in the aversive properties of the least-preferred environment.

Studies in rodents have shown that drugs that function as positive reinforcers in other paradigms produced conditioned preferences for an environment associated with their administration (Cunningham *et al.*, 1999; Mucha and Herz, 1985; for review see Bardo and Bevins, 2000; Shippenberg and Elmer, 1998). In contrast, drugs that produce dysphoric or aversive effects in humans produce conditioned aversions for the drug-associated place. This procedure, thus, permits assessment of the conditioning of drug reinforcement and can provide indirect information regarding the positive and negative reinforcing effects of drugs. More recently, place conditioning has been used in conjunction with gene transfer and homologous recombination techniques to delineate the neural basis of drug-induced reinforcement (Carlezon *et al.*, 1998; Risinger *et al.*, 1996). It is particularly useful in the former case since the effects of virally mediated gene transfer are transient and require a procedure that can be completed within several days after gene transfer (Carlezon *et al.*, 1998).

Evaluation of Conditioned Place Preference Procedures

The conditioned place preference paradigm has reliability and predictive validity. Drugs that produce conditioned preferences for the drug-associated environment are those that function as positive reinforcers in other paradigms. Conditioned place aversions also are observed in response to drugs that are negative reinforcers or those that produce aversive or dysphoric states in human subjects (Mucha and Herz, 1985). In contrast to many other procedures, place conditioning is assessed in the absence of drug. Therefore, the potential confound of drug-induced alterations in locomotor activity on performance are alleviated. Finally, it was initially argued that the conditioned place preferences produced by drugs may result from their ability to increase locomotor activity. This, in turn, would increase exploration within a particular environment and decrease neophobia. Subsequent studies, have, however, clearly shown that this is not the case (Shippenberg and Elmer, 1998).

Several issues must be considered when interpreting data from place conditioning studies. First, the drug is administered non-contingently and there is evidence that the behavioural and neurochemical effects of abused drugs differ depending upon whether drug administration is controlled by the subject (Hemby *et al.*, 1997). Although the conditioned place preference paradigm has been validated as a protocol for measuring the rewarding effects of drugs in non-human primates self-administering a drug (Foltin and Evans, 1997, 2001), studies in human subjects are lacking. The issue of whether humans or non-human primates would exhibit conditioning in response to non-contingent drug administration has not been examined.

Route of drug administration and number of environmental pairings, as well as the number of conditioning sessions, can profoundly affect place conditioning (Bechara and van der Kooy, 1985; Shippenberg and Heidbreder, 1995). Strain-related differences in the conditioned response to opiates and alcohol have also been observed (Cunningham *et al.*, 1999; Shoaib *et al.*, 1995). Since tests of conditioning are usually conducted in the absence of drug, the issue of state-dependency (Overton, 1974) must also be considered. Finally, place conditioning now is used in many studies assessing genotype-dependent differences in drug sensitivity. However, a lack of a conditioned response may indicate a loss of the reinforcing effects of a drug or a generalized impairment of learning or memory processes required for the acquisition or performance of a conditioned response, or differences in state-dependent learning. In addition, genotype-dependent differences in the saliency of environmental cues used for conditioning may occur. These factors are rarely controlled for and should be considered before concluding that a particular manipulation impacted on reinforcement.

Conditioned Reinforcement Paradigm

The conditioned reinforcement paradigm allows characterization of the incentive value imparted on formerly neutral environmental stimuli that have been repeatedly associated with drug self-administration. In a conditioned reinforcement paradigm, subjects are trained in an operant chamber containing two levers. Responses on one lever, denoted as the active lever, result in the presentation of a brief stimulus (termed the conditioned stimulus or CS) followed by presentation of a primary reinforcer (e.g. drug) whereas responses on the other lever have no consequences (inactive lever) (Davis and Smith, 1976). The ability of the previously neutral CS to maintain responding in the absence of the primary reinforcer provides a measure of the reinforcing value of these stimuli. This

procedure provides a test for the conditioned incentive effects of drugs because responding for drug-associated stimuli occurs under extinction conditions (e.g. in the absence of drug). It also provides an animal model of drug craving since the incentive motivational effects of a stimulus are examined in the absence of drug taking.

Evaluation of Conditioned Reinforcement Procedures

This procedure has validity. Humans will work to obtain stimuli previously associated with drug use, and drug-associated stimuli produce drug craving. Many of the same limitations discussed for the conditioned place preference paradigm apply to the conditioned reinforcement paradigm. Interpretation of the data is limited by the fact that animals do not control their intake and it remains unclear as to whether similar effects would be observed with contingent drug injections. A potential interpretational advantage of this paradigm over that of place preference conditioning is that operant responding, rather than approach or avoidance, is quantified.

Second-Order Schedules

Second-order schedules also can be used to evaluate the conditioned reinforcing effects of drugs. As described above, completion of the first component or unit of the schedule rather than an individual response produces the terminal event according to another overall schedule (Goldberg and Gardner, 1981). In some versions of a second-order schedule, completion of the first component or unit produces a stimulus and then completion of a fixed number of first components produces the stimulus and drug. Manipulation of these stimuli can modify acquisition, maintenance, resistance to extinction, and recovery from extinction. To assess the effects of conditioned reinforcement, the number of responses with the paired stimulus can be compared to the number of responses with a non-paired stimulus. For example, substitution of drug-paired stimuli with non-drug-paired stimuli actually can decrease response rates.

Evaluation of Second-Order Schedules

Second-order schedules are reliable and have predictive validity. Until recently, this procedure was limited to non-human primates. However, several investigators have effectively implemented this procedure in the rat. The maintenance of performance in second-order schedules with drug-paired stimuli may be analogous to the maintenance and reinstatement of drug seeking in humans with the presentation of drug-paired stimuli. Drug craving in the absence of drug can also be assessed by terminating sessions immediately after the first drug infusion that occurs after completion of the terminal schedule (see below).

MODELS OF THE SUBJECTIVE EFFECTS OF DRUGS: DRUG DISCRIMINATION

The drug discrimination paradigm is based on the capacity of animals to use the interoceptive effects produced by drug or placebo administration as discriminative cues to control responding maintained by food or other stimuli that reinforce behaviour. Currently, it is the only animal model used to evaluate the subjective effects of drugs. This usage is based on studies showing: (i) a high correlation between patterns of cross-generalization in animal drug discrimination experiments and subjective effects in human subjects and (ii) that, in many instances, there is a correlation between the measured subjective effects of drugs in human subjects and their discriminative responses (Dykstra *et al.*, 1997; Preston and Bigelow, 1991). Although considerable controversy exists as to which, and to what extent, subjective effects of drugs contribute to the maintenance of drug taking, it has been hypothesized that the stimulus effects of drugs may contribute to bouts of drug taking in intermittent users and to relapse to dependence in former drug addicts (Meyer and Mirin, 1979; Stolerman, 1992). In this view, discriminative stimuli signal the availability of a reinforcer and therefore set the occasion to engage in those behaviours that enable consumption of the reinforcing drug. Consistent with hypothesis, self-administration studies have shown that stimuli predictive of drug administration elicit drug-seeking and drug-taking behaviour and also retard the extinction of responding for psychostimulants and opiates (Katner *et al.*, 1999; McFarland and Ettenberg, 1997; See *et al.*, 1999; Weiss *et al.*, 2000).

For drug discrimination studies, animals are trained to emit a particular response following administration of a fixed drug dose (e.g. depression of one lever) and to press another lever following administration of saline under a fixed schedule of reinforcement. Most commonly, an appetitively motivated operant procedure is used in which animals are food or water deprived. Responding on the training-condition-appropriate lever results in the delivery of food or water. Training is continued until the animal reliably selects the appropriate lever after drug or saline administration. Once trained, tests of stimulus generalization or antagonism are interposed between training sessions to determine whether other doses of the training drug or a specific drug treatment produce stimulus effects qualitatively similar to or different from those of the training drug. As with other operant paradigms, various reinforcement schedules (e.g. fixed-ratio, fixed-interval, differential reinforcement of low response rate) and response measures (e.g. nose poking, maze running) can be used. Dose 1 versus dose 2 and drug 1 versus drug 2 versus saline discriminations also can be employed (Colpaert and Janssen, 1982; Gauvin and Holloway, 1991; Picker and Cook, 1997).

Drug discrimination studies in non-human primates and rodents have shown that the discriminative stimulus effects are homologues to the subjective effects they produce in humans, and that comparison of the subjective and discriminative stimulus effects of a test drug to those produced by a known drug of abuse can predict abuse liability (for review see Colpaert, 1999). They have also been used to model the subjective effects of drug withdrawal (Emmett-Oglesby *et al.*, 1990; Gellert and Holtzman, 1979) and drug tolerance (Sannerud and Griffiths, 1993).

Evaluation Of Drug Discrimination Procedures

Drug discrimination offers both reliability and predictive validity. Stimulus generalization gradients are stable once drug discrimination is acquired and the stimulus effects of various drugs are altered predictably by neurotransmitter antagonists. Drug discrimination also has predictive validity in that drugs that produce discriminative stimulus effects that generalize to drugs of abuse are those with known abuse liability.

Generalization gradients are dependent upon the dose of drug used for training. Certain neurotransmitter antagonists attenuate the discriminative stimulus effects of a drug when a low training dose is employed. However, these same antagonists fail to modify the discriminative stimulus effects of the same drug when a higher training is employed. Therefore, the use of multiple training doses is essential.

Different test procedures (extinction versus reinforced responding on the lever on which the first schedule requirement is completed) may yield different results depending upon the variable that is used to measure generalization. As with all animal models, species and strain differences as well as the experimental history of an animal can alter the discriminative stimulus effects of a drug (Morgan *et al.*, 1999).

MODELS OF THE NEGATIVE REINFORCING EFFECTS OF DRUG WITHDRAWAL

One criterion used to define substance dependence in human subjects is the presence of a withdrawal syndrome following the cessation of drug use. Although many of the overt physical signs associated with withdrawal from drugs are easily quantified, abstinence from chronic drug use is also associated with long-lasting alterations in motivation and affect that can occur even in the absence of somatic withdrawal signs. It has been postulated that the negative affective states precipitated by drug withdrawal contribute to continued drug use (Koob and Le Moal, 2001). Furthermore, according to the theory of Wikler and Pescor (1967), the high rate of relapse observed in addicts is due in part to conditioned responses to stimuli that have been paired either with the aversive effects of drug withdrawal or the positive reinforcing effects of drug taking.

Operant Drug Self-Administration

Drug self-administration can be conducted in animals rendered physically dependent upon the drug (e.g. abstinence from drug use results in a withdrawal syndrome). Although it is clear that animals will self-administer drugs in the absence of withdrawal, the reinforcing values of drugs may change depending upon the presence of absence of a withdrawal state. Indeed, evidence that physical dependence can increase the reinforcing efficacy of drugs has been presented. Monkeys made physically dependent upon morphine show increases in their progressive-ratio performance compared to animals that do not exhibit withdrawal sympomatology (Yanagita, 1973). Rats with a history of self-administration of alcohol will self-administer alcohol during withdrawal in sufficient quantities to prevent withdrawal symptoms (Roberts *et al.*, 1996).

Conditioned Place Preference

The conditioned place preference paradigm has become an important tool with which to examine the conditioned motivational responses that develop as a consequence of withdrawal and their neurobiological basis. For such studies, subjects are exposed to one environment while undergoing withdrawal and to another in the absence of a withdrawal state. During tests of conditioning, animals are allowed access to both environments and the time spent in each is determined. Rodent studies (Bechara and van Der Kooy, 1995; Funada *et al.*, 1996; Hand *et al.*, 1988) have shown that individuals rendered physically dependent upon morphine exhibit dose-related conditioned aversions for an environment associated with spontaneous or opioid receptor antagonist-precipitated withdrawal. These conditioned responses can be observed after only a single conditioning session and are not observed in opiate naïve animals. Importantly, these conditioned effects are extremely long-lasting and persist for some weeks following the cessation of opiate administration. They can be observed in the absence of a quantifiable somatic withdrawal syndrome. Recent studies using the conditioned place preference paradigm in mice in conjunction with gene knockout techniques have provided new information regarding the neural substrates mediating the somatic versus the affective components of opiate withdrawal (Matthes *et al.*, 1996; Murtra *et al.*, 2000).

Brain Stimulation Reward

ICSS thresholds have been used to assess changes in systems mediating reinforcement processes during the course of drug dependence. In contrast to acute administration of psychostimulant drugs that lowers ICSS threshold, withdrawal from chronic administration of these same drugs elevates ICSS thresholds (Kokkinidis and McCarter, 1990; Wise and Munn, 1995). Similar results have been observed following withdrawal from ethanol and nicotine (Epping-Jordan *et al.*, 1998; Schulteis *et al.*, 1995) and precipitated withdrawal in opiate-dependent rats.

Drug Discrimination

Drug discrimination can be used to characterize both specific and nonspecific aspects of withdrawal. Generalization to an opiate antagonist provides a more general nonspecific measure of opiate withdrawal intensity and time course (Gellert and Holtzman, 1979). Examples of a more specific aspect of withdrawal are animals that have been trained to discriminate pentylenetetrazol, an anxiogenic-like substance, from saline in alcohol-, diazepam- and opiate-dependent animals. During withdrawal, generalization to the pentylenetetrazol cue has suggested an anxiogenic-like component to the withdrawal syndrome (Emmett-Oglesby *et al.*, 1990; Gauvin and Holloway, 1991).

MODELS OF DRUG-SEEKING AND RELAPSE

As discussed above, environmental cues repeatedly paired with primary reinforcers can acquire incentive properties via classical conditioning processes (Davis and Smith, 1976; Katner *et al.*, 1999; Weiss *et al.*, 2000; Wikler and Pescor, 1967). It has been postulated that the development of these conditioned reinforcing effects plays an important role in drug craving and relapse to addiction. Indeed, human studies have shown that the presentation of stimuli previously associated with drug delivery increases the likelihood of relapse as well as self-reports of craving and motivation to engage in drug taking (Ehrman *et al.*, 1992; O'Brien *et al.*, 1977, 1992). Recently, several techniques have been developed to model drug seeking (e.g. craving) and relapse in experimental animals.

Reinstatement of Self-Administration After Extinction

The reinstatement procedure has been used extensively in recent years to model relapse in the experimental animal. Individuals are trained to self-administer a drug, usually under a fixed ratio schedule of reinforcement, until stable rates of responding are achieved. Responding (e.g. lever pressing) for drug is then extinguished by substituting saline for drug for several sessions. Once responding is extinguished, test sessions are conducted in which the ability of non-contingent administration of the training drug or a test drug (e.g. drug priming) to reinstate responding is determined (deWit and Stewart, 1981). Various laboratories have shown that non-contingent drug administration leads to the reinitiation of responding for opiates as well as psychostimulants. Furthermore, compounds that are in a different pharmacological class from that of the training drug are generally less effective in reinstating responding that those of the same pharmacological class (deWit and Stewart, 1981, 1983; Gerber and Stretch, 1975). The ability of stimuli that have previously signalled drug infusions or of other manipulations (e.g. stress) to reinstate self-administration behaviour can be assessed (Ranaldi and Roberts, 1996; Shaham and Stewart, 1995).

Second-Order Schedules

In contrast to other schedules of reinforcement, in second-order schedules, completion of the first component or unit of a second-order schedule, rather than an individual response, produces drug infusion according to another overall schedule. Therefore, it has

been argued that responding during the first interval that occurs prior to any drug delivery, in contrast to other procedures or during subsequent intervals of the second-order schedule, provides a measure of drug seeking in the drug-free state (Everitt and Robbins, 2000). Analysis of responding for cocaine has indicated that in the first interval, a monotonic relationship between dose and responding is seen (Arroyo *et al.*, 1998). This contrasts with later intervals in which self-administration increases for lower doses and decreases for higher doses. These data indicate that responding during the first interval may provide a measure of the reinforcing efficacy of a drug. To date, however, this relationship has not been observed with other classes of abused drugs.

Using second-order schedules, the ability of cues associated with drug administration to reinstate self-administration behaviour can also be assessed (for review see Everitt and Robbins, 2000). Studies in non-human primates have shown that responding for morphine decreased when presentation of a light that served as the conditioned stimulus was omitted. When, however, the light was reinstated, responding resumed (Goldberg and Tang, 1977). Rats exhibit a decrease in responding and an increased latency to initiate responding when a stimulus paired with cocaine self-administration is withheld (Alderson *et al.*, 2000; Arroyo *et al.*, 1998). In animals in which the stimulus was still present, a greater number of responses are seen, indicating that presentation of the conditioned stimulus retarded extinction (Arroyo *et al.*, 1998; Ranaldi and Roberts, 1996).

Extinction with and Without Cues Associated with Intravenous Drug Self-Administration

Extinction procedures assess the persistence of drug-seeking behaviour in the absence of response-contingent drug availability. In this paradigm, subjects first are trained to self-administer a drug until stable self-administration patterns are exhibited. Extinction sessions are identical to training sessions for self-administration except that no drug is delivered after the completion of the response requirement. The probability of reinstating responding under extinction conditions with drug-paired stimuli or even stimuli previously paired with drug withdrawal can be examined (Weiss *et al.*, 2000). Discriminative stimuli that are paired with infusions of cocaine or vehicle can also be employed to examine reinstatement of responding. Using this method, it has been shown that a discriminative stimuli associated with self-administration of cocaine elicits responding for drug for several months following the termination of extinction sessions (Ciccocioppo *et al.*, 2001).

Evaluation of Models of Drug-Seeking and Relapse

Each of the techniques described has reliability and predictive validity. Presentation of stimuli associated with drug injection induces drug craving in humans and maintains responding in the extinction and second-order schedules (Ehrman *et al.*, 1992; O'Brien *et al.*, 1992). Re-exposure to drugs increase self-reports of craving in human addicts (O'Brien *et al.*, 1991). Human drug users, especially those who abuse psychostimulants, often go through periods of drug use and abstinence (e.g. extinction). Therefore, it would appear that extinction paradigms provide a particularly useful model for examining the neurobiology of abstinence. Second-order schedules can be used to examine extinction, and, by examining responding during the first interval of the schedule, can also provide a measure of drug seeking that does not require the imposition of extinction by the experimenter. This distinction is important since it is likely that the motivational effects that drive responding in these two conditions differ profoundly.

Finally, as mentioned previously, increasing evidence indicates that the neurochemical and behavioural responses to a drug can differ depending upon whether it is administered contingently or non-contingently (Di Ciano *et al.*, 1998; Hemby *et al.*, 1997). Therefore, interpreting the effects of drug priming in self-administration and, in particular, in extinction–reinstatement procedures is not without difficulty. The extent to which 'priming', which can entail contingent administration of relatively large doses of drug, models the human condition is unclear.

SUMMARY AND CONCLUSIONS

To what extent do the procedures described above model the human condition? Table XVI-1.1 summarizes the DSM IV criteria used for the diagnosis of substance dependence. Criteria 1 (tolerance) and criteria 3 (withdrawal) can be assessed using a number of techniques discussed here as well as with others that provide a more physiological approach to these phenomena (e.g. quantification of somatic withdrawal signs or tolerance to opiate-induced antinociception). Mice, rats and non-human primates readily self-administer drugs that have high abuse liability in humans. When unlimited-access conditions are employed, an escalation of drug self-administration and a binge-like pattern of consumption is seen (Ahmed and Koob, 1998; Fitch and Roberts, 1993). In rats and non-human primates, progressive-ratio schedules can be used to determine reinforcing efficacy (Griffiths *et al.*, 1978; Stafford *et al.*, 1998). Therefore, it would appear that criterion 3 (the substance is often take in larger amounts or over a longer period than was intended) can be modelled in experimental animals. Criterion 6 (important social, occupational or recreational activities given up because of substance use) has been demonstrated in animal models involving choice procedures and behavioural economics paradigms (Carroll *et al.*, 1989; Elsmore *et al.*, 1980). It is, however, apparent that existing procedures can only model particular components of substance dependence and that a battery of animal models must be used to understand the factors leading to the initiation and maintenance of compulsive drug use.

Drug addiction in humans has been characterized as occurring in several stages, although progress from one stage to the next is not inevitable. The first stage is initiation or acquisition, which may lead to habitual use, physical or psychic dependence, and loss of control. An individual may stop taking a drug at any stage. However, relapse to drug taking after a period of abstinence is common. Although the factors responsible for relapse are not well understood, accumulating evidence suggests that drug-associated environmental stimuli, acute re-exposure to drug, and stress can act as triggers of craving leading to relapse in humans (Jaffe *et al.*, 1989; Robbins *et al.*, 1997). Animal models of drug craving and relapse continue to be developed and refined. Second-order schedules can be used as a measure of the conditioned reinforcing properties of drugs (Goldberg and Gardner, 1981). Recent work suggests that reliable responding for cocaine can be obtained with a second-order schedule in rats as well as in non-human primates (Arroyo *et al.*, 1998; Katz and Goldberg, 1991; Markou *et al.*, 1999; See *et al.*, 1999). The conditioned place preference paradigm also provides a measure of conditioned reinforcement that is conceptually similar to the measures provided by the operant paradigms (see above). More recently, stimuli that predict drug availability have been shown to be powerful cues for reinstating drug-seeking behaviour in studies using second-order schedules or extinction procedures (McFarland and Ettenberg, 1997; Weiss *et al.*, 2000). Priming injections of cocaine or heroin have also been shown to reinstate drug-seeking behaviours in extinction models and similar effects have been observed in response to certain stressors (deWit and Stewart, 1981; 1983; Shaham and Stewart,

1995; Spealman *et al.*, 1999). The extent to which the procedures currently available model the human condition with reliability and predictive validity requires additional study.

XVI-2

Amino Acid Transmitter Systems in Substance-Related Disorders

A. Dahchour and P. De Witte

INTRODUCTION

There is increasing evidence suggesting that ethanol, psychostimulants, nicotine and opioids may affect the central nervous system (CNS) by interfering with amino acid neurotransmitter systems. This review aims to clarify recent knowledge that has accumulated over the last decade in the understanding of the pharmacological, cellular and behavioural basis of such substances of abuse.

AMINO ACID TRANSMITTERS

Among the amino acid neurotransmitter systems are excitatory amino acids (aspartate, glutamate) which activate postsynaptic cells, the inhibitory amino acid GABA which depresses the activity of the postsynaptic cells, as well as the sulphonated amino acid taurine to which both neurotransmitter and neuromodulator functions have been assigned.

Glutamate

Glutamic acid (glutamate) is the major excitatory amino acid neurotransmitter in the CNS. Its excitatory effect on neurones is mediated by activating receptors, which are gated to ion channels, or to a protein that mediates a second messenger. This neurotransmitter has been reported to play an important role in alcoholism (Tsai *et al.*, 1995, Tsai and Coyle, 1998). Glutamate receptors in the mammalian CNS are divided into ionotropic (NMDA, kainate, AMPA) (Nakanishi, 1994; Hollmann *et al.*, 1994; Schoepfer *et al.*, 1994; Westbrook, 1994) and metabotropic receptors (Collingridge and Lester, 1989). The NMDA receptor, which is coupled to a voltage-sensitive ion channel, is permeable to calcium and monovalent cations Na^+ and K^+, and has been implicated in many physiological and pathological processes including synaptic plasticity, learning and memory, epileptiform seizures (Dingledine *et al.*, 1986) as well as neurotoxicity (Lovinger, 1993).

γ-Amino Butyric Acid

γ-Aminobutyric acid (GABA) is the major inhibitory amino acid neurotransmitter in the vertebrate CNS (Krnjevic, 1974, 1997; Curtis, 1995; McKernan and Whiting, 1996). The GABA receptors are divided currently into two types. The classical GABA receptor and its ion channel are specifically stimulated by muscimol and antagonized by bicuculline and termed the $GABA_A$ receptor or $GABA_A$ receptor channel. $GABA_A$ receptors belong to the ligand-gated ion channel family of receptors. The $GABA_A$ receptor consists of several protein subunits (at least five), which form a picrotoxin-sensitive anion channel and a number of allosteric regulatory sites for various drugs such as barbiturates, benzodiazepines, convulsants, neurosteroids, and possibly even anaesthetics and ethanol (Olsen, 1981; Sieghart, 1992, 1995; Morrow, 1995). Stimulation of these receptors usually brings about hyperpolarization of the cell membrane by opening of the Cl^- channel and entry of Cl^- into the neurone (Krnjevic, 1997; Perkins and Wong, 1997; van den Pol *et al.*, 1996). For more detail see chapter XIX-3, particularly the paragraph on the molecular biology of $GABA_A$ receptors.

GABA receptors which are specifically activated by baclofen and antagonized by phaclofen are the $GABA_B$ receptors. $GABA_B$ receptors are functionally coupled to K^+ and Ca^{2+} channels via G protein, and their stimulation causes an increase in the K^+ permeability or a decrease in Ca^{2+} currents in the target cell, which can result in decreased neurotransmitter release (Dolphin, 1990; Nicoll *et al.*, 1990; Gage, 1992; Malcangio and Bowery, 1995; Bowery and Brown, 1997; Kerr and Ong, 1995; Nishikawa *et al.*, 1997).

Taurine

Taurine (2-aminoethane sulphonic acid, $H_2NCH_2CH_2SO_3H$) is a β-non-essential sulphonated amino acid, which is synthesized from cysteine, and present in many mammalian cells at relatively high concentrations (millimolar). Although a multitude of studies of its possible function within the cell have been suggested, which include stabilization of membranes, osmoregulation of the cell and modulation of neurotransmitters, many of its biological effects remain unclear. However, recent studies have suggested that taurine is able to exert a multitude of functions in the CNS such as modulation of ion movements at both the calcium and chloride channels while interacting with many neurotransmitter systems to combat ethanol effects.

Interaction of Taurine with Neurotransmitters

The functions of taurine within the brain remain obscure although an increasing literature has identified a variety of roles. It has been proposed that taurine may play an important role either as an inhibitory neurotransmitter (Davison and Kaczmarek, 1971) or neuromodulator in the CNS (Lombardini, 1976; Scheibel *et al.*, 1981; Oja *et al.*, 1990) modulating synaptic activities, stabilizing and regulating cell volume (Oja and Kontro, 1983; Huxtable, 1989). It is clear that one of taurine's principal roles is to modulate calcium homeostasis, by reducing calcium accumulation within the cell

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

(Li and Lombardini, 1991; Vislobokov *et al.*, 1992), stimulating the pumping rate of the Ca^{2+}-activated ATPase pump when necessary (Huxtable, 1992). Taurine alters chloride movements (Haas and Hösli, 1973) by increasing the chloride conductance, and as a consequence of this modulation of ion channels taurine could alter neurotransmission by interacting with many neurotransmitter systems and receptors. Taurine interacts with the GABA recognition site at [^{35}S]*t*-butylbicyclophosphorothionate (TBPS) of the GABA receptor complex (Quinn and Harris, 1995) and modulates GABA release by its binding to both $GABA_A$ and $GABA_B$ receptors (Kontro *et al.*, 1990; Williams *et al.*, 1980; Bureau and Olsen, 1991; Malminen and Kontro, 1986). Such modulation of neurotransmission could be mediated by taurine's action on brain GABA and glycine (Huxtable, 1989, 1992; Kontro *et al.*, 1990) receptors. Furthermore, taurine could stimulate glutamic acid decarboxylase (GAD) in the brains of genetically bred epileptic rats (Bonhaus and Huxtable, 1985) influencing the conversion of glutamate to GABA. Taurine has also been suggested to modulate the dopaminergic transmission in the striatum (Kontro, 1987) by modifying taurine release in this brain region (Kontro and Oja, 1988).

Taurine interacts with glutamate and its receptors. As such, taurine has the ability to inhibit NMDA, kainate and quisqualate receptors (Kurachi *et al.*, 1983); both *in vitro* and microdialysis studies of various brain regions have shown that agonists of glutamate receptors, namely NMDA, kainate or quisqualic acid, induced taurine release (Lehmann *et al.*, 1985; Menéndez *et al.*, 1990; Shibanoki *et al.*, 1993; Saransaari and Oja, 1994). This interaction of taurine with the glutamatergic system could be of interest regarding the mechanism underlying the protective effects of taurine against toxic agents acting via excitatory amino acids. Many studies showed that taurine may protect cells from cytotoxicity (French *et al.*, 1986; Waterfield *et al.*, 1994; Oja and Saransaari, 1996; Saransaari and Oja, 1997; Obyrne *et al.*, 1997).

ETHANOL DEPENDENCE AND AMINO ACID TRANSMITTERS

Effect of Ethanol on Glutamate

Acute Effect of Ethanol

Electrophysiological and neurochemical studies showed that ethanol at pharmacologically relevant concentrations (50–100 mM) inhibits or antagonizes the action of agonists at the NMDA receptor in several neuronal preparations (Dildy Mayfield and Leslie, 1989; Hoffman *et al.*, 1989; Lovinger *et al.*, 1989, 1990; Woodward and Gonzales, 1990; Simson *et al.*, 1991; Hoffman, 1995). Furthermore, a decrease in glutamate extracellular striatal concentration occurs in an *in vivo* microdialysis study after administration of $2\,g\,kg^{-1}$ ethanol (Carboni *et al.*, 1993), while another microdialysis study showed a biphasic response with either $0.5\,g\,kg^{-1}$ (increase) or $2\,g\,kg^{-1}$ (decrease) ethanol on the glutamate release in both hippocampus and nucleus accumbens regions (Moghaddam and Bolinao, 1994). The inhibitory effect of ethanol on the NMDA receptor was not selective. Indeed, electrophysiological studies in *Xenopus* oocytes expressing mRNA from rat hippocampus and cerebellum demonstrated that there was a different degree of inhibition by ethanol on NMDA and non-NMDA receptors (Dildy Mayfield and Harris, 1992a, 1992b; Lovinger, 1993). However, ethanol appears to be less potent in inhibiting the function of non-NMDA ionotropic glutamate receptors (Hoffman *et al.*, 1989; Lovinger *et al.*, 1989).

Acute ethanol-induced inhibition of the NMDA receptor leads to many serious consequences on developmental, learning and memory processes. Alteration of NMDA receptor function during development can lead to severe and potentially permanent brain dysfunction (Weaver *et al.*, 1993), as well as ethanol-prevented long-term potentiation (LTP), which is a process that underlies learning (Maren and Baudry, 1995), particularly in hippocampus (Morrisett and Swartzwelder, 1993). Moreover, data from *in vivo* hippocampal studies showed that the decrease in hippocampal glutamate transmission induced by ethanol or benzodiazepines closely correlated with spatial memory deficits (Shimizu *et al.*, 1998). Interestingly, this phenomenon was blocked by NMDA antagonists (Coan *et al.*, 1987).

Conclusion 1

- Acute ethanol induced a decrease in intracellular glutamate level.
- Acute ethanol inhibits the NMDA receptor. This could have many serious consequences on developmental, learning and memory processes.

Chronic Effect of Ethanol

Chronic ethanol intoxication results in an upregulation of NMDA receptor number and function caused by the physiological response to the depressant effects of ethanol (Michaelis *et al.*, 1990; Chandler *et al.*, 1993a; Snell *et al.*, 1993; Trujillo and Akil, 1995; Whittington *et al.*, 1995). This upregulation may be explained by the enhancement of receptor expression and exchanger-associated proteins (Trevisan *et al.*, 1994; Follesa and Ticku, 1995; Snell *et al.*, 1996; Chen *et al.*, 1997). For example, an increase in NMDA receptor subunit NR1 and NR2 polypeptide levels was reported by Ticku (1998), and an upregulation of the NMDA receptor NR2B subunit mRNA without altering NR1 mRNA in rat brain and cortical neurones was reported by Hu *et al.* (1996) and Ticku (1998). Furthermore, Western blot analysis indicates that chronic ethanol treatment upregulates NMDA receptor subunits NR1, NR2A and NR2B in the rat cerebral cortex and hippocampus; these returned to almost control levels 48 h after the last dose of ethanol administration (Kalluri *et al.*, 1998).

These results are supported by the finding that NMDA antagonists such as dizocilpine (MK-801) or CGP 39551 administered during ethanol withdrawal significantly attenuated ethanol-induced deficit in spatial reversal memory (Riaz and Faingold, 1994; Thomas *et al.*, 1997). Such antagonists are useful in curbing ethanol withdrawal, seizure and tremors (Grant *et al.*, 1990, 1992; Liljequist, 1991; Ripley and Little, 1995). Exposure to MK-801 during ethanol withdrawal will also protect against alcohol-related disruption in spatial learning (Thomas *et al.*, 1997). In addition, during ethanol withdrawal, calcium channels are upregulated and become hyperexcited (Morton *et al.*, 1992; Whittington *et al.*, 1995) and neuronal calcium effects are amplified (Whittington *et al.*, 1995; Molleman and Little, 1997). The use of calcium channel antagonists (e.g. nitrendipine, nimodipine, isradipine and darodepine) prevented or suppressed behavioural signs of ethanol withdrawal (Littleton *et al.*, 1990; Colombo *et al.*, 1995).

Chronic ethanol treatment (CET) enhances NMDA-stimulated, but not kainate-stimulated, intracellular calcium levels. Seven days after treatment with 100 mM ethanol, the magnitude of cell death mediated by NMDA, but not AMPA, increased (Smothers *et al.*, 1997). In addition, recent studies suggested that nitric oxide may also play a part in the neuroadaptation that develops during chronic ethanol intoxication which could be mediated by changes in Ca^{2+} flux. Four days of CET (100 mM ethanol) enhanced NMDA-stimulated, but neither kainate nor AMPA-stimulated, nitric oxide formation (Chandler *et al.*, 1997), which is reputed to be an important biological messenger and regulator of the CNS (Bredt and Snyder, 1994). Nitric oxide may play an important role in alcohol dependence and withdrawal as well as alcohol-induced brain damage. Studies where nitric oxide synthase inhibitors, such

as L-NAME and 7-NI, are administered to chronically alcoholized rats at the cessation of alcoholization show reduction or alleviation of the signs of ethanol withdrawal (Adams *et al.*, 1995; Uzbay *et al.*, 1997). However, in all of these studies no results for nitric oxide production or nitric oxide synthase activity have been reported.

Ethanol Withdrawal Effect

Cessation of chronic ethanol treatment leads to seizure, hyperexcitability and ethanol withdrawal. Animal studies have revealed that overactivation of glutamate receptors contributes to the generation of these symptoms (Grant *et al.*, 1990; Gulya *et al.*, 1991) and could lead to excitotoxic death (Iorio *et al.*, 1993; Davidson *et al.*, 1995). Human studies have indicated that excitatory neurotransmitters were elevated in the cerebrospinal fluid (CSF) of alcohol-dependent patients and positive correlation between excitatory neurotransmitters and oxidative markers were identified (Tsai and Coyle, 1998). The increase of c-fos mRNA in alcohol withdrawal may result from activation of NMDA receptors (Morgan *et al.*, 1992) which appears to be independent of withdrawal seizures (Morgan and Linnoila, 1991; Morgan *et al.*, 1992).

Recent microdialysis studies showed that ethanol withdrawal was associated with increases in glutamate in the striatum (Rossetti and Carboni, 1995), the nucleus accumbens (Dahchour and De Witte, 1996) and hippocampus (Dahchour and De Witte, 1998) approximately 5–8 h after cessation of ethanol inhalation, which reached a maximum value at 12 h in the nucleus accumbens.

Glutamate-Induced Excitotoxicity and Ethanol

Glutamate receptor-induced excitotoxicity (Michaelis, 1990; Lovinger, 1993; Hoffman and Tabakoff, 1994; Hoffman, 1995) may be one mechanism by which ethanol induces behavioural teratogenicity, i.e. foetal development (Tsai *et al.*, 1995). It is known that an increase in the excitatory amino acid glutamate will have a dramatic effect on neurones by the process of excitotoxicity with associated depolarization of the membrane. Neurotoxic effects are observed after application of glutamate or its agonist to neurones in tissue culture (Choi, 1988, 1992) while even 5 min exposure of glutamate (10–1000 μM) induces neuronal swelling followed by degeneration over the proceeding 24 h (Peterson *et al.*, 1989; Regan and Choi, 1991). Furthermore, addition of NMDA (25–100 μM) to cultured cerebral neurones for 25 min induced excitotoxicity, while prior exposure to chronic ethanol (100 mM for 96 h) further sensitized these neurones to excitotoxic NMDA receptor activation (Chandler *et al.*, 1993b). In conclusion, ethanol administered acutely disrupts glutamatergic neurotransmission by inhibiting the response of the NMDA receptors. Prolonged inhibition of NMDA receptors by ethanol results in development of hypersensitivity; cessation causes marked augmentation of activity in postsynaptic neurones and, in the extreme, induces glutamate-induced excitotoxicity.

Conclusion 2

- Upregulation of the NMDA receptor is a consequence of a physiological response to the depressant effects of ethanol.
- Chronic ethanol treatment yields many changes in NMDA receptor subunits, which could be responsible for their hyperexcitability.
- Cessation of chronic ethanol treatment leads to many symptoms, including seizure and hyperexcitability, which are characteristic of ethanol withdrawal.
- During ethanol withdrawal, an increase in glutamate and hypermotility was reported. Antagonists of glutamate receptors were able to block many withdrawal symptoms.

Effect of Ethanol on GABA

Acute Effect of Ethanol on GABA

Increasing evidence indicates that the effects of acute ethanol are mediated by its effects on GABA or its receptors. Indeed, many studies have documented that ethanol induced increases in $GABA_A$ responses (Nestoros, 1980; Suzdak *et al.*, 1986; Allan and Harris, 1986, 1987; Mehta and Ticku, 1988; Deitrich *et al.*, 1989; Aguayo, 1990; Nishio and Narahashi, 1990; Engblom and Akerman, 1991; Ueha and Kuriyama, 1991; Mihic and Harris, 1996). However, several other groups have failed to detect any robust ethanol-induced enhancement of $GABA_A$ responses in either biochemical (Uusi-Oukari and Korpi, 1989; Mihic *et al.*, 1991) or electrophysiological (White *et al.*, 1990; Osmanovic and Shefner, 1990; Korpi and Seeburg, 1993; Morrisett and Swartzwelder, 1993) experiments. These conflicting results could be explained by the differences in ethanol doses, material preparations, animal strains and animal lines. For example, studies of ethanol effects on $GABA_A$ receptors in mice specifically bred for their differences in sensitivity to ethanol have reported that ethanol enhanced GABA-mediated chloride uptake into brain microsacs in long sleep (LS) but not in those of short sleep (SS) mice (Mihic and Harris, 1996).

Chronic Effect of Ethanol on GABA

Biochemical and electrophysiological studies have reported that chronic ethanol exposure reduces $GABA_A$ receptor-mediated chloride channel function in rats and mice (Allan and Harris, 1987; Morrow *et al.*, 1988; Buck and Harris, 1991; Sanna *et al.*, 1993; Morrow, 1995). Such 'downregulation' occurs after chronic ethanol treatment and may represent a mechanism for tolerance to ethanol. In addition, studies have clearly demonstrated that chronic ethanol treatment differentially alters $GABA_A$ receptor subunit (See chapter XIX-3 for more detail on molecular biology of $GABA_A$ receptors) expression in the cerebral cortex (Morrow *et al.*, 1990; Montpied *et al.*, 1991; Devaud *et al.*, 1995) and cerebellum (Morrow *et al.*, 1992). After CET, a benzodiazepine inverse agonist (Ro 15-4513) binding was selectively upregulated (Becker and Jarvis, 1996; Ticku, 1998) with a decrease in $GABA_A$ receptor α_{1-3} subunit and a decrease of α_6 (in cerebellum) and β_{2-3} subunit without alteration in γ_2 subunit (Ticku, 1998). The level of $GABA_A$ receptor α_1 subunit mRNA is reduced, while α_4 subunit mRNA is increased, both in the cerebral cortex and cerebellum (Devaud *et al.*, 1996), while decreases in $GABA_A$ receptor α_1 subunit mRNAs and increases in α_6 subunit mRNA levels are detectable (Morrow *et al.*, 1992). The levels of α_1 and α_5 subunit mRNA are also decreased in cortex, cerebellum and the ventral tegmental area (VTA), while the level of hippocampal α_5 mRNA was increased (Charlton *et al.*, 1997). Long-term ethanol exposure decreased immunoreactivity levels of α_l subunit of the $GABA_A$ receptor complex in the VTA (Ortiz *et al.*, 1995). However, many studies have suggested that there are selective alterations of the $GABA_A$ receptor subunit after chronic ethanol treatment (Mahmoudi *et al.*, 1997). These findings support the hypothesis that tolerance to ethanol involves reduction in $GABA_A$ receptor numbers and/or function, which may result from a decrease in receptor levels or changes in the protein composition of the receptor leading to decreased sensitivity to neurotransmitters. Such alterations would contribute to ethanol withdrawal symptoms such as hyperexcitability, seizures and tremors.

Ethanol Withdrawal Effect on GABA

Withdrawal from chronic ethanol treatment has been shown to lead to increased seizure susceptibility (Kokka *et al.*, 1993). This is believed to be caused by decreases in GABAergic function

(McQuilkin and Harris, 1990; Mehta and Ticku, 1992). Human studies indicate that GABA concentrations were lower in both the CSF (Tsai and Coyle, 1998) and blood (Adinoff *et al.*, 1995) of alcohol-dependent patients by comparison to those of controls. This may contribute to the symptoms of ethanol withdrawal and associated neurotoxicity. Changes in $GABA_A$ receptor subunit during ethanol withdrawal are also observed. $GABA_A$ receptor α_1 α_4 and γ_1 subunit mRNA levels return to control levels, while β_{2-3} subunit mRNA level increases compared to both controls and ethanol-dependent rats (Devaud *et al.*, 1996, 1997). The reduced activity of inhibitory GABA neurotransmission might contribute to the hyperexcitability and withdrawal seizures. GABA agonists are used to alleviate these symptoms during ethanol withdrawal. Flumazenil (Ro15-1788) a benzodiazepine receptor antagonist, reduces seizure severity and reverses anxiogenic response in mice and rats during acute ethanol withdrawal (Buck *et al.*, 1991a, 1991b, 1991c; File *et al.*, 1992) and suppresses or ameliorates symptoms of tremors (Gerra *et al.*, 1996; Nutt *et al.*, 1993).

Outcomes of the Effects of Ethanol on GABA

LTP requires activation of glutamate receptors and inhibition of $GABA_A$ receptors, and plays a fundamental role in learning and memory formation (Bliss and Collingridge, 1993; Maren and Baudry, 1995). The finding that ethanol enhances $GABA_A$ receptor function in the hippocampus (Weiner *et al.*, 1994; Peris *et al.*, 1997) suggests that ethanol may have an inhibitory effect on memory by its effect on both glutamate and GABA systems (Weiner *et al.*, 1997; Valenzuela and Harris, 1997).

Conclusion 3

- Evidence from many studies has documented that ethanol induced an increase in $GABA_A$ receptor function.
- Chronic ethanol treatment differentially alters $GABA_A$ receptor subunits and this may represent a mechanism for tolerance to ethanol.
- During ethanol withdrawal both concentration and function of GABA and $GABA_A$ receptors were reduced. This could exacerbate withdrawal symptoms.

Effect of Ethanol on Taurine

Implication for Taurine in Ethanol Effects

The interaction of taurine and ethanol has been demonstrated in many physiological experiments where ethanol-induced behavioural activity such as hypnosis (sleep time) in mice (Boggan *et al.*, 1978; McBroom *et al.*, 1986; Ferko, 1987; Ferko and Bobyock, 1988) and rats (Mattucci-Schiavone and Ferko, 1985), locomotion activity in the open field (Aragon *et al.*, 1992) and conditioned taste aversion (Aragon and Amit, 1993) have been modified after taurine co-administration. It should also be remembered that the osmoregulatory and electrical activities of cells are interdependent, and depolarization will induce ionic changes and cell swelling (Huxtable, 1989). Therefore, the taurine modulatory action on membrane excitability and neurotransmitter processes could be mediated by ionic changes resulting from osmotic regulation of the cells. Exposure of primary astrocyte cultures to iso-osmotic ethanol from 10 to 100 mM leads to cell swelling and the release of [^{3}H]taurine and D-[^{3}H]aspartate. In contrast, exposure to hyperosmotic ethanol, at the same concentrations, caused neither swelling nor release (Kimelberg *et al.*, 1993). Moreover, many studies showed increases in taurine after the administration of agents which induce osmolarity changes within the cells, such as water intoxication (Wade *et al.*, 1988) and glutamate analogues (Menéndez *et al.*, 1990). Membrane depolarization also induces taurine release from brain cells (Oja and Saransaari, 1992).

The action of taurine on ethanol metabolism will also be considered in the context of its modulatory effects. Previous studies have clearly demonstrated that taurine, when administered either intraperitoneally or intragastrically at various concentrations, has no effect on peripheral ethanol metabolism (Aragon and Amit, 1993; Watanabe *et al.*, 1985). However, taurine may enhance the metabolism of acetaldehyde, the major metabolite of ethanol, by activating the hepatic enzyme aldehyde dehydrogenase and thereby reducing blood acetaldehyde levels. Indeed, taurine ($0.5\,g\,kg^{-1}$) given orally significantly reduced the elevated blood and liver acetaldehyde concentrations following ethanol loading ($1.5\,g\,kg^{-1}$ body weight; Watanabe *et al.*, 1985). Whether brain acetaldehyde levels would be decreased after a taurine supplementation is unknown, since levels of this major metabolite of ethanol oxidation in the brain are extremely low (Ward *et al.*, 1997) and difficult to assay. In addition, the activities of brain acetaldehyde dehydrogenase isoenzymes remain undefined. However, the demonstration of the rewarding effects of acetaldehyde after intraventricular injection (Smith *et al.*, 1984) clearly indicates a role for this major ethanol metabolite in the rewarding action of ethanol.

One of our contributions to the knowledge of alcohol research is that administration of acute ethanol to rats increases the level of the sulphonated amino acid taurine in many brain regions, including nucleus accumbens (Dahchour *et al.*, 1994, 1996), hippocampus, frontal cortex (Dahchour, 1998) and amygdala (Quertemont *et al.*, 1998, 1999). To our knowledge this is the first time that such increases were identified using the microdialysis technique combined with electrochemical detection. No changes in either GABA or glutamate were identified in any of these brain regions. Furthermore, an increase in taurine microdialysate level was also detected after intraperitoneal acetaldehyde injection (Ward *et al.*, 1997).

Conclusion 4

- Acute ethanol increases extracellular taurine concentration in different brain regions.
- The action of taurine has been demonstrated in ethanol-induced behavioural activity such as hypnosis, locomotor activity and conditioned taste aversion.
- The action of taurine on ethanol metabolism has also been reported.

PSYCHOSTIMULANT DEPENDENCE AND AMINO ACID TRANSMITTERS

Sensitization is a phenomenon which refers to the progressive augmentation of behavioural response to repeated administration of psychomotor stimulants such as cocaine and amphetamine. Although behavioural sensitization to psychostimulants appears to be mediated by dopaminergic system (for review, see Kalivas and Stewart, 1991), there is increasing evidence that excitatory amino acids play a role in this phenomenon (for review, see Wolf, 1998).

The acute systemic administration of a high dose of cocaine ($30\,mg\,kg^{-1}$ intraperitoneally) increases glutamate and aspartate microdialysate content in the nucleus accumbens (Smith *et al.*, 1995; Reid *et al.*, 1997), and this increase in glutamate was much higher in rats that have been sensitized to cocaine (Pierce *et al.*, 1996). Furthermore, the ability of glutamate receptor antagonists to prevent behavioural sensitization to cocaine or morphine in mice and rats (Karler *et al.*, 1989, 1990, 1994; Kalivas and Alesdatter, 1993; Li *et al.*, 1999) has demonstrated the implication of excitatory amino acids in the mechanism underlying behavioural sensitization. In addition, co-administration of glutamate receptor

antagonists with psychostimulants interferes with the development of behavioural sensitization in mice and rats (Kalivas and Alesdatter, 1993; Karler *et al.*, 1994; Li *et al.*, 1999; Wolf and Jeziorski, 1993). Whether the effects of psychostimulants are directly linked to excitatory amino acids or act indirectly by interfering with the dopaminergic system (or other transmitter system) raises an important question concerning the interaction between neurotransmitter systems in behavioural sensitization. In fact, a microdialysis study showed that agonists of dopamine receptors administered by reverse dialysis in the nucleus accumbens increased extracellular glutamate and stimulated locomotor activity (Dalia *et al.*, 1997). On the other hand, other studies showed that glutamate agonists administered in the nucleus accumbens increased the dopamine microdialysate content (Ohno and Watanabe, 1995; Svensson *et al.*, 1994). As such, both dopaminergic and glutamatergic systems are required for locomotor activity and thereby behavioural sensitization to psychostimulants. In addition, the GABAergic system is linked anatomically and functionally to the dopaminergic and glutamatergic systems particularly in brain regions that are implicated in drug dependence. Evidence from many studies demonstrated that the GABAergic system is also implicated in the motor stimulatory effects induced by psychostimulants, and administration of both $GABA_A$ (muscimol) (Austin and Kalivas, 1991; Mogenson and Nielsen, 1983) and $GABA_B$ (baclofen) (Kalivas *et al.*, 1990; Johnson *et al.*, 1996) agonists prevent the locomotor activity induced by psychostimulants. Furthermore, Karler *et al.* (1995) described an amphetamine- and cocaine-induced interaction between dopaminergic, glutamatergic and GABAergic systems in the striatum and suggested that the motor stimulatory effects of amphetamine and cocaine are mediated by dopaminergic activation of glutamatergic and GABAergic pathways in the striatum. There is also direct evidence that acute administration of psychostimulants, particularly amphetamine, produced an increase of extracellular GABA and taurine concentrations in the striatum (Porras and Mora, 1993; Del Arco *et al.*, 1997). In contrast, both GABA concentration and release were reduced in many brain regions, including ventral pallidum, nucleus accumbens and striatum, following repeated administration of amphetamine (Bourdelais and Kalivas, 1990; Linderfords *et al.*, 1992; Jung *et al.*, 1999).

Conclusion 5

- Excitatory amino acids are implicated in the development of behavioural sensitization to psychostimulants and glutamate receptor antagonists were able to prevent this behavioural sensitization.
- High doses of cocaine induced increases in glutamate and aspartate in the nucleus accumbens.
- Acute administration of psychostimulants, particularly amphetamine, produced an increase of extracellular GABA and taurine concentrations in the striatum.

OPIOID DEPENDENCE AND AMINO ACID TRANSMITTERS

There is increasing evidence suggesting that glutamate and or its receptors are implicated in the genesis of opioid tolerance and dependence. The NMDA receptor antagonist MK-801 has been reported to inhibit both the development of tolerance to the analgesic effect of morphine and the expression of morphine (μ-opioid receptor agonist) withdrawal (Trujillo and Akil, 1991, 1994). In addition, glutamate administration was able to precipitate the withdrawal signs from chronic morphine or butorphanol (a mixture of $\mu\delta/\kappa$-opioid receptor agonist) and this withdrawal sign was blocked by pretreatment with MK-801 (Tokuyama *et al.*, 1995). Moreover, naloxone, which is an opioid receptor antagonist also, precipitated withdrawal from morphine and studies showed that this effect was associated with increased glutamate concentration in the locus coeruleus (Aghajanian *et al.*, 1994; Zhang *et al.*, 1994).

Regarding the effect of opioids on GABA, it has been reported in a microiontophoresis study that morphine administration into the ventral pallidum attenuated the GABA-evoked response (Johnson and Napier, 1997). This results are in agreement with another electrophysiological study which reported that local administration of morphine in the dorsal raphe nucleus and periaqueductal grey area of freely moving rats decreased GABA release (Stiller *et al.*, 1996). However, chronic morphine increased GABA tone on 5-HT neurones of dorsal raphe nucleus (Jolas *et al.*, 2000).

Conclusion 6

- The NMDA receptor antagonist MK-801 has been reported to inhibit both the development of tolerance to the analgesic effect of morphine and the expression of morphine withdrawal.
- The acute administration of morphine attenuates GABA function and decreases GABA release. However, chronic morphine increased GABA.

NICOTINE DEPENDENCE AND AMINO ACID TRANSMITTERS

There is also evidence that nicotine dependence is associated with perturbation in many neurotransmitter systems, including amino acid transmitters. An acute dose of nicotine produced an increase of glutamate in the nucleus accumbens and in different forebrain regions (Reid *et al.*, 2000; Toth *et al.*, 1993; Vidal, 1994), and stimulated the release of GABA in various brain regions, including striatum (Lu *et al.*, 1998). Glutamate receptor antagonists attenuated the development of sensitization after chronic administration of nicotine (Shoaib *et al.*, 1997).

Conclusion 7

- An acute dose of nicotine produced an increase of glutamate in the nucleus accumbens and in different forebrain regions, and stimulated the release of GABA in various brain regions including striatum.

CONCLUSIONS

Substance-related disorders induced by ethanol, psychostimulants, opioids, nicotine and other substances are a major health problem in which several neurotransmission systems are involved, including the dopaminergic, serotonergic, glutamatergic and GABAergic systems. However, the most relevant question of such a multifunctional mechanism found in different substance-related disorders is whether the action of such substances is directly upon neurotransmitters and their receptors or whether it functions indirectly by altering the neurotransmission network in the brain. It was clear from this chapter that two major amino acid systems, i.e. excitatory (glutamate) and inhibitory (GABA) amino acids, were involved in the action of different addictive substances and could be responsible for tolerance and dependence related to these substances. Furthermore, long-term exposure to these substances induced wide and specific changes in the molecular biology of different receptor subunits of both glutamate and GABA receptor amino acids.

ACKNOWLEDGEMENTS

The authors wish to thank Anne D'Hauwer for her technical assistance in the preparation of the manuscript.

Endocrinology of Drug Dependence

Pier Vincenzo Piazza and Bruno Aouizerate

AIMS AND SCOPE

This chapter will analyse the relationships between glucocorticoid hormones and drug abuse, focusing principally on clinical studies. The reason for this choice is that a growing body of evidence from investigations in animals suggests that glucocorticoids play an important role in mediating behavioural and neurochemical responses to drugs of abuse (for review see Piazza and Le Moal, 1996, 1997). Unfortunately, studies in humans on the relationships between drugs of abuse and glucocorticoids are still at an early stage and many of the available investigations are performed on small groups of subjects. Furthermore, many studies addressing the same issue are difficult to compare because they often use subjects who differ in drug history, current medication or withdrawal and abstinence periods. The goal of this chapter is therefore not to draw firm conclusions but to try to generate a working hypothesis that could lead future research.

First we will brief by review the interaction between glucocorticoids and the behavioural responses to drugs of abuse. Then we will summarize the principal methods used for studying the activity of this hormonal system in humans; this could be a useful companion for readers not familiar with the field. The following four sections will analyse the relationships between glucocorticoids and the abuse of drugs belonging to four different classes: opiates, cocaine, alcohol and nicotine. Finally, we will try, through a synthesis of the available information, to extract a working hypothesis of the potential role of glucocorticoids in drug abuse. Therapeutic implications and future directions will conclude the chapter.

GLUCOCORTICOIDS AND THE BEHAVIOURAL RESPONSES TO DRUGS OF ABUSE

Glucocorticoid hormones (cortisol in humans and corticosterone in rodents) are the final step in the activation of the hypothalamic–pituitary–adrenal (HPA) axis, one of the major systems implicated in responding to environmental modifications and stress (see previous chapters for a description of the physiology of this neuroendocrine system).

During the last decade, a large amount of experimental evidence has suggested that glucocorticoids may play an important role in modulating the behavioural effects of drugs of abuse. This research has been prompted by the discovery (Piazza *et al.*, 1991) that animals spontaneously vulnerable to drug abuse had a longer stress-induced secretion of glucocorticoids and that administration of these hormones to drug-resistant subjects could increase the likelihood of their self-administering psychostimulant drugs. Since this initial observation, several reports using complementary approaches have shown that the suppression of glucocorticoid secretion decreases stimulant and reinforcing effects of drugs of abuse (for review see Piazza and Le Moal, 1996, 1997, 1998). In particular, glucocorticoids seem to increase the motivation of the individual to self-administer drugs. This effect is probably mediated by a stimulation of drug-induced dopamine release in the nucleus accumbens (for review see Piazza and Le Moal, 1996), one of the principal neurobiological changes mediating the reinforcing effects of drugs of abuse (Wise and Rompre, 1989; Piazza and Le Moal, 1996).

Some investigations have also been devoted to understanding the origin of the interaction between glucocorticoids and drugs of abuse (for review see Piazza and Le Moal, 1997). This research has led to the discovery that glucocorticoids, in the range of concentrations induced by stress, have positive reinforcing effects and stimulate dopamine release (Piazza *et al.*, 1993, 1996). Consequently, it has been hypothesized that these hormones are part of the endogenous reward system and are secreted during stress in order to counteract the aversive effect of stressors (for review see Piazza and Le Moal, 1997). In this respect, the action of glucocorticoids in the central nervous system would be similar to the effect of these hormone in the periphery, where they are supposed to help in controlling the primary response of the organism to stress (for review see Munck *et al.*, 1984).

METHODS FOR STUDYING THE ACTIVITY OF THE HPA AXIS IN HUMANS

Glucocorticoid Secretion

One of the most used approaches to evaluate the functional activity of the HPA axis is measurement of glucocorticoid concentration in biological fluids. Glucocorticoid levels are generally measured by radioimmunoassay (RIA) in plasma and in saliva. These two measurements evaluate different fractions of circulating glucocorticoids. In the blood, glucocorticoids are distributed in three fractions. The largest one (89.5%) is bound to a corticosterone-binding globulin (CBG), a smaller fraction is bound to albumin (6.5%) and the remaining portion (4.0%) is free. Only free and albumin-bound glucocorticoids can pass the blood–brain barrier (Pardridge and Mietus, 1979a, b), and only free glucocorticoids can enter the cell and have biological effects. Measurement of plasma glucocorticoids evaluates the total levels of the hormone, including the fractions binding to CBG and albumin. In contrast, saliva glucocorticoids reflect only the free fraction of the hormone, i.e. the biologically active one. Finally, levels of glucocorticoids can also be estimated by measuring urinary excretion of 17-ketosteroids.

Glucocorticoid Negative Feedback

Two major tests are used to determine the functional status of glucocorticoid negative feedback: the dexamethasone suppression test and the metyrapone test.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Dexamethasone is a potent synthetic glucocorticoid agonist which inhibits the secretion of adrenocorticotrophic hormone (ACTH) and of cortisol for at least 24 h after a single dose of 1–2 mg. This test is usually utilized to study a decrease in glucocorticoid feedback revealed by a lower or absent suppression of endogenous glucocorticoids by dexamethasone (Liddle, 1960).

Metyrapone decreases glucocorticoid biosynthesis by inhibiting the steroid $P450_{11\beta}$, the enzyme that allows 11β-hydroxylation, which is the final step of cortisol production by the adrenal cortex. The blockade of cortisol biosynthesis by metyrapone releases the HPA axis from the inhibitory influence of glucocorticoids, resulting in a large increase in plasma ACTH during the 2–8 h following a single administration (Kreek, 1987, 1996, 2000). Higher levels of ACTH after metyrapone are considered an index of an enhanced glucocorticoid feedback. Conversely, a blunted ACTH response to metyrapone can be an index of a decreased glucocorticoid feedback.

Stimulation Tests

Infusion of corticotrophin-releasing factor (CRF) and ACTH-derived peptides is used to evaluate the functional activity of the HPA axis at different levels. The CRF stimulation test evaluates the sensitivity and functional capacity of pituitary corticotrophic cells to secrete ACTH. The ACTH stimulation test evaluates the sensitivity of the system at the level of the adrenal gland, measuring its sensitivity and functional capacity to produce glucocorticoids.

HPA FUNCTION IN OPIATE-RELATED DISORDERS

Synopsis

Opiate drugs induce a significant suppression of the activity of the HPA axis, decreasing the secretion of ACTH and cortisol. They also induce a blunted response to CRF, ACTH and to stress challenges, as well as a decreased response to metyrapone administration. These effects are observed after acute and chronic exposure to opiates without clear signs of tolerance except after long periods of methadone treatments at high doses (60–120 mg per day). Abrupt opiate withdrawal is, in contrast, accompanied by a strong activation of the HPA axis that occurs several days after the last drug intake. However, during abstinence, glucocorticoid levels appear to normalize. In contrast, a blunted response to stress and an increase in glucocorticoid feedback seem to persist for years after the last drug consumption.

Opiate Abuse and the Secretion of Glucocorticoids

Acute and Chronic Exposure to Opiate Drugs

In subjects non-addicted to opiates, reduction in circulating concentrations of cortisol has been reported in response to a single injection of various opiate agonists, such as morphine (McDonald *et al.*, 1959; Delitala *et al.*, 1983; Zis *et al.*, 1984; Banki and Arato, 1985; Facchinetti *et al.*, 1985), codeine (Garland and Zis, 1989) or methadone (Gold *et al.*, 1980; Delitala *et al.*, 1983) and also in response to the mixed agonist–antagonist buprenorphine (Rolandi *et al.*, 1983). A similar decline in cortisol levels has also been observed after chronic treatment with morphine (3–27 months) in patients with pain syndromes (Palm *et al.*, 1997; Abs *et al.*, 2000). Only two studies have failed to demonstrate an effect of opiates on the secretion of glucocorticoids (Tolis *et al.*, 1975; Oyama *et al.*, 1977).

Opiates also reduce the secretion of glucocorticoids in opiate-addicted subjects. A decrease in 17-ketosteroid excretion (Eisenman *et al.*, 1958, 1961) and in plasma cortisol levels (Higgins *et al.*, 1992) was observed after a single injection of morphine to former heroin-dependent patients. Decrements in both urinary 17-ketosteroid excretion and plasma levels of 17-hydroxycorticosteroids were found in narcotic addicts during both a 3-week period of morphine induction and a 1- to 5-month period of dose stabilization (Eisenman *et al.*, 1958, 1961). Similarly, during the active phase of heroin addiction, in which addicts were exposed daily to multiple high-amplitude fluctuations of this short-acting opiate, ACTH and cortisol levels were decreased, with reduced or flattened circadian diurnal rhythms (Facchinetti *et al.*, 1984, 1985; Kreek, 1972, 1973, 1987, 1996, 2000; Cami *et al.*, 1992). Only one study reported no significant change in plasma cortisol in opiate-dependent patients during a phase of heroin acquisition compared to the drug-free baseline condition (Mendelson *et al.*, 1975). The persistence of an inhibitory effect of opiates on glucocorticoid secretion even after chronic exposure is also confirmed by studies in methadone-treated subjects. Methadone is a synthetic agonist of the μ-opioid receptors characterized by a long half-life and largely used as a substitutive treatment in opiate addicts. During methadone-aided detoxification, decreased plasma (Mendelson *et al.*, 1975; Hellman *et al.*, 1975) and saliva cortisol (Cami *et al.*, 1992) have been reported. Only when methadone is administered as a long-term maintenance treatment at high doses (60 mg per day) is partial tolerance to the inhibitory effects of opiates observed (Kreek, 1972, 1973, 1984, 1987, 1996, 2000; Woody *et al.*, 1988).

Opiate Withdrawal and Abstinence

Abrupt withdrawal from opiates is followed by a striking rise in urinary 17-ketosteroid excretion (Eisenman *et al.*, 1958, 1961) and an increase in plasma (Hellman *et al.*, 1975) and saliva cortisol concentrations (Cami *et al.*, 1992). Similar effects are observed when withdrawal is precipitated by the administration of the opiate antagonist naloxone (Higgins *et al.*, 1992; Rosen *et al.*, 1995). This hypercortisolism seems to persist at least for the first 2 weeks following the last opiate consumption (Cami *et al.*, 1992). However, long-term abstinence from opiates results in a normalization of the HPA axis activity. Former heroin addicts, tested after 2 years or longer drug-free periods, show plasma cortisol levels that do not differ from controls (Woody *et al.*, 1988).

Opiate Abuse and Sensitivity to Stimulation Tests

Although information on this issue is scarce, the entire cascade leading to glucocorticoid secretion seems blunted in subjects exposed to opiate drugs. In healthy subjects morphine was observed to reduce the CRF-induced increase in plasma ACTH and cortisol levels (Rittmaster *et al.*, 1985; Allolio *et al.*, 1987). Similarly, in subjects under a long-term methadone maintenance treatment a significant blunted cortisol secretion was found after administration of 1-24αACTH (Dackis *et al.*, 1982).

Opiate Abuse and Glucocorticoid Negative Feedback

The ACTH response to metyrapone has been shown to be blunted during active cycles of heroin addiction (Kreek, 1972, 1973), during the first 3 months of the induction phase of methadone treatment (Kreek, 1987, 1996, 2000), and after longer methadone treatments up to a dose of 40 mg per day of methadone (Vescovi *et al.*, 1990). However, when higher doses of methadone are used (60–120 mg per day), a normal response to metyrapone was found (Cushman *et al.*, 1970; Kreek *et al.*, 1983). Similarly, in subjects receiving

long-term high-dose methadone, dexamethasone produced normal suppression of cortisol secretion (Kreek, 1972, 1973). These data suggest a decreased glucocorticoid feedback during exposure to opiates. However, a blunted ACTH response to metyrapone could also result from the hyposensitivity of pituitary corticotrope cells to CRF that is also induced by opiates (Rittmaster *et al.*, 1985; Allolio *et al.*, 1987). In this case, the results of the metyrapone test could just be another index of a blunted functional status of the HPA axis.

During abstinence from opiate drugs, quite the reverse results have been found. Thus, an enhanced response to metyrapone, suggesting an increased glucocorticoid feedback, has been reported in drug-free or medication-free former opiate addicts. This enhanced response seems to persist for at least one year following the last exposure to opiates (Kreek, 1987, 1996, 2000).

Opiate Abuse and Sensitivity to Stress

An inhibition of the activation of the HPA axis induced by a psychological performance stress has been found in opiate addicts who had stopped heroin use during the 12-h period preceding the study (Folli *et al.*, 1992). Although this finding could be attributed to the effect of an early withdrawal, they are more likely due to an inhibitory effects of opiate drugs on stress response. Thus, the increase in plasma cortisol levels induced by surgical stress has been found to be suppressed when morphine is administered during general anaesthesia to non-addict subjects (Reier *et al.*, 1973; George *et al.*, 1974). A blunted response to stress has also been found in opiate addicts after short- and long-term abstinence. In heroin-dependent patients tested after 14–24 days of abstinence from heavy heroin abuse (Vescovi *et al.*, 1989), the increase in ACTH secretion induced by sauna-elicited hyperthermia is suppressed. Suppression of the activation of the HPA axis by a psychological performance stress has also been described after a 4-year period of abstinence from heroin use (Mutti *et al.*, 1992). This suppression of stress-induced activation of the HPA axis is consistent with the enhanced glucocorticoid negative feedback that seems to persist after long periods of abstinence (Kreek, 1987, 1996, 2000).

HPA FUNCTION IN COCAINE-RELATED DISORDERS

Synopsis

Acute administration of cocaine increases the secretion of glucocorticoids and a reduction of this effect appears after chronic exposure to the drug. Abrupt withdrawal from protracted heavy cocaine use has been associated with an increased glucocorticoid secretion. However, after a short period of abstinence, glucocorticoid secretion normalizes. In parallel, in former cocaine addicts without comorbidity with depression, enhanced glucocorticoid negative feedback has been described after short and long periods of abstinence. Abstinent cocaine addicts also show suppression of stress-induced cortisol secretion except when a stressor inducing craving for cocaine is used.

Cocaine Abuse and the Secretion of Glucocorticoids

Acute and Chronic Exposure to Cocaine

Acute administration of cocaine has been found largely to increase cortisol levels in different populations of subjects: in normal healthy volunteers (Heesch *et al.*, 1995), in patients with concomitant opiate and cocaine dependence (Mendelson *et al.*, 1992; Teoh *et al.*, 1994) and in cocaine abusers (Wilkins *et al.*, 1992; Baumann *et al.*, 1995). Furthermore, exposure to cocaine *in utero* has also been found to elevate cortisol levels in the neonate (Scafidi *et al.*, 1996).

A certain degree of tolerance to cocaine-induced activation of the HPA axis has been reported (Mendelson *et al.*, 1998). Acute cocaine injection in cocaine- and opiate-dependent patients causes a blunted elevation in ACTH levels when compared to occasional cocaine users. Heart rate, systolic and diastolic blood pressure, perception of 'high' and 'euphoria' were also attenuated in cocaine and opiate addicts compared to episodic cocaine users.

Cocaine Withdrawal and Abstinence

Cocaine-addicted patients, tested after 24 hours of cessation from cocaine abuse, show significantly higher diurnal plasma ACTH and cortisol levels when compared to normal healthy controls (Vescovi *et al.*, 1992a). Another study, however, within the same time window, suggested no effects (Mendelson *et al.*, 1988). It is noteworthy that in the latest study no control group was included; cortisol levels were considered normal since they were within the high normal limits for healthy adult men (between 20 and $23\,\mu g\,dl^{-1}$). Nevertheless, abstinence from continuous cocaine use seems to be associated with a normalization of glucocorticoid secretion. Thus, cocaine abusers tested after 15 days of abstinence did not differ from normal volunteers for plasma ACTH and cortisol levels (Vescovi *et al.*, 1992a).

Cocaine Abuse and Glucocorticoid Negative Feedback

The dexamethasone suppression test, when performed in cocaine-dependent patients between 4 and 10 days after the last cocaine intake, revealed 42% non-suppressors, as defined by post-dexamethasone cortisol levels above $5\,\mu g\,dl^{-1}$ (Gawin and Kleber, 1985). After 4 weeks of abstinence a normal response to dexamethasone was detected (Gawin and Kleber, 1985). Resistance to dexamethasone in some cocaine-dependent patients may reflect concomitant symptoms of depression, which has been associated with non-suppression of cortisol by dexamethasone (Asnis *et al.*, 1981, 1982a, 1982b, 1986; Carroll *et al.*, 1968, 1981). Thus, in another study 37.5% of cocaine abusers who were treated with antidepressants for their self-reported dysphoric mood failed to suppress cortisol secretion after dexamethasone (Boza *et al.*, 1986). The influence of concomitant depression on the activity of the HPA axis in cocaine abusers is also suggested by the observation that the severity of depressive symptoms has been found to be positively correlated with the cocaine-induced elevation in ACTH and cortisol concentrations (Elman *et al.*, 1999).

In non-depressed cocaine-dependent subjects, conversely, there seems to be an increase in glucocorticoid feedback. Thus, cocaine addicts tested with metyrapone over a period of 1–155 days following the last cocaine exposure have shown an enhanced response of the HPA axis to metyrapone (Schluger *et al.*, 1997).

Cocaine Abuse and Sensitivity to Stress

Cocaine abusers studied after a 14-day period of abstinence from cocaine (Vescovi *et al.*, 1992b) failed to show activation of the HPA axis induced by sauna-elicited hyperthermia in healthy volunteers. Also cocaine exposure *in utero* has been found to attenuate the pituitary–adrenal axis response to stress. After an invasive stressor heel-stick procedure, cocaine-exposed premature infants were observed to exhibit lowered cortisol levels when compared to infants not exposed to cocaine (Magnano *et al.*, 1992).

Although the response to stress seems to be decreased by cocaine, an elevation in cortisol levels has been found in cocaine-dependent subjects when an acute psychological stress inducing a significant increase in craving was used (Sinha *et al.*, 1999).

HPA FUNCTION IN ALCOHOL-RELATED DISORDERS

Synopsis

Acute and chronic alcohol ingestion increases the secretion of glucocorticoids. During alcohol withdrawal, there is a further increase in cortisol concentration that rapidly normalizes if abstinence is maintained. However, one study has reported reduced concentrations of cortisol after prolonged abstinence. During early abstinence, there is also an attenuated response to CRF or stress and a blunted suppression of cortisol secretion in response to dexamethasone. More prolonged periods of abstinence appear to allow a complete normalization of the HPA axis activity. Finally, risk for alcohol abuse seems to be associated with a deregulation of the HPA axis function.

Alcohol Abuse and the Secretion of Glucocorticoids

Acute and Chronic Exposure to Alcohol

A dose-dependent increase in plasma cortisol levels has been observed in response to acute ethanol administration in normal volunteers with significant effects for plasma concentrations of ethanol above $100\,mg\,100\,ml^{-1}$ (Fazekas, 1966; Jenkins and Connolly, 1968; Merry and Marks, 1969; Bellet *et al.*, 1970; Linkola *et al.*, 1979; Välimäki *et al.*, 1984a). However, gastrointestinal symptoms after ethanol drinking may be involved in these effects of ethanol. In a study that controlled for this factor (Inder *et al.*, 1995), enhanced plasma ACTH and cortisol concentrations were found only in subjects who experienced significant gastrointestinal side effects (nausea, vomiting) after ethanol intake. This observation could explain why several studies have failed to reveal a significant effect of alcohol on cortisol secretion (Leppäluoto *et al.*, 1975; Jeffcoate *et al.*, 1980; Davis and Jeffcoate, 1983; Prinz *et al.*, 1980; Ida *et al.*, 1992; Waltman *et al.*, 1993). In normal volunteers, cortisol secretion is also increased during repeated exposure to ethanol (4-day period of ethanol intoxication) and this for ethanol blood concentrations below $100\,mg\,100\,ml^{-1}$. Also in this case, gastrointestinal symptoms were present during ethanol ingestion (Mendelson and Stein, 1966). In alcohol-dependent subjects an increase in plasma cortisol levels has been reported during drinking periods ranging from 4 to 31 days (Mendelson and Stein, 1966; Mendelson *et al.*, 1971; Stokes, 1973; Wilkins *et al.*, 1992). However, an attenuation of the stimulant effects of ethanol seems to occur after 10 days of consumption (Wilkins *et al.*, 1992). This persistent elevation in adrenocortical secretion during chronic heavy drinking of alcohol may contribute to the clinical picture of 'pseudo-Cushing's syndrome' reported in some chronic alcoholics and usually reversible after cessation of drinking (Smals *et al.*, 1977; Ylikahri *et al.*, 1980; Cobb and Van Thiel, 1982; Elias *et al.*, 1982; Kirkman and Nelson, 1988; Jeffcoate, 1993).

Alcohol Withdrawal and Abstinence

Acute alcohol withdrawal syndrome has been extensively associated with an enhanced secretion of glucocorticoids (Mendelson and Stein, 1966; Mendelson *et al.*, 1971; Bannan *et al.*, 1984; Välimaki *et al.*, 1984b; Risher-Flowers *et al.*, 1988; Bardeleben *et al.*, 1989; Adinoff *et al.*, 1991; Wilkins *et al.*, 1992). A marked rise in plasma cortisol levels has been found on the first day of withdrawal from alcohol along with suppression of the diurnal rhythm. Furthermore, plasma cortisol levels seem positively correlated with the severity of the alcohol withdrawal syndrome. Reversal of these hormonal elevations and restoration of diurnal rhythm appear during the first week of ethanol withdrawal. Normal ACTH and cortisol levels have also been reported in studies examining longer periods of abstinence (from 1 week to 6 months) (Margraf *et al.*, 1967; Bardeleben *et al.*, 1989; Adinoff *et al.*, 1990; Vescovi *et al.*, 1992c). However, one study describes a reduced cortisol secretion after 4 weeks of abstinence from alcohol (Bailly *et al.*, 1989).

Alcohol Abuse and Sensitivity to Stimulation Tests

Early abstinence from chronic alcohol exposure seems to be associated with an attenuated response of the pituitary–adrenal axis to CRF stimulation. A significantly blunted ACTH (Bardeleben *et al.*, 1989; Adinoff *et al.*, 1990; Costa *et al.*, 1996) and cortisol (Bardeleben *et al.*, 1989; Bailly *et al.*, 1989; Costa *et al.*, 1996) responses to CRF were found in alcohol-dependent subjects when tested within 12 hours to 3 weeks after the last ethanol drink. However, after a more prolonged abstinence from alcohol (from 3 weeks to 6 months) normal ACTH and cortisol responses to CRF have been observed (Adinoff *et al.*, 1990).

Alcohol Abuse and Glucocorticoid Negative Feedback

When tested during the first week of abstinence from chronic alcohol consumption, 10–50% of alcoholics did not suppress plasma cortisol in response to the standard 1 mg or 2 mg dose of dexamethasone (Oxenkrug, 1978; Swartz and Dunner, 1982; Newsom and Murray, 1983; Dackis *et al.*, 1984; Targum *et al.*, 1984; Del Porto *et al.*, 1985; Burov *et al.*, 1986; Majumdar *et al.*, 1988; Bailly *et al.*, 1989; Costa *et al.*, 1996). Association with the diagnosis of major depression, family alcoholism or disturbances of the liver's metabolic capacity has been described in some of these studies (Swartz and Dunner, 1982; Newsom and Murray, 1983; Burov *et al.*, 1986). Nevertheless, after 4 weeks of cessation of alcohol intake the response to dexamethasone seems to normalize (Newsom *et al.*, 1983; Dackis *et al.*, 1984; Del Porto *et al.*, 1985; Bailly *et al.*, 1989).

Alcohol Abuse and Sensitivity to Stress

ACTH and cortisol activation produced by various stress procedures (mental arithmetic, cold pressure, isometric handgrip task and sauna) have been found blunted after a period of cessation of alcohol drinking varying from 3 to 5 weeks (Errico *et al.*, 1993; Bernardy *et al.*, 1996; Vescovi *et al.*, 1997). However, after 12 weeks of controlled abstinence (Ehrenreich *et al.*, 1997) a normal ACTH response to stress has been reported.

HPA Axis Activity in Subjects with High and Low Risk of Alcoholism

Over the past decade, a series of studies have shown that the sons of alcoholics have a three- to four-fold elevated risk of developing alcoholism in late adolescence and adulthood (Goodwin, 1985; Schuckit, 1985). A deregulation of the pituitary–adrenal axis appears to be associated with a high risk of future development of alcoholism although the nature of this perturbation seems influenced by sex. A decreased intensity of ACTH and cortisol responses to ethanol in subjects with a positive family history (FHP) for alcoholism was found when compared with subjects with a negative family history (FHN) (Schuckit, 1984; Schuckit *et al.*, 1987, 1988, 1996; Schuckit and Gold, 1988). However, opposite findings have been described when the response to an acute ethanol challenge was examined in females (Lex *et al.*, 1991). In this pilot study, plasma cortisol levels after ethanol drinking were observed to be higher in the FHP females than in the FHN controls. In contrast, similar responses were found in male and female FHP/FHN when the effects of acute ethanol on the

secretion of the peptide β-endorphin were studied (Gianoulakis *et al.*, 1989, 1996). β-Endorphin shares with ACTH the same precursor, pro-opiomelanocortin (POMC) (Akil and Morano, 1995). In response to ethanol, there were higher β-endorphin circulating levels in both male and female FHP groups compared to the FHN control groups (Gianoulakis *et al.*, 1989, 1996). Finally, a lower response to CRF stimulation appears to be associated with a familial history of alcoholism. A blunted ACTH response to CRF in FHP compared to FHN subjects was found, although cortisol levels were comparable in the two groups (Waltman *et al.*, 1994).

HPA FUNCTION IN NICOTINE-RELATED DISORDERS

Synopsis

Acute and chronic administration of nicotine through intense cigarette smoking has been shown to increase the secretion of glucocorticoids although signs of tolerance to this effect appear over prolonged periods of cigarette smoking. Acute withdrawal from heavy cigarette smoking is associated with an increase in cortisol levels followed by a progressive decrease and normalization. However, cortisol levels seem to drop below baseline after a prolonged period of abstinence from nicotine. Dexamethasone and CRF stimulation tests seem unaltered in nicotine abusers. Controversial data exist on the effects of nicotine on stress-induced glucocorticoid secretion.

Nicotine Abuse and the Secretion of Glucocorticoids

Acute and Chronic Exposure to Nicotine

A dose-dependent increase in plasma ACTH and cortisol levels has been found after intravenous nicotine infusion in normal healthy volunteers without history of regular cigarette smoking (Newhouse *et al.*, 1990). Similarly, when examined in nicotine-addicted subjects, acute nicotine administration (mainly through smoking) was found to cause a dose-dependent elevation in plasma 11-hydroxycorticosteroid (Kershbaum *et al.*, 1968), ACTH and cortisol concentrations (Wilkins *et al.*, 1982; Seyler *et al.*, 1984; Gossain *et al.*, 1986; Meliska and Gilbert, 1991; Gilbert *et al.*, 1992; Baron *et al.*, 1995; Coiro and Vescovi, 1999). Subjective distress (nausea, sickness and unpleasantness) after smoking cigarettes containing high concentrations of nicotine has been found to be correlated with the increase in plasma cortisol concentrations (Gilbert *et al.*, 1992). Furthermore, plasma cortisol levels after cigarette smoking in laboratory conditions have been found to be significantly higher in smokers compared to non-smokers (Gossain *et al.*, 1986; Baron *et al.*, 1995), but no differences have also been reported (Meliska and Gilbert, 1991).

Although it seems clear that acute exposure to nicotine in laboratory conditions increases cortisol levels, this does not appear to be the case when smokers are studied during their usual smoking conditions. Indeed, several studies investigating cortisol concentrations in subjects who were asked to follow their habitual pattern of smoking did not find any significant increase in glucocorticoids (Tucci and Sode, 1972; Cherek *et al.*, 1982; Benowitz *et al.*, 1984; Yeh and Barbieri, 1989; Kirschbaum *et al.*, 1994). Therefore, the elevation in cortisol induced by nicotine in the laboratory setting may be the result of an interaction between nicotine and the stress of the experimental condition or the result of rapid smoking procedures. This possibility is also suggested by the absence of changes in cortisol and ACTH concentrations as a function of the dose of nicotine when the latest is delivered transdermally (Pickworth *et al.*, 1996).

Nicotine Withdrawal and Abstinence

Nicotine withdrawal seems to be associated with an enhanced adrenocortical secretion. After 24 h of abstinence, plasma cortisol concentrations were found to be higher than those observed during smoking (Hughes *et al.*, 1988). However, this increase seems short lasting since there were no significant changes in plasma ACTH and cortisol levels after 3 days of cessation from *ad lib* smoking, and this despite a significant increase in several subjective and physiological measures of the severity of nicotine abstinence (Pickworth *et al.*, 1996). After a longer period of abstinence (2–6 weeks), plasma cortisol concentrations were observed to decrease below control levels (Puddey *et al.*, 1984; Frederick *et al.*, 1998). The magnitude of the drop in cortisol was strongly related to post-quit distress (Frederick *et al.*, 1998).

Nicotine Abuse and Negative Glucocorticoid Feedback

The few studies that have analysed glucocorticoid feedback in nicotine abusers by using the dexamethasone suppression test have not found any significant modification. No changes in post-dexamethasone cortisol levels were observed after 1–2 days of abstinence when compared to the *ad lib* smoking period (Hughes *et al.*, 1988). Scores for withdrawal symptoms or heart rate were not correlated with dexamethasone-induced suppression (Hughes *et al.*, 1988). Also the percentage of cortisol suppression after dexamethasone before, and 2 or 4 weeks after, quitting smoking has not been found to be related to abstinence success (Frederick *et al.*, 1998).

Nicotine Abuse and Sensitivity to Stimulation Test and Stress

There have been few investigations on the response of the HPA axis to stimulation tests or stress in smokers. Conflicting findings have been reported. Kirshbaum *et al.* (1994) studied the response of smokers to CRF stimulation and psychological stress. Smokers exhibit a trend toward smaller ACTH and cortisol responses in both stimulation conditions. However, these results failed to reach statistical significance. In another study conducted in females, Baron *et al.* (1995) failed to reveal differences between smokers and non-smokers in CRF-induced release of cortisol. An attenuation of the response to stress by nicotine smoking is, in contrast, suggested by the study of Gilbert *et al.* (1997). These authors found no effect of a noise stress in smokers exposed to nicotine. However, in another study, Pomerleau and Pomerleau (1990) observed an additive effect of smoking and stress (competitive mental arithmetic) on plasma cortisol concentrations.

SUMMARY OF CHANGES IN ACTIVITY OF THE HPA AXIS OBSERVED DURING DIFFERENT PHASES OF DRUG ABUSE

Exposure to Drugs

The data analysed in the previous sections indicate that exposure to drugs of abuse profoundly modifies the secretion of glucocorticoids, although not in a homogeneous way. Acute exposure to cocaine, alcohol and nicotine increases the secretion of glucocorticoids. These effects persist over chronic exposure to the drugs although a partial tolerance is observed after long periods of very high drug regimens. Opposite effects have been observed for opiate drugs that reduce the secretion of glucocorticoids upon acute and chronic exposure.

Much scarcer data are available on other functional indices of the HPA axis activity during periods of drug exposure. Opiate intake or

administration of substitutive therapies has been associated with a reduced response to CRF, ACTH and stress stimulation as well as to a blunted response to metyrapone. Similar investigations conducted on nicotine addicts have failed to reveal a decrease in the response to CRF and stress in an unequivocal way. Unfortunately, there is no information available on the other drugs of abuse.

Withdrawal

During withdrawal from drug taking, more homogeneous changes in glucocorticoid secretion have been observed. Indeed, during withdrawal from opiates, cocaine, alcohol and nicotine, an increase in the level of glucocorticoids has convincingly been reported. This increase seems of longer duration for opiates than for the other drugs.

Data on other functional analyses of the activity of the HPA axis during withdrawal are scarcer. A decrease in glucocorticoid feedback, as studied with the dexamethasone suppression test, has been reported for cocaine and alcohol but there are no available data for opiates and no modifications have been reported for nicotine. For alcohol, a decrease of sensitivity to CRF stimulation has been described.

Abstinence

During abstinence from different drugs of abuse, the secretion of glucocorticoids does not seem to change in a homogeneous way. A normalization of glucocorticoid levels has been reported in former opiate and cocaine abusers. In contrast, in abstinent nicotine addicts glucocorticoid concentrations seem to decrease below baseline levels. In former alcoholics, normalization but also a decrease below baseline of glucocorticoids levels, similar to that observed for nicotine, have been described.

During abstinence from opiates, cocaine and alcohol, a reduction of the glucocorticoid response to stress has been observed. Unfortunately, we do not have available data for nicotine. This decrease in stress response, at least in former opiate and cocaine addicts, seems to be maintained even after long periods (years) of abstinence. This blunted response to stress is accompanied by an increase in glucocorticoid feedback, as suggested by results obtained using the metyrapone test in abstinent opiate and cocaine addicts. Again, we do not have available data in nicotine and alcohol addicts. Finally, stimulation tests during abstinence have been studied only in former alcohol addicts showing a decreased response to CRF that normalizes after longer period of abstinence.

POSSIBLE RELATIONSHIPS BETWEEN CHANGES IN THE ACTIVITY OF THE HPA AXIS AND DRUG ABUSE

Changes in Glucocorticoid Secretion During Drug Exposure

Although most of the drugs of abuse increase the secretion of glucocorticoids, it is unlikely that these changes can be involved in mediating the positive reinforcing effects of drugs. First, this idea is not supported by the observation that opiates decrease glucocorticoid secretion. Second, in the case of psychostimulant drugs or alcohol, which increase glucocorticoid levels, research in animals does not suggest that drug-induced glucocorticoid secretion plays a role in mediating the behavioural effects of drugs. Thus, although behavioural effects of drugs are reduced by the suppression of endogenous glucocorticoids, most of them are completely restored by replacement of basal glucocorticoid levels or by levels of glucocorticoids that are lower than that observed after drug administration (for review see Piazza and Le Moal, 1996, 1997). Finally, biological effects of glucocorticoids are principally mediated by modifications of protein transcription which occur in a time window that is much longer than the one within which the rapid reinforcing effects of drugs take place. This idea is also supported by a recent observation in humans (Wachtel *et al.*, 2001) showing that an increase in glucocorticoid levels before the administration of psychostimulant drug does not modify its subjective effects.

Drug-induced secretion of glucocorticoids could instead be involved in the mediation of some drug effects that appear after repeated exposure, such as sensitization (Robinson and Berridge, 2001). Thus, it has been shown that behavioural sensitization, induced by drugs and in particular by stress, is at least in part dependent on an increase in glucocorticoid secretion (for review see Piazza and Le Moal, 1998). For example, repeated treatment with glucocorticoids can increase the behavioural response to psychostimulants or morphine (Deroche *et al.*, 1992; Stohr *et al.*, 1999). Furthermore, blockade of stress-induced glucocorticoid secretion totally suppresses the stress-induced sensitization (for review see Piazza and Le Moal, 1998). A sensitized state can also be reversed by the administration of glucocorticoid antagonist (De Vries *et al.*, 1996) or by synthesis inhibitors such as metyrapone (Marinelli *et al.*, 1996).

Changes in Glucocorticoid Secretion During Withdrawal

The increase in glucocorticoids observed during withdrawal could have two effects. The first one could be to counteract the negative state associated with withdrawal. Thus, it has been shown that glucocorticoids have positive reinforcing effects that could at least partially substitute for that of drugs (for review see Piazza and Le Moal, 1997). The second potential effect of an increase in glucocorticoid concentrations during withdrawal could be to increase drug craving. Thus, it has been shown that injections of glucocorticoids can reinstate drug seeking in animals (Deroche *et al.*, 1997). This effect is dose dependent, and shows an inverted U-shaped curve. Up to doses of corticosterone that induce plasma levels of the hormones similar to that observed during stress, an increase in reinstatement is produced. However, when doses of glucocorticoids are above the physiological range, a dose-dependent decrease in reinstatement is observed (Deroche *et al.*, 1997).

Changes in Glucocorticoid Secretion During Abstinence

Although changes during abstinence could seem disparate, they can be interpreted as an increase in the central effects of glucocorticoids. Indeed, an increase in the central effects of these hormones is consistent with: (1) a decrease of basal glucocorticoid secretion, which has been reported for alcohol and nicotine; (2) an increase in glucocorticoid negative feedback, which has been reported for cocaine and opiate; (3) a blunted response to stress, which has been reported for cocaine, opiate and alcohol.

A higher sensitivity to the central effects of glucocorticoids in former drug abusers could be a long-lasting modification induced by prolonged exposure to drugs or a pre-existing phenotype related to vulnerability to drugs. Data from animal research support the latest hypothesis. Studies in rats that differ for vulnerability to drugs (for review see Piazza and Le Moal, 1996) have shown that drug-vulnerable subjects (HR) have a higher sensitivity to glucocorticoids than more drug-resistant individuals (LR) (Piazza *et al.*, 1993, 1996). Thus, before any exposure to drugs, HR animals are more sensitive to the reinforcing and stimulant effects of glucocorticoids and show a higher release of dopamine in the nucleus accumbens in response to the administration of these hormones (Piazza *et al.*, 1993, 1996). It is important to remember that the mesoaccumbens

dopamine system is considered one of the major substrates of the addictive effects of drugs of abuse.

Therapeutic Implications

On the basis of the data and hypothesis described above, it is suggested that pharmacological strategies modifying the activity of glucocorticoid hormones could be a useful companion for the treatment of drug abuse. Given the scarcity of available treatments, this hypothesis needs to be taken into account. Two opposite therapeutic strategies could be foreseen. The first strategy could consist in using glucocorticoid agonists during withdrawal. Indeed, the data analysed above suggest that relatively high doses of glucocorticoid agonists could have a double effect. These drugs, by their positive reinforcing effects (Piazza *et al.*, 1993), could help to reduce the negative state associated with withdrawal and at the same time, by bringing glucocorticoid levels above the physiological range, they could also reduce drug craving (Deroche *et al.*, 1997). The second strategy could consist in using antagonists of glucocorticoid receptors during abstinence. These antagonists could help in preventing relapse by two action mechanisms. First, they could counteract the high sensitivity to glucocorticoids observed in former drug abusers and that probably contributes to their vulnerability to drugs. Second, they could prevent the relapse that seems to be prompted by an increase in glucocorticoid levels (Deroche *et al.*, 1997).

Two studies have analysed the effects of manipulations of the activity of the HPA axis on cocaine self-administration in humans. The results are not encouraging since both the blocker of cortisol synthesis ketoconazole and the glucocorticoid agonist dexamethasone have shown no effects (Ward *et al.*, 1998, 1999). However, some caution should be used in the interpretation of these negative results. First, the treatments were short lasting. In fact, since glucocorticoids mainly act through modification of transcriptional activity, it is probable that longer treatments are needed to obtain an effect. Second, ketoconazole and dexamethasone were tested under an active phase of drug taking and using a schedule of self-administration that allows the subject to readily obtain high drug doses. On the basis of results obtained in animals, it is unlikely that blockade of glucocorticoid secretion or glucocorticoid agonists can have effects under such self-administration schedule. Indeed, animals totally deprived of glucocorticoids still self-administer cocaine (Deroche *et al.*, 1997). What seems to be reduced by manipulations of glucocorticoid levels is the amount of work the animal is ready to do to obtain drugs (for review see Piazza and Le Moal, 1997). In other words, the motivation to seek drugs seems to be reduced. For this reason, it is not surprising that in conditions in which the drug is readily available manipulations of the HPA axis do not show significant effects. These treatments, which could decrease the motivation to seek drugs and the probability of relapse, have a higher chance of being effective in a phase in which the individual is actively trying to discontinue drug intake.

FUTURE DIRECTIONS

In our opinion, one of the most interesting avenues for future investigations is to study more deeply if in addicts there is an increase in the central effects of glucocorticoids. In parallel, it would be important to study in animals the molecular mechanisms of such an enhanced functional state of the HPA axis. In humans, this can be done by using the metyrapone test but also by using a modified version of the dexamethasone suppression test. This test is currently used principally to investigate a decrease in glucocorticoid negative feedback. For this purpose, it is performed by giving high dexamethasone doses and measuring the lack of suppression. The opposite strategy should be used in order to search for an increase in glucocorticoid feedback. In this case, low doses of dexamethasone should be used in order to evaluate whether certain subjects suppress endogenous glucocorticoids more readily than others. A lower threshold for suppression would certainly be convincing evidence of a higher sensitivity to glucocorticoid central effects. Animal studies on hypersensitivity to glucocorticoids will certainly benefit from new transgenic approaches. In particular, the development of reporter animals enabling measurement of changes in the transcriptional activity of the glucocorticoid receptor will be very important in order to identify the anatomical and cellular targets of such a phenomenon.

Finally, there has not been an active effort to develop agonists or antagonists of the glucocorticoid receptors that act efficiently at the level of the central nervous system. This development is certainly a priority if we want to analyse the possible relevance of manipulations of the activity of the HPA axis for the treatment of drug abuse.

Neuroimmunology

Claudia Spies, Helge Schönfeld, Ulrich Dirnagl, Wolfgang J. Kox and Hans Rommelspacher

Bidirectional communication of the immune system between the central nervous system (CNS) and the periphery appears to be essential for appropriate antigen response and restoration of homeostasis. Immune activation induced by bacteria and virus proteins is associated with the production of various cytokines from monocytes and macrophages. These cytokines activate immune cells and regulate the production of glucocorticoids and β-endorphin from the hypothalamic–pituitary–adrenal (HPA) axis, may activate the autonomic nervous system (ANS) or may influence the CNS. Stimuli that alter this communication can potentially threaten homeostasis (Sarkar, 1996). Drugs represent a threat to this system because on one hand they can alter the activity of the neuronal circuitries that are important for appropriate immune responses, and on the other they may expose the individual to other risks, e.g. subsequent infections or organ dysfunction, which may impose secondary immune changes and interfere with different neuronal pathways. This may also limit the interpretation, in particular of the central effects of all drugs as receptor subtypes, in many different neuronal tissues are usually involved in the immune response. Previous studies reflect the net effects of global receptor activation. However, compensatory or synergistic effects may cloud the interpretation of specific tissue involvement in the drug modulation of these immune parameters.

ALCOHOL

Clinical Relevance

Alcohol is the most abused drug worldwide (Lieber, 1995). Alcohol-associated health problems are a major social and medical problem in the United States and other Western countries. In the United States, over 50% of adults consume alcohol regularly, and approximately 15 million people are chronic alcoholics (Lieber, 1995; O'Connor and Schottenfeld, 1998). In a recent survey of the Substance Abuse and Mental Health Services Administration in the United States, heavy drinking was reported by 5.6% of the population aged 12 and older, or 12.6 million people (Substance Abuse and Mental Health Services Administration, 2001). Alcoholism has been associated with over 100 000 deaths in the United States and results in more than $100 billion in annual cost (Secretary of Health and Human Services, 1997).

Immune Modulation

Alcohol has profound effects on the expression and function of immune system mediators and the brain. Among the most intensely investigated cytokines related to alcohol are tumour necrosis factor (TNF)-α, interleukin (IL)-1 and IL-6, which are collectively grouped as pro-inflammatory cytokines. Most of our understanding about the impact of alcohol on these mediators comes from studies of the peripheral immune system, where cytokines play a pivotal role in the regulation of immune and inflammatory responses. At present much less is known about how ethanol affects the protein networks in the brain. Alcohol freely enters the brain and it is likely to have similar effects on the function of cytokines in the CNS as it does on those in the periphery. However, in the brain, cytokines impart their effect via interactions with different target cells such as astrocytes and neurones, as well as through novel mechanisms such as modulating neurotransmitter receptor function (Gahring *et al.*, 1999, 1997; Miller and Fahey, 1994; Miller *et al.*, 1991). Therefore, cytokine-mediated effects must be evaluated in terms of their function within the CNS which, overall, may not be equivalent to those in the periphery.

Alcohol and Lipopolysaccharide

Heavy alcohol use results in endotoxaemia, which is a systemic inflammatory response caused by the interaction of intestinal-derived endotoxin/lipopolysaccharide (LPS) with Kupffer cells and other cells in the liver (Fleming *et al.*, 2001; Lands, 1995; Bhagwandeen *et al.*, 1987; Bode *et al.*, 1987). Experimentally, LPS treatment increased adrenocorticotropic hormone (ACTH) and corticosterone levels both in alcohol- and non-alcohol-treated rats, but corticosterone levels were significantly higher in alcohol-treated rats (Rivier, 1999).

A gut leak was observed in chronic alcoholics upon examination of gastroduodenal and intestinal permeability through the measurement of the urinary excretion of sucrose, after oral administration of lactulose and mannitol (Keshavarzian *et al.*, 1999). Endotoxin concentrations in the plasma of alcoholics were more than five-fold increased as compared to non-alcoholic controls (Parlesak *et al.*, 2000).

Pro-/Anti-Inflammatory Immune Modulation

Rapid changes in the production of several cytokines can be evoked by acute exposure to alcohol in LPS-stimulated rats (Nelson *et al.*, 1995) and in normal isolated human monocytes (Mandrekar *et al.*, 1996; Szabo *et al.*, 1996a). Pro-inflammatory cytokines such as TNF-α and IL-6 send important signals, resulting in peripheral immune stimulation of the brain. Specifically, their ability to increase the neuronal activity of hypothalamic perikarya involved in the release of ACTH and corticosteroids (Tilders *et al.*, 1994; Rivier, 1995; Chrousos, 1995; Ericsson *et al.*, 1994; Rivier, 1999) appears essential in mediating an appropriate endocrine response to immune challenges (Turnbull and Rivier, 1999). At present, there is still a fair amount of controversy regarding the role of specific cytokines involved in the HPA axis response to immune signals.

Regardless of the mechanism involved, the ability of alcohol to alter the HPA axis response to central cytokines has important

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

implications. While originally only thought to occur following CNS infections or trauma, increases in brain cytokines are now known to take place in response to stress (Minami *et al.*, 1991) or during periods of elevation in blood-borne cytokines (Lee and Rivier, 1994; vanDam *et al.*, 1992; Schoebitz *et al.*, 1993; Hagan *et al.*, 1993; Fontana *et al.*, 1984), such as those that occur during immune activation (Lee and Rivier, 1994; Shalaby *et al.*, 1989; Ertel *et al.*, 1991; Bristow *et al.*, 1991; Dinarello and Cannon, 1993). Brain cytokines probably play an important role in regulating the activity of neuronal circuits in subjects whose homeostasis is threatened. Indeed the appropriate secretion of corticotropin-releasing factor (CRF), ACTH and corticosteroids upon exposure to cytokines plays a necessary role in the mechanisms that mediate the survival of an organism exposed to an antigen, which includes monitoring the number and activity of immune cells (Munck and Guyre, 1986; Irwin and Hauger, 1988; Irwin *et al.*, 1990).

TNF-α

Because TNF-α is the first such protein to be released during endotoxaemia (Rivier, 1999), it has been considered important in modulating at least the early phase of LPS-induced ACTH release (Ebisui *et al.*, 1994), most likely through an increased release of CRF by nerve terminals in the median eminence (Watanobe and Taskebe, 1992). However, studies conducted with TNF-α antagonists have not always provided clear results, which has raised the possibility that secretagogues such as prostaglandins, produced independently of TNF-α, might also play a predominant role (Rivier, 1999).

TNF-α provides a particularly striking example of the potential contrast between the function of a cytokine in the periphery versus the CNS. In the periphery, engagement of the TNFR1/p55 receptor by TNF-α often results in cell death through apoptosis (Ware *et al.*, 1996). In the brain, however, under non-chronic pathological conditions, it was demonstrated that TNF-α functions as a neuroprotective agent (Gahring *et al.*, 1999). TNF-α mediates its neuroprotective effect against an excitotoxic challenge by glutamate receptor agonists such as *N*-methyl-D-aspartate (NMDA) primarily through the TNFR1/p55 receptor, which is present on neurones both *in vivo* and *in vitro*. Exposure to the equivalent of an intoxicating level of alcohol on cultured murine cortical neurones did not quantitatively alter NMDA-excitotoxic neuronal death. However, it inhibited the neuroprotective properties of TNF-α, suggesting that the effect of ethanol at this concentration is specific to the TNF-α pathway and not due to altered NMDA receptor function in this excitotoxicity assay. This was further supported by the fact that neuroprotection against NMDA induced by IL-1α IL-1β, IL-6 or nicotine was not affected by the presence of 20 mM alcohol (Gahring *et al.*, 1999). However, alcohol can inhibit NMDA receptors at 100 mM concentrations (Gahring *et al.*, 1999). At these concentrations the addition of human tumour necrosis factor (hTNF)-α had no further neuroprotective effect nor did it antagonize the ethanol-induced neuroprotection (Gahring *et al.*, 1999).

The nuclear factor κB (NFκB) is a major intracellular mediator of TNF-α-induced effects. Inhibition of the NFκB translocation to the nucleus has been reported to inhibit TNF-α-induced neuronal protection (Barger *et al.*, 1995). The effects of alcohol on NFκB translocation and the composition of the complex (p50/p65 heterodimers vs. p50 and p52 homodimers) have been investigated (Mandrekar *et al.*, 1997). Alcohol (25 mM) induced the activation of p50/p50 homodimers that suppressed the induction of cytokine transcripts.

Events downstream of TNF-α-mediated activation of NFκB, including the production of nitric oxide (NO), may also be affected by the presence of alcohol. Chronic alcohol exposure seems to enhance NMDA-mediated increases in NO production by neurones, but in contrast greatly reduced NO synthesis by glial cells (Syapin, 1998). Furthermore, acute alcohol treatment decreased cytokine-stimulated NO synthesis in glia and neurones in cortical cell cultures but enhanced cytokine-stimulated NO synthesis in other cells such as the endothelial cells lining the blood–brain barrier (Syapin, 1998). In C6 glial cells, ethanol also suppressed cytokine-induced inducible nitric oxide synthase (iNOS) expression and reduced IL-1β and TNF-α potency without affecting interferon (IFN)-γ potency. Ethanol-mediated reductions in cytokine-induced iNOS messenger ribonucleic acid (mRNA) and immunoreactive protein levels suggested an effect on gene transcription. IFN-γ-responsive elements did not participate in the acute ethanol-induced inhibition of rat iNOS gene transcription (Syapin *et al.*, 2001). In a previous report supporting these results it was found that ethanol markedly blocked the TNF-α-induced increase in intercellular adhesion molecule (ICAM)-1 and mRNA levels, whereas IFN-γ did not inhibit this response (DeVito *et al.*, 2000).

Several studies showed that polymorphism in TNF-α and TNF-β genes affect TNF-α and TNF-β protein production *in vivo* (Messer *et al.*, 1991; Pociot *et al.*, 1993). Individuals who carry $TNFB^2/TNFB^2$ have a higher TNF-α secretory capacity than those who carry the $TNFB^1/TNFB^1$ genotype. According the reports of Bruce *et al.* (1996), who showed that neurones from TNF receptor knock-out mice exhibited reduced survival in culture compared to those from wild-type mice, individuals with $TNFB^1/TNFB^1$ may be susceptible to alcohol-induced brain damage. A multivariate analysis showed that the $TNFB^1/TNFB^1$ genotype was an independent risk factor for the development of alcoholic brain atrophy (Yamauchi *et al.*, 2001).

IL-1β

The cytokine IL-1β increases ACTH release by stimulating the synthesis of CRF and vasopressin in the paraventricular nucleus (PVN) of the hypothalamus and the release of these peptides from nerve terminals in the median eminence (Rivier, 1995, 1996). Alcohol, like IL-1β, stimulates ACTH secretion by activating the synthesis and release of CRF and vasopressin in the PVN neurones in adult rats. Not surprisingly, it was found that alcohol altered IL-1β-stimulated ACTH secretion (Rivier, 1996). However, alcohol effects were dependent on the dose and duration of alcohol treatments. Acute treatment with high doses of ethanol, but not low doses, blunted IL-1β-stimulated ACTH release through increased glucocorticoid feedback (Rivier, 1993). Long-term treatment with ethanol using an ethanol liquid diet also decreased the ACTH response to IL-1β (Lee and Rivier, 1993), possibly by reducing PVN neuronal activity and by blunting pituitary ACTH response to vasopressin (Lee and Rivier, 1995). Acute ethanol exposure has been shown to reduce the IL-1β inhibitory influence on β-endorphin release, while chronic exposure potentiated the cytokine action on β-endorphin release (Sarkar, 1996). Furthermore, the cytokine action on β-endorphin release may be regulated by endogenous NO. The ability of NO blockers to prevent IL-1β action on β-endorphin release was increased following acute treatment with ethanol, but was reduced following long-term treatment with ethanol (Sarkar, 1996).

IL-6

Another important pro-inflammatory cytokine is IL-6, which, despite the fact that it is usually secreted after the initial peak ACTH secretion has taken place (Besedovsky and Del Rey, 1991), also plays a role in the HPA axis response to immune stimulation (Perlstein *et al.*, 1993). After LPS treatment, IL-6 is released into the general circulation but it is also manufactured in tissues such as the pituitary and adrenal glands, where it may play paracrine/autocrine roles in regulating ACTH and corticosterone secretion (Rivier,

1999). On the basis of these data, it seems probable that circulating TNF-α and IL-6 play different roles at different times, and that their appearance in various tissues supports a participatory role in the endocrine responses to endotoxaemia (Rivier, 1999). In a study by Rivier (1999) in intact rats, the alcohol-induced plasma ACTH and corticosterone responses had returned to basal levels 3 h after LPS was injected, and alcohol pretreatment increased the corticosterone but not the ACTH response after LPS treatment. In contrast, in adrenalectomized corticosterone-replaced animals the alcohol-induced ACTH response was still elevated at the time of LPS injection. However, the overall ACTH response of rats pretreated with alcohol was statistically similar. As expected, LPS also significantly stimulated both TNF-α and IL-6 release into the general circulation. The IL-6, but not the TNF-α, response was inhibited by alcohol pretreatment in intact rats, a phenomenon that was not present in adrenalectomized rats. Finally, LPS also augmented the TNF-α and/or IL-6 content of the pituitary, adrenal glands and spleen, and it was shown that these responses were not altered by alcohol pretreatment. Therefore, it was concluded that acute alcohol treatment increased LPS-induced corticosterone response, while it blunted the IL-6 response. LPS also significantly elevated the pituitary, adrenal and splenic content of TNF-α and IL-6, and alcohol did not influence these changes (Rivier, 1999).

IL-10

The balance between the monocyte production of cytokines IL-12 and IL-10 was determined in the presence and absence of both alcohol and LPS. Alcohol alone, and in combination with LPS, stimulates monocyte production of IL-10 at the expense of IL-12 and TNF-α monocytes (Mandrekar *et al.*, 1996; Szabo *et al.*, 1996a). These results are very important for understanding the immune response in alcoholics since IL-10 inhibits some of the cellular immune reactions that are dependent on IL-12 for their initiation and continuation. These observations, including *in vitro* exposure and/or alcohol feeding, suggest that alcohol enhances IL-10 production and decreases IL-12 secretion (Irwin and Miller, 2000; Szabo *et al.*, 1996b; Waltenbaugh *et al.*, 1998; Zisman *et al.*, 1998; Girouard *et al.*, 1998).

IL-12

Shortly summarized, IL-12 production was increased or unchanged after acute *in vitro* ethanol treatment of human monocytes (Girouard *et al.*, 1998), was increased after alcohol challenge in human volunteers (Szabo, 1998) and in the serum of alcoholics without cirrhosis (Laso *et al.*, 1998), and was decreased after physiological ethanol doses in splenic cell cultures in mice (Friedman, 1998) and in ethanol-fed mice (Waltenbaugh *et al.*, 1998; Zisman *et al.*, 1998). The variability in results makes it unclear whether the immune alterations associated with alcoholism occur with relatively uniform risk or tend to affect individuals whose susceptibility is higher than average (Irwin and Miller, 2000).

Th1/Th2 Subsets

The specific effects of ethanol on T helper cell (Th)1 and Th2 cytokines are still unclear (Irwin and Miller, 2000). An increase in Th2 responses was reported in alcohol-dependent rats (Na *et al.*, 1997), whereas an increase in Th2 responses and a decrease in Th1 responses was observed in mouse models (Waltenbaugh *et al.*, 1998; Zisman *et al.*, 1998). It has been shown that alcohol enhances IL-10 production and decreases IL-12 secretion, therefore shifting the Th1/Th2 ratio towards a decreased cellular immune response (Starkenburg *et al.*, 2001; Irwin and Miller, 2000; Szabo *et al.*, 1996; Waltenbaugh *et al.*, 1998; Zisman *et al.*, 1998; Girouard *et al.*, 1998, Cohen *et al.*, 1995). Yet in contrast, Laso *et al.* (1998, 1999) found an increased Th1 response and a decreased Th2 response.

In chronic alcoholics an increased number of Cluster of differentiation (CD)4+ T cells ('helper cells'), CD8+ T cells ('cytotoxic and suppressor cells'), and natural killer (NK) cells (Laso *et al.*, 1996a, 1997) were found. The ratio of CD4+ T cells and CD8+ T cells was normal or elevated (Cook, 1998). Cook *et al.* (1995) demonstrated an increased expression of CD57 in alcoholics. CD57 is commonly associated on both CD8+ T cells and in CD4+ T cells during chronic increased antigenic exposure (Cook *et al.*, 1995). Cook *et al.* concluded that these and other T cell alterations in alcoholics are cytokine driven in part, and result in T cell differentiation states that are functionally inappropriate. It was reported recently that IL-6 derived from antigen-presenting cells is able to polarize naive Th cells into effector Th2 cells by inducing the initial production of IL-4 in CD4 T cells (Rincon *et al.*, 1997). The inducing effect of IL-4 is dominant such that if IL-4 levels reach a necessary threshold, then differentiation of the T cells to the Th2 subset occurs (Romagnani, 1997).

B Cells

Investigations into the B cell count in chronic alcoholics have not yielded uniform results. The B cell count in patients without liver diseases tends to be normal (Cook *et al.*, 1996) or slightly reduced (Sacanella *et al.*, 1998). In chronic alcoholics the major classes of immunoglobulins (Ig), IgA, IgG and IgM, may all be elevated (Cook, 1998). Typically, IgA is also increased in alcoholics without liver disease, and tissue deposits of IgA are often observed, especially in skin, liver and kidney (Paronetto, 1993; Cook, 1998). Alcoholic patients with elevated immunoglobulin levels are often immunodeficient (Cook, 1998). It was also shown that ethanol exposure reduced B cells more than T cells in the spleen of normal adult mice (Meadows *et al.*, 1992). Serum IgE was found to be increased in alcoholic patients compared to healthy volunteers (Gonzalez-Quintela *et al.*, 1999). Acute ethanol administration decreases the basal level of major histocompatibility complex (MHC) class Ia expression on murine splenic B cells by a glucocorticoid mechanism, as well in immunized as in non-immunized mice (Weiss *et al.*, 1996, 1998). Reduced expression of Ia decreases Th-dependent responses to antigen (Bekkhoucha *et al.*, 1984; Matis *et al.*, 1983). Short-term ethanol administration provoked a decrease in the total number of T and B cells in the Peyer's patches, but changes were detected either in the total number of cells or in the absolute number of T and B cells studied in the mesenteric lymph nodes (Lopez *et al.*, 1997). Long-term ethanol administration decreased the number of T and B cells in the Peyer's patches but not in the mesenteric lymph nodes (Lopez *et al.*, 1997). The authors concluded that ethanol impaired the mucosal immune system at the level of the Peyer's patches, which is the site for antigen presentation and, therefore, for the induction of a mucosal immune response (Lopez *et al.*, 1997).

Prenatal Ethanol Exposure

Maternal ethanol consumption impacts the endocrine and immune functions of the offspring (Sarkar, 1996). The maternal HPA axis appears important for the development of immunocompetency in 'Fetal Alcohol Effects' (FAE) animals, since maternal adrenalectomy abolished the suppression of T cell-dependent function in the male offspring (Redei *et al.*, 1993). These data also support the notion that alcohol-induced changes in the mother's adrenal function produce an altered thymic development in the foetus, leading to immune suppression in the offspring (Sarkar, 1996).

FAE animals have an HPA hyper-responsiveness to immune signals, in contrast to adult rats exposed to ethanol. The enhanced

HPA response in these animals may be related to the increased ability of PVN neurones to secrete CRF and vasopressin in response to IL-1β challenge (Lee *et al.*, 1996). FAE animals have a reduced lymphocyte proliferative response to concanavalin A (ConA) and a reduced lymphoblast response to IL-2. Importantly, FAE males showed more vulnerability to the adverse effects of foetal ethanol exposure on immune function (Weinberg and Peterson, 1991). In a separate study, the determination of immune responsiveness (lymphocyte proliferation to mitogens ConA and pokeweed mitogen) following a chronic metabolic stressor (1 day of cold exposure) revealed that FAE females also had an altered immune response (Giberson and Weinberg, 1995).

FAE attenuates the febrile response to the systemic administration of an endotoxin, and the febrile and anorectic responses to IL-1 (Yirmiya *et al.*, 1993, 1996). Hypothalamic levels of IL-1 after intraperitoneal administration of LPS and fever induced by intracerebroventricular IL-1 was significantly lower in FAE rats (Taylor *et al.*, 1999). Whereas FAE does not affect central thermoregulatory mechanisms *per se*, FAE alters the kinetics of hypothalamic IL-1 production/appearance and decreases the responsiveness of central mechanisms which mediate the febrile response to IL-1 (Taylor *et al.*, 1999).

Phenotypic analysis of spleen and bone marrow cells, taken between 1 and 5 weeks after birth from animals exposed to ethanol *in utero*, has shown quantitative alterations in the developmental intermediates in the B cell lineage. Cells from the ethanol-exposed animals showed decreased numbers of pre-B cells in the bone marrow and total B cell counts in both the bone marrow and spleen were also low (Moscatello *et al.*, 1999). B cell numbers were reduced as well in ethanol-exposed neonatal mice (Giberson and Blakley, 1994).

Alcohol and Liver Disease

Clinical Relevance

It was suggested that host or environmental factors may play a role in the genesis of alcohol-related liver disease (Tilg and Diehl, 2000). Alcohol can injure the liver even in the absence of dietary deficiencies because of its intrinsic toxicity (Lieber, 1995), and long-term consumption of alcohol results in a spectrum of liver abnormalities (MacSween and Burt, 1986). Despite the possible mild systemic effects of alcohol, severe effects may be seen resulting primarily from a complex syndrome called alcoholic liver disease (ALD), which has three increasingly destructive forms: steatosis (fatty liver), alcoholic hepatitis (AH) and cirrhosis (AC) (Fleming *et al.*, 2001). Steatosis can be followed by early fibrosis, which in turn can be associated with AH, leading to irreversible damage caused by severe fibrosis and, subsequently, to cirrhosis (Lieber, 1995). Alterations in the immune system occur in ALD (Paronetto, 1993). Whether these alterations are a consequence or a cause of the liver injury has yet to be determined (Lieber, 1995).

Alcohol and LPS/Intestinal Permeability

Tilg and Diehl (2000) concluded that intestinally derived endotoxin and endotoxin-induced cytokines play an important role in the pathogenesis of steatohepatitis because it was observed that long-term alcohol abuse increases intestinal permeability (Fukui *et al.*, 1991), and that patients with the highest serum cytokine concentration had the highest rate of in-hospital mortality (Felver *et al.*, 1990; Hill *et al.*, 1992). LPS derived from the cell walls of bacteria commonly found in the intestine is a well-known and powerful activator of many immune system cells. It could be suggested that Kupffer cell activation and liver damage in chronic alcoholics are accentuated by the interaction of alcohol and this bacterial product (Schenker and Bay, 1995; Cook, 1998). Therefore, the gut leak was suggested as a necessary cofactor for development of ALD in chronic alcoholics (Keshavarzian *et al.*, 1999).

Pro-/Anti-Inflammatory Immune Modulation

The production of TNF-α is one of the earliest events in many types of liver injury. It triggers the production of other cytokines that together recruit inflammatory cells, kill hepatocytes, and initiate a healing response including fibrinogenesis (Tilg and Diehl, 2000). Comparing TNF-α response in patients with alcoholic fatty liver (AF), AH, AC and healthy controls after LPS stimulation of monocytes, only patients with AC had elevated TNF-α plasma levels, and the release of IL-6 from monocytes was increased only in AF (Schafer *et al.*, 1995). Regional and systemic production of TNF-α and other pro-inflammatory cytokines is stimulated by the translocation of bacterial products from the intestinal lumen to the mesenteric circulation and its lymphatics (Tilg and Diehl, 2000). Initially increased serum levels of TNF-α (Bird *et al.*, 1990; Felver *et al.*, 1990) as well as several TNF-inducible cytokines, such as IL-1 (McClain *et al.*, 1986), IL-6 (Hill *et al.*, 1992) and IL-8 (Sheron *et al.*, 1993; Hill *et al.*, 1993), were reported in hospitalized patients with AH. Because TNF-α is toxic to many cells, and is known to induce apoptosis, it is thought that excessive secretion of TNF-α by monocytes and Kupffer cells contributes to the death of cells such as liver cells (Cook, 1998).

Patients with severe acute AH have a worse outcome when they have elevated TNF-α serum levels (Bird *et al.*, 1990; Felver *et al.*, 1990). The presence of elevated TNF-α was more significantly associated with death than recovery (Bird *et al.*, 1990; Felver *et al.*, 1990). IL-6 levels showed independent associations with the presence of ascites, encephalopathy and low mean arterial pressure (Genesca *et al.*, 1999). Neopterin and IL-8 plasma levels were raised in patients with alcohol-induced cirrhosis and were predictive of mortality associated with infections and upper gastrointestinal bleeding, respectively (Homann *et al.*, 2000).

Th1/Th2 Subsets

The balance of Th1/Th2 in alcoholics suffering from late-stage chronic cirrhosis may be different from alcoholics during an early episode of acute AH, or during an episode of infection due to immune deficiency (Cook, 1998).

The increased production of both IL-12 and Th-1-associated cytokines and the expansion of the peripheral blood cytotoxic cell compartment can contribute to the understanding of the pathogenetic mechanisms causing ALD, since self-reactive clones of cytotoxic cells may contribute to hepatocyte necrosis (Laso *et al.*, 1999).

B Cells

In ALD B cell numbers are often decreased, despite the fact that they produce abnormally large amounts of immunoglobulins (Cook, 1996, 1998; Laso *et al.*, 1996a). Typically, IgA is increased in alcoholics without liver disease as well as in patients with ALD. IgG is elevated in ALD, and IgM is increased only in patients with ALD and active disease, such as AH (Cook, 1998).

NK Cells

Various studies on NK lymphocytes in chronic alcoholics have yielded different results. In contrast to the findings of Laso and colleagues (1996a, 1997), who demonstrated a significant increase of NK in patients with alcoholic hepatitis and cirrhosis, Cook *et al.*

(1997) observed a reduced NK count and loss of NK activity in some patients with ALD.

Alcohol and Hepatic Encephalopathy

Liver diseases, and in particular alcoholic liver diseases, are conditions characterized by high circulating levels of cytokines, namely IL-1, IL-6 and TNF-α. Interactions between cytokines and CNS endothelial cells may trigger a cascade of events including enhanced blood–brain barrier permeability, brain oedema, astrocyte alterations and gliosis. Cytokine-induced production of nitrogen-reactive molecules by endothelial cells may also lead to further cellular damage and neuronal dysfunction (Duchini, 1996). Brain tissue has a remarkable ability to accumulate glutamate. This ability is due to transporter proteins present in the plasma membranes of both glial cells and neurones. The transporter proteins represent the only significant mechanism for removal of glutamate from the extracellular fluid (Danbolt, 2001). TNF-α- and IL-1β-potentiated glutamate-mediated oxidative stress results in a decrease in glutamate transporter activity (Liao and Chen, 2001). During hepatic encephalopathy ammonium ions penetrate the blood–brain barrier, where an astroglia-specific enzyme, glutamine synthetase, catalyses the formation of glutamine from glutamate. In hepatic encephalopathy, the osmotic action of glutamine appears to be largely responsible for cerebral oedema, oedema-associated disturbances of cerebral blood flow and ionic homeostasis. In chronic hepatic encephalopathy not accompanied by cerebral oedema, glutamine contributes to the impairment of cerebral energy metabolism. The increased transport of glutamine from the brain to the periphery accelerates the blood-to-brain transport of aromatic amino acids, resulting in the conversion of tryptophan to metabolites which are directly implicated in hepatic encephalopathy (Albrecht and Dolinska, 2001). Tryptophan was also shown to be increased before ethanol withdrawal occurred (Badawy *et al.*, 1998). The metabolism of tryptophan to quinolinic acid is activated by the pro-inflammatory cytokine TNF-α (Fuegener *et al.*, 2001). Therefore, pro-inflammatory cytokines due to liver disease, as well as due to infections, may make patients more prone to, or may further aggravate, encephalopathy.

Alcohol and Traumatic Stress

Clinical Relevance

Chronic alcohol misuse is at least as common in surgical patients as in neurological or psychiatric patients (Moore *et al.*, 1989; Spies *et al.*, 2001). The rate of infections after surgery is increased three to four times in chronic alcoholics compared to non-alcoholic patients (Spies *et al.*, 1996; Tønnesen and Kehlet, 1999) Wound infections, urinary tract infections, tracheobronchitis and pneumonia are two to four times more frequent among alcoholics compared with controls (Spies *et al.*, 2001; Rantala *et al.*, 1997; Tønnesen and Kehlet, 1999). Due to the increased post-operative complications in chronic alcoholics, the median hospital stay is significantly prolonged (Spies *et al.*, 1995; Jensen *et al.*, 1988).

Preoperative immune suppression and altered response to surgical stress were found in patients with chronic alcohol abuse (Spies *et al.*, 2001; Spies and Rommelspacher, 1999; Tønnesen, 1999; Tønnesen and Kehlet, 1999; Tønnesen *et al.*, 1992). The rate of post-operative infections in chronic alcoholics may be related to preoperative immune suppression (Christou, 1985).

Immune Modulation

Surgical injury induces a generalized immune response associated with decreased LPS responsiveness (Kawasaki *et al.*, 2001) and an increased stress response (Tønnesen *et al.*, 1992). Recently it was shown that ether laparotomy resulted in a robust increase in [^{125}I]IL-1α binding and IL-1R1 mRNA levels in the pituitary 2 h after the onset of stress. Therefore, CRF plays a pivotal role in the regulation of IL-1 receptors under stress conditions (Narzaloo *et al.*, 2001). In patients undergoing pancreatoduodenectomy, increased plasma levels of ACTH and cortisol were associated with stimulated production of cytokines. The appearance of endotoxin in the blood circulation was followed by an increase in plasma TNF-α and IL-6 levels. In contrast, after gastrectomy plasma TNF-α remains undetectable but an increase in plasma concentrations of IL-10 and cortisol was observed (Ogata *et al.*, 2000).

Pro-/Anti-Inflammatory Immune Modulation

The reasons for post-operative immunodeficiency in alcoholics are complex. High levels of glucocorticoids have inhibitory effects on the immune system, while levels that are too low can lead to inflammation (Sarkar, 1996). TNF-α and IL-6 are considered important signals in the peripheral immune stimulation of the brain. These pro-inflammatory cytokines are especially able to enlarge the neuronal activity of hypothalamic perikarya that are involved in the release of ACTH and corticosteroids (Rivier, 1999; Tilders *et al.*, 1994; Chrousos, 1995). TNF-α is one of the first proteins released during endotoxaemia (Givalois *et al.*, 1994), and it was thought that this cytokine plays an important role in modulating at least the early phase of LPS-induced ACTH release through the release of CRF by nerve terminals (Ebisui *et al.*, 1994; Watanobe and Taskebe, 1992; Rivier, 1999). IL-6 also plays a role in the response of the HPA axis to immune stimulation (Perlstein *et al.*, 1993). In a recent investigation Sander *et al.* (2002) showed that the IL-6/IL-10 ratio in chronic alcoholic patients dropped immediately following surgery, which was predictive for infections during the ICU course.

Th1/Th2 Subsets

Experimentally an alcohol-induced reduction of the delayed-type hypersensitivity (DTH) response in mice was reported together with a profound inhibition of this immune response. This indicates that an alcohol-induced inhibition of cell-mediated immunity occurs independently of antigen priming (Schodde *et al.*, 1996). In a clinical study the skin response of DTH was decreased in patients who underwent colorectal surgery (Tønnesen *et al.*, 1992). Among chronic alcoholics the reduced DTH response was already present preoperatively and, compared with non-alcoholics, was enhanced to a significantly lower extent post-operatively (Tønnesen *et al.*, 1992; Spies *et al.*, 2001).

Summary (See Tables XVI-4.1 and XVI-4.2)

Taken together, chronic alcohol exposure increased endotoxin release, decreased the ratio of pro- to anti-inflammatory cytokines, decreased the Th1/Th2 ratio and B cells, but increased immunoglobulin levels peripherally, whereas it decreased pro-inflammatory release centrally. In ALD, responses with respect to pro-inflammatory release, NK cell activity and immunoglobulins were exaggerated.

NICOTINE

Clinical Relevance

An estimated 65.5 million people in the United States reported current use of a tobacco product in 2000, which accounts for 29.3%

Table XVI-4.1 Central immune effects of alcohol

Stimulus: Alcohol	Central	
	Cytokines	Cells
Acute, experimental	IL-1β down in hypothalamus cells (Lee and Rivier, 1993) TNF-α down in murine cortical cells (Gahring *et al.*, 1999)	
Chronic, experimental	IL-1β down in hypothalamus cells (Lee and Rivier, 1993)	
+ Stimuli, acute, experimental	Stimulus LPS: IL-1β, TNF-α down in C6 glia cells (Syapin *et al.*, 2001) Stimulus LPS: IL-6, TNF-α no change in pituitary cells (Rivier, 1999) Stimulus TNF-α: ICAM-1 down in astrocytes (DeVito *et al.*, 2000) Stimulus IFN-γ: ICAM-1 no change in astrocytes (DeVito *et al.*, 2000)	

Intercellular adhesion molecule (ICAM); interferon (IFN); interleukin (IL); lipopolysaccharide (LPS); natural killer (NK) cell; tumour necrosis factor (TNF).

Table XVI-4.2 Peripheral immune effects of alcohol

Stimulus: Alcohol	Peripheral	
	Cytokines	Cells
Chronic, human	Endotoxin up (Parlesak *et al.*, 2000) IL-12 up (Laso *et al.*, 1998) IL-6, IL-8, IL-10, IL-12, and IL-13 up (Gonzalez-Quintala *et al.*, 1999)	Th1/Th2 ratio up (Laso *et al.*, 1998) NK cell count up (Laso *et al.*, 1997) IgE up (Gonzalez-Quintala *et al.*, 1999; Dominguez-Santalla *et al.*, 2001) IgA up (Cook *et al.*, 1998)
Experimental	IL-12 down (acute) (Friedman *et al.*, 1998) IL-4, IL-10 up (acute) (Friedman *et al.*, 1998)	B cell count down (acute) (Lopez *et al.*, 1997) B cell count down (chronic) (Lopez *et al.*, 1997, Starkenburg *et al.*, 2001) Th1/Th2 ratio down (acute) (Na *et al.*, 1997) Th1/Th2 ratio down (chronic) (Starkenburg *et al.*, 2001) IgE up (chronic) (Starkenburg *et al.*, 2001)
+ Stimuli, acute, human (healthy volunteers)	Stimulus LPS: TNF-α, IL-1β down (Szabo *et al.*, 1996b) Stimulus LPS: IL-10 up (Szabo *et al.*, 1996b) Stimulus SEB: IL-1β down (Szabo *et al.*, 1996b) Stimulus SEB: IL-12 up (Girouard *et al.*, 1998)	
+ Stimuli, acute, experimental	Stimulus LPS: IL-10 up, IL-12 down (Mason *et al.*, 2000) Stimulus LPS: IL-6 down (Rivier, 1999)	
Alcohol and ALD		
Chronic, human	TNF-α up in AC (Schafer *et al.*, 1995) IL-6 up in AC (Genesca *et al.*, 1999) IL-8 up in AC (Homann *et al.*, 2000) TNF-α up in AH (Bird *et al.*, 1990; Felver *et al.*, 1990) IL-1 up in AH (McClain *et al.*, 1986) IL-6 up in AH (Hill *et al.*, 1992; Genesca *et al.*, 1999) IL-8 up in AH (Sheron *et al.*, 1993; Hill *et al.*, 1993) IL-6 up in FL (Schafer *et al.*, 1995)	Th1/Th2 ratio up in AC (Laso *et al.*, 1999) NK count and activity in AH up (Laso *et al.*, 1997) NK count and activity in ALD down (Cook *et al.*, 1997) B cell count down (Cook *et al.*, 1996) IgG, IgA up in ALD (Cook *et al.*, 1998) IgM up in AH (Cook *et al.*, 1998)
Alcohol and surgery		
Chronic, human	IL-6/IL-10 ratio down (Sander *et al.*, 2002)	Th1/Th2 ratio down (Tønnesen *et al.*, 1992)

Alcoholic liver disease (ALD); alcoholic cirrhosis (AC); alcoholic hepatitis (AH); fatty liver (FL); immunoglobulin A (IgA); immunoglobulin E (IgE); immunoglobulin G (IgG); immunoglobulin M (IgM); intercellular adhesion molecule (ICAM); interferon (IFN); interleukin (IL); lipopolysaccharide (LPS); natural killer (NK) cell; staphylococcal enterotoxin B (SEB); T helper cell (Th); tumour necrosis factor (TNF).

of the population aged 12 and older. Among that same population 55.7 million (24.9%) smoked cigarettes. Cigarette smokers are more likely to use other tobacco products, illicit drugs and alcohol than non-smokers. In 2000, 39.4% of smokers were binge drinkers and 13.6% were heavy alcohol users (Substance Abuse and Mental Health Services Administration, 2001). Cigarette smoking has long been reported as having negative health consequences. In the United States, cigarette smoking is responsible for over 400 000 deaths per year and the direct health care costs exceed $50 billion per year (US Department of Health and Human Services, 1994). The noxious effect of smoking can be due, in part, to its immunosuppressive activity (Sopori and Kozak, 1998; Hakki *et al.*, 2000). Recent studies suggest smoking as a risk factor for faster development of acquired immunodeficiency syndrome (AIDS) in human immunodeficiency virus (HIV)-1 seropositive individuals, higher susceptibility to *Pneumocystis carinii* infections in AIDS patients, and higher frequency of transmission from AIDS from smoking mothers to their offspring (Burns *et al.*, 1991; Nieman

et al., 1993; Burns *et al.*, 1994; Sopori and Kozak, 1998). Smokers have an increased susceptibility for respiratory tract diseases and cancer, which may reflect cigarette smoke-induced impairment of the immune system (Holt and Keast, 1977).

Cigarette smoke contains thousands of different compounds including nicotine, polycyclic aromatic hydrocarbons, tobacco glycoprotein and some metals (Sopori and Kozak, 1998). Chronic nicotine exposure leads to the inhibition of antibody responses, indicating that nicotine is a major immunosuppressive component in cigarette smoke (Geng *et al.*, 1996). Nicotine is also the major addictive component of tobacco. The mechanism of cigarette smoke-induced immunosuppression is not clear, and several potential mechanisms are being considered.

Immune Modulations

Mellon and Bayer (1999) suggest that nicotine mimics the effects of morphine on peripheral blood lymphocyte responses. These effects appear to decrease the overall magnitude of the response to mitogen treatment without clearly altering the sensitivity of the cells to this potent stimulus. They demonstrated that nicotinic agonists, such as epibatidine, produce their immunomodulatory effects on blood lymphocyte proliferation by acting predominantly at peripheral nicotinic receptors (Mellon and Bayer, 1999). The nicotinic receptor-mediated immunomodulation, like that produced by opioids, appears independent of the ability to activate the HPA axis (Mellon and Bayer, 1999).

CD4 T cells, NK and B cells, as well as the percentages of total lymphocytes, monocytes and granulocytes, were unaffected by acute nicotine in experimental settings. This suggests that the acute effect of nicotine on cell function in the blood, such as non-specific proliferation, is not due to changes in cell distribution (McAllister-Sistilli *et al.*, 1998).

Pro-/Anti-Inflammatory Immune Modulation

Matsunaga *et al.* (2001) showed that nicotine exposure to murine macrophages infected with bacteria enhanced the growth of *Legionella pneumophila*, and led to a downregulated production of IL-6, IL-12 and TNF-α. In this setting the IL-10 production induced by bacteria was not affected by nicotine (Matsunaga *et al.*, 2001). In another experimental study, pretreatment with nicotine inhibited LPS-induced IL-1β, IL-8 and prostaglandin E_2 (PGE_2) protein production (Sugano *et al.*, 1998).

It has been shown that LPS-stimulated human alveolar macrophages in heavy smokers release less IL-1 and PGE_2 (Brown *et al.*, 1989), as well as less TNF-α and IL-6 than in non-smokers (McCrea *et al.*, 1994).

Th1/Th2 Subsets

Geng *et al.* (1995) demonstrated that splenic lymphocytes from rats treated chronically with nicotine exhibited a substantial loss of the antibody-forming cell (AFC) responses to both T-dependent and T-independent antigens without significantly affecting the number or percentage of lymphocyte subpopulation. Similar results were shown in chronic smoke-exposed rats, which showed suppressed AFC response without altering the total number or subpopulation of lymphocytes (Kalra *et al.*, 2000). The inhibition of the AFC response was evident in nicotine-treated animals up to 14 days following the termination of nicotine exposure. These results indicate that nicotine-induced T cell anergy, a condition in which antigen-specific T cells fail to respond to an antigen and develop tolerance (Sopori and Kozak, 1998), lasts for a significant period after nicotine has been cleared from the circulation (Geng *et al.*, 1996). The nicotine-induced activation is thought to be responsible for making T cells refractory to antigen-induced biochemical changes. Furthermore, there are indications that nicotine only partially activates T cells (Geng *et al.*, 1996). This partial activation by nicotine may be a general mechanism for the induction of T cell tolerance leading to immunosuppression (Geng *et al.*, 1996).

Nicotine exposure decreases T cell CD28 expression, which results in T cell anergy (Zhang and Petro, 1996). Both CD4 and CD8 T cell subpopulations may be increased in smokers (Smart *et al.*, 1986). The altered Th1/Th2 ratios could explain how cigarette smoke affects the immune response. It has been demonstrated that the exposure of responding T cells to nicotine results in decreased plasma levels of IL-2 and IFN-γ and leads to an increased accumulation of IL-4 and IL-10 in mice (Zhang and Petro, 1996; Petro *et al.*, 1999). The leucocytes of smokers produce higher levels of IL-4, a cytokine which inhibits the Th1 cells required for the inflammatory response (Sopori and Kozak, 1998). In contrast, LeCam *et al.* (1996) did not find a nicotine effect on the *in vitro* release of IL-4 and IFN-γ. However, Ouyang *et al.* (2000) showed that even at concentrations as high as 200 $\mu g\,ml^{-1}$, nicotine inhibited the production of IL-2, IFN-γ, IL-1β and TNF-α. IL-2, IFN-γ, IL-1β and TNF-α are important mediators of antitumour immunity and suppression of these cytokines by components of cigarette smoke, especially nicotine, may increase the risk of infection, lung cancer and other malignancies (Ouyang *et al.*, 2000). In an experimental study nicotine caused an increase in IL-1α mRNA levels, but despite the increase in mRNA the IL-1α protein level in the rat adrenal gland was reduced (Andersson *et al.*, 1992).

The ability of nicotine to influence CD4 T cell cytokine production may not just have a significant impact on microbial disease progression (Zhang and Petro, 1996). Progression towards both human and mouse AIDS is associated with decreased production of Th1 cytokines such as IFN-γ and increased production of Th2 cytokines, like IL-4 and IL-10 (Clerici and Shearer, 1994).

B Cells

Nicotine stimulates IgE production (Sopori and Kozak, 1998). Gerrard *et al.* demonstrated that IgE levels in smoking humans are higher as compared to non-smokers (Gerrard *et al.*, 1980). Furthermore, the levels of IgM, IgA and IgG were found to be decreased in smokers (Gerrard *et al.*, 1980; Andersen *et al.*, 1982).

NK Cells

It has been shown that smokers have decreased NK activity (Tollerud *et al.*, 1989; Hughes *et al.*, 1985), which has also been confirmed in experimental settings (Nair *et al.*, 1990).

HPA Axis and ANS

Nicotine may affect immune and/or other physiological functions via activation of CRF and the eventual release of corticosterone and other neurohormones (Rosecrans and Karin, 1998). Nicotine and muscarinic receptors play an important role in corticotropin-releasing hormone (CRH) release, as they both mediate IL-2-stimulated CRH release (Karanth *et al.*, 1999). Nicotine together with cigarette smoke stimulates the release of noradrenaline (norepinephrine) and adrenaline (epinephrine) and ACTH (Cryer *et al.*, 1976; Seyler *et al.*, 1984). ACTH and catecholamines have been shown to inhibit the immune response (Fuchs and Sanders, 1994).

Both acute and chronic nicotine treatments regulate T cell proliferation via nicotinic acetylcholine receptors (nAChR). However, while the chronic effects of nicotine appear to be independent of the HPA axis, activation of this axis may play a critical role in the response of T cells to acute nicotine exposure (Singh

et al., 2000). Acute administration did not inhibit the proliferation of spleen cells to ConA, a T cell mitogen (Singh *et al.*, 2000). However, acute nicotine administration inhibited the ConA-stimulated proliferation of peripheral blood cells; but this effect was short lived and not observed at 24 h after nicotine administration (Singh *et al.*, 2000). It was also found that acute exposure increased the plasma corticosterone concentration. Adrenalectomized animals did not exhibit the inhibition of the ConA response after acute nicotine treatment. Because glucocorticoids primarily affect the activation of IL-2, and the IL-2-induced signalling cascade, acute nicotine may not significantly affect the early steps in the T cell receptor-mediated signalling in T cells (Almawi *et al.*, 1991; Iseki *et al.*, 1993; Paliogianni *et al.*, 1993; Singh *et al.*, 2000). Unlike acute treatment, chronic nicotine treatment does not increase the plasma corticosterone levels, and chronic, sustained exposure to nicotine in rats inhibited the response of spleen cells to ConA (Singh *et al.*, 2000; Geng *et al.*, 1995). These authors concluded that the effects of chronic nicotine on T cell function are independent of the HPA axis (Singh *et al.*, 2000).

CNS

Cytokines present in the CNS originate not only from the peripheral sources of the immune system but also through endogenous production by cells of the brain, including astrocytes and neurones whose production can be stimulated by peripheral cytokines (Carlson *et al.*, 1999). By itself, nicotine is neuroprotective against NMDA-mediated excitotoxicity. It is important to note that nicotine inhibits TNF-α-induced, but not IL-1- (both α and β) or IL-6-induced neuroprotection in cortical cell cultures (Carlson *et al.*, 1999). Nicotine stimulates neurones via activation of nAChRs and, specifically for neuroprotection, those nAChRs composed of $\alpha 7$ subunits (Lindstrom, 1996; Sargent, 1993). Activation of these ligand-gated ion channels induces a flux of calcium into the cell, leading to other intracellular events (Harkins and Fox, 1998; Tang *et al.*, 1998; Warashina, 1998; Darnay and Aggarwal, 1997). After the initial agonist action of nicotine the channel closes, rapidly terminating the effects of nicotine and its consequent pharmacological effects. A nicotine-induced nAChR desensitization associated with the development of tolerance and an upregulation of central nAChR was observed (Rosecrans and Karin, 1998; Marks *et al.*, 1983). How these intracellular events interfere with TNF-α-induced effects is unknown.

Summary (See Tables XVI-4.3 and XVI-4.4)

Taken together, there is a good evidence that nicotine peripherally and centrally suppresses pro- and stimulates anti-inflammatory responses. Except for IgE upregulation all cell-mediated responses seem to be downregulated.

BENZODIAZEPINES

Clinical Relevance

Benzodiazepines are one of the most prescribed and consumed medication groups in the world (Kapczinski *et al.*, 2001). For example, 10% of the inhabitants in a Dutch community of 13 500 people receive benzodiazepine prescriptions at least once a year (van Hulten *et al.*, 1998). Stress, depression and psychotic disturbances have been shown to provoke severe immunological disorders (Lechin *et al.*, 1994; Muller *et al.*, 1991; Stein *et al.*, 1991). The 1,5- and particularly the 1,4-benzodiazepines are the most widely prescribed anxiolytic drugs, and function by binding to the central benzodiazepine receptor, which is allosterically coupled to the γ-aminobutyric acid (GABA) A receptor (Fruscella *et al.*, 2001; Zavala, 1997). Indirectly, benzodiazepines can also regulate neurotransmitter release via the modulation of neurosteroid synthesis in the mitochondria (Freeman and Young, 2000). Peripheral benzodiazepine receptor binding sites have been found in all mammalian tissues, including glial cells and blood mononuclear cells, with the following cell distribution: monocytes > B cells and large granular lymphocytes > T cells (Ferrarese *et al.*, 1990, 1993; Rocca *et al.*, 1993).

Immune Modulation

Stimulation of peripheral benzodiazepine receptors may have an important impact on phagocyte activity, therefore influencing essential functions such as chemotaxis, the generation of oxidative bursts and cytokine production (Ruff *et al.*, 1985; Ferrarese *et al.*, 1993; Zavala, 1997). However, there are marked differences between the augmentation *in vitro* and inhibition *ex vivo* of cytokine production and oxidative burst potential (Zavala, 1997).

Benzodiazepine and LPS/Intestinal Permeability

To our knowledge nothing is known about benzodiazepine abuse or withdrawal and intestinal permeability or endotoxin liberation.

Pro-/Anti-Inflammatory Immune Modulation

Fruscella *et al.* (2001) demonstrated that benzodiazepine derivatives have an anti-inflammatory effect in mice. They reduce the exudate production of IL-6 and PGE_2 as well as vascular permeability, which is partially involved in the reduction of pouch leucocyte recruitment (Fruscella *et al.*, 2001). It has been shown that peripheral (Ro5-4864) and mixed-type benzodiazepine (diazepam) receptor agonists suppress phytohaemagglutinin- and ConA-induced proliferation of human peripheral blood mononuclear cells, and inhibit IL-2- and IL-3-like activity (Bessler *et al.*, 1992).

In mice, the production of bioactive TNF-α by splenocytes and peritoneal macrophages, and the LPS-induced production of IL-1 and IL-6 by spleen macrophages, is inhibited by injections of

Table XVI-4.3 Central immune effects of nicotine

Stimulus: Nicotine	Central	
	Cytokines	Cells
Acute, experimental	TNF-α in cortical cells down (Carlson *et al.*, 1999) IL-1α, IL-1β and IL-6 in cortical cells no change (Carlson *et al.*, 1999)	
Chronic, experimental		AFC response down (Sopori *et al.*, 1998)

Antibody plaque-forming cell (AFC); interleukin (IL); tumour necrosis factor (TNF).

Table XVI-4.4 Peripheral immune effects of nicotine

Stimulus: Nicotine	Peripheral	
	Cytokines	Cells
Acute, human	IL-1β, IL-2, IFN-γ, TNF-α down (Ouyang *et al.*, 2000)	CD4 T cells, total lymphocytes, monocytes, granulocytes, NK, B cells no change (McAllister-Sistilli *et al.*, 1998)
Chronic, human	IL-2 down (van Dijk *et al.*, 1998) IL-2, TNF-α no change (Madretsma *et al.*, 1996) IL-10 down (Madretsma *et al.*, 1996)	NK cell count down (Tollerud *et al.*, 1989) NK cell activity down (Hughes *et al.*, 1985) IgE up (Gerrard *et al.*, 1980) IgM down (Gerrard *et al.*, 1980) IgA, IgG down (Andersen *et al.*, 1982)
Acute, experimental	IL-2, IFN-γ down (Zhang and Petro, 1996; Petro *et al.*, 1999) IL-4, IL-10 up (Zhang and Petro, 1996; Petro *et al.*, 1999) IL-4, IFN no change (LeCam *et al.*, 1996) IL-1α mRNA up (Andersson *et al.*, 1992) IL-1α protein level down (Andersson *et al.*, 1992)	Th1/Th2 ratio no change (McAllister-Sistilli *et al.*, 1998) Th1/Th2 ratio down (Zhang and Petro, 1996) B cell count, NK cell count no changed (McAllister-Sistilli *et al.*, 1998) NK cell activity down (Nair *et al.*, 1990)
Chronic, experimental	IL-8 mRNA down (colonic mucosa) (Louvet *et al.*, 1999)	AFC response down (Geng *et al.*, 1995, Kalra *et al.*, 2000) Th1/Th2 ratio down (Zhang and Petro, 1996)
+ Stimuli, chronic, human heavy smokers	Stimulus LPS: IL-1, PGE_2 down (Brown *et al.*, 1989) Stimulus LPS: TNF-α, IL-6 down (McCrea *et al.*, 1994)	
+ Stimuli, acute, experimental	Stimulus LPS: IL-1β, IL-8, PGE_2 down (Sugano *et al.*, 1998) Stimulus *L. pneumophila*: IL-6, IL-12, TNF-α down (Matsunaga *et al.*, 2001) Stimulus *L. pneumophila*: IL-10 no change (Matsunaga *et al.*, 2001)	Stimulus ConA: proliferation of PBC down (Singh *et al.*, 2000)
+ Stimuli, chronic, experimental		Stimulus ConA: proliferation of PBC and spleen cells down (Singh *et al.*, 2000)

Antibody plaque-forming cell (AFC); cluster of differentiation (CD); concanavalin A (ConA); interferon (IFN); interleukin (IL); *Legionella pneumophila* (*L. pneumophila*); lipopolysaccharide (LPS); messenger ribonucleic acid (mRNA); natural killer (NK) cell; peripheral blood cell (PBC); prostaglandin E_2 (PGE_2); T helper cell (Th); tumour necrosis factor (TNF).

ligands selective for peripheral benzodiazepine receptors (Zavala *et al.*, 1997; Zavala and Lenfant, 1987; Fruscella *et al.*, 2001). A comparable study performed on human cells from subjects given a single injection of the mixed-type benzodiazepine receptor agonist midazolam (0.08 mg kg^{-1}) showed that LPS-mediated IL-1β, TNF-α and IL-6 production was decreased (Taupin, 1991). Taken together, the *in vivo* experiments show that peripheral benzodiazepine receptor ligands inhibited the synthesis of IL-1β, IL-6 and TNF-α in response to LPS (Zavala, 1997). However, in contrast to the *in vivo* data, the mixed/peripheral benzodiazepine receptor agonist increased rather than inhibited cytokine generation, producing bell-shaped concentration–response curves. Thus, at concentrations of 0.1–10 nm, Ro5-4864 and diazepam produced approximately a twofold increase in the production of bioactive and immunoreactive IL-1β, TNF and IL-8 induced by LPS. However, at lower or higher concentrations the effects of the drugs were diminished (Ruff *et al.*, 1985; Zavala, 1997; Fruscella *et al.*, 2001; Taupin *et al.*, 1991).

In addition, intra- and extracellular levels of benzodiazepines may differ. Midazolam has been shown to cause a significant decrease in the LPS-induced extracellular accumulation of IL-8 in human subjects, whereas the intracellular IL-8 levels increased with exposure to LPS and remained increased after treatment with midazolam. Furthermore, IL-8 mRNA levels also increased in the presence of midazolam, indicating that midazolam has a modulating effect on the transport or secretion of IL-8 from the cell, which would account for the differences in intra- and extracellular concentrations (Galley *et al.*, 1998).

The selective central benzodiazepine ligand clonazepam did not affect the cellular immune functions examined, suggesting an *in vitro* immunosuppressive activity of peripheral and mixed type, but not central type benzodiazepine ligands (Bessler *et al.*, 1992).

Using the high-affinity peripheral benzodiazepine ligand 1-(2-chlorophenyl)-*N*-methyl-*N*-(1-methylpropyl)-3-isoquinolinecarboxamide (PK11195), which was previously used to judge the activation of microglia *in vivo* by TNF-α as an increase in the density of peripheral benzodiazepine receptors (PBR) (Iida *et al.*, 2000; Stephenson *et al.*, 1995; Bourdiol *et al.*, 1991), the respiratory burst response was inhibited, the release of glutamate and IL-1β was reduced, and the secretion of products cytotoxic to neuronal cells was suppressed. Selectivity was suggested by the failure of PK11195 to influence TNF-α secretion or expression of human leucocyte antigen (HLA)-DR and CDw32. Therefore, PK11195 may be a useful inhibitor of selective macrophage functions, retarding both local and systemic inflammation. Since PK11195 enters the brain readily, it may be beneficial in treating central as well as peripheral inflammatory diseases (Klegeris *et al.*, 2000).

During HIV-1 encephalitis, the chemotaxis-inducing activity of terminal deoxynucleotidyltransferase (Tat) may enhance the viral life cycle through the recruitment of additional susceptible microglial cells to the foci of infection. Benzodiazepines readily penetrate the blood–brain barrier and are known to possess anti-inflammatory properties. Pretreatment of human microglial cells with peripheral (Ro5-4864) and mixed (diazepam), but not central (clonazepam), benzodiazepine receptor ligands was found to potently suppress HIV-1 Tat-induced chemotaxis. The inhibitory effect of diazepam was associated with the ability to block Tat-induced $[Ca^{2+})]_i$ mobilization. These data support the notion that PBR ligands could alter the neuropathogenesis of HIV-1 via effects

on microglia, and may provide new therapeutic options for AIDS dementia (Lokensgard *et al.*, 2001).

T and B Cells

In human benzodiazepine users a lower than normal CD4 (T helper/inducer) cell count was shown. Considering that CD8 (T-suppressor/cytotoxic) cells did not show abnormal values, the lower CD4/CD8 ratio registered in benzodiazepine users was due to lower CD4 values (Lechin *et al.*, 1994).

It was reported that PBR agonists and mixed-type ligands like diazepam stimulate the humoral immune response to sheep red blood cells in mice, a T cell-dependent antigen (Zavala *et al.*, 1984; Ferrarese *et al.*, 1993). Due to the observed immunomodulating activity the day after immunization, it was suggested that the immunomodulation observed *in vivo* could be mediated by the binding of these molecules to macrophages, which may result in a modulation of the physiological function of these cells in the immune system (Ferrarese *et al.*, 1993).

NK Cells

Pretreatment with the benzodiazepine diazepam completely blocked CRH-induced suppression of NK activity (Irwin *et al.*, 1993). Animals that received diazepam prior to CRH showed NK activity similar to the lytic activity observed in rats treated with diazepam alone (Irwin *et al.*, 1993). Benzodiazepine may antagonize sympathetic outflow, and thereby attenuate CRH-induced immune suppression, because benzodiazepine reduced plasma catecholamines (Vogel *et al.*, 1984) and elevated sympathetic activity following stress, which mediates the reduction of NK activity following CRH (Irwin *et al.*, 1990, 1993). The NK activity was significantly greater in benzodiazepine users than in controls (Lechin *et al.*, 1994).

Summary (See Tables XVI-4.5 and XVI-4.6)

Taken together, there is good evidence that peripheral and mixed benzodiazepine agonists influence the immune system. However, nothing is known at present about the effects of benzodiazepine abuse and withdrawal on immune functions, to the best of our knowledge.

OPIOIDS

Clinical Relevance

In 2000, approximately 130 000 people in the United States were current heroin users, which represents 0.1% of the population aged 12 and older (Substance Abuse and Mental Health Services Administration, 2001).

Although the idea that central opioids can modulate the immune response is a relatively recent one, the understanding that systemic opioids produced alterations in the immune system began more than 100 years ago. At this time, Cantacuzene (1898) described the effects of opium on the phagocytic function of guinea-pig immunocytes. More recent research has shown that people addicted to heroin have increased rates of infection (Hussey and Katz, 1950; Haverkos and Lange, 1990). Closer examination of addicts has revealed abnormalities in many immunological parameters, including decreased NK cytolytic activity, blood lymphocyte proliferation responses to mitogen, and alterations in more complex immune responses including antibody-dependent cell-mediated cytotoxicity and antibody production (Mellon and Bayer, 1998a; Brown *et al.*, 1974; Layon *et al.*, 1984; Nair *et al.*, 1986). Several studies in healthy non-addicted individuals exposed to opioids either

Table XVI-4.5 Central immune effects of benzodiazepines

Stimulus: Benzodiazepines	Central	
	Cytokines	Cells
Experimental	IL-1β down (Klegeris *et al.*, 2000) HIV-1-Tat-induced chemotaxis down (Lokensgard *et al.*, 2001)	

Human immunodeficiency virus type 1 (HIV-1); interleukin (IL); terminal deoxynucleotidyltransferase (Tat).

Table XVI-4.6 Peripheral immune effects of benzodiazepines

Stimulus: Benzodiazepines	Peripheral	
	Cytokines	Cells
Acute, human	IL-3-like activity, IL-2 down (Bessler *et al.*, 1992)	
Chronic, human		CD4 down, CD8 no change (Lechin *et al.*, 1994)
Experimental	IL-6, PGE_2 down (Fruscella *et al.*, 2001)	
+ Stimuli, human healthy volunteers	Stimulus LPS: IL-8 extracellular down (Galley *et al.*, 1998) Stimulus LPS: IL-8 mRNA intracellular up (Galley *et al.*, 1998) Stimulus LPS: IL-1, TNF-α up (Taupin *et al.*, 1991)	
+ Stimuli, acute, experimental	Stimulus LPS: IL-1β, IL-6, TNF-α down (Zavala *et al.*, 1997)	
Benzodiazepine and stress/trauma		
Acute, experimental		NK cell activity up (Irwin *et al.*, 1993)

medicinally or occupationally have also demonstrated immunological abnormalities (Mellon *et al.*, 1998; Crone *et al.*, 1988; Biagini *et al.*, 1995). The immunosuppressive effects of the opiate could result in an increased susceptibility to infections in the post-operative period, a possible lack of defences in cancer patients and an increased susceptibility to HIV infections in drug abusers (Peterson *et al.*, 1990; Sacerdote *et al.*, 1997).

Animal studies have further reinforced the conclusions drawn from human subjects, showing that morphine can alter the resistance of an organism to infection. In rodents, multiple doses of morphine increased the susceptibility to *Klebsiella pneumoniae* and *Candida albicans* infections (Tubaro *et al.*, 1983), and increased lethality in *Toxoplasma gondii*-infected mice (Chao *et al.*, 1990). Even a single dose of morphine increased lethality in mice infected with Friend virus (Starec *et al.*, 1991). In swine, chronic morphine altered the course of the response to herpes virus infection (Risdahl *et al.*, 1993).

On the other hand, both human and rodent T lymphocytes, B lymphocytes and monocytes are able, upon appropriate stimulation, to produce and release β-endorphin (Buzzetti *et al.*, 1989; Blalock, 1989; Manfredi *et al.*, 1995; Sacerdote *et al.*, 1998). β-Endorphin is a potent local analgesic compound that is released by the activation of immune cell CRF receptors within inflamed tissue (Cabot, 2001; Schäfer *et al.*, 1996). It was shown that β-endorphin affects the tonic inhibition of the immune responses (Manfredi *et al.*, 1993; Panerai *et al.*, 1995).

Immune Modulation

Opioids can alter the function of all types of immunocytes (T cells, B cells, NK cells, lymphocytes, monocytes, macrophages and neutrophils) (Peterson *et al.*, 1993, 1998). Investigations have indicated that opioids can operate as cytokines (Bidlack, 2000), both within somatic tissues and in the CNS (Peterson *et al.*, 1998). All of the major properties of cytokines are shared by opioids, i.e. production by immune cells with paracrine, autocrine and endocrine sites of action, functional redundancy, pleiotropy and time- and dose-dependent effects (Peterson *et al.*, 1998). Because the CNS is populated predominantly by astroglia and microglia, which have properties of immune cells, it is possible that certain opioid effects on the CNS involve cytokine-like interactions with glial cells. Although there is mounting evidence to support the concept that opioids are members of the cytokine family, the relative contribution of chronic opioid use and abuse to immunoregulation remains unclear (Bianchi *et al.*, 1999; Roy *et al.*, 2001b).

The immunomodulatory activity of opioids is likely to be due to complex interplay between direct and indirect influences (McCarthy *et al.*, 2001). It is well established that the opioid system affects a number of parameters related to innate and acquired immunity (Radulovic *et al.*, 1995), which then indirectly affect the immune cells (Roy *et al.*, 2001b). When opioids have a direct effect on immune function, they must act through opioid receptors expressed on immune cells. These receptors are often the same as, or similar to, neuronal-type opioid receptors, i.e. κ-opioid, δ-opioid and μ-opioid receptors (Bidlack, 2000). But it was reported that the morphine binding sites are different from the classical neuronal μ-opioid receptor (Roy and Loh, 1996; Sharp *et al.*, 2001; Makman *et al.*, 1998; Roy *et al.*, 2001a). It has been shown that another morphine receptor is also present, namely the μ-3-opioid receptor, which is opiate alkaloid sensitive and opiate peptide insensitive (Makman *et al.*, 1998; Stefano and Scharrer, 1996). These μ-3 receptors have been identified in human peripheral blood monocytes and intervertebrate immunocytes (Stefano and Scharrer, 1996; Stefano *et al.*, 2000; Makman *et al.*, 1998; Roy *et al.*, 2001a; Law *et al.*, 2000). The influence of the opioids on the immune response *in vivo* is also likely to be a result of the participation of both the CNS and the HPA axis (McCarthy *et al.*, 2001). Through this indirect mechanism opioids bind to classical opioid receptors in the CNS, causing the release of catecholamines and/or steroids.

Phagocytic Cells and Pro-/Anti-Inflammatory Immune Modulation

In all but one study (Eisenstein *et al.*, 1998), morphine was found to suppress the phagocytosis and chemotaxis of phagocytic cells in animals and humans (animals: Casellas *et al.*, 1991; Szabo *et al.*, 1993; Tubaro *et al.*, 1993; Rojavin *et al.*, 1993; Pacifici *et al.*, 1994; humans: Perez-Castrillon *et al.*, 1992 — macrophages; Stefano *et al.*, 1993 — human PBMC; Makman *et al.*, 1995 — granulocytes). Pacifici *et al.* (1994) found a biphasic response in the phagocytic function of elicited murine polymorphonuclear leucocytes (PMN). They reported that 20 or 40 min after morphine administration there was an increase in phagocytosis and killing of the organism, whereas cells harvested 24 h later demonstrated a decrease in phagocytic activity. Roy *et al.* (1991) found that morphine pellets inhibited the ability of bone marrow macrophage precursors to develop into viable colonies in response to macrophage stimulating factor *in vitro*, and that the effect was inhibited by naltrexone. Also, the *in vitro* addition of morphine or β-endorphin to precursor cells had a similar result, indicating that morphine acted directly on the precursor cells.

Morphine blocked the activity of several chemotactic agents including TNF-α, IL-1, IL-8 and formyl-methionyl-leucyl-phenylalanine (fMLP) (Makman, 1995). In response to ConA or phorbol myristate, human peripheral blood mononuclear cells (PBMC) exposed to morphine had reduced production of superoxide and peroxide (Peterson, 1987a) due to the release of transforming growth factor (TGF)-β (Chao *et al.*, 1992). In a study by Peterson *et al.* (1989), methadone-maintained patients had similarly impaired generation of superoxide.

In PBMC, morphine has been shown to increase TGF-β production in cells stimulated by LPS or phytohaemagglutinin (PHA) (Chao *et al.*, 1992). However, morphine inhibited IFN-γ production in PBMC stimulated with ConA or varicella zoster virus. In this case, the morphine appeared to affect the macrophages directly, and be mediated by macrophage-reactive oxygen intermediates and PGE_2 (Peterson *et al.*, 1987b). Morphine also blocked the release of bioactive TNF-α from PBMC cultures treated with LPS or PHA (Chao *et al.*, 1993). The synthetic κ-opioid agonist U50, 488 H has also been shown to inhibit LPS-driven IL-1 and TNF-α release from the murine macrophage cell line P388D1 (Belkowski *et al.*, 1995), and from primary murine peritoneal macrophages (Alicea *et al.*, 1996). However, IL-6 levels were unaffected in the primary cultures (Alicea *et al.*, 1996). All of these effects on cytokines were shown to be opioid receptor mediated using appropriate antagonists.

Interestingly, almost all of the effects of morphine and of non-peptide opioids on phagocytes are inhibitory. Some opioid peptide effects are also inhibitory, such as with the phagocytosis of yeast (Szabo *et al.*, 1993). In contrast, it has been reported that opioid peptides that bind various types of opioid receptors are stimulatory in a variety of assays. For example, Ruff *et al.* (1985) reported that [D-Ala(2), D-Leu(5)]enkephalin (DADLE), β-endorphin and dynorphin (1–13) were stimulators of human mononuclear cell chemotaxis. This finding was confirmed and extended to show that DADLE, D-Ala(2), Mephe(4), Gly-ol(5)-enkephalin (DAGO), [D-Pen(2), D-Pen(5)]enkephalin (DPDPE), D-Ala2,Met5-enkephalinamide (DAMA), dynorphin A(1-17), D-Ala2-deltorphin I and methionine-enkephalin (met-enkephalin) were all chemotactic for human granulocytes (Makman *et al.*, 1995). Dynorphin A has also been reported to enhance tumoricidal activity of mouse macrophages (Foster and Moore, 1987; Hagi *et al.*, 1994) and to stimulate superoxide production of human PMN and

peritoneal macrophages (Sharp *et al.*, 1985). β-Endorphin was also active in stimulating superoxide activity (Sharp *et al.*, 1985).

The existence of two types of receptors (Carr *et al.*, 1991; Sedqi *et al.*, 1995; Stefano *et al.*, 1992; Makman *et al.*, 1995) would help to explain the generally divergent effects of the alkaloids and the opioid peptides on monocyte and granulocyte function. In general, the non-peptide opioids are functionally suppressive while the peptides upregulate. It is of interest that these differences do not seem to exist in the nervous system.

It has been shown that morphine treatment decreases IL-2 and IFN-γ and increases IL-4 and IL-5 as a function of concentration (Lauw *et al.*, 2000). In studies using high dosage (*in vivo*) or high concentrations (*in vitro*) that correspond to levels seen in drug-addicted populations (Roy *et al.*, 2001a), it was demonstrated that morphine inhibits dose-related ConA-induced IL-2 and IL-4 production that is not mediated through μ-, δ- or κ-opioid receptors (Jessop and Taplits, 1991; Carr *et al.*, 1993, 1994a; Eisenstein *et al.*, 1993; Flores *et al.*, 1995; Roy *et al.*, 2001a).

In contrast to human PBMC, morphine was shown to potentiate the production of TNF-α with murine (Chao *et al.*, 1994) and human microglial cells (Peterson *et al.*, 1994). The ability of morphine to potentiate TNF-α production by microglia appeared to explain the amplification of HIV-1 expression in a chronically infected promonocyte line (U1 cells) after the cells were co-cultured with LPS-stimulated human foetal brain cell cultures (Peterson *et al.*, 1994). Sundar *et al.* (1995) have shown that the endogenous opioid β-endorphin stimulated the expression of HIV-1 in acutely infected microglia via a naloxone-inhibitable mechanism involving IL-1, IL-6 and TNF-α. In studies with the κ-opioid receptor, the peptide dynorphin was shown to directly stimulate TNF-α and IL-6 expression in human brain cell cultures that were cultured with U1 cells. The direct stimulatory effects of dynorphin results in an enhanced upregulation of HIV-1 (Chao *et al.*, 1995) whereas the κ-opioid receptor ligands, when exposed to κ-agonists U50, 488 and U69, 593 in human microglia cells, suppressed HIV-1 expression if acutely infected (Peterson *et al.*, 1998). Thus, it appears that the effects of opioid agonists on HIV-1 expression in the brain may be influenced both by the type of opioid receptors on microglia and the nature of infection (acute vs. chronic).

T Lymphocyte Proliferative Responses

Hernandez *et al.* (1993) provided the first evidence that central opioid receptors modulate circulating T lymphocyte function. Using the polyclonal mitogen ConA, it was demonstrated that a systemic dose of morphine suppressed mitogen-stimulated whole blood lymphocyte proliferation, whereas *N*-methyl morphine had no effect. However, both morphine and *N*-methyl morphine administered into the third ventricle suppressed T lymphocyte proliferation. Therefore, T lymphocyte proliferative responses appear to be mediated predominantly, if not entirely, by opioid receptors located within the brain (Hamra and Yaksch, 1996; Hoffman *et al.*, 1995; Lysle *et al.*, 1996). These central opioid receptors appear to be located suprasinally, as intrathecal morphine does not alter peripheral lymphocyte function (Hamra and Yaksch, 1996). Extended periods of exposure to morphine may be required to suppress splenic lymphocyte activity (Hamra and Yaksch, 1996; Fecho *et al.*, 1996).

Taken together, the studies suggest that morphine inhibits mitogen-stimulated peripheral lymphocyte proliferation through central opioid receptors (Weber and Pert, 1989; Bayer *et al.*, 1990a, 1992; Fecho *et al.*, 1993a). Evaluating selective agonists ([(3)H]Tyr-D-AlaGly-MePhe-Gly-ol (DAMGO) μ-selective, DPDPE δ-selective and U50, 488 κ-selective), it was demonstrated that proliferative responses of peripheral lymphocytes are mediated by central μ-receptors (Mellon and Bayer, 1996, 1998a; Schneider and Lysle, 1996).

Cellular and Humoral Immune Responses

Veljic *et al.* (1990) first reported decreased humoral immune responses in rats chronically treated with met-enkephalin directly into the lateral ventricle. A 4-day treatment with this endogenous opioid produced a dose-dependent effect on the humoral immune response to sheep red blood cells, as measured by the number of plaque-forming cells (PFC) produced, as well as antibody production: A high dose of met-enkephalin decreased the number of PFC and antibody production, whereas lower doses enhanced the responses (Veljic *et al.*, 1990; Jankovic, 1991). A dose-dependent effect was also found for modified delayed-type hypersensitivity skin test (DTH) reactions (Jankovic *et al.*, 1991). The effects of low-dose met-enkephalin on both humoral and cellular immune responses were due to the tonic activation of δ-receptors, because the specific δ-receptor antagonist (ICI 174864) not only antagonized the met-enkephalin effects, but also suppressed the responses when administered alone (Radulovic *et al.*, 1994). Whether high-dose met-enkephalin effects are mediated centrally by μ- or κ-receptors or whether peripheral components are involved remains unclear (Radulovic *et al.*, 1995; Corbett *et al.*, 1993).

T Cells

McDonough *et al.* (1980) showed that heroin addicts have reduced numbers of cells that can rosette with sheep erythrocytes, and that treatment with naloxone restored binding to a normal frequency. Studies in addicts are complex, as many are polydrug abusers. Donahoe *et al.* (1986) found that simultaneous abusers of heroin and cocaine did not have depressed T cell rosettes, suggesting that the two drugs have cancelling effects. Heroin addicts have also been reported to have reduced CD4+ cells and elevated CD8+ cells (Donahoe *et al.*, 1987) in one study, but no change in T lymphocyte cell subsets in another study (Novick *et al.*, 1989). Whether the observed alterations in cell numbers are due to drug abuse or to other life-style alterations in abusers cannot be easily tested. Other parameters of T cell function in response to drug abuse have not been studied in humans.

Animal studies have provided a clearer delineation of the cause-and-effect relationship between opioid administration and alteration in T cell function. Morphine has been shown to alter the ratio of CD4+ and CD8+ T lymphocytes in both the spleen (Arora *et al.*, 1990) and thymus (Arora *et al.*, 1990; Freier and Fuchs, 1993) of mice implanted with a 75 mg morphine pellet, as well as the peripheral blood of monkeys which received daily injections of morphine for 2 years (Carr and France, 1993). On a functional level, morphine administration has been shown to inhibit the capacity for a DTH response (Pellis *et al.*, 1986; Bryant and Roudebush, 1990; Molitor *et al.*, 1992). Morphine has also been reported to inhibit the induction of cytotoxic T cell responses in mice following immunization with allogenic spleen cells (Carpenter and Carr, 1995; Carpenter *et al.*, 1994). Ho and Leung (1979) observed a depression in the proliferative response of lymphocytes to ConA in mice addicted to morphine, indicating a diminished T cell response to an antigen. Bryant *et al.* (1987) had a similar finding but, in contrast to the previous report, observed that the depression in T cell activation disappeared as mice became tolerant. Similar results were observed in monkeys given daily injections of morphine (Chuang *et al.*, 1993). In contrast to the immunosuppressive effects of morphine reviewed so far, there are two reports in the literature that demonstrate the of stimulation of T cell responses to mitogens by morphine (Bocchini *et al.*, 1983; Bidlack and Hemmick, 1990).

A number of investigators have examined mechanisms by which morphine induces suppression of T cell activities. Flores *et al.* (1994) showed that the depression of ConA responses in peripheral blood cells of rats was not dependent on glucocorticoids or on

pituitary factors, as neither adrenalectomy nor hypophysectomy abrogated the suppression. In addition, adrenalectomy, alone or in combination with drugs, suggested that the sympathetic system was involved in morphine suppression of the splenic responses to PHA (Fecho *et al.*, 1996). There are several studies which failed to find an effect when morphine was added to T cells *in vitro* and only a few investigations found direct morphine effects. This is a surprising situation, since the inhibition of T rosette formation has been confirmed by two groups using human cells (De Carolis *et al.*, 1984; Donahoe *et al.*, 1987, 1988) since it was first described in 1979 (Wybran *et al.*, 1979). The κ-opioid agonist U50, 488 H has been reported by Guan *et al.* (1994) to suppress the capacity of T cells to participate in an *in vitro* antibody response to sheep erythrocytes. A weak suppressive effect of heroin on IL-2 production by murine spleen cells was observed at some doses, but not others, and the effect of antagonists was not tested (Thomas, P.T. *et al.*, 1995).

B Cells

Following initial work by Lefkowitz and Chiang (1975), Bryant *et al.* (1988) found that implantation of a 75 mg morphine slow-release pellet reduced the mitogenic responses of splenic B cells to LPS, which has been confirmed using an injection dosing regimen (Bhargava *et al.*, 1994). Bussiere *et al.* (1992) reported that 75 mg morphine pellets also inhibited induction of antibody-forming cells to sheep red blood cells in a variety of mouse strains and showed that suppression was naltrexone inhibitable in some mouse strains, but not others (Pruett *et al.*, 1992). Further, Bussiere *et al.* (1992) showed that both mice with defects in response to LPS, and beige mice, which lack NK cells, had suppressed antibody responses when treated with morphine, while mice which lack κ-opioid receptors did not (Bussiere *et al.*, 1992). Formation of an antibody response to sheep red blood cells requires the interaction of macrophages, T cells and B cells. Thus, depression of the capacity to produce antibodies does not necessarily mean that the drug affects B cells. In fact, Bussiere *et al.* (1993) found that antibody responses could be restored by adding normal macrophages or IL-1, IL-6 or IFN-γ, cytokines which are produced by or which activate macrophages, suggesting that the morphine-induced suppression is due in part to a lack of macrophage activity. Weber *et al.* (1987) also found that morphine inhibited serum antibody responses to a T-dependent, but not to a T-independent antigen, suggesting that morphine did not affect B cell function.

Taub *et al.* (1991) has shown that morphine, as well as the κ-opioids U50, 88 H and U69, 593, inhibited antibody formation to sheep erythrocytes when added to mouse spleen cells *in vitro*. Eisenstein *et al.* (1995) confirmed that both morphine and U50, 488 H could inhibit *in vitro* antibody responses, showing that the drugs directly affect immune cells, and that suppression is not mediated by the HPA axis. In this study, there were marked differences in mouse strain susceptibility to the effects of morphine and the agonist, raising the possibility that *in vitro* effects of morphine may be affected by the strain used (Eisenstein *et al.*, 1995). A direct effect of morphine on murine splenic B cell proliferation to mitogen has also been reported (Thomas *et al.*, 1995a). Endogenous peptides have also been reported to be suppressive, which is interesting in the context of antibody formation (Johnson *et al.*, 1982a, b; Morgan, 1996).

NK Cells

A large number of studies examining the effects of opioids on immune function have focused on the perturbation of NK cell function. Provocative reports that supported a neuroimmune circuit involving NK cells were published starting in 1984 when Shavit *et al.* (1984b) first found that subcutaneous (s.c.) injections of morphine into rats suppressed splenic NK cell activity. Depression of NK activity has been demonstrated in heroin abusers (Novick *et al.*, 1989) and in polydrug abusers (Nair *et al.*, 1986b). In the latter study, depression of antibody-dependent cellular cytotoxicity (ADCC) was also observed (Nair *et al.*, 1986). In a definitive experiment, reduced NK cell activity, as well as reduced ADCC mediated by NK cells, has been shown using human volunteers that were given morphine intravenously (i.v.) for 24 h (Yeager *et al.*, 1995). Subcutaneous injection of morphine has also led to depressed NK cell function in rats (Bayer *et al.*, 1990a) and mice (Carr *et al.*, 1994a). Monkey NK cell function has also been reported to be suppressed when morphine was injected s.c., on a daily basis, for 2 years (Carr and France, 1993). It can be concluded that there is strong evidence that opioids given *in vivo* depress NK and ADCC activity.

A number of investigators have addressed the question of whether this depression is due to a direct effect on NK cells or is centrally mediated. Shavit *et al.* (1986) showed that delivery of morphine into the lateral ventricle of the brain suppressed NK cell activity to the same degree as a single s.c. injection. The observation that *N*-methylmorphine, which does not cross the blood–brain barrier, was ineffective when given peripherally to rats suggested that the depression of NK responses was mediated via opioid receptors in the brain (Shavit *et al.*, 1986). These studies were confirmed and extended by Weber and Pert (1989), who found that morphine depresses NK activity in the periaqueductal grey region of the rat brain. Evidence for involvement of sympathetic pathways (Carr *et al.*, 1993, 1994b) or the HPA axis (Freier and Fuchs, 1994) in *in vivo* morphine effects on NK cell function in the rat has been published. Carr *et al.* (1993, 1994b) have shown that pretreatment of mice with α-adrenergic receptor antagonists blocked the morphine-induced suppression in NK cell activity. In contrast, Fecho *et al.* (1993b) reported that β-adrenergic receptor antagonists could not block the suppressive effects of morphine on NK cell activity in the rat. A role for HPA axis involvement in morphine-induced suppression of NK cell activity was suggested by Freier and Fuchs (1994), and Band *et al.* (1992) reported that central administration of the κ-opioid agonist DAGO suppressed NK cell function without elevation of plasma corticosterone. These papers provide strong evidence that the effects of morphine on NK activity are centrally mediated.

There is little evidence that morphine can modulate NK function directly (Eisenstein *et al.*, 1998). Mathews *et al.* (1983) reported that β-endorphin added to human PBMCs enhanced NK cell activity, but that morphine was inactive. Variable stimulatory activity of β-endorphin and met-enkephalin was observed by other investigators (Puente *et al.*, 1992; Oleson and Johnson, 1988). Ochshorn-Adelson *et al.* (1994) reported that naloxone did not affect NK cell cytotoxicity when added to human PBMC. Similarly, other investigators have failed to find an effect of morphine *in vitro* on NK cell activity in rodents (Freier and Fuchs, 1994). It is interesting that, as with the phagocytic cells, the endogenous opioids seem to have an upregulating rather than a downregulating effect. Further, *in vitro* effects have been demonstrated with some of the peptides, but not with morphine. The discordance between peptide and alkaloid data indicates that if the receptor is the same, then downstream signalling events are different. The paucity of studies reporting an *in vitro* effect of morphine on NK cell activity and the substantial literature showing that effects on NK activity are centrally mediated support the conclusion that the alkaloid is not acting directly on the NK cell.

Neuroendocrine and Autonomic Involvement

Because the CNS communicates with the periphery via two major physiological systems, i.e. the neuroendocrine system and the

ANS, the identification of efferent mechanisms mediating central opioid modulation of the immune system has focused on these two systems.

Neuroendocrine Involvement

Although a central site of action for morphine-stimulated corticosterone release in the rat was suggested as early as 1969 (Lotti *et al.*, 1969), to date the exact neuronal structure(s) and receptor subtype(s) within specific neuronal tissues that mediate these responses have not been clearly delineated. In fact, μ, δ and κ-receptors appear to independently modulate the HPA axis (Iyengar *et al.*, 1987).

Chronic morphine administration in wild-type mice led to lymphoid organ atrophy and a diminished CD4+/CD8+ ratio in the thymus (Gavériaux-Ruff *et al.*, 1998). Roy *et al.* (2001b) used *in vivo* and *in vitro* studies to demonstrate that morphine induces thymic hypoplasia and results in a glucocorticoid-dependent lymphopaenia (Jessop and Taplits, 1991; Carr *et al.*, 1993, 1994a; Eisenstein *et al.*, 1993; Flores *et al.*, 1995; Roy *et al.*, 2001b). The immune modulatory effects of prolonged morphine exposure on both lymphocyte proliferative responses and NK cell activity appear to be the activation of the HPA axis, despite the fact that the effects of prolonged exposure are not entirely explained by glucocorticoids (Bryant *et al.*, 1987, 1988, 1990, 1991; Freier and Fuchs, 1994). In contrast, the effects of acute morphine showed that the lymphopaenia observed was dependent upon the HPA axis whereas the decreased proliferative response to mitogen was adrenal independent (Bayer *et al.*, 1990a, 1990b; Flores *et al.*, 1994, 1995; Bayer *et al.*, 1992).

Autonomic Nervous System

Several investigators have explored opioid modulation in the ANS (Appel *et al.*, 1986; Marson *et al.*, 1996). Direct administration of opioid into the CNS has been shown to produce elevations in plasma adrenaline, noradrenaline and dopamine, suggesting that catecholamines are released from both the adrenal medulla, as well as sympathetic nerve terminals (Gomes *et al.*, 1976; Vogel *et al.*, 1984; Kiritsy-Roy *et al.*, 1986). Therefore, catecholamines from either synaptic terminals or the adrenal medulla may mediate the effects of morphine on NK cell activity or lymphocyte proliferative responses. It is hypothesized that the activation of the sympathetic nervous system by morphine elicits the release of catecholamines into primary and secondary lymphoid organs (Hall *et al.*, 1998; Felten *et al.*, 1985), which results in the suppression of NK cells (Shavit *et al.*, 1986; Weber *et al.*, 1989) and lymphocyte functionality (Fecho *et al.*, 1993a; Felsner *et al.*, 1995). However, many of the drugs used at doses required to produce a significant effect have been shown to have their own effects on immune cell activity (Fecho *et al.*, 1996; Flores *et al.*, 1996) and therefore the specific role of the ANS in opioid-mediated effects remains unclear.

Tolerance

Animals made tolerant to an analgesic dose of morphine also appeared to develop tolerance to the effects of morphine on lymphocyte proliferation (Bayer *et al.*, 1994, 1996). This observation suggests that consistent use of opioid compounds may lead to a state of tolerance in the immune system. If tolerance develops to this immunological parameter, the potential significance of the altered lymphocytes in drug-naive animals must be questioned. However, animals made tolerant to morphine and exposed to stress demonstrated clear lymphocyte suppression (Bayer *et al.*, 1994), while previous studies showed that drug-naive animals did not show alterations in lymphocyte proliferation (Flores *et al.*, 1990). These observations suggest an increased susceptibility to stress in morphine-tolerant animals, a finding with significant implications regarding the immunological stability of individuals chronically exposed to opioids, either for pain relief or due to drug addiction.

Summary (See Tables XVI-4.7–XVI-4.10)

There is incontrovertible evidence that morphine inhibits the function of NK cells, B cells, T cells and phagocytic cells when it is given *in vivo*. Direct effects of the drug have also been demonstrated *in vitro* in phagocytic cells. It is less clear whether morphine has a direct effect on NK cells or B cells. There is strong evidence that morphine can directly modulate receptor expression on T cells, but consistent alteration of other functional parameters *in vitro* has been difficult to demonstrate.

Research to date indicates that the cellular responsiveness to opioids may depend on the state of cell activation, which can influence receptor expression. Alternatively, various immune cells may express more than one type of opioid receptor, and functional alterations may depend upon the relative activation of one type as compared with another. As endogenous peptides seem to have opposite functional effects from non-peptide agonists in a number of cases, and immune cells may even synthesize such peptides (Zurawski *et al.*, 1986; Kuis *et al.*, 1991), the interactions of exogenous and endogenous opioids may result in complex alterations in immune cell function. The presence of unrecognized endogenous opioid peptides that can antagonize the alkaloids or synthetic opioid peptides may account for the variable effects of morphine seen in different studies of T cell function (Eisenstein *et al.*, 1998).

Taken together, opiates down regulate pro-inflammatory cytokines, decrease IL-2 but increase IL-4, decrease phagocytosis and chemotaxis, decrease lymphocyte proliferation, decrease NK cell activity at high doses peripherally, whereas opiates increase TNF-α centrally. A decreased CD4/CD8 ratio was also seen in heroin addicts. However, opiates in higher doses decrease both IL-2 and IL-4, and diminish the depression in T cell activation to antigens, but with stress lymphocyte suppression was observed.

Table XVI-4.7 Central immune effects of opioids

Stimulus: Opioids	Central	
	Cytokines	Cells
Acute, human	Morphine: TNF-α up (human microglial cells) (Peterson *et al.*, 1994)	
Acute, experimental	Morphine: TNF-α up (murine microglial cells) (Chao *et al.*, 1994)	
	Morphine: μ receptor agonist: NFκB up (red cortical neurones) (Hou *et al.*, 1996)	

Nuclear factor κB (NFκB); tumour necrosis factor (TNF).

Table XVI-4.8 Peripheral immune effects of opioids

Stimulus: Opioids	Peripheral	
	Cytokines	Cells
Acute, human	Morphine: IL-2, IFN-γ down (Lauw *et al.*, 2000) Morphine: IL-4, IL-5 up (Lauw *et al.*, 2000) Morphine: IL-1,IL-8, TNF-α, fMLP down (Makman *et al.*, 1995)	Morphine: antibody-dependent cell-mediated toxicity down (Yeager *et al.*, 1992) Morphine: NK cell activity up (Yeager *et al.*, 1992) Morphine: NK cell activity down (Yeager *et al.*, 1995) Morphine: phagocytosis, chemotaxis down. (Perez-Castilloun *et al.*, 1992; Stefano *et al.*, 1993; Makman *et al.*, 1995)
Chronic, human	Morphine: IL-2, IL-4 down (Roy *et al.*, 2001a) Heroin: IL-2 down (weak effect) (Thomas, P.T. *et al.*, 1995)	Heroin: CD4+ cells down, CD8+ cells up (Donahoe *et al.*, 1987) Heroin: T cell subsets no change (Novick *et al.*, 1989) Heroin: NK cell activity down (Roy *et al.*, 2001; Novick *et al.*, 1989; Nair *et al.*, 1986b)

Table XVI-4.9 Peripheral immune effects of opioids

Stimulus: Opioids	Peripheral	
	Cytokines	Cells
Acute, experimental		Morphine and all opioid peptides: phagocytosis, chemotaxis down (Casellas *et al.*, 1991; Szabo *et al.*, 1993) Morphine: NK cell activity down (Weber and Pert, 1989) Morphine: splenic NK cell activity down (Shavit *et al.*, 1986; Hoffman *et al.*, 1995; Lysle *et al.*, 1996)
Chronic, experimental		Morphine: CD4+/CD8+ ratio up (chronic) (Arora *et al.*, 1990) Morphine: CD4+/CD8+ ratio down (chronic) (spleen, thymus) (Freier and Fuchs, 1990; Gavériaux-Ruff *et al.*, 1998) Morphine: NK cell activity down (Gavériaux-Ruff *et al.*, 1998) High-dose met-Enk: humoral response down (plaque-forming cells, antibody production) (Jankovic *et al.*, 1991; Radulovic *et al.*, 1994) High-dose met-Enk: DTH response down (Jankovic *et al.*, 1992; Radulovic *et al.*, 1994) Low-dose met-Enk: humoral response up (plaque-forming cells, antibody production) (Jankovic *et al.*, 1992; Radulovic *et al.*, 1994) Low-dose met-Enk: DTH response up (Jankovic *et al.*, 1992; Radulovic *et al.*, 1994) Morphine: lymphocyte proliferation no change (Bayer *et al.*, 1994)

Cluster of differentiation (CD); concanavalin A (ConA); delayed-type hypersensitivity reaction (DTH); formyl-methionyl-leucyl-phenylalanine (fMLP); interferon (IFN); interleukin (IL); lipopolysaccharide (LPS); methionine-enkephalin (met-Enk); natural killer (NK) cell; nuclear factor κB (NFκB); peripheral blood mononuclear cells (PBMC); phorbol myristate acetate (PMA); phytohaemagglutinin (PHA); transforming growth factor (TGF); tumour necrosis factor (TNF).

COCAINE

Clinical Relevance

In 2000, an estimated 1.2 million Americans were current cocaine users. This represents 0.5% of the population aged 12 and older. The estimated number of crack users in 2000 was 265 000 (Substance Abuse and Mental Health Services Administration, 2001).

Cocaine abuse is associated with a variety of clinical disorders. These disorders involve cardiovascular complications, including cardiac arrhythmias and sudden death (Ferreira *et al.*, 2001), neurovascular complications such as cerebral infarction, intraparenchymal and subarachnoid haemorrhage and cerebral vasculitis (Conway and Tamargo, 2001). Ischaemic as well as haemorrhagic neurovascular sequelae have been associated with the alkaloid form of cocaine ('crack'), whereas cocaine hydrochloride has generally been associated only with intracranial haemorrhage (Conway and Tamargo, 2001; Levine *et al.*, 1991). Cocaine use has been linked to hypertension and acute and chronic renal failure (Norris *et al.*, 2001).

In the last 10 years the increased susceptibility to infections among cocaine users has caught the attention of many researchers and clinicians. For example, the incidence of HIV seroprevalence is significantly higher in cocaine addicts (Anthony *et al.*, 1991; Chaisson *et al.*, 1989; Pellegrino and Bayer, 1998; Pellegrino *et al.*, 2001), and cocaine users have a higher incidence of hepatitis C infection than other intravenous drug abusers (Thomas, D.L. *et al.*, 1995; Ward *et al.*, 2000). It has also been suggested, however, that the increased susceptibility to HIV and hepatitis C cannot be explained by intravenous drug abuse alone (Pellegrino *et al.*, 2001).

Pharmacologically, cocaine binds to monoamine reuptake pumps, preventing removal of serotonin, dopamine and noradrenaline from

Table XVI-4.10 Peripheral immune effects of opioids

the synapse (Szabo *et al.*, 1995). Cocaine also acts as a muscarinic cholinergic antagonist and as a local anaesthetic (Szabo *et al.*, 1995; Pellegrino *et al.*, 2001). The multiplicity of pharmacological actions may contribute to be varied immune response to cocaine, particularly when doses are varied (Pellegrino *et al.*, 2001).

Immune Modulation

Pro-/Anti-Inflammatory Immune Modulation

In addition to measures of cellular and humoral immunity, the effects of chronic cocaine treatment on cytokine production have also been examined. It was hypothesized that an altered cytokine expression during cell activation can result in immune changes (Pellegrino and Bayer, 1998). Only a few studies have examined the possible effects of cocaine on cytokine production by immune cells. The pattern of cytokine secretion from LPS-stimulated mouse splenocytes was altered by chronic cocaine exposure. Decreased secretion of IL-4 and IL-10, but increased levels of TNF-α, IL-6 and IL-2, were observed 24 h after mitogen stimulation. Contrary to the increase at 24 h, at 72 h there was a decrease in TNF-α (Chen and Watson, 1991; Wang *et al.*, 1994; Pellegrino and Bayer, 1998). Cocaine administered to mice during *in vivo* antigen-stimulated differentiation of effector T cells suggests that the immunomodulatory effects of cocaine may be due to the upregulation of IL-2 and IFN-γ production by CD8+ cells with a type 0 cytokine profile (Di Francesco *et al.*, 1999).

Cell-Mediated Immune Functions

One possibility is that cocaine decreases cell-mediated immune function in cocaine addicts. In studies measuring cell-mediated immunity alterations in immune cell numbers and distribution, mitogen-induced lymphocyte proliferation and NK cytolytic activity have been observed (Pellegrino and Bayer, 1998).

A significant dose-dependent decrease in the number of thymocytes and white blood cells was detected 96 h after acute cocaine administration in mice (Ou *et al.*, 1989). Acute intravenous cocaine exposure resulted in a decrease in mitogen-induced T lymphocyte proliferation in rats in a dose- and time-dependent manner (Bayer *et al.*, 1995). Cocaine and its major metabolites increased B cell proliferation in human B-lymphoblastoid cells at concentrations equivalent to serum levels produced during cocaine abuse in humans (Phillips *et al.*, 1995). The effects varied with gender (Xu *et al.*, 1997): acute *in vivo* cocaine exposure inhibited the proliferation of T lymphocytes in response to ConA in both thymocytes and splenocytes. However, the attenuated IL-2 production was only seen in thymocytes. These effects on T cells were greater in male mice than in female mice. The function of macrophages was also impaired with acute cocaine exposure. However, the impact was greater in female than in male mice.

Chronic treatment of cocaine resulted in a decrease in thymus weight and a decrease in CD8+ cells, and is, therefore, possibly related to the inhibition of thymocyte proliferation (Choi *et al.*, 1998; Lopez *et al.*, 1992). But after 30 days of cocaine administration the decrease in cell number was no longer present, so it was suggested that a possible tolerance to the effect developed (Di Francesco *et al.*, 1994; Pellegrino and Bayer, 1998). When rats were chronically exposed to cocaine, the decrease in mitogen-induced T lymphocyte proliferation was no longer observed (Bayer *et al.*, 1996).

Human studies have shown only small changes in lymphocyte function and number in some cocaine addicts (Ruiz *et al.*, 1998). But the same group found decreases in CD4+ T cells and increases in NK cell number among different group of addicts (Ruiz *et al.*, 1994).

Although tolerance may develop to some immune parameters after chronic cocaine exposure, this does not necessarily imply

Table XVI-4.11 Central immune effects of cocaine

Stimulus: Cocaine	Central	
	Cytokines	Cells
Acute, human	Endothelial adhesion molecule up (Gan *et al.*, 1999) ICAM-1, VCAM-1, ELAM-1 up (Gan *et al.*, 1999)	
Chronic, experimental	NFκB induction p105 up (nucleus accumbens, cytoplasmatic) (Ang *et al.*, 2001)	
+ Stimuli, acute, experimental	Stimulus LPS: IL-6, TNF-α up (BMVEC/monocyte co-culture) (Gan *et al.*, 1999)

that the immune function of the animal is normal. Potentially, compensatory mechanisms could develop, which under stress or infection may result in inadequate immunocompetence (Pellegrino and Bayer, 1998). Chronic ingestion of coca alkaloids has been shown to result in a decrease in the DTH response in mice (Watson *et al.*, 1983). Cocaine at low doses was found to be associated with an accelerated tumour growth in mice, suggesting a potential decrease in NK cell or cytotoxic T cell function (Ou *et al.*, 1989).

Doses of cocaine which were not accompanied by increases of corticosterone did not induce the suppression of blood lymphocyte proliferation to mitogens, which suggests a possible role for increased steroid levels in the immunosuppressive effects of cocaine (Pellegrino and Bayer, 1998). Cocaine administration has been found to result in the activation of the HPA axis, which leads to an elevation in plasma corticosterone levels in rodents and cortisol levels in humans (Baumann *et al.*, 1995; Bayer *et al.*, 1995; Saphier *et al.*, 1993). At least, the T cell-dependent antibody response is evidently mediated by corticosterone (Stanulis *et al.*, 1997). However, in a previous study an HPA axis-independent mechanism was favoured (Pellegrino *et al.*, 2001). In the study by Pellegrino *et al.* (2001) it was found that cocaine was acting through peripheral receptors to decrease lymphocyte proliferation. This hypothesis is supported by the fact that systemic cocaine methiodide, which should not cross the blood–brain barrier, decreased lymphocyte proliferation in a similar way, and that cocaine and cocaine methiodide were unable to alter lymphocyte activity when administered directly into the CNS. However, peripheral effects should not be equated with direct effects on lymphocytes. In fact, the high doses required to decrease immune cell function *in vitro* make it unlikely that cocaine was acting directly on lymphocytes to decrease proliferation (Berkeley *et al.*, 1994; Javaid *et al.*, 1978; Luo *et al.*, 1992; Martinez and Watson, 1990). Therefore, cocaine-induced decreases in lymphocyte function may be produced indirectly through alteration of other neurotransmitters or the neuroendocrine system. Another possibility is that cocaine is decreasing lymphocyte function through alterations in peripheral monoamine levels. This is supported by the observation that the monoamine reuptake inhibitor RTI-55 resulted in a similar decrease in lymphocyte activity. However, the effects of systemically administered RTI-55 could be the result of elevations in central monoamine levels, especially since a similar decrease in lymphocyte proliferation was observed following central administration of high doses of RTI-55. The inhibitory effect might also be mediated via serotonin reuptake inhibition (Pellegrino *et al.*, 2001). The ability of the local anaesthetic lidocaine to decrease lymphocyte proliferation in a similar manner as cocaine suggests that this pharmacological property may also be involved in cocaine-induced lymphocyte suppression (Pellegrino *et al.*, 2001).

Whether signal transduction, such as the induction of NFκB or mitogen-activated protein (MAP) kinases, is affected by cocaine remains to be determined (Ang *et al.*, 2001; Pierce *et al.*, 1999). NFκB p105 is a precursor that is cleaved into NFκB p50 and IκB-γ p70, while NF-κB p65 is a distinct gene. Ang *et al.* (2001) found that chronic cocaine administration increased the levels of the precursor NFκB p105, the inhibitory subunit IκB-γ p70, and the active transcription factor NFκB p65. It is unclear from these results what the net activity of the NFκB system is. In cultured neurones, cocaine and amphetamine increase the neurotoxic effects of the HIV proteins Tat and gp 120 (Nath *et al.*, 2000) and NF-κB activates the HIV promoter (Rattner *et al.*, 1993). Whether this immunological disorder is associated with HIV-1-associated dementia remains unclear (Goodkin *et al.*, 1998). It has been shown that cocaine enhances brain endothelial adhesion molecules and monocyte migration across the cerebral vessel wall (Gan *et al.*, 1999; Fiala *et al.*, 1998) and opens the blood–brain barrier to HIV-1 invasion (Zhang *et al.*, 1998).

Prenatal cocaine exposure did enhanced B cell responsiveness (Bohn *et al.*, 1997). Chronic administration to female rats during pregnancy significantly elevated IgG levels in the absence of lymphocyte proliferation (Masten *et al.*, 1996). However, PBMC stimulated with phytohaemagglutinin and phorbol-12-myristate PBMC isolated from foetal cord blood in cocaine-using mothers showed significantly decreased IL-1 and IL-2 concentrations (Karlix *et al.*, 1998).

Summary (See Tables XVI-4.11 and XVI-4.12)

Although these studies suggest cocaine may suppress overall immunity (decreased pro- and enhanced anti-inflammatory cytokines, decreased lymphocyte proliferation, decreased DTH response), alterations in dose duration and frequency of cocaine administration, as well as differences in the animal models used in these studies, make it difficult to reach a definitive conclusion. The differences between the human and animal studies could be accounted for by multi-drug use, differences in dose, route of administration, timing, duration, species and assay protocols (Pellegrino and Bayer, 1998).

SYNTHETIC DRUGS

LSD

Clinical Relevance

The hallucinogenic agent lysergic acid diethylamide (LSD) is used recreationally by large numbers of individuals in developed countries (Ghuran and Nolan, 2000). In 2000, approximately 1 million Americans were current users of hallucinogens. This number represents 0.4% of the population 12 and older (Substance Abuse and Mental Health Services Administration, 2001). The

Cluster of differentiation (CD); concanavalin A (ConA); dinitrofluorobenzene (DNFB); delayed-type hypersensitivity reaction (DTH); interferon (IFN); interleukin (IL); lipopolysaccharide (LPS); natural killer (NK) cell; peripheral blood lymphocytes (PBL); tumour necrosis factor (TNF).

drug is an indole derivative and chemically resembles serotonin. It is usually ingested orally. The adrenergic effects are usually mild and do not produce the profound sympathetic storms that can occur after taking cocaine, amphetamine or 'ecstasy' (Ghuran and Nolan, 2000). LSD is well known for its powerful mind-altering properties, causing feelings of euphoria, anxiety, paranoia, and visual and auditory hallucinations which can occur days, months or even up to 5 years after the last use (Abraham and Aldridge, 1993; Ghuran and Nolan, 2000). Clinical symptoms that correspond to general sympathetic arousal include dilated pupils, tachycardia, hypertension and hyporeflexia (Abraham and Aldridge, 1993; Ghuran and Nolan, 2000).

Immune Modulation

LSD alters immune function. *In vitro* it was demonstrated that LSD suppresses the production of the cytokines IL-2, IL-4 and IL-6. Additionally, LSD is able to suppress the B cell proliferation and the induction of cytotoxic T lymphocytes (House *et al.*, 1995a). LSD affects the NK cell activity in a dose-related manner. *In vitro* exposure to LSD had differential effects on NK cell activity, showing significant enhancement of both basal and IL-2-augmented NK cell function at concentrations that correspond to average levels of human exposure, and showing suppression of the NK response at higher doses (House *et al.*, 1994). *In vivo* immunological effects of LSD are not yet clear and remain to be investigated.

Summary (See Table XVI-4.13)

Taken together, LSD in high doses suppresses all immune functions (cytokines, T and B cells, NK cells).

3,4-Methylenedioxymethamphetamine

Clinical Relevance

3,4-Methylenedioxymethamphetamine (MDMA, 'ecstasy') is a ring-substituted phenylisopropylamine that is structurally related to both amphetamines and hallucinogens (Connor *et al.*, 1998). MDMA was first synthesized in 1912 but never marketed. It became popular in the 1970s and 1980s because it induces feelings of euphoria, friendliness, closeness to others and empathy (Mas *et al.*, 1999). Known under the street name 'ecstasy', which is derived from the characteristic euphoria that the drug produces, MDMA is one of the most popular recreational drugs in the Western world (Croft *et al.*, 2001). In the United States, an estimated 6.4 million persons have tried 'ecstasy' at least once in their lifetime (Substance Abuse and Mental Health Services Administration, 2001).

Adverse effects associated with the recreational use of MDMA include loss of appetite, jaw clenching, nausea, headache, trismus, bruxism, sweating, muscle aches, fatigue and insomnia. MDMA abuse can lead to the life-threatening serotonin syndrome (Sternbach *et al.*, 1991; Mas *et al.*, 1999; Dowling *et al.*, 1987; Henry *et al.*, 1992; Huether *et al.*, 1997; Croft *et al.*, 2001; Ricaurte *et al.*,

Table XVI-4.13 Peripheral immune effects of LSD. No central immune modulatory effects were found

Stimulus: LSD	Peripheral	
	Cytokines	Cells
Acute, experimental	IL-2, IL-4, IL-6 down (House *et al.*, 1995a)	Cytotoxic T cell down (House *et al.*, 1995a) NK cell activity in low doses up (House *et al.*, 1995a) NK cell activity in high doses down (House *et al.*, 1995a) B cell proliferation down (House *et al.*, 1995a)

Interleukin (IL); natural killer (NK) cell.

1988). MDMA ingestion can lead to an increased risk for immune system-related diseases (Pacifici *et al.*, 1999).

Immune Modulation

The main neurochemical action of MDMA is that it is a potent releaser of 5-hydroxytryptamine (5-HT, serotonin) within the CNS (Hegadoren *et al.*, 1999; Connor *et al.*, 2001). To evaluate the role of 5-HT release in MDMA-induced immunosuppression Connor *et al.* (2001) examined the *in vivo* effect of pretreatment with the selective paroxetine and the tryptophan hydroxylase inhibitor *p*-chlorophenylamine, on MDMA-induced suppression of IL-1β and TNF-α secretion following LPS challenge in rats. The treatment regimen of *p*-chlorophenylamine caused in excess of a 90% depletion of 5-HT concentration in both the frontal cortex and hypothalamus. In addition, MDMA administration produced a reduction in both cortical and hypothalamic 5-HT concentration, and further enhanced the *p*-chlorophenylamine-induced 5-HT depletion in both brain regions (Connor *et al.*, 2001). The suppressive effects of MDMA on LPS-induced IL-1β and TNF-α were equivalent in both saline and *p*-chlorophenylamine-treated groups (Connor *et al.*, 2001). Thus the authors suggest that the immunosuppressive effects of MDMA occur by a mechanism independent of 5-HT release (Connor *et al.*, 2001). Connor *et al.* (1998) pointed out that although *in vitro* data can be valuable in assessing the effect of MDMA on immune cells, these data also have limitations. Peripheral metabolism of MDMA may yield active metabolites which may act directly or indirectly on the immune system. Furthermore, MDMA exposure resulted in a release of CRF from the median eminence in the hypothalamus and HPA axis, as well as sympathetic nervous system (SNS) activation (Connor *et al.*, 1998). Both increased HPA axis and SNS activity can alter leucocyte distribution and function (Dhabhar *et al.*, 1995; Irwin, 1993). Another limitation is that *in vitro* studies are limited because they do not account for the effect of MDMA metabolites on immune function (Connor *et al.*, 1998).

MDMA and Mitogen

In rats, MDMA impairs the ability to respond to an *in vivo* challenge with bacterial LPS. An MDMA-associated reduction in IL-1β and TNF-α production after LPS challenge was recently shown (Connor *et al.*, 2000b, 2001). It was demonstrated that LPS-induced secretion of TNF-α was much more sensitive to the suppressive effects of MDMA than LPS-induced secretion of IL-1β (Connor *et al.*, 2000b). Connor *et al.* (2000b) demonstrated that *in vitro* exposure to MDMA at concentrations equivalent to serum levels following *in vivo* administration did not alter LPS-stimulated IL-1β or TNF-α production in diluted whole blood cultures. This suggests that the suppressive effect of MDMA on IL-1β and TNF-α following an *in vivo* LPS challenge might not be attributed to a direct effect on immune cell function.

Acute MDMA administration in rats has shown a reduction in the ConA-induced lymphocyte proliferation, and a reduction in the total leucocyte count (Connor *et al.*, 1998, 2000a). The effect of MDMA on ConA-stimulated Th1/Th2 cytokine production was associated with an increase in IL-2 production and a decrease in IL-10 and IFN-γ production. LPS treatment in MDMA-exposed rats resulted in a decrease in TNF-α production, whereas LPS-stimulated IL-1β secretion was not significantly altered (Connor *et al.*, 2000a).

Pro-/Anti-Inflammatory Immune Modulation

The immunological effects of MDMA administration include a reduction in the number of circulating lymphocytes, suppression of T lymphocyte proliferation and changes in Th1 and Th2 cytokine production (Connor *et al.*, 2000a, 2001). Cytofluorimetric analysis in men revealed that the observed reductions in lymphocyte subset counts were mainly due to T cells and not to B cells. It was also shown that MDMA treatment was associated with decrease in the production of Th1-type cytokines IL-2 and IFN-γ and an increase in the production of Th2-type cytokines IL-4 and IL-10. These results suggest that MDMA might be inducing an unbalanced differentiation of lymphocytes in peripheral blood based on the observed decrease in CD4 T lymphocytes. This partially explains the immunodysfunction caused by MDMA (Pacifi *et al.*, 2001).

In an *in vitro* study MDMA exposure resulted in the enhancement of IL-2 at low doses but resulted in suppression at high doses. The IL-4 production was not affected by MDMA treatment (House *et al.*, 1995b).

Cells

MDMA produced a suppression of cytotoxic T lymphocyte induction *in vitro* (House *et al.*, 1995b). Exposure to MDMA in rats demonstrated a reduced count of total leucocytes, lymphocytes, monocytes and neutrophils (Connor *et al.*, 2000a).

MDMA exposure had no effect on B cell proliferation at any concentration (House *et al.*, 1995b). In human MDMA experiments there were no differences found in the amount of cytotoxic/suppressor lymphocytes (CD8) and of B lymphocytes, and the total leucocyte count remained unchanged (Pacifici *et al.*, 2001).

Th1/Th2 Subsets

MDMA treatment on human PBMC was associated with a decrease in the production of the Th1-type cytokines IL-2 and IFN-γ (Pacifici *et al.*, 2001). When MDMA-treated lymphocytes in rats were ConA-simulated it has been shown that there is an increase in IL-2 levels, but IFN-γ levels were unchanged (Connor *et al.*, 2000a).

MDMA has been shown to result in the modulation of NK cell activity and macrophage function (House *et al.*, 1995b). Acute MDMA treatment resulted in a time-dependent immune dysfunction associated with MDMA plasma concentrations (Pacifici *et al.*, 2000). A decrease in CD4 T cells and in the CD4 T helper/CD8 T suppressor cell ratio was observed, whereas the percentage of NK cells was significantly increased. The total leucocyte count remained unchanged. After MDMA administration a decrease in CD4 T cell counts and simultaneous increase in NK cell activity

were confirmed, and a decrease in the functional responsiveness of lymphocytes to mitogenic stimulation was also observed (Pacifici *et al.*, 1999, 2001). The combination of MDMA with ethanol produced the greatest suppressive effect on CD4 T cell count and phytohaemagglutinin-stimulated lymphoproliferation (Pacifici *et al.*, 1999, 2001).

Summary (See Tables XVI-4.14 and XVI-4.15):

In conclusion, the recreational use of MDMA alters the immunological status in humans. The correlation between MDMA pharmacokinetics and the profile of MDMA-induced immune dysfunction suggests that the alteration may be mediated by the CNS. Based on previous findings, MDMA may act directly on immune cells or indirectly by promoting the release of serotonin from platelet stores in the periphery. To the best of our knowledge there are only a few clinical studies which examine the immunological parameters in MDMA abusers. However, there was no change in the pro-inflammatory, cell-mediated immune reaction and it is not yet clear how MDMA doses taken by social users affect immune function.

Amphetamines

Clinical Relevance

Among the US population aged 12 and older in 2000, an estimated 800 000 persons used stimulants such as amphetamines (Substance Abuse and Mental Health Services Administration, 2001). Amphetamines are CNS stimulants that produce 'pro-conflict' and 'anxiogenic-like' effects, enhance behavioural responsiveness to stressful stimuli, and increase corticosterone secretion (Freire-Garabal *et al.*, 1991). Anxiety as well as other emotional or psychosocial stresses were reported to produce a series of well-known adverse effects on host-defence mechanisms, particularly cell-mediated immune responses (Freire-Garabal *et al.*, 1991). Amphetamines cause a marked reduction in the resistance to bacteria, viruses and tumours (Nunez-Iglesias *et al.*, 1996). Chronic treatment with amphetamine in mice strongly inhibits natural and specific cellular immune responses in a dose-related manner (Nunez-Iglesias *et al.*, 1996).

Immune Modulation

In another experimental study amphetamine treatment resulted in the suppression of IL-2, but not IL-4 production by T lymphocytes

Table XVI-4.14 Central immune effects of 'ecstasy'

Stimulus: Ecstasy	Central	
	Cytokines	Cells
+ Stimuli, acute, experimental	Stimulus LPS: IL-6, TNF-α down (paroxetine pretreatment) (cortical and hypothalamic cells) (Connor *et al.*, 2001)	

Interleukin (IL); lipopolysaccharide (LPS); tumour necrosis factor (TNF).

Table XVI-4.15 Peripheral immune effects of 'ecstasy'

Stimulus: Ecstasy	Peripheral	
	Cytokines	Cells
Acute, human healthy volunteers	IL-2, IL-6, TNF-α, IFN-γ down (Pacifici *et al.*, 2001) IL-4, IL-10, TGF-β1 up (Pacifici *et al.*, 2001)	Th1/Th2 ratio down (Pacifici *et al.*, 2001) Total leucocyte count no change (Pacifici *et al.*, 2001) T helper cell (CD4) count down (Pacifici *et al.*, 2001) Cytotoxic T cell (CD8) count no change (Pacifici *et al.*, 2001) T helper cells, CD4/CD8 ratio down (Pacifici *et al.*, 2001) NK cell count up (Pacifici *et al.*, 2001) B cell count no change (Pacifici *et al.*, 2001)

+ Stimuli, acute, experimental	Stimulus ConA: IL-2 up (Connor *et al.*, 2000a) Stimulus ConA: IL-10, IFN-γ down (Connor *et al.*, 2000a) Stimulus LPS: TNF-α down (Connor *et al.*, 2000a) Stimulus LPS: IL-1β no change (Connor *et al.*, 2000a) Stimulus LPS: IL-1β, TNF-α down (*in vivo*) (Connor *et al.*, 2000b, 2001) Stimulus LPS: IL-1β, TNF-α no change (*in vitro*) (Connor *et al.*, 2000b)	Stimulus ConA: lymphocyte proliferation down (Connor *et al.*, 2000a) Stimulus KLH: IgG down (Connor *et al.*, 2001) Stimulus PHA: lymphocyte proliferation down (Pacifici *et al.*, 1999) Stimulus ethanol: CD4 cell count down (Pacifici *et al.*, 2001) Stimulus ethanol: NK count up (Pacifici *et al.*, 2001)

Cluster of differentiation (CD); concanavalin A (ConA); interferon (IFN); interleukin (IL); keyhole limpet haemocyanin (KLH); lipopolysaccharide (LPS); natural killer (NK) cell; T helper cell (Th); transforming growth factor (TGF); tumour necrosis factor (TNF).

Table XVI-4.16 Central immune effects of amphetamines

Stimulus: Amphetamines	Central	
	Cytokines	Cells
Acute, experimental	bFGF up in astrocytes (amphetamine) (Flores *et al.*, 2000) NFκB activity up in striatum (methamphetamine) (Asanuma and Cadet, 1998)	

Basic fibroblast growth factor (bFGF); nuclear factor κB (NFκB).

Table XVI-4.17 Peripheral immune effects of amphetamines

Stimulus: Amphetamines	Peripheral	
	Cytokines	Cells
Acute, human		NK cell activity up (*dl*-amphetamine) (Gagnon *et al.*, 1992)
Acute, experimental	IL-2 down (amphetamine) (House *et al.*, 1994) IL-4 no change (amphetamine) (House *et al.*, 1994)	Cytotoxic T cell down (amphetamine) (Nunéz-Iglesias *et al.*, 1996) NK cell activity down (amphetamine) (Nunéz-Iglesias *et al.*, 1996; House *et al.*, 1994) NK cell activity up (methamphetamine) (House *et al.*, 1994) B cell proliferation down (amphetamine) (House *et al.*, 1994)
Chronic, experimental		T cell count down (amphetamine) (Freire-Garabal *et al.*, 1991) NK cell activity up (amphetamine) (Swerdlow *et al.*, 1991)
+ Stimuli, chronic, experimental		Stimulus ConA: spleen cell response down (Freire-Garabal *et al.*, 1991) Stimulus PHA: T cell proliferation down (Gagnon *et al.*, 1992) Stimulus Stress: T cell count down (amphetamine) (Basso *et al.*, 1999) Stimulus Stress: DTH reaction down (amphetamine) (Basso *et al.*, 1999)

Delayed-type hypersensitivity reaction (DTH); interleukin (IL); natural killer (NK) cell; phytohaemagglutinin (PHA).

(House *et al.*, 1994). Nunez-Iglesias *et al.* (1996) showed a reduction in the T cell-mediated generation of cytotoxic T lymphocytes both in mixed lymphocyte cultures and *in vivo* assays with amphetamine. This indicates that amphetamine depresses the specific immune responses. After chronic amphetamine treatment in mice, the number of cells in the thymus fell to approximately 40% of baseline. Changes in spleen were similar. The decrease in peripheral blood lymphocytes was greater than the decrease in thymus cells. Amphetamine exposure also showed a reduced in the blastogenic response to ConA (Freire-Garabal *et al.*, 1991). The *in vitro* effects of 'designer' amphetamines, including *d*-, 1-, 4-proproxy- and *dl*-amphetamine, on human peripheral blood mononuclear leucocytes resulted in a wide range of suppressive actions. Treatment with each of these amphetamines led to reduced proliferation in response to T cell mitogen PHA (Gagnon *et al.*, 1992). Since T cells are essential for the development of immune responses to *Listeria* in mice, Freire-Garabal *et al.* (1991) postulated that the capacity of mice to develop immunity to an intracellular pathogen would be impaired at the time of, or immediately following, amphetamine treatment. The number of bacteria in the spleens and livers of mice injected with amphetamine was greater than that of placebo mice. Column-purified spleen cells from amphetamine-immunized mice had a reduced capacity to confer immunity as compared to placebo-immunized mice, thus confirming that T cell immunity was defective (Freire-Garabal *et al.*, 1991). Stress, i.e. foot shock, resulted in an immunosuppressive effect in rats previously subjected to chronic amphetamine treatment. These rats had a reduced percentage of T lymphocytes and a decreased DTH reaction (Basso *et al.*, 1999).

The function of NK cells was slightly suppressed by amphetamine exposure, but was enhanced by methamphetamine exposure (House *et al.*, 1994). An inhibition of NK cell activity by chronic amphetamine treatment has been shown in a dose-related manner (Nunez-Iglesias *et al.*, 1996). In contrast, *in vitro* studies have shown that only very low concentrations of *dl*-amphetamine (10^{-10} M) could increase the human NK cell activity (Gagnon *et al.*, 1992). Chronic amphetamine treatment in rats causes a significant increase in NK cell activity (Swerdlow *et al.*, 1991).

The murine B cell proliferation was suppressed in high-dose exposure to amphetamine (100 μM) (House *et al.*, 1994).

Amphetamines can either directly target cells or act indirectly by affecting neuroendocrine pathways. Amphetamines have numerous effects on neuronal and endocrine systems (Nunez-Iglesias *et al.*, 1996). Other experimental studies show that chronic amphetamine exposure has a stimulatory effect on ACTH secretion which is proportional to the decrease in T cell numbers and blastogenic response (Freire-Garabal *et al.*, 1991). Adrenalectomized mice showed reduced, but still significant, immunosuppression in response to amphetamine administration (Nunez-Iglesias *et al.*, 1996). It was suggested that other neuropeptides and neurotransmitters could be involved in the immunological response to amphetamine (Nunez-Iglesias *et al.*, 1996).

Lasting structural changes in the neurones of the nucleus accumbens and prefrontal cortex have been observed after repeated exposure to amphetamines (Robinson and Kolb, 1997, 1999b). Amphetamine injections induced increased expression of the neurotrophic and neuroprotective basic fibroblast growth factor (bFGF) in astrocytes, in the ventral tegmental area and substantia nigra pars compacta (Flores *et al.*, 2000). There are increases in both extracellular dopamine and glutamate in the ventral tegmental area after amphetamine injection (Wolf and Xue, 1999). Increased extracellular glutamate activates astrocytic bFGF (Pechan *et al.*, 1993), which acts directly on neurones or indirectly through astrocytes (Gómez-Pinilla *et al.*, 1995).

A cytokine that might contribute to methamphetamine-induced severe neurological deficits is IL-6. IL-6 is considered to play an important role in the development, differentiation, regeneration and degeneration of the CNS (Gruol and Nelson, 1997). It was shown that methamphetamine-induced damage to dopamine and serotonin terminals, apoptotic cell death and reactive gliosis are attenuated in IL-6 knock-out mice. Although the role of IL-6 in methamphetamine-induced damage is not yet clear, the protection afforded by the IL-6 null genotype suggests that the cytokine might be an important component of the toxic cascade induced by the drug (Ladenheim *et al.*, 2000). In addition to influencing neural development, IL-6, which can penetrate the blood–brain barrier (Banks *et al.*, 1994), affects the neuroendocrine and neurochemical effects of amphetamines (Zalcman *et al.*, 1999). IL-6 increased the sensitivity to the locomotor-stimulating effects of amphetamines (Zalcman *et al.*, 1999).

Summary (See Tables XVI-4.16 and XVI-4.17)

Taken together, amphetamines decreased in particular cell-mediated immune responses.

The Psychophysiology of Substance-Related Disorders

Alex Gamma and Matthias E. Liechti

INTRODUCTION

The psychophysiological study of substance abuse and related disorders is based on three major rationales. The first rationale is the identification of the biological underpinnings and functional consequences of substance abuse and dependence and their development; the second rationale is the search for biological 'markers' that are present before the onset of substance use and that identify young individuals who are at risk for developing substance abuse or related disorders during adolescence or adulthood. This rationale also opens an interface between psychophysiological and molecular genetic research. As seen in chapter XVI-9, a substantial part of the risk for substance abuse is genetically transmitted. By finding a marker that is linked to these high-risk genes, psychophysiology can assist molecular genetics in the identification of high-risk gene carriers who are not detected by psychiatric diagnosis (be it that they remain unaffected throughout their lifetime or that they are children not yet affected by the disorder). The third rationale is to use the knowledge gained by these efforts to improve intervention and prevention strategies. A better understanding of the neurobiological mechanisms of substance abuse behaviour will render treatment interventions more effective and specific. Furthermore, given a reliable marker for increased susceptibility for substance abuse and related psychopathology, prevention efforts could be geared selectively to high-risk children years before they reach the age of possible onset of the disorder.

Psychophysiological research into substance-related disorders has largely taken place during the past 30 years. In general, these three decades have substantially advanced the field, although in our view there has been more palpable progress for the work based on the second rationale than that based on the first. Studies using event-related brain potentials have been successful in finding a promising marker for the risk of developing substance abuse and a spectrum of associated disturbed behaviours. The identification of the biological underpinnings and functional significance of substance-related psychophysiological alterations, however, still faces important difficulties. Some of these problems have to do with limitations in the inferences from and functional interpretations of psychophysiological data (see final section). Another set of problems that is largely unavoidable in this field of research is rooted in the fact that most studies are cross-sectional and compare two or more different groups of subjects that differ in some dimension of interest. Typically, a group of substance users is experimentally compared with a group of non-drug-using subjects, and differences in test results between the groups are attributed to the variable of interest subjects were grouped by; i.e. in this case, substance abuse. But in order for this attribution to be valid, the two study groups would have to be identical in every respect but the fact that one uses substances and the other does not; otherwise some other difference between the groups (e.g. age, sex, psychopathology) could be responsible for the observed experimental differences. Although many researchers try to control this problem by matching the study groups for as many of these confounding variables as possible, a complete matching of the groups will never be possible. This is a serious limitation for the interpretation of research data in this field, since substance abuse is characterized by substantial comorbidity with internalizing disorders on the one hand, and externalizing disorders like antisocial personality on the other. In addition, there are major differences in lifestyle between drug users and non-users that might affect psychophysiological variables. Finally, polydrug use is a frequent phenomenon, so that the biological and behavioural effects of a given drug are difficult to study in isolation. Thus, it is an important task of research to disentangle the associations of substance abuse with comorbid psychopathology, variations in personality traits, use of other drugs and substance-related disturbed behaviours, and to isolate the contributions of these various factors to the observed experimental differences.

In acknowledging the essentially comorbid nature of substance abuse, we will, after reviewing the literature on single substances, deal with the possible common causes and psychophysiological and behavioural dispositions underlying the propensity to use various kinds of mind-altering substances. We start our review with alcohol, which, to date, has garnered the most attention within psychophysiological drug research. The study of alcoholism is an exemplary case that will bring up many of the issues and problems that also pertain to the other substances. We therefore suggest that our readers read this section also if their main interest is with another substance of abuse.

The methods most frequently used by psychophysiological research include the electroencephalogram (EEG), the recordings of event-related and evoked potentials (ERP/EP) as well as measurements of autonomic, including cardiovascular and electrodermal, activity. These will be introduced in the following sections whenever needed.

ALCOHOL

Studies on alcoholism or alcoholism risk have so far mainly focused on male subjects. The reasons for this bias may be that alcoholism is far more frequent in men than in women, and that evidence for the heritability of alcoholism has been strong in men, but equivocal in women. Recent studies, however, have found genetic influences on alcoholism to be comparable in women and men. The future may thus see an increased interest in research on female subjects. In the present review, studies focusing on female subjects will be specifically mentioned.

Sensory Evoked Potentials

Over two decades ago, reports on electrophysiological abnormalities in adults increasingly surfaced in the literature. Measurements of

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

brain stem auditory evoked responses (BAERs) showed a prolonged neural transmission time and delayed peak latencies in alcoholics (Begleiter *et al.*, 1981; Cadaveira *et al.*, 1991). BAERs occur in response to a train of auditory ultra-short-duration clicks. They are characterized by seven peaks that mark the path of the neural impulse from the auditory nerve via the cochlear nucleus and inferior colliculus to higher cortical areas. Neural brain stem transmission time is usually measured as the latency between peaks 1 and 5 of the evoked response. A slowing of brain stem transmission was observed primarily in chronic alcoholics who already showed signs of neurological dysfunction, and substantiated evidence for demyelination of nerve tracts as a consequence of excessive drinking.

Visual evoked potentials (VEPs) can be elicited by a checkerboard-reversal paradigm, in which the colours of a black-and-white checkerboard are inverted about every second. VEPs are characterized by several peaks, including the P100, a positive-voltage deflection occurring about 100 ms after stimulus onset. The P100 has been found to be prolonged in some (Kriss *et al.*, 1982; Meinck *et al.*, 1990; Cadaveira *et al.*, 1991) but not all (Emmerson *et al.*, 1987; Bauer and Easton, 1996), studies in alcoholics. It has been suggested that the presence of a P100 delay depends on the severity of the patients' neurological alterations, since P100 latency is sensitive to neurological disorders such as multiple sclerosis, glaucoma, optical neuritis or occipital tumours. Animal studies indicate that heightened VEP amplitudes may reflect transient cortical hyperexcitability during withdrawal. However, in humans, increased VEP amplitudes persist beyond withdrawal in some (Coger *et al.*, 1976; Emmerson *et al.*, 1987), but not all (Chan *et al.*, 1986) studies. Another measure of CNS hyperexcitability is the amplitude–intensity gradient (A/I slope). It has been found that alcoholics are 'augmenters', who tend to react to increasing stimulus intensity with increasing physiological responses. 'Reducers', on the other hand, tend to reduce their responses to increasing stimulus intensities. Thus, alcoholics show increasing VEP responses (P100 amplitudes) to increasing stimulus intensities (positive A/I slopes), while controls do not. Interestingly, alcohol ingestion reduces augmentation in alcoholics. It has therefore been suggested that alcoholics may use alcohol to dampen their oversensitivity to sensory stimuli. However, enhanced A/I slopes have been found in alcoholics only during early, but not after prolonged abstinence (Coger *et al.*, 1976; Emmerson *et al.*, 1987). Thus, while A/I slopes appear to normalize after withdrawal, P100 amplitudes and latencies may not. Possibly, A/I gradients are a measure of transient CNS hyperexcitability during withdrawal, whereas P100 characteristics may reflect structural changes of visual pathways.

The P300 Component of the Event-Related Potential

The event-related potential (ERP) is a time-locked electrophysiological response to a stimulus and shows a characteristic temporal profile of positive and negative peaks occurring up to about 1000 ms after stimulus onset. These peaks (called 'components') are named after the direction of their deflection from baseline and their latency (e.g. 'N100' denotes a negative-going wave with a peak latency of about 100 ms after stimulus onset). In general, early, 'sensory' components reflect the physical parameters of the stimulus, while later 'cognitive' components reflect the subjective significance of the stimulus and the attention allocated to it. The P300 (also simply called 'P3') is a positive-going cognitive ERP component with a modal latency of 300 ms. The P3 is elicited by stimuli that are novel or that are particularly attended to, independent of the sensory modality in which they occur. A typical method of evoking a P3 is the auditory oddball paradigm: a sequence of frequent tones of a given frequency is presented to a subject. Randomly interspersed are rare tones of a different frequency. The subject is instructed to attend to the rare, target tones (e.g. by counting them or by pressing a button whenever they occur) and to ignore the frequent, non-target tones. The ERP in response to the target tones, but not to the non-target tones, will then show a P3 wave. A P3 can also be elicited by novel non-target tones, i.e. tones that are rare but not attended to. It has been shown that the P3 in response to rare targets (called P3b) is maximal over the parietal cortex, while the P3 as an orienting response to novel non-targets (called P3a) shows a central–frontal distribution. (In the remainder of this chapter, 'P3' will refer to the P3b, unless otherwise stated.) The P3 is thought to reflect the allocation of attentional resources when a new stimulus is processed. It occurs whenever the model of the stimulus environment in the working memory is updated. P3 amplitude increases with the amount of attention demanded by the stimulus and its informational value. P3 latency, on the other hand, is thought to reflect the speed and timing of attentional processing of the stimulus. It increases with increasing level of task difficulty, when degraded stimuli are used and with increasing age. On some cognitive tasks, increased P3 amplitude has been linked to better memory performance, while increases in P3 latency were associated with increased reaction time (Pfefferbaum *et al.*, 1991).

Early studies in chronic male alcoholics indicated ERP deficits in the form of prolonged P3 latency and reduced P3 amplitude. Initially, these findings were thought to reflect a direct consequence of chronic alcohol abuse. However, subsequent attempts to replicate these findings yielded mixed results. While a majority of investigations confirmed the P3 amplitude deficits (Figure XVI-5.1) (Pfefferbaum *et al.*, 1991; Cohen *et al.*, 1995; Holguin *et al.*, 1999a; Hada *et al.*, 2000; Malone *et al.*, 2001; Prabhu *et al.*, 2001), there was a not much smaller number of negative reports (Hermanutz *et al.*, 1981; Steinhauer *et al.*, 1987; Lille *et al.*, 1987; Cadaveira *et al.*, 1991; Hill *et al.*, 1995b, 1999a). P3 latency slowing was even more resistant to replication: most later studies did not find deviations of P3 latency in alcoholics as reported in the early work. These discrepancies indicated that alcohol use alone could not completely account for the observed alterations in P3 characteristics. There had to be some other factor(s) that substantially contributed to the variance in these findings. A number of alternative sources of variance have been evaluated: differences in study sample source, ERP task, severity of alcoholism, length of abstinence, comorbid psychiatric or personality disorders, or family history of alcoholism. We will now examine each one of these candidates for their possible contribution to the conflicting findings.

Sample Source

Alcoholic study subjects have been recruited from three main sources: hospital and VA treatment programmes, community treatment programmes and from the community at large. Typically, there is an increasing degree of cognitive impairment and of the severity of alcoholism from hospitalized patients to community-recruited alcoholics. Since the P3 reflects cognitive processes, it is reasonable to assume that P3 measures may also differentiate between alcoholics from these different sources. A look at the relevant literature, however, shows that neither positive nor negative P3 findings are distributed across these three sources in a systematic way. Particularly, P3 findings obtained in community alcoholics do not differ from those found in their hospitalized counterparts. Glenn *et al.* (1996) explicitly addressed the hypothesis that alcoholics from VA treatment programmes may have stronger P3 deficits than alcoholics from community treatment programmes, reflecting their poorer neuropsychological performance. Contrary to their hypothesis, they found no differences in P3 measures across groups. The conclusion is that differences in the source of subject recruitment do not appear to explain the variability of P3 findings in alcoholics.

ERP Task

Tasks employed to produce ERPs can vary along several axes, two important ones being stimulus modality and level of difficulty. The majority of studies reporting decrements in P3 amplitude used tasks involving visual stimulation, while auditory tasks were less effective in producing P3 alterations in alcoholics. It thus appears that stimulus modality has some bearing on the P3 effects in alcoholics. A higher likelihood for P3 amplitude reductions to occur with visual tasks is also seen in studies of non-alcoholic children or adolescents who are at increased risk for later alcohol abuse owing to a positive family history of alcoholism (see below). It is possible that deficits in P3 amplitude related to current alcoholism or risk for alcoholism are largely restricted to the brain substrate for visual as opposed to auditory P3 generation. An alternative explanation is that the visual tasks used in these studies were more powerful in revealing P3 amplitude decrements in virtue of their being more difficult, i.e. cognitively demanding. In fact, it has been suggested that visual tasks are generally more difficult than auditory tasks because of visual stimuli being less alerting than auditory stimuli, thereby demanding more 'effortful processing'. Apart from this possible general effect of stimulus modality on task difficulty, however, the tasks used to reveal P3 deficits in alcoholics do not seem to be in any consistent way more difficult than those that failed to produce P3 deficits. Pfefferbaum *et al.* (1991) and Realmuto *et al.* (1993) even observed P3 amplitude reductions in an automatic ERP paradigm involving no task and therefore very little processing resources.

Severity of Alcoholism

Assuming that the severity of previous alcohol exposure is one cause of P3 deficits, then the variability in P3 findings in adult alcoholics might stem from the fact that studies reporting negative results included subjects whose previous exposure to alcohol on average was not severe enough to produce significant changes in the P3. This hypothesis, particularly regarding deficits in P3 amplitude, finds little support in the literature. A number of studies failed to find associations between several measures of severity of drinking and visual (Pfefferbaum *et al.*, 1987, 1991; Malone *et al.*, 2001) or auditory (Hill *et al.*, 1995b) P3 amplitude and latency. Olbrich *et al.* (2000) extended these findings to topographical P3 measures, finding no correlation between the gravity centre of visual and auditory P3 scalp distribution and severity of alcoholism. Furthermore, a lack of association between P3 amplitude and drinking history was reported in non-alcoholic young men (Baribeau *et al.*, 1987).

In contrast, Polich and Bloom (1987) reported an association between quantity of alcohol consumed per drinking occasion and reduced amplitude and increased latency of the P3 in non-alcoholic college students. However, in a subsequent study (Polich and Bloom, 1988), they failed to replicate these results. Steinhauer *et al.* (1987) found delayed P3 latency in the more difficult of two auditory ERP paradigms only in alcoholic subjects and their alcoholic siblings, but not in their non-alcoholic siblings or controls. They inferred that P3 latency prolongation could be primarily related to drinking history, and less to a positive family history of alcoholism. It should be noted, however, that this conclusion was not based on a statistical assessment of the direct relationship between drinking history and P3 latency. In sum, it appears that severity of alcoholism as indexed by various measures of alcohol exposure had little influence on P3 characteristics in these studies. This does not necessarily mean that excessive drinking has no effect on P3, but only that there does not seem to be a linear relationship between the two. Porjesz and Begleiter (1981) point out that even among alcoholics with similar drinking histories there are great individual differences in susceptibility to alcohol-related brain deficits, and thus, possibly, in P3 characteristics. In fact, this individual variability may be the main reason for the general lack of correlations of severity of alcoholism with P3 measures.

Length of Abstinence

Brain pathology in most alcoholics has been shown to recover at least partially with increasing time of abstinence. The question therefore arises whether abstinence may also normalize the observed deficits in the P3 component. The literature offers little support for this view. Alterations in P3 amplitude and latency can invariably be observed in alcoholics with different durations of abstinence ranging up to several years (Whipple *et al.*, 1991; Glenn *et al.*, 1994). Several studies (Pfefferbaum *et al.*, 1991; Realmuto *et al.*, 1993; Hill *et al.*, 1995b) found no significant correlations of duration of abstinence with any ERP component measure in alcoholics abstinent up to 3 months. This apparent immunity of P3 deficits to the length of abstinence has attracted several explanations: either the effects of alcohol on the neural substrate of P3 generation are irreversible, or the persistent P3 deficits are not primarily the consequence of alcohol use but of some other, co- or premorbid, factor. The first conjecture seems at odds with findings of brain recovery in abstinent alcoholics, but cannot be definitely ruled out. The second suggestion has gained credibility in the light of studies demonstrating reduced P3 in alcoholics with comorbid internalizing disorders like depression and externalizing disorders like antisocial personality disorder, as well as a positive family history of alcoholism. These issues will be discussed below.

Comorbid Psychopathology

P3 alterations are not specific to alcoholism. Decreases in P3 amplitude have, for example, also been found in clinical psychiatric disorders like schizophrenia or depression and in externalizing and personality disorders. There is substantial comorbidity between psychiatric disorders and alcoholism or other substance dependence. It is therefore possible that the positive P3 findings in alcoholics might be due to the presence of comorbid psychiatric disorders rather than to alcohol abuse itself. Two gender-specific forms of this hypothesis have received a fair amount of support in recent research. In women, there is a link between internalizing disorders, particularly depression, alcoholism and P3 deficits. Parsons *et al.* (1990) investigated male and female alcoholics and failed to find an effect of alcoholism on P3 in women without comorbid psychiatric diagnosis, whereas the effect in men was present despite the lack of a psychiatric diagnosis. Hill *et al.* (1999a) compared depressed with non-depressed female alcoholics and controls, and found auditory P3 amplitude reductions in the depressed group relative to the non-depressed alcoholics and the controls. There was no difference between the non-depressed alcoholics and the controls. The authors concluded that the observed P3 deficits in alcoholic women were most likely due to comorbid depression. Using a visual P3 paradigm, Prabhu *et al.* (2001) found no effect of depression on P3 decrements in alcoholic women. However, these researchers relied on a not further specified self-report measure of depression, which makes their findings difficult to interpret.

In men more than in women, alcohol and drug abuse are frequently comorbid with and predicted by a spectrum of externalizing disorders, which, in turn, has been found to be associated with P3 amplitude reductions. These externalizing disorders include antisocial personality disorder (ASPD) in adults, as well as conduct disorder (CD), oppositional defiant disorder (ODD) and attention deficit with hyperactivity disorder (ADHD) in children. A common basis underlying these disorders is the lack of behavioural inhibition and control, as expressed by personality traits such as low constraint and impulsivity. These and related personality traits are known to be significant risk factors for the development of externalizing psychopathology and substance abuse. With regard to alcoholism in particular, low harm avoidance and high novelty-seeking in children have been identified as personality traits predictive of later alcoholism. Several studies indicate that externalizing psychopathology as an expression of these critical personality traits is characterized by reduced P3 amplitudes. Bauer *et al.* reported significantly reduced frontal P3 amplitudes in a sample of non-alcoholic (Bauer *et al.*, 1994) and cocaine-abusing (Bauer, 1997) men with ASPD, independent of any family history of alcoholism. Similarly, Bauer and Hesselbrock (1999) found P3 amplitude reductions in adolescents with CD that were unrelated to a family history of substance dependence. Some studies have found that in addition to being related to ASPD and childhood externalizing disorder, small P3 amplitudes were also associated with increased substance (including alcohol) dependence (Carlson *et al.*, 1999; Costa *et al.*, 2000) and a family history of alcoholism (O'Connor *et al.*, 1994). Several longitudinal studies support these results. Stabenau (1990) found that ASPD and a positive family history of alcoholism (FHA) made independent, additive contributions to the development of alcoholism 5 years later. The risk for alcoholism was increased threefold by an ASPD diagnosis and 1.5-fold by an FHA. Windle (1990) reported that antisocial delinquent behaviour in early adolescence was significantly predictive of alcohol use and dependence in late adolescence, particularly in men. A possible contribution of family history status was not analysed in that study. In a male sample, Mannuzza *et al.* (1993) found that childhood ADHD predicted ADHD symptoms, ASPD and drug abuse at age 26, with significant comorbidity between ASPD and drug disorders. There are a few contrasting reports. Herning *et al.* (1989) studied delinquent male adolescents and found that the presence of drug use, not delinquency, differentiated between low and high P3 amplitude, although delinquency itself was associated with alterations in other ERP components and with delayed BAERs. A very recent investigation by Malone *et al.* (2001) revealed P3 amplitude decrements in 'pure' alcoholics without comorbid psychiatric diagnoses. In pure ASPD subjects, the reduction in P3 amplitude did not reach statistical significance, but drug-using subjects with concomitant ASPD had particularly low amplitudes. The authors concluded that the presence of alcoholism alone may be sufficient to affect P3 amplitude, but that drug use and ASPD can amplify this effect.

Summed up, comorbid depression may largely account for the P3 deviations found in alcoholic women. In male alcoholics, the presence of comorbid CD or ASPD explains some of the variance in P3 findings, but alcohol and drug use appear to make additional, independent contributions.

High-risk children have significantly smaller amplitudes in both easy and difficult task conditions. Reprinted with permission from Begleiter, H., Porjesz, B., Bihari, B. and Kissin, B., 1984. Event-related brain potentials in boys at risk for alcoholism. *Science* **225**, 1493–1496. Copyright 1984 by the American Association for the Advancement of Science

Family History of Alcoholism

Two decades ago, two seminal papers first reported decrements in P3 amplitude in non-alcoholic boys (Begleiter *et al.*, 1984) and young men (Elmasian *et al.*, 1982) who were at risk for developing alcoholism due to a positive FHA (Figure XVI-5.2). A commonly applied criterion for a positive FHA is the presence of one or several alcohol-dependent or -abusing first-degree relatives (parents, siblings). Because of the strong heritability of alcoholism, family history positive (FHP) individuals are at high risk for developing alcoholism. The findings by Begleiter and colleagues and Elmasian and colleagues opened up the intriguing possibility that reduced P3 amplitudes in high-risk children could be a psychophysiological marker for an inherited susceptibility to alcoholism. The research efforts that followed these initial findings largely confirmed the presence of P3a and P3b decrements in FHP children (Begleiter *et al.*, 1987; Hill and Steinhauer, 1993a, Brigham *et al.*, 1995; Hill *et al.*, 1995a, 1995c, 1999b), adolescents (van der Stelt *et al.*, 1997; Steinhauer and Hill, 1993) and young adults (O'Connor *et al.*, 1987; Ramachandran *et al.*, 1996; Cohen *et al.*, 1997; Ramsey and Finn, 1997; Holguin *et al.*, 1999b; Hada *et al.*, 2001). In a meta-analysis of this literature, Polich *et al.* (1994) came to the conclusion that positive P3 findings in FHP individuals were most consistently found in studies using difficult visual ERP tasks. Thus, as in studies of adult alcoholics, the visual stimulus modality is more effective in producing P3 differences in FHP subjects, but task difficulty appears to be more relevant to P3 in FHP than in alcoholic subjects. Of course, these two types of studies cannot be completely separated. In fact, one important question is to what extent and how family history status may have interfered with the results attributed to the effects of alcohol abuse in alcoholism studies. Several studies investigated alcoholism and FHA status in the same subject samples, all between 30 and 40 years of age. Pfefferbaum *et al.* (1991) tested male alcoholics in an automatic and two easy auditory and visual ERP paradigms and found significant auditory, and near-significant visual P3 decrements in FHP subjects. They also reported a correlation between increasing family density of alcoholic relatives and P3 amplitude. Similarly, Cohen *et al.* (1995) found a significant auditory P3 amplitude reduction over the occipital lobe in high-density compared to low-density alcoholics. Using a mixed audiovisual oddball paradigm, Parsons *et al.* (1990) found no FHA effect in either a male or female alcoholic sample. However, a subgroup of their male sample had earlier shown a significant FHP effect on P3 amplitude in the same audiovisual paradigm (Patterson *et al.*, 1987). Neither alcohol nor FHA effects on auditory P3 measures were found by Hill *et al.* (1995b) in male alcoholics from high-density families, using a counting task and a choice-reaction task. The same paradigm was used by Steinhauer *et al.* (1987), who reported an FHA effect on P3 latency, but not amplitude. Hill and Steinhauer (1993) employed auditory and visual ERP paradigms of increasing difficulty in an exclusively female sample, and found P3 decrements across all levels of task difficulty in alcoholic FHP subjects, but not in their non-alcoholic FHP sisters, indicating an effect of alcoholism, but not FHA. A similar lack of an FHA effect in female alcoholics was reported by Prabhu *et al.* (2001). Finally, results from the longitudinal, multi-centred Collaborative Study on the Genetics of Alcoholism (COGA) in mixed-gender samples demonstrated P3 decrements in alcoholics vs. non-alcoholics, but also in unaffected relatives of alcoholics vs. unaffected relatives of controls, indicating both an FHA and an alcohol effect (Porjesz *et al.*, 1998; Hesselbrock *et al.*, 2001).

Although these reports, particularly the opposite findings of Patterson and colleagues and Parsons and colleagues in overlapping subject samples, are difficult to reconcile, it appears that FHA effects are more consistently found in male than in female subjects, while task difficulty and modality do not seem to influence P3 findings in FHP alcoholics. Possible clues to understanding this putative gender-specific effect might come from a hypothesis that has been most strongly advocated and supported by Hill and colleagues. These authors argue that the P3 decrements seen in FHP children reflect a developmental delay. The idea is that FHP children are lagging behind family history negative (FHN) children with respect to the maturation of brain processes underlying P3 generation. Thus, at a given age, FHP children will evince smaller P3 amplitudes than FHN control children. Assuming that these differences do not resolve by adulthood in boys, we could attribute the P3 differences in alcoholic FHP men found in some studies to a developmental delay persisting into adulthood.

However, this assumption is not consistently supported by the relevant work. In a large longitudinal study (Hill and Steinhauer, 1993a; Steinhauer and Hill, 1993; Hill *et al.*, 1999a), Hill and co-workers followed a group of FHN and FHP children up to 7 years to document the developmental course of auditory and visual P3 amplitude from childhood (age 8) to late adolescence (age 18). These researchers found that auditory P3 amplitude increases with age, whereas visual P3 amplitude decreases with age. With regard to family history status, the earlier studies by this group indicated that the auditory P3 amplitude in FHP boys starts at the same level as in FHN boys, but increases much more slowly with age, producing increasing differences with increasing age. Visual P3 amplitude in FHP boys, however, started at a lower level than in FHN control boys, and increased with age to catch up with control levels by about age 18. In girls, the developmental trajectories for

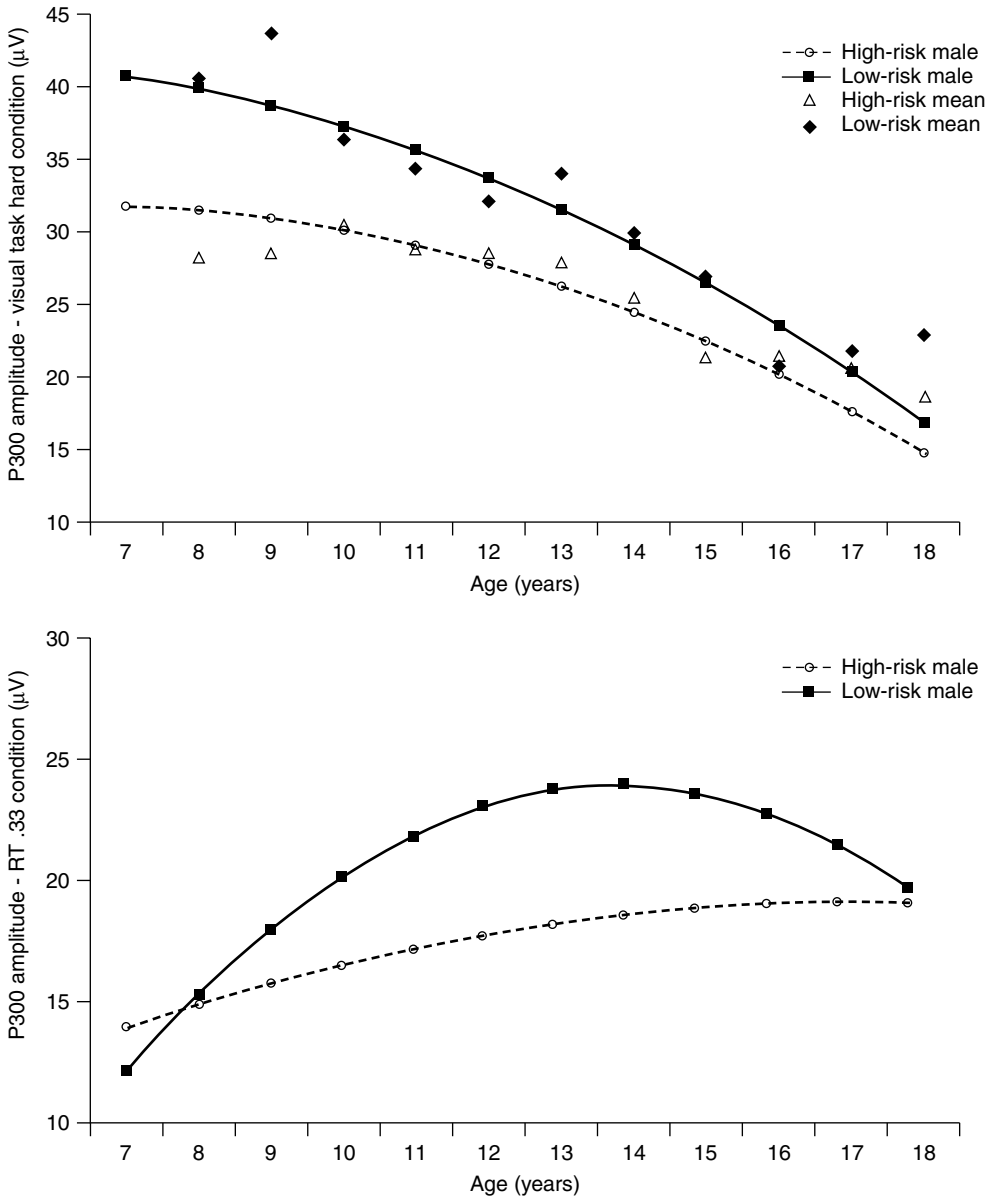

Figure XVI-5.3 Developmental trajectories of visual (above) and auditory (below) P3 amplitudes in 8- to 18-year-old male children at low and high risk for developing alcoholism. Note the convergence of visual and auditory P3 trajectories at age 18 and the inverted U-shaped curve for auditory P3 in low-risk children. Reprinted by permission of Elsevier Science from 'Developmental delay in P300 production in children at high risk for developing alcohol-related disorders' by Hill, S.Y., Shen, S., Locke, J., Steinhauer, S.R., Konicky, C., Lowers, L. and Connolly, J., *Biological Psychiatry* **46**, 970–981. Copyright 1999 by the Society of Biological Psychiatry

the auditory and visual P3 amplitude did not differ significantly by family history status. At this point, we find our assumption of persisting P3 decrements in boys but not girls confirmed, but only for the auditory modality. However, the 1999 study, using a much larger number of subjects and quadratic rather than linear modelling, found that the auditory P3 trajectories in boys did not continuously diverge with increasing age, but met again at age 18. This difference was obtained because the quadratic modelling algorithm fitted an inverted U-shaped curve to the amplitude data from the FHN boys. As a result, the trajectory of auditory P3 amplitudes in FHN boys started and ended at the same level as those in FHP boys, but in between it was sharply convex, resulting in the largest differences between FHN and FHP boys occurring at age 12–14 (Figure XVI-5.3). Thus, the latest findings indicate that developmental delays in the size of the P3 in both female and male FHP children resolve by adulthood, leaving little room for arguing that P3 decrements in male FHP alcoholics are residual childhood effects.

Summary

We can now summarize our extensive discussion of the possible sources of variance in the P3 findings in adult alcoholics. When observed, P3 decrements probably reflect to some extent an independent effect of chronic alcohol abuse that is not linearly related to the severity of drinking, indicating a more complex

relationship. P3 decrements occur independently of the duration of abstinence, suggesting that they are irreversible or pre-existing. In some, but not all, studies a positive FHA was found to make an additive contribution to the P3 deficits in alcoholics. This effect may be specific to men, but whether it represents a residual childhood effect or not is unclear. Externalizing disorders such as ADHD, CD and adult ASPD appear to make another independent contribution to the P3 decrements in some studies, particularly in alcoholic men. In alcoholic women, adult P3 reductions may be partly attributable to comorbid depression. P3 differences are more reliably detected in the visual than in the auditory modality, but are largely unaffected by task difficulty. There is a similar lack of effect of the source of subject recruitment. Delays in P3 latency may reflect structural brain changes related to chronic alcohol use, since P3 delays are typically found in organic brain disease.

Is the P3 a Marker for Alcoholism Risk?

The findings of P3 decrements in FHP children or adolescents are rather robust, which has led some (e.g. Iacono, 1998; Hesselbrock *et al.*, 2001) to propose that a reduced or small P3 response could be a psychophysiological 'endophenotype', i.e. a risk marker for the later development of alcoholism. The concept of an endophenotype defines it as an endogenous characteristic of a person that is a product of the predisposing genotype (Iacono, 1998). According to Iacono, there are several requirements for something to qualify for an endophenotype. Let us briefly examine how well a small or reduced P3 amplitude satisfies these criteria.

Potential endophenotype is evident in unaffected relatives.

This requirement is met for children and adolescents, where P3 decrements can be found in unaffected, i.e. non-alcoholic, individuals with a positive FHA. It is also met for unaffected male, but possibly not female, adults.

It is evident in affected relatives.

As discussed above, about half of the studies in FHP alcoholic men have observed P3 decrements. Two studies in FHP alcoholic women have not. This requirement is therefore only partly satisfied.

It is specific to the disease in question.

This requirement is not satisfied. As mentioned earlier, P3 deficits are not specific to alcoholism. Both in adults as well as in children and adolescents, they are also associated with other substance abuse, internalizing disorders such as depression and schizophrenia, or externalizing disorders such as ADHD, ODD, CD and ASPD.

It has predictive power.

The evidence we have so far indicates that this requirement is met. Two longitudinal studies in teenagers reported that reduced P3 amplitude predicted alcoholism or general substance abuse 4 (Berman *et al.*, 1993) and 8 (Hill *et al.*, 1995a) years later, respectively.

It indicates risk for the disease.

This requirement is met: the prevalence of alcohol and substance dependence is significantly higher in adolescents with a small rather than a large P3, irrespective of family history status (Carlson *et al.*, 1999). Furthermore, the presence of a small P3 is linked to a positive FHA, which in turn has been shown to increase the risk for alcoholism by about five times or more (Cloninger *et al.*, 1981).

It is heritable (follows from the definition).

This requirement is satisfied: various characteristics of the ERP, including the P3 amplitude, are heritable (e.g. O'Connor *et al.*, 1994a; Katsanis *et al.*, 1997; Almasy *et al.*, 2001).

As we see, a small P3 response basically satisfies four out of six criteria required for an endophenotype. Fortunately, the failure to completely satisfy the other two requirements need not worry us too much — it merely calls for a modification of the scope of our marker. Even if the second requirement were never met and the P3 findings in adult FHP alcoholics turned out to be unrelated to a heightened risk for alcoholism, a small P3 amplitude would still be a valuable risk marker in children and adolescents up to about age 18 (as seen in the work on developmental delay discussed above). This means that, although it would not identify adult high-risk individuals (both affected and unaffected), it would identify high-risk non-adults before they reach the age of onset of substance abuse, which seems to us to be much more important with regard to early prevention and intervention. The other issue is specificity. Here we should first say that the presence of our marker in diseases other than alcoholism does not necessarily mean that the marker indexes a *risk* for these other diseases. For example, while reduced P3 amplitude can be found in schizophrenia, it does not seem to *predict* or indicate an increased risk for this disorder in unaffected non-adults. However, our marker also appears to index risk for externalizing (and possibly internalizing) psychopathology and the abuse of substances other than alcohol. But this should not lead us to discard the marker, since it is unreasonable to expect a complete absence of the endophenotype in disorders that are comorbid with the target disorder and show considerable symptom overlap. In fact, it is even possible, although not necessarily the case, that the presence of the marker in a cluster of disorders indicates a shared aetiology, which may finally lead to a redefinition of these disorders at the clinical level.

In conclusion, our reading of the extant literature supports the following modified definition: *The presence of a small or reduced P3 amplitude is an endophenotype in children and adolescents marking the risk for alcoholism and other substance disorders as well as a spectrum of externalizing (and possibly internalizing) disorders.*

Other Components of the ERP

Although the P3 component has attracted most research, earlier ERP components, including the N100, P100, N200 and P200, have also been studied in alcoholics. The few studies that have focused on female subjects failed to find differences in pre-P3 components (Parsons *et al.*, 1990; Hill and Steinhauer, 1993). The results obtained in male subjects are mixed: for every positive finding, there are usually equally many, if not substantially more, negative findings. The most robust results are decreases in N100 amplitude and increases in N200 latency, while alterations in P100 or P200 characteristics are seldom reported.

The N100 is a negative wave with a typical post-stimulus latency of 120 ms. The N100 is larger after stimuli that occur in an 'attended channel', regardless of whether they are task relevant (i.e. targets) or task irrelevant (i.e. non-targets). The attended channel can be stimulus modality or some other stimulus dimension. Besides having deceased N100 amplitudes, alcoholics also failed to enhance N100 amplitude in response to stimuli in the attended vs. non-attended channel (Lille *et al.*, 1987; Parsons *et al.*, 1990). Lille *et al.* (1987) even found an inverted N1 effect, with alcoholics responding more strongly to stimuli in the non-attended channel. These findings can be interpreted as a failure of selective attention. Alcoholics seem unable to discriminate electrophysiologically between signals from the attended and non-attended channel.

The N200 is a negative wave occurring at around 200 ms after stimulus delivery. It is an automatic reaction to deviant stimuli within a homogeneous, repetitive stimulus sequence, reminiscent of the orienting response. It is largely independent of task relevance or stimulus significance. The N200 or its subcomponent, the N2a,

is therefore also called 'mismatch negativity' (MMN), because it is thought to be produced by a comparison process between the current deviant sensory input and a neural representation or 'template' of the 'standard input' (Realmuto *et al.*, 1993). A mismatch between the current and the standard input will elicit an MMN response. The latency of this component increases with increasing difficulty of discrimination between the standard and the deviant stimuli, suggesting that MMN latency is an index of stimulus evaluation time. Increases in N200 latency reported in alcoholics may reflect delays in stimulus evaluation (Porjesz *et al.*, 1987; Parsons *et al.*, 1990; Cadaveira *et al.*, 1991). Porjesz *et al.* (1987) additionally observed that alcoholics as opposed to controls did not show increasing N200 latencies with increasing difficulty of stimulus discrimination. Given a concomitant delay in P3 latency, these authors concluded that their alcoholic subjects have difficulties evaluating stimuli either for task relevance or for ease of discrimination.

A few studies further reported abnormalities in the amplitude of the MMN (Realmuto *et al.*, 1993; Ahveninen *et al.*, 2000), although in different directions. Realmuto and colleagues interpreted the MMN decrements found in their sample of alcoholic men as possibly reflecting a deficient neuronal template, which may fail to form in the first place, rapidly decay, or may be inaccessible. Ahveninen and colleagues, however, reported increased MMN amplitudes in alcoholic men with similar characteristics. They further found increased MMN responses to be significantly correlated with increased distractibility by the task-irrelevant deviant stimuli and with poorer hit rates. The authors took these data to indicate impaired neural inhibition of involuntary attention shifting. Despite MMN deviations in opposite directions, both reports agree that their findings represent a deficit in mismatch processing. The source of the differences between the two reports is unclear, but may be related to differences in task (automated processing vs. forced-choice-reaction time task) or in component detection. In view of the many negative reports, the findings concerning MMN in particular, and pre-P3 components in general, should be interpreted cautiously. The reasons for the mixed picture of results are currently unknown and await future research.

Topographical ERP Changes

So far, we have focused on the size and latency of various ERP components and ignored their topographical dimension. This approach reflects the preponderance of reports in the literature that used very few electrode sites (typically the midline leads Fz, Cz, Pz, and sometimes two adjacent bilateral leads) and offers little in the way of topographical analysis. Only a few studies have made recordings from the full or even an extended 10/20 system array. What most studies with reduced electrode sets agree on is that deviations of (primarily visual) P3 amplitude in alcoholics are largest over parietal areas (Pz) (Patterson *et al.*, 1987; Porjesz *et al.*, 1987; Parsons *et al.*, 1990; Whipple *et al.*, 1991; Glenn *et al.*, 1996), although some reports located the largest deviations at central (Cz) (Olbrich *et al.*, 2000) or right central (C4) (Emmerson *et al.*, 1987) recording sites.

Studies using a full electrode array have yielded conflicting results. Some studies showed that visual P3 decrements in alcoholics follow a gradient from anterior, where they are smallest, to posterior, where they are largest (Figure XVI-5.1) (Pfefferbaum *et al.*, 1991; Cohen *et al.*, 1995, 1997). More recent work has found the opposite: differences in visual P3 amplitude in alcoholics were more pronounced at anterior than posterior sites (Costa *et al.*, 2000; Prabhu *et al.*, 2001). Prabhu and colleagues also used a new EEG source localization method called low-resolution brain electromagnetic tomography (LORETA; Pascual-Marqui *et al.*, 1994; Pascual-Marqui, 1999) and confirmed prefrontal P3 differences located in the right dorsolateral prefrontal cortex and ventromedial frontocentral cortex. Not only the P3b, but also the visual and auditory P3a components have been topographically analysed and found to be globally different between male alcoholics and controls (Holguin *et al.*, 1999a; Hada *et al.*, 2000). In adult FHP individuals, topographical P3a differences were found globally (Holguin *et al.*, 1999b), frontally (Hada *et al.*, 2001), and posteriorly (van der Stelt *et al.*, 1997). The reason for the discrepancies in P3b results in alcoholics and in P3a results in FHP individuals is currently unclear.

Olbrich *et al.* (2000) analysed the electric gravity centres (centroids) of the negative and positive half-field of the N100 and P3 distribution, and found a shift of the positive P3 centroid to the right and of the negative P3 centroid posteriorly and to the left. The authors remark that a similar right shift of the positive P3 centroid along with decreased N100 amplitudes (as also found by Olbrich *et al.*) can be observed in schizophrenic patients, suggesting a common cerebral dysfunction in alcoholism and schizophrenia manifested by deficits in attentional filtering.

EEG

The EEG in Alcoholics

The use of the EEG in the study of acute and chronic alcohol effects goes back over half a century. Early studies using clinical EEG evaluation were primarily concerned with the search for salient abnormalities such as irregular spike and wave complexes characteristic of withdrawal seizures. With the advent of increasingly powerful tools for computerized analysis, the focus of research shifted to the identification of more subtle quantitative EEG (qEEG) changes. Although much the same confounding factors as discussed in the ERP section also afflict the study of EEG in alcoholics, there have been some fairly consistent findings. The most common changes in baseline EEG are elevated beta (>12 Hz) (Spehr and Stemmler, 1985; Kaplan *et al.*, 1985; Frank *et al.*, 1986; Krauss and Niedermeyer, 1991; Bauer, 1994a; Costa and Bauer, 1997; Günther *et al.*, 1997) and decreased alpha (8–12 Hz) activity (Coger *et al.*, 1976; Spehr and Stemmler, 1985; Kaplan *et al.*, 1985). Increases (Kaplan *et al.*, 1985; Pollock *et al.*, 1992) or decreases (Propping *et al.*, 1981) in delta or theta activity are also occasionally reported.

Despite its being frequently observed in alcoholics, elevated beta is not specific to alcoholism and probably is not even directly related to alcohol use. In fact, it is likely that multiple independent factors can produce increases in beta activity. For example, elevated beta activity has been found to depend on the degree of cognitive impairment (Coger *et al.*, 1978) and the level of medication administered during withdrawal (Kaplan *et al.*, 1985) in alcoholics, on the presence of depression (Pollock and Schneier, 1990), a positive FHA (Gabrielli *et al.*, 1982; Pollock *et al.*, 1995) or ASPD (Bauer and Hesselbrock, 1993). This multifactorial dependence may also explain why some studies found beta activity to normalize with increasing abstinence (Kaplan *et al.*, 1985; Pollock *et al.*, 1992), while others found beta changes to persist for up to half a year (Costa and Bauer, 1997). Recent work has shown that beta activity can be independent of drinking history, and may index the risk for relapse in alcohol and other substance abusers. Bauer (1994a) found that abstinent alcohol-dependent patients who later relapsed were characterized by enhanced high EEG beta activity while those who would remain abstinent did not differ from controls. Bauer (2001d) extended these findings, demonstrating that fast beta activity significantly predicted later relapse (with 75% accuracy) in a group of alcohol- and drug-abusing subjects. The beta elevation in relapsing subjects was related to increased levels of childhood CD and paternal alcoholism, but not to drug use. In a similar manner, other studies have observed beta elevations in alcohol- and cocaine-dependent (Costa and Bauer, 1997) as well as in 'ecstasy'-using subjects

(Gamma *et al.*, 2000) and these changes were not correlated to the degree of drug exposure. Thus, elevated beta may be a premorbid factor common to the abuse of several substances.

Low alpha activity in alcoholics may also have different sources. Most studies indicate that decreases in alpha activity recover with continued abstinence (Zilm *et al.*, 1981; Pollock *et al.*, 1992), suggesting that alpha is a state-dependent measure, possibly related to transient withdrawal-related CNS hyperexcitability. However, low alpha voltage may also be a heritable trait in a subgroup of alcoholics with comorbid anxiety disorder (Enoch *et al.*, 1999).

Despite the many possible sources for EEG frequency changes, some investigations suggest a general relationship between the degree of EEG changes and the severity of alcoholism or alcohol-related symptoms. Most studies that report EEG deviations have been conducted in hospitalized patients, who typically exhibit the most severe forms of alcoholism in the population. An investigation in young, abstinent, medication-free, non-hospitalized community alcoholics revealed no EEG changes (Emmerson *et al.*, 1987). Similarly, a subgroup of alcoholics with little neurological and cognitive impairment showed a normal EEG compared to both a neurologically and cognitively impaired subgroup (Zilm *et al.*, 1980). Early-onset alcoholics within a larger group of alcoholics were found to have the most EEG abnormalities (Johannesson *et al.*, 1982). As a caveat, it should be said that Emmerson *et al.* (1987) limited frequency analysis to the range between 4–14 Hz, thus excluding most beta activity. Also, the findings in early-onset alcoholics may not be a consequence of severe alcoholism but could mark the presence of a predisposing trait.

The EEG in High-Risk Individuals

A branch of alcoholism research has been concerned with possible EEG differences between non-alcoholic FHP and FHN children and adolescents in order to evaluate potential EEG markers for alcoholism risk, but also to identify the possible contribution of family history status to the findings in adult alcoholics. These studies have either been conducted under baseline conditions or have involved an ethanol challenge. The results were mixed, particularly those concerning baseline EEG findings. A majority of studies reported alpha differences in the baseline or placebo-induced EEG of (predominantly male) FHP children, adolescents and young adults. But while some observed lower levels of slow (<9 Hz) and fast (>9 Hz) alpha activity (Pollock *et al.*, 1983) others found higher levels of fast alpha and no difference in slow alpha activity (Ehlers and Schuckit, 1991; Bauer and Hesselbrock, 1993). Still others reported no alpha differences at all (Kaplan *et al.*, 1988; Cohen *et al.*, 1991). Higher levels of beta have been found in FHP children (Gabrielli *et al.*, 1982), young FHP adults (Bauer and Hesselbrock, 1993), and in a sample of older (65 years) FHP subjects (Pollock *et al.*, 1995), but only in male individuals. Several studies, however, failed to confirm this finding in young FHP men (Kaplan *et al.*, 1988; Ehlers and Schuckit, 1990; Cohen *et al.*, 1991).

As with the studies in alcoholics, the variability in beta findings may have various origins. Bauer and Hesselbrock (1993) found higher beta levels in FHP subjects only in the presence of concomitant ASPD. Some of the older FHP subjects investigated by Pollock and colleagues had relatives with depressive, bipolar or substance use disorders other than alcoholism, but without ASPD. The parents of the FHP children in the report by Gabrielli *et al.* were not only alcoholic, but also included schizophrenic, psychopathic and character-disordered individuals. Thus, it is possible that rather than a positive FHA being the primary determinant of higher beta activity in these studies, other factors such as comorbid ASPD or an inherited risk for personality, mood or psychotic disorder were responsible. In fact, it has been proposed that high beta activity may have a similar function in EEG studies as small P3 amplitudes have in ERP studies: that of an unspecific marker for a spectrum of psychopathology including substance abuse and psychiatric disorders.

The variability in alpha results may reflect a — perhaps genetically mediated — electrophysiological heterogeneity within FHP individuals. Pollock *et al.* (1988) found that two subgroups of young FHP men, formed on the basis of differences in their EEG alpha responses to ethanol, also differed with respect to indices of self- and observer-rated alcohol intoxication. The first group (called HR-A) showed larger ethanol-induced decreases of mean alpha frequency than controls and less self-reported intoxication. The second group (HR-B), which had normal ethanol-induced decreases of mean alpha frequency, showed even fewer signs of self- and observer-rated intoxication, compared to both the HR-A and control group. The authors relate these two different profiles to two different theories of the aetiology of alcoholism. One (Tarter *et al.*, 1984) posits that pre-alcoholics are characterized by excessive physiological lability and are prone to use alcohol because it stabilizes their physiological functions. The other (Goodwin, 1981) postulates that pre-alcoholics have a high 'innate' tolerance to alcohol and are therefore less physiologically sensitive to alcohol. Both theories predict that pre-alcoholics are less subjectively sensitive to alcohol. Obviously, the response profile of subgroup HR-A with their high EEG and low subjective response would be more consistent with Tarter and colleagues' theory, while the low EEG and subjective responses of subgroup HR-B are more compatible with the perspective of Goodwin. There is evidence from other studies that bears on these theories. Abnormally low subjective as well as cardiovascular and electrodermal sensitivity to alcohol indeed seems to be a general characteristic of high-risk, FHP individuals, as evidenced by lower ratings of self-reported intoxication (Pollock, 1992), and reduced heart rate, blood volume amplitude and skin conductance (Finn and Pihl, 1987; Pihl *et al.*, 1988; Finn *et al.*, 1990) after alcohol intake. Schuckit (1994) even found that a low subjective response to alcohol in male adolescents entailed a fourfold risk of developing alcoholism (but no other substance abuse) 12 years later, indicating that subjective sensitivity to alcohol may have predictive power.

In addition, EEG alpha responses to alcohol may be predictive of later alcoholism. A preliminary but intriguing finding by Volavka *et al.* (1996) indicates that the two FHP subtypes identified by Pollock and colleagues may be at differential risk for developing alcoholism. These researchers measured ethanol-induced mean alpha changes in 19-year-old sons of alcoholic fathers and conducted psychiatric follow-up assessments 10 years later. They found that those FHP subjects with the smallest amount of ethanol-induced alpha slowing (corresponding to the HR-B group) developed alcohol dependence 10 years later, whereas those with larger amounts of alpha slowing (the HR-A subjects) were either 'mere' alcohol abusers or without alcohol-related problems.

Ethanol-induced changes of EEG alpha and subjective ratings of intoxication are not unrelated. In a study by Bauer and Hesselbrock (1993) the presence of ethanol-induced alpha slowing (i.e. a relative decrease in fast vs. slow alpha activity) was associated with reduced feelings of intoxication. Interestingly, these researchers also found that alpha acceleration (i.e. a relative *increase* in fast vs. slow alpha activity), as observed in FHP individuals after placebo, was associated with *increased* feelings of intoxication. A related observation was made by Kaplan *et al.* (1988), who found alpha acceleration in FHP individuals after *ethanol*, not placebo, but also associated with higher ratings of intoxication.

By way of summarizing the psychophysiological findings in FHP individuals, we would like to offer the following hypotheses: (1) FHP subjects show a large variability in ethanol-induced alpha frequency changes, which may reflect heritable EEG patterns associated with different subtypes of high-risk subjects that may be predisposed for different types of alcoholism, possibly involving different aetiological pathways; (2) low levels of subjective, and possibly autonomic, sensitivity to alcohol may also predict or

predispose to later alcoholism; (3) ethanol-induced alpha slowing is associated with decreased intoxication, while alpha acceleration is related to increased intoxication in FHP individuals; (4) high levels of beta activity may serve as an unspecific marker for a spectrum of psychopathology including substance abuse and psychiatric disorders.

Although at present these hypotheses do not have a strong empirical basis, they nevertheless outline an area of research whose exploration may be very fruitful for understanding how psychophysiological processes influence, and are influenced by, heritable and environmental risk factors for the development of alcoholism.

COCAINE

ERP/EP

P300

There are relatively few electrophysiological studies in chronic cocaine abusers. This paucity may be due to the fact that cocaine dependence, as opposed to alcoholism, has only recently become a socially relevant problem. Like alcoholics, adult cocaine abusers or addicts have been found to show decrements in P3 amplitude (Herning *et al.*, 1990; Branchey *et al.*, 1993; Kouri *et al.*, 1996; Herning and King, 1996; Biggins *et al.*, 1997; Bauer, 2001b) and delays in P3 latency (Amass *et al.*, 1989; Biggins *et al.*, 1997; Bauer, 2001b). While P3 decrements are quite consistently observed during withdrawal or early abstinence, it is unclear whether P3 amplitudes recover with longer periods of abstinence. Two studies by Bauer (1997, 2001b) reported correlations between increasing time of abstinence from 1 to 5 months and increasing P3a and P3b amplitudes (Figure XVI-5.4). Bauer also found that P3a decrements were seen in cocaine-dependent patients only up to 2 months post withdrawal and then disappeared. Biggins *et al.* (1997), on the other hand, did not find evidence for recovery of P3a amplitudes in patients dependent on cocaine or dually dependent on cocaine and alcohol. However, these patients had been drug free for 2–6 weeks, which is less than the 2 months of abstinence that marked the transition from reduced to normal P3a amplitude in Bauer's 1997

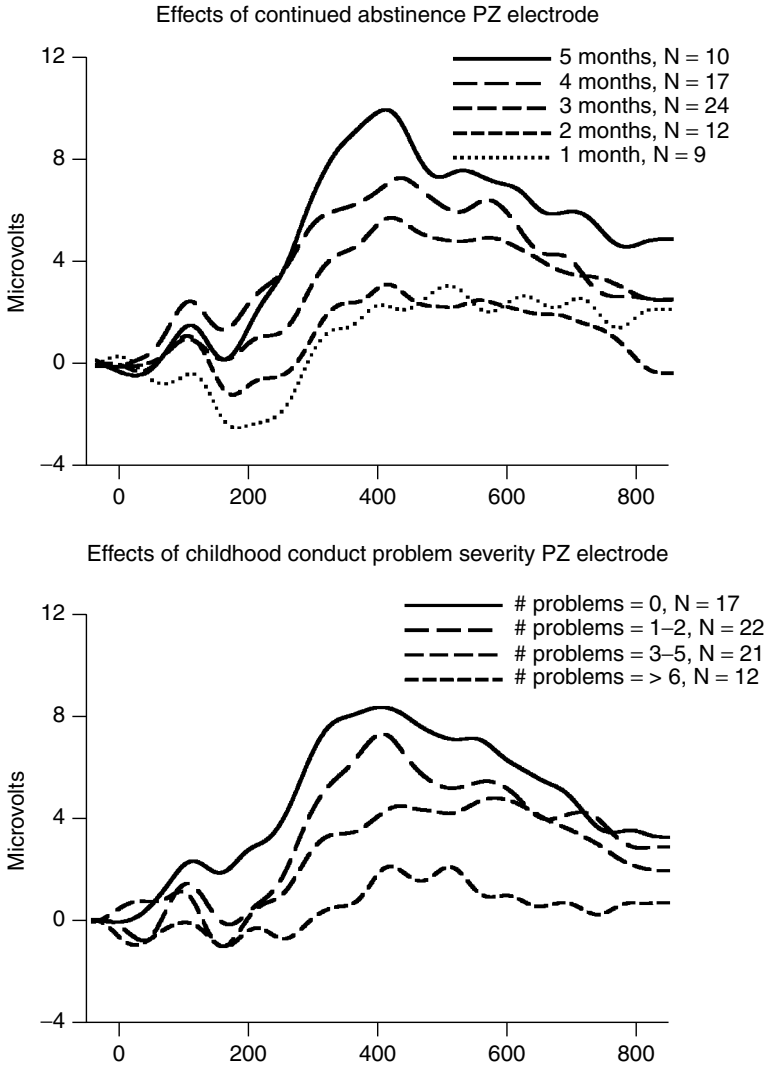

Figure XVI-5.4 Visual P3 amplitude in cocaine-, cocaine–alcohol- and opioid-dependent subjects recovers with increasing time of drug abstinence (above), but decreases with increasing number of childhood conduct disorder symptoms (below). Reprinted by permission of Elsevier Science from 'CNS recovery from cocaine, cocaine and alcohol, or opioid dependence: a P300 study' by Bauer, L.O., *Clinical Neurophysiology* **112**, 1508–1515. Copyright 2001 by the Society of Biological Psychiatry (See Colour Plate XVI-5.4)

study. Thus, shorter periods of abstinence may have obscured a possible relationship between abstinence and P3a recovery in the study by Biggins and colleagues. An earlier study by Branchey *et al.* (1993) appears to be more difficult to reconcile with the notion of P3 recovery. Although these researchers did not assess correlations of P3 size with duration of abstinence, they found reduced P3 responses in cocaine-, opioid- and mixed cocaine-opioid-dependent patients drug free for over half a year, suggesting that P3 does not recover even with prolonged abstinence.

There is, however, a theoretical framework which has gained considerable empirical support particularly by the work of Bauer and co-workers, that could reconcile findings of P3 recovery with the results of Branchey and colleagues. Several investigations by Bauer and co-workers have focused on the influence of an ASPD diagnosis or ASP features such as aggression, impulsivity or psychopathy on ERP characteristics in substance abusers. As we have already seen in our discussion of alcoholism, antisocial personality features are associated with P3 decrements over and above those produced by drug use or family history. In some cases, these features may even solely account for P3 findings previously attributed to the latter sources. The relationship between ASP symptoms and substance abuse does also hold for cocaine abuse. The lifetime prevalence of ASPD in cocaine-dependent patients is about 50%, and conduct disorder (CD), the childhood form of ASPD, is a known risk factor for cocaine abuse. Comorbid ASPD has been found to be linked to P3 decrements not only in healthy subjects (Bauer *et al.*, 1994; O'Connor *et al.*, 1994b) and alcoholics (Costa *et al.*, 2000) but also in cocaine-dependent patients (Bauer, 1997). The latter study included ASPD-negative controls as well as two cocaine-dependent groups, with and without comorbid ASPD. The ASPD-positive cocaine abusers were found to have lower P3a amplitudes than the two other groups, between which there was no difference. Furthermore, P3 size negatively correlated with the number of childhood, but not adult, CD/ASP symptoms (Figure XVI-5.4) (Bauer, 1997, 2001b). Other studies found P3 decrements in relation to aggressiveness, impulsivity or violent behaviour (Branchey *et al.*, 1988, 1993).

These results provide strong evidence that antisocial personality characteristics that predate substance abuse are one important determinant of P3 size. On the other hand, P3 in cocaine addicts also appears to be influenced by chronic drug use, as it is found to recover once the pharmacological stimulation provided by the drug is cut off. Given these two determinants, Bauer (2001b) speculated that pre-existing P3 decrements in individuals with childhood CD may limit the degree to which P3 can recover with prolonged abstinence from cocaine. This means that P3 amplitudes in abstinent cocaine abusers with childhood CD may recover only to the level present before cocaine use, which is still below the level of healthy individuals without childhood CD. Thus, the P3 decrement found by Branchey and colleagues after 6 months of abstinence could reflect the residual effect of childhood CD after P3 recovery from chronic drug use was largely complete. Consistent with this view, these authors in fact found the lowest P3 amplitudes in subjects with high impulsivity or with a history of incarceration. In sum, two effects might operate independently to lower P3 size: the first one is a pharmacological effect of cocaine that recovers within a few months of drug abstinence; after that, any residual decrement in P3 size solely reflects the effect of pre-existing antisocial personality features. An interesting piece of evidence in favour of this view comes from the Bauer (1997) study. He found that the P3a response that recovered with prolonged abstinence was topographically distinct from the P3a that differentiated ASPD-positive from ASPD-negative subjects. The former P3a was more frontally located than the latter, suggesting that there are different neural subsystems that mediate the effects of abstinence and of ASP features. Interestingly, the frontal location of the ASPD-related P3a is consistent with mounting evidence for a frontal dysfunction in aggression, violence and other antisocial behaviours. In sum, substance use and the presence of childhood antisocial personality features make independent, additive contributions to the P3 decrements seen in cocaine- and alcohol-dependent individuals. The ASPD-related contribution may be more frontally located, consistent with evidence for frontal dysfunction in subjects with ASP features.

Other factors such as depression, anxiety, severity of drug use and family history of alcoholism may also influence P3 in cocaine users. Unfortunately, the lack of studies does not offer much of a handle on assessing these factors. The few studies that addressed these issues found no effects of depressive mood, anxiety, duration of cocaine use or a positive FHA (Bauer, 1997, 2001b) on P3 measures. Biggins *et al.* (1997) found auditory and visual P3a amplitudes in cocaine users to be inversely related to the amount or duration of alcohol use, respectively.

Other ERP Components

Very few studies have examined ERP components other than the P3. Two recent studies focused on the P50, an early sensory component occurring about 50 ms after brief auditory stimuli (Fein *et al.*, 1996; Boutros *et al.*, 2000). The P50 is elicited in the absence of a cognitive task and is independent of attentional manipulations. Two paradigms are frequently used to evoke the P50: a trains paradigm involving trains of identical auditory clicks, with P50 becoming smaller as the interstimulus interval decreases; and pairs of auditory clicks, with short intervals between clicks of a pair (e.g. 500 ms) and longer intervals between pairs of clicks (e.g. 7–8 s). In the paired-click paradigm, the P50 response to the second click relative to the first click is suppressed in normal subjects. This 'gating' is thought to reflect a pre-attentive mechanism underlying the filtering out of irrelevant sensory information.

Both studies found P50 gating in the paired-click paradigm to be impaired in cocaine-abusing or -dependent subjects, although this effect just missed statistical significance in the study by Boutros and colleagues. The studies differ in that Fein *et al.* also observed large decreases in P50 responses to the first click, while Boutros *et al.* did not. However, the latter researchers found reduced P50 amplitudes with longer interstimulus intervals in the trains paradigm (this paradigm was not used by Fein *et al.*). The differences between these studies are not surprising given substantial differences in subject selection. Subjects in Fein *et al.* were abstinent from cocaine for 2 weeks, were heavy cannabis and alcohol users, and included cases with neurological or psychiatric disorders secondary to chronic substance abuse. Boutros and colleagues included subjects who had used cocaine in the last 48 hours before testing, but did not use alcohol or other substances and were free of neurological and psychiatric disorders. Despite these differences, both studies indicate that pre-attentive processing as indexed by P50 characteristics are impaired in chronic cocaine users, possibly reflecting impaired sensory gating. Interestingly, the lack of P50 abnormalities in a control group of active alcoholics included by Fein and colleagues indicates that P50 deficits may be specific to cocaine abusers. These authors therefore propose the P50 as a candidate electrophysiological measure that may differentiate between the effects of chronic alcohol and cocaine use.

Findings involving other ERP components are isolated. Biggins *et al.* (1997) reported significant increases in auditory N200 latency and no changes in auditory P200 amplitude or latency. This finding is in agreement with similar results in alcoholic subjects. Bauer (2001a) found the contingent negative variation (CNV), a negative wave in preparation of a motor response, to be subject to the same dependencies as the P3: its size at frontal electrodes differentiated between cocaine abusers with and without APS features, it recovered with increasing periods of abstinence, and

it was relatively unaffected by depressed or anxious mood and the duration of cocaine use. Another study by Bauer and Easton (1996) demonstrated a slight delay of P100 latency in a checkerboard-reversal paradigm, similar to that found in some studies in alcoholics. In a related study, Bauer (1994b) found decreased EEG responsiveness (i.e. decreasing alpha power with increasing light intensity) to square-wave modulated light, but increased responses to sine-wave modulated light, in chronic cocaine abusers. Taken together, it appears that chronic cocaine abuse attenuates the responsiveness of the visual system to square-wave, but not sine-wave modulated input. Since cocaine is known to be a potent vasoconstrictor, and numerous cases of cerebrovascular ischaemic and haemorrhagic complications are associated with its use, these EEG/ERP alterations may originate from detrimental effects on the optic nerve or occipital vasculature. There is also evidence for chronic cocaine effects on olfactory perception. Olfactory-evoked potentials (OEP) in cocaine-dependent patients have been found to be reduced, possibly reflecting damage to the peripheral or even central olfactory apparatus (Bauer and Mott, 1996).

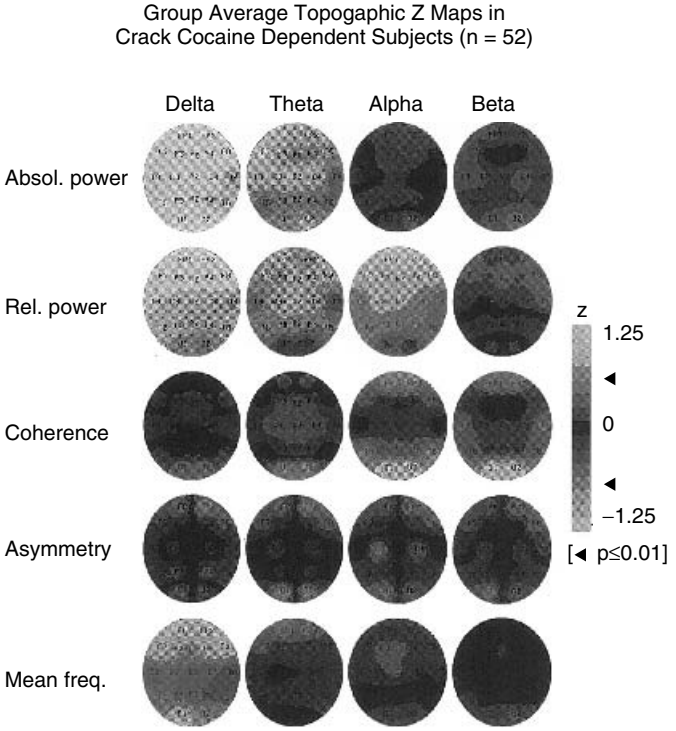

Figure XVI-5.5 Colour-coded topographic brain maps showing differences in absolute and relative power, coherence, hemispheric asymmetry and mean frequency between control subjects and recently detoxified cocaine abusers. Cocaine abusers have decreased absolute and relative slow wave and increased relative alpha power. Quantitative electroencephalographic characteristics of crack cocaine dependence. *Biological Psychiatry* **40**, 986–993, copyright 1996, with permission from Elsevier Science (See Colour Plate XVI-5.5)

EEG

The recency of cocaine abuse as a socially important phenomenon is also reflected in the fact that the first EEG study in cocaine-dependent subjects appeared as late as 1990 (Alper *et al.*, 1990). This study reported increases in alpha activity and decreases in delta and theta activity. Later work only partly replicated these findings. Several studies found decreases in delta and/or theta (Roemer *et al.*, 1995; Prichep *et al.*, 1996, 1999; Herning *et al.*, 1997; King *et al.*, 2000) and increases in alpha activity (Figures XVI-5.5 and XVI-5.6) (Roemer *et al.*, 1995; Prichep *et al.*, 1996, 1999), sometimes paired with elevated beta activity (Roemer *et al.*, 1995; Herning *et al.*, 1997; Prichep *et al.*, 1999; King *et al.*, 2000). Other studies reported beta increases in the absence of alterations in slow wave and alpha activity (Costa and Bauer, 1997), while still others found no EEG changes at all (Bauer and Kranzler, 1994; Bauer, 1994b; Hersh *et al.*, 1995). Finally, one study (Pascual-Leone *et al.*, 1991) found beta elevations together with a pattern of slow wave and alpha activity opposite to the one typically reported, characterized by increased delta and theta and decreased alpha activity. In all bands but delta, changes predominantly occurred in relative compared to absolute EEG activity.

This heterogeneity of findings stems from important differences between the studies, mainly involving criteria for subject selection and experimental procedures. Many researchers have studied samples of cocaine-dependent subjects contaminated by the presence of other substance dependence or abuse or by comorbid DSM Axis I psychiatric diagnoses, all of which are known to have an impact on the EEG. Although these studies certainly reflect the clinical reality, they make it difficult to ascribe positive EEG findings to the chronic use of cocaine alone. For example, it is striking that increases in alpha and decreases in delta activity, although sometimes described as typical for cocaine addicts, are found almost exclusively in studies including subjects with a diagnosis of major depression (Alper *et al.*, 1990; Roemer *et al.*, 1995; Prichep *et al.*, 1996, 1999). It is tempting to speculate that comorbid depression may account for these findings, since increased alpha and decreased delta have been found in clinically depressed patients. Consistent with this view, Prichep *et al.* (1999) found higher depression scores and a higher incidence of concurrent depression in cocaine-dependent patients characterized by excess alpha and reduced delta activity. Roemer *et al.* (1995), however, failed to find any EEG deviations in a subsample of their subjects diagnosed with depression. In addition, some studies (Pascual-Leone *et al.*, 1991; Roemer *et al.*, 1995; Prichep *et al.*, 1996) found changes in delta and alpha frequency to be related to measures of cocaine exposure, although these relations appear somewhat inconsistent. A relation of changes in delta and alpha, but also theta activity, to chronic cocaine use and not depression is further suggested by studies showing that changes in this frequency range do not persist beyond early abstinence (about 1 month). Although not longitudinal in nature, these studies found either no changes (Bauer, 1994b, 1994c), or increased activity exclusively in the beta band (Costa and Bauer, 1997) after several months of abstinence. This may indicate recovery of chronic drug-induced slow wave and alpha abnormalities.

Regarding the increases in beta activity, the situation is very similar to that in alcoholism, and many of the same considerations apply. Although there is some limited evidence that beta activity is related to cocaine exposure (Herning *et al.*, 1997) and partially recovers during early abstinence (Noldy *et al.*, 1990; Noldy and Carlen, 1997), other studies found beta elevations to be unrelated to previous drug use and to persist beyond early abstinence (Costa and Bauer, 1997). Possibly, altered beta activity may reflect both short-term drug effects and long-term premorbid features, similarly as was hypothesized for P3 alterations. These premorbid features could be related to the presence of ASPD (Bauer and Hesselbrock, 1993) or the risk for relapse (Bauer, 1994a; Prichep *et al.*, 1999; Bauer, 2001d). Evidence for a relation of beta to a positive FHA in non-drug-using populations is inconsistent (see section on alcohol). In cocaine users, this relation has been ignored by most studies so far. One exception is Costa and Bauer (1997), who found no effect of a positive FHA on beta activity. Furthermore, beta alterations may be gender specific: King *et al.* (2000) reported that male cocaine abusers abstinent for 6 days have increased

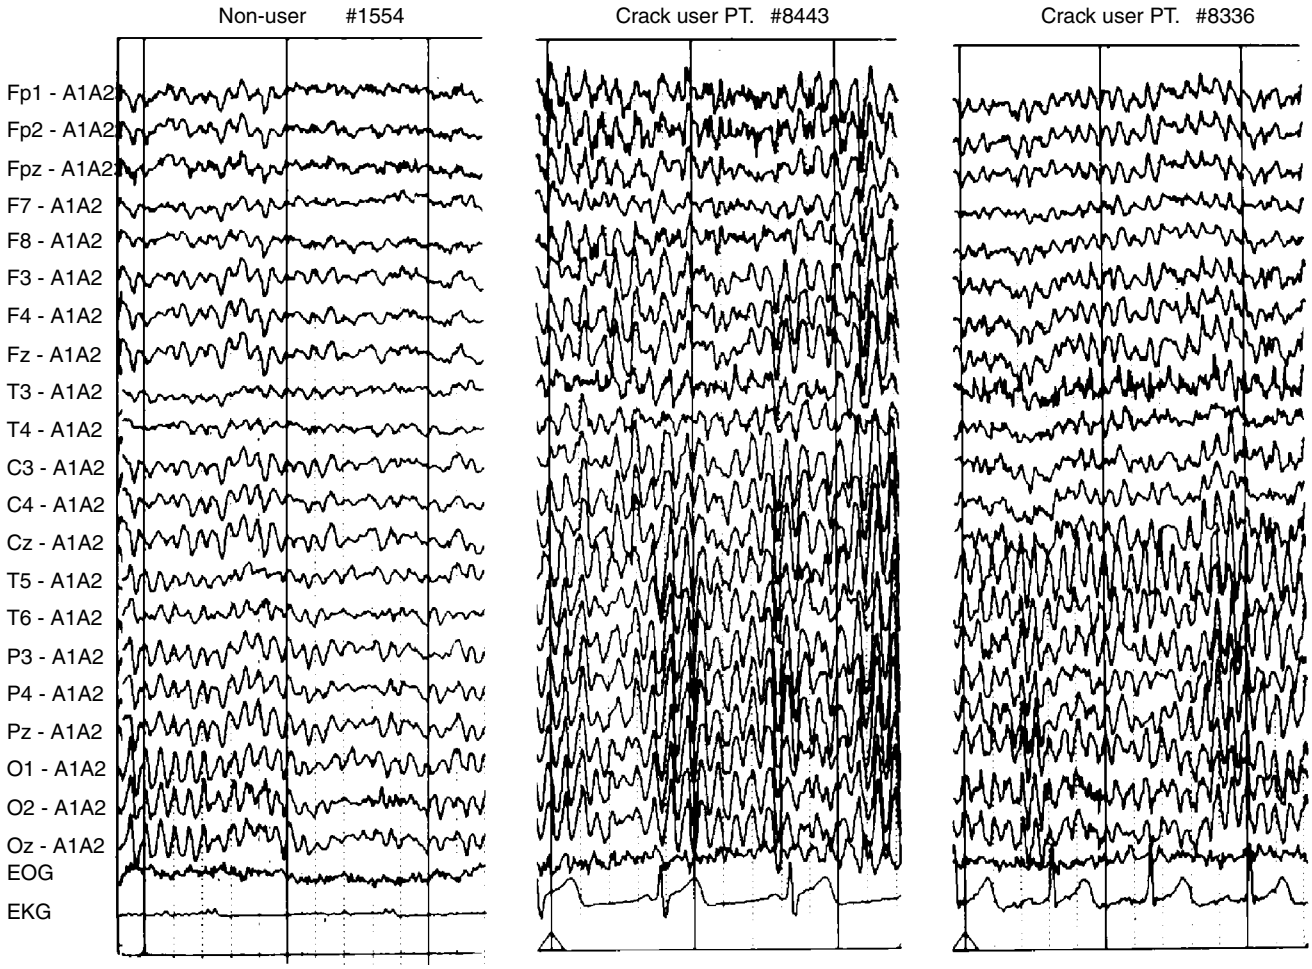

Figure XVI-5.6 Representative 2.5 s EEG epochs from a normal subject and two crack cocaine-dependent individuals. Note the excessive high-amplitude alpha activity (8–10 Hz) in the cocaine-dependent subjects. Reprinted from Alper, K.R., Chabot, R.J., Kim, A.H., Prichep, L.S. and Roy John, E., 1990. Quantitative EEG correlates of crack cocaine dependence. *Psychiatry Research: Neuroimaging* **35**, 95–105, copyright 1990, with permission from Elsevier Science

levels of beta activity compared to matched female cocaine abusers and healthy controls. This increase was not related to psychiatric status, since males had lower psychiatric distress, anxiety and depression than females. A similar failure to relate symptoms of depression and anxiety to beta activity has been reported by Costa and Bauer (1997) and Herning *et al.* (1997). Thus, although a diagnosis of major depressive disorder is commonly associated with increased beta activity (Pollock and Schneier, 1990), it does not appear to account for the presence of beta changes in male and their absence in female cocaine abusers. King and colleagues speculated that, since female compared to male cocaine abusers show a similar absence of changes in regional cerebral blood flow (rCBF), beta increases in male users might stem from a heightened susceptibility to cocaine-induced cerebrovascular complications. Cocaine is a potent vasoconstrictor, and may reduce rCBF through an overstimulation of dopaminergic innervation of cortical vasculature. Reductions of rCBF, in turn, may be linked to heightened beta activity. It has been suggested that women might be relatively protected from these complications by the presence of oestrogens.

A similar neurobiological hypothesis is available for explaining reductions in delta activity, to the extent they are cocaine induced. Some authors (e.g. Prichep *et al.*, 1999) have linked delta decreases to a current theory of the pathophysiology of cocaine dependence. This theory states that chronic cocaine use induces a desensitization of dopaminergic neurons in the ventral tegmental area, which, through inhibitory projections to the forebrain, may lead to a disruption of burst-firing of pyramidal cells in deeper cortical layers. Burst-firing has been implicated in the generation of delta rhythms and its disruption would therefore result in diminished delta wave activity. Functionally, normal delta has been suggested to mediate inner concentration by suppressing extraneous inputs in order to allocate maximal attention. In this view, deficits in delta may have similar consequences as is hypothesized for deficient P50 suppression: a failure of a pre-attentive gating mechanism filtering out irrelevant sensory information.

Finally, methodological differences between studies may account for some of the heterogeneity of EEG findings in cocaine-dependent subjects. Bauer (1994b, 1994c) failed to detect any, including beta, changes in the EEG of cocaine abusers abstinent for 3 months. This result is in contrast to a later study by the same group (Costa and Bauer, 1997), which found beta power to be increased in cocaine addicts after similar abstinence times. In the later study, the researchers attribute their previous negative beta finding to an overly conservative bandpass filter which cut off parts of the relevant beta spectrum.

In conclusion, changes in EEG frequency spectrum in cocaine-abusing or -dependent subjects are probably to some degree effects of cocaine exposure that tend to normalize during abstinence, but may, particularly in the case of increased beta activity, also reflect pre-existing factors possibly related to gender, the risk for relapse or the presence of ASP features. Alpha and delta changes are observed in studies including depressed cocaine addicts, suggesting a contribution of depressive disorder. On the neural level, delta and beta abnormalities may result from hyperactive dopaminergic projections to cortical vasculature and pyramidal cells. Increased beta activity is common to alcoholism and cocaine dependence, but changes in slow wave and alpha rhythms tend to be opposite in alcoholism.

Cocaine/Alcohol Co-Dependence

Both cocaine and alcohol dependence are associated with abnormalities in ERP and EEG measures. The question arises whether co-dependence on both substances produces additive effects greater than those produced by either drug alone. A specific pharmacological mechanism for such an additive effect could be the formation of cocaethylene, a cocaine metabolite that is produced in the liver exclusively in the presence of alcohol. Cocaethylene is more toxic than cocaine and might potentiate possible harmful consequences that alcohol or cocaine use has by itself. It has not been possible so far to examine levels of this metabolite in relation to electrophysiological characteristics of individuals co-dependent on both substances. Some researchers, however, have compared cocaine- and alcohol-dependent subjects with dually dependent subjects with respect to ERP and EEG measures. They found that alcohol/cocaine co-dependent, but not pure alcohol- or cocaine-dependent, subjects had normal EEGs (Costa and Bauer, 1997). Two other studies (Biggins *et al.*, 1997; Bauer 2001b) found P3 decrements similar in magnitude in both cocaine-dependent and cocaine/alcohol-co-dependent patients. It therefore appears that co-dependence on alcohol and cocaine does not affect ERP and quantitative EEG measures to a greater extent than cocaine dependence alone. Some have argued that this may be so because chronic cocaine effects on the ERP are larger (Bauer, 1996) and obscure the additional smaller contribution of alcohol use. There is, however, isolated evidence from clinical EEG evaluation for a unique effect of alcohol/cocaine co-dependence. Roemer *et al.* (1995) reported a pattern of abnormal alpha bursts with paroxysmal characteristics they call C-complexes. This pattern was observed in co-dependent, but not in pure cocaine- or alcohol-dependent, patients. The authors consider the possibility that C-complexes are a consequence of cocaethylene formation. Future studies should clarify whether this finding is replicable and can be quantified. Possibly, also animal electrophysiological studies involving the administration of cocaethylene could shed light on this issue.

OPIOIDS

ERP/EP

Although opioids are among the most addictive drugs, there has been very little electrophysiological research into their chronic effects. Opioid addicts are often concurrently dependent on cocaine, therefore the effects of pure opioid abuse are difficult to investigate. There is one study that compared nearly pure opioid-dependent male and female patients with cocaine-dependent, cocaine–alcohol-co-dependent and control subjects (Bauer, 2001b). All drug-using subjects, who were abstinent for 1–5 months, were found to have significantly lower P3 responses in a visual ERP paradigm. Opioid-dependent patients exhibited the lowest P3 of all drug users, but they were essentially not different from them in terms of demographic, psychological or substance use characteristics. P3 amplitude significantly decreased with increasing number of childhood symptoms of conduct disorder and with increasing duration of abstinence, but was not affected by a positive FHA, depression, anxiety, duration of drug use or the number of drug-related problems. These findings agree with a smaller study in male opioid and opioid–cocaine-dependent patients abstinent for over half a year (Branchey *et al.*, 1993). These researchers found reduced auditory P3 amplitudes in all drug-using subjects, with lowest amplitudes found in subjects with a history of incarceration. P3 amplitudes significantly decreased with increasing impulsiveness. Taken together, these two studies suggest that P3 decrements in opioid addicts are related to pre-existing antisocial personality characteristics present in childhood and/or adulthood, but also to opioid exposure as evidenced by their dependence on the length of abstinence.

A somewhat different interpretation of P3 decrements is suggested by results from Kouri *et al.* (1996). These researchers found auditory P3 decrements in male opioid–cocaine co-dependent patients *after*, but not *before*, detoxification. This may indicate that P3 reductions are a sign of drug withdrawal rather than previous drug exposure or pre-existing antisocial symptoms. If this were true, however, then these abnormalities would be expected to normalize with prolonged abstinence, which does not seem to be the case.

One study (Bauer, 1998) used pattern-shift VEPs to compare a group of opioid-dependent patients, abstinent for 2–4 months, with two groups of recent opioid users maintained on methadone, one positive and one negative for HIV, and a control group. Compared to the controls and the abstinent users, methadone-maintained opioid patients showed significantly delayed N75 and P100 components. N75 latency significantly correlated with the duration of opioid abuse, but not with duration of cocaine, alcohol or other drug use, length of abstinence or methadone levels. Possibly, altered N75 shows some specificity to opioid abuse, while P100 alterations have also been found in alcohol and cocaine abusers.

EEG

The EEG in chronic opioid addicts is largely unexplored territory. An early study by Volavka *et al.* (1970) reported irregularities in the clinical EEG of 50% of 64 heroin-dependent patients abstinent for at least 1 week. Recently, Costa and Bauer (1997) have resumed this line of research. They recorded the resting EEG in groups of alcohol-, cocaine- and opioid-dependent patients and control subjects. The opioid group included cases with concurrent cocaine or alcohol dependence. All patients were abstinent from their drug of choice for 1–6 months. As we have discussed in the previous sections, both the alcohol- and cocaine-dependent group showed increased EEG beta power. The authors concluded that enhanced beta activity, being common to both drugs, may not be a consequence of drug use, but a premorbid factor. However, the lack of beta abnormalities in the opioid-dependent patients seemed to challenge this interpretation, since these were the subjects with the highest prevalence of premorbid features such as CD, ASPD and other risk factors. To address this concern, Bauer (2001c) reanalysed this data set, hypothesizing that premorbid beta enhancement is indeed present in opioid patients, but masked by the antagonizing effect of chronic opioid exposure. He compared two subgroups of the opioid group, one with less and one with more than the median number of years of opioid abuse (6.5 years). Compared to the controls, those patients with less than 6.5 years of opioid use showed significantly more beta power, while those with longer histories of opioid use showed significantly less beta power and an additional increase in alpha power, similar to that previously found

in active opioid abusers (Shufman *et al.*, 1996). The dramatic EEG slowing associated with a longer history of opioid use suggests a drug-induced progressive beta reduction. On the other hand, the beta enhancement present in patients with shorter drug histories still leaves room for premorbid influences, possibly related to antisocial personality traits.

CANNABIS

ERP/EP

ERP findings in chronic cannabis users appear to be inconsistent. Most frequently, reduced amplitudes and prolonged P3 latencies were found in chronic cannabis users (reviewed in Patrick *et al.*, 1995). Struve and Straumanis (1990) measured auditory ERPs in psychiatric inpatients with a history of chronic cannabis use compared to non-cannabis-using psychiatric patients and normal controls. P3 responses were significantly reduced and delayed in the cannabis group compared to both non-user groups. Because psychiatric comorbidity and medication effects were not controlled for in this study, the investigators repeated the study with daily cannabis users and non-user controls that were both psychiatrically screened to be healthy volunteers (Patrick *et al.*, 1995). Auditory and visual P3 responses were elicited by a relatively simple oddball paradigm. The researchers found no differences in test performance, but the cannabis users displayed reduced auditory and near-significantly reduced visual P3 amplitudes. However, when age differences between the cannabis users and controls were statistically removed, significant P3 differences were removed as well. These results illustrate the need for well-matched control groups. They further indicate that reduced P3 in chronic cannabis users may only be found in those with comorbid psychopathology.

However, it is of note that there were no differences in test performance between the cannabis users and non-users in that study, although such differences are commonly found when difficult tasks are used. Solowij *et al.* (1991) recorded ERPs from long-term pure cannabis users during a complex multidimensional auditory selective attention task, where users performed clearly worse than controls. Subjects had to respond to stimuli that were long-duration tones of a particular pitch and location, with all three factors being varied. P3 amplitudes were found to be decreased in cannabis users as opposed to controls. Thus, a P3 task with difficult target–non-target discrimination is needed to detect any differences in P3 amplitudes between cannabis users and non-cannabis-using subjects. Another interesting finding observed in the user group of the Solowij *et al.* study was enhanced early processing negativity to short-duration stimuli which matched the target on location only. According to the investigators, this would be indicative of users engaging in unnecessary pitch processing and thus having difficulty in setting up an accurate focus of attention and in filtering out irrelevant information. This finding may reflect a dysfunction in the allocation of attentional resources and stimulus evaluation strategies in cannabis users, similarly as it is hypothesized for alcoholics.

In a further study Solowij *et al.* (1995) confirmed and extended their findings of cognitive impairments and related ERP changes in a group of cannabis users who had used cannabis for a mean time of 6.7 years at a mean frequency of three times per week. It appeared that frequency and duration of cannabis use differentially affected cognitive functions as assessed by this ERP paradigm. Frontal processing negativity to irrelevant stimuli was increased, indicating a decreased ability to focus attention and filter out irrelevant information, and this effect was progressive with the number of years of use, but was unrelated to frequency of use. In contrast, the speed of information processing, as measured by the latency of P3, was delayed significantly with increasing frequency of use, but was unaffected by duration of use. Solowij *et al.* note that with regard to the real world these ERP findings may reflect increased distractibility and hence impairment in any situation where concentration and focused attention are essential. In addition, long-term effects of cannabis may only become readily apparent after about 5 years of exposure.

Patrick *et al.* (1999) compared auditory P50 measures in chronic, psychiatrically normal daily cannabis users and control subjects. P50 suppression was reduced in the cannabis users. These sensory gating deficits were not significantly associated with the duration or frequency of cannabis use in this study, but were correlated with the frequency of cannabis use per week in another small group of cannabis users assessed by the same researchers (Patrick and Struve, 2000).

In sum, although there is evidence that chronic cannabis use might be associated with electrophysiological changes including reduced and delayed P3 responses and deficits in sensorimotor gating, these data are inconclusive given the small samples and the many possible confounding factors. Particularly, most cannabis users assessed in studies so far have also used cannabis on the days prior to the test session and cannabis intoxication may therefore be an important confounding factor given the long half-life of THC plasma levels. Nevertheless, the electrophysiological changes described above might reflect subtle impairments of memory, attention and processing of complex information in chronic cannabis users. It remains unclear, however, to what extent these deficits relate to a state of chronic intoxication with cannabis that would be reversible after prolonged abstinence. Since cannabis is the most widely used recreational drug, the effect of chronic cannabis administration should be more thoroughly studied.

EEG

A number of clinical EEG studies in the 1970s (reviewed in Struve and Straumanis, 1990) reported mild qualitative EEG abnormalities in casual to chronic cannabis users. Many of these studies, however, failed to include normal control subjects or to report population base rates of such abnormalities. Moreover, the effects of polydrug abuse or concomitant psychiatric or medical pathology were not considered. Finally, clinical, qualitative EEG assessment is based on subjective judgement and the decision what to count as abnormal is therefore prone to rater bias. This effect is particularly concerning when, as was mostly the case, intra- or interrater reliabilities are not reported or the rater is not blind to experimental condition or subject status. The prevalence of EEG abnormalities in most of these early studies ranged from 0 to 17%, which is in fact not higher than that in the normal population. Those studies that did include control groups confirmed that the prevalence of abnormal EEG findings was similar for cannabis users and normal subjects. One early study reported striking rates of EEG abnormalities as high as 90%. However, this study was severely criticized for methodological flaws by several authors. Early quantitative EEG studies of chronic cannabis effects have also often not compared cannabis users with control groups, but instead focused on the effects of daily cannabis consumption by very small numbers of normal subjects over several weeks under experimental observation. Two such studies found evidence for time-dependent increases in alpha and theta, and decreases in beta activity. One early study that included cannabis users and an age- and sex-matched control group reported increased delta activity and coherence, increased theta activity and, contrary to the other studies, decreased alpha. In a more recent qEEG study, Struve and colleagues found elevations of absolute and relative power and interhemispheric coherence of alpha activity over the frontal cortex in cannabis using inpatients, but also in healthy daily cannabis users, compared to non-users (Struve *et al.*, 1989). Although differences in psychiatric diagnosis,

medication and the use of other drugs were not controlled for, these results were later confirmed in a replication study in an independent sample. In addition, a more recent investigation by the same researchers (Struve *et al.*, 1998), including cannabis users free of serious psychopathology and without significant use of other drugs, found that users with previous daily exposures to cannabis for 15–24 years had more absolute theta power over the frontal cortex than non-users or subjects who had used cannabis for a shorter period (Struve *et al.*, 1998). This theta increase apparently developed with increasing duration of cannabis use. Trudeau *et al.* (1999) analysed EEG data from subjects with mixed cannabis and stimulant use disorder. In the stimulant-only group, relative power differences were dramatic and included diffuse frontal and right parietal excess alpha and deficit theta, as well as diffuse deficit beta. Cannabis and stimulant dependence together produced more EEG changes than either drug alone. In the absence of stimulant use, however, the EEG effects of cannabis were relatively small. There was only a moderate deficit in frontal relative delta power which was not seen in the stimulant-only group. Thus, the Struve *et al.* findings of alpha hyperfrontality were not replicated. However, subjects in the Trudeau *et al.* study were abstinent for at least 1 month, whereas Struve and colleagues tested active cannabis abusers. Possibly, alpha hyperactivity is a withdrawal-related EEG characteristic that disappears with prolonged abstinence.

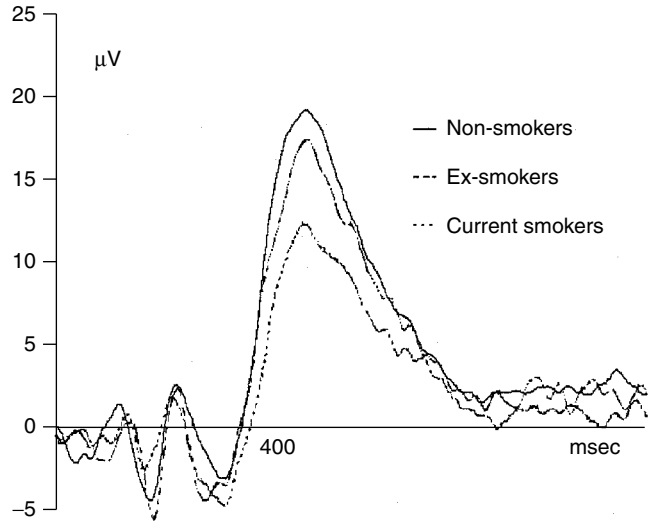

Figure XVI-5.7 Visual P3 amplitudes at the parietal lead in non-smokers, ex-smokers and current smokers. Current smokers show significant P3 decrements compared to both controls and ex-smokers. The P300 brain potential is reduced in smokers. *Psychopharmacology* **149**, 409–413. Copyright 2000, Springer-Verlag

NICOTINE

ERP

Most studies involving electrophysiological techniques focused on acute effects of nicotine rather than on chronic changes due to nicotine dependence. The literature on possible ERP alterations in smokers compared to non-smokers is therefore very scant. Among the very few studies, Anokhin *et al.* (2000) assessed P3 of the ERP in 17- to 74-year-old current daily tobacco smokers, ex-smokers and never-smokers in a large sample drawn from the COGA. Smokers consumed a mean number of 20 cigarettes daily. Ex-smokers used to smoke a mean number of 19 cigarettes daily and quit smoking 1 year or more prior to the study. Never-smokers had never smoked on a daily basis for a month or more. A visual oddball task was used to elicit ERP responses. Visual P3 amplitude was significantly lower in current smokers compared to never-smokers, while ex-smokers did not differ from never-smokers (Figure XVI-5.7). In addition, there were smaller but significant reducing effects of alcoholism and family density of alcoholism (FDA) on P3 amplitude. However, the effect of alcoholism (and other substance dependence) was no longer significant after adjusting for current smoking and FDA, while the FDA effect remained significant after controlling for smoking and alcoholism. In fact, smoking and family density of alcoholism diminished P3 amplitude in an additive fashion. Psychopathology, drinking and use of medication did not affect P3. The researchers speculate that P3 amplitude reduction may be a consequence of chronic tobacco smoking and may reflect a reversible change in brain function. Alternatively, low P3 amplitude may indicate greater vulnerability to nicotine addiction and, specifically, a reduced ability to quit smoking. Low P3 may therefore be associated with smoking persistence and dependence rather than with smoking initiation itself. Regardless of which possibility is true, a potentially grave implication for alcoholism research follows from these results: Since alcohol and nicotine dependence are highly comorbid (as was also the case in this study), uncontrolled nicotine co-dependence might be responsible for a substantial part of the P3 amplitude reduction seen in alcoholics or other substance-dependent individuals.

Knott *et al.* (1999) found no P3 alterations in a small sample of smokers from a similar age range (18–81 years). However, in contrast to Anokhin and colleagues, these researchers used an auditory ERP paradigm, and this difference in task modality may account for the divergent findings. Indeed, a similar failure to detect P3 decrements after auditory, but not visual, paradigms is observed in studies of alcohol-dependent or FHP individuals.

EEG

The EEG effects of both current smoking and short-term smoking abstinence have been studied. Knott and colleagues (Knott and Harr 1996, 1997) have examined spontaneous EEG activity in their sample of 18- to 81-year-old smokers and non-smokers presented above. The EEG was recorded before and after sham smoking in non-smokers and cigarette smoking in smokers. Smokers evinced higher beta activity and interhemispheric alpha coherence. The beta findings are reminiscent of similar findings in alcohol and cocaine users. The same group as well as other researchers have also studied the EEG within the first 2 days of smoking abstinence and found an EEG slowing characterized by increased slow wave power and a decrease of dominant alpha frequency (Pickworth *et al.*, 1989; Knott, 1990). This EEG slowing continued throughout 10 days of abstinence, and returned to pre-quit levels after resumption of smoking (Pickworth *et al.*, 1989). Only one well-controlled study monitored physiological and subjective changes during a longer period of abstinence. Gilbert *et al.* (1999) studied male smokers using EEG, mood questionnaires, a visual rapid information-processing task, and measurements of heart rate during eyes-closed and eyes-open relaxation and stress conditions. Subjects were first measured at baseline and were then randomly assigned to a quit vs. a continue-to-smoke group. Quitters and smokers were later reassessed on the same days, corresponding to days 3, 10, 17 and 31 of abstinence for the quitters. Compared to smokers, quitters showed increased delta, theta, slow alpha and slow beta power as well as a decrease in mean alpha frequency. The slow alpha difference was most pronounced over the posterior scalp. Post-quit heart rate was decreased in the quitters. Importantly, these

changes did not resolve across 31 days of abstinence. In general, EEG, heart rate and mood changes were highly dependent on condition (eyes closed vs. eyes open, stress vs. relaxation). Pre-quit nicotine exposure was positively correlated with alpha slowing on day 3, but not later. Higher trait depression was correlated with increases in left-greater-than-right slow alpha power on days 3 and 31.

The authors draw several conclusions from their findings. EEG slowing lasted for the entire 31 days of abstinence, indicating that it may be permanent or recover very slowly. The correlation of pre-quit nicotine exposure with EEG slowing on day 3 suggests that the initial portion of EEG slowing may reflect a transient abstinence effect. The correlation of trait depression with hemispheric alpha asymmetry on days 3 and 31, on the other hand, indicates a sustained effect. Subjects with high trait depression had greater left than right-frontal alpha power during abstinence along with increased depressiveness. Relatively decreased activity in the left compared to the right-frontal cortex has also been found in clinical depression and depressive mood states. These findings therefore support the hypothesis that smoking abstinence results in frontal EEG asymmetries that predispose depression-prone individuals to depression. Conversely, there is evidence that nicotine might attenuate depressive and other negative affective states by reducing right-frontal and enhancing left-frontal information processing.

Startle Reflex

The startle reflex is a response to a sudden, intense stimulus that can be observed across different species and sensory modalities. In humans, presentation of a loud startling noise (pulse) leads to a sharp eye-blink response. Pre-pulse inhibition (PPI) of the startle reflex refers to a reduction in the magnitude of the eye blink when the startling pulse is preceded by a weak pre-pulse, which itself does not evoke a measurable response. PPI is thought to reflect a pre-attentive sensorimotor gating process that serves to filter out irrelevant stimuli and protect against stimulus overload. Deficits in PPI have been found in disorders in which sensorimotor gating is thought to be deficient, such as schizophrenia.

There are few studies of the startle reflex and PPI in smokers. They showed that nicotine dependence has no effect on the magnitude of the startle response (Mueller *et al.*, 1998), but strong relative to weak dependence is characterized by reduced PPI (Kumari and Gray, 1999). Mueller and colleagues compared healthy male and female non-smokers to smokers after either prolonged, brief or no smoking deprivation in experimental sessions at baseline, after smoking-cue exposure and after cigarette smoking. No group differences in startle magnitude emerged for any session. Kumari and Gray studied healthy male smokers after overnight smoking withdrawal. Smokers with high nicotine dependence scores had significantly less PPI than those with low nicotine dependence.

Three explanations for these findings are conceivable. Increasing levels of nicotine dependence could lead to increasing cumulative levels of nicotine-induced neurobiological alterations that may manifest in decreased PPI. Alternatively, the heavily nicotine-dependent subjects may have suffered more severe withdrawal symptoms after overnight smoking withdrawal, which may have been reflected in lower levels of PPI. Finally, heavy nicotine intake may be an attempt to restore some trait-like cognitive deficit through self-medication, and this deficit could be indexed by deficient PPI. In this case, reduced PPI would reflect a premorbid characteristic of smoking dependence, similar to that hypothesized for alterations of P3 and EEG beta in other substance abusers. Future research will show which one of these alternatives is most likely.

AMPHETAMINES

ERP

While some studies have examined ERPs, we were unable to find studies of EEG in subjects dependent on amphetamine or its close congeners (the amphetamine derivative MDMA will be covered in the next section). There is a research tradition concerned with the study of methamphetamine dependence and psychosis in Japan. That country has seen two epidemics of methamphetamine abuse, the first shortly after the Second World War, the second starting in the 1970s. Iwanami and colleagues conducted several studies to assess the effects of chronic methamphetamine-induced psychosis on ERP measures (Iwanami *et al.* 1991, 1994, 1995, 1998). In their earlier studies (Iwanami *et al.*, 1991, 1994), these researchers found delayed P3 latency and reduced frontal and central, but not parietal, auditory P3 amplitudes in remitted methamphetamine psychotics receiving antipsychotic medication. A later study (1995) in unmedicated subjects revealed no significant delays in P3 latency and only a non-significant decrease in P3 amplitude. However, this study found a reduced area under the negative-difference wave spanning the period of 0 to 400 ms after stimulus onset. This wave is associated with attention to stimuli in the attended channel, and its reduction may indicate impaired auditory stimulus processing in methamphetamine psychotics. Recently (1998), these authors extended their investigation to the frontal P3a component of the ERP and found reduced P3a amplitude and area with delayed P3b latency, but normal P3b amplitude, in neuroleptic-maintained methamphetamine abusers abstinent for at least 2 weeks. P3a amplitude reductions are also present in patients with prefrontal lesions, and may thus indicate frontal damage in methamphetamine psychotics. However, the fact that Iwanami and colleagues have found P3 deficits only in medicated patients indicates that they may be related to antipsychotic medication rather than to chronic methamphetamine abuse. On the other hand, the abnormalities in the attention-related negative-difference wave are consistent with similar findings in amphetamine-dependent patients. The Australian researchers McKetin and Solowij (1999) compared highly and weakly dependent amphetamine users on ERP measures in a selective attention task that involved detecting infrequent long-duration target tones presented among short-duration tones that varied in location and pitch. Highly dependent amphetamine users were found to have reduced early processing negativity and peak N1 amplitudes. Early processing deficits were correlated with poor task performance and with poor attention and concentration. Taken together, these findings are consistent with the view of a dysfunction in selective attention in severe chronic amphetamine or methamphetamine abusers. Iwanami and colleagues also point out the similarities between their findings and those in schizophrenic patients, which support the hypothesis that methamphetamine psychosis may be a model for paranoid schizophrenic psychosis.

MDMA ('ECSTASY')

MDMA (3,4-methylenedioxymethamphetamine) is the main component of the drug 'ecstasy', which is predominantly consumed in clubs and at weekend 'raves' where users dance to 'techno' music. In public and scientific circles, MDMA has generated interest mainly due to its possible harmful effects. In particular, a wealth of animal studies showing that high or repeated doses of MDMA can cause massive depletion of central serotonin and damage to serotonergic cell bodies have raised concern over the possibility of similar neurotoxic damage in human MDMA users. While to date these concerns have mainly been addressed and supported in neuropsychological, neuroendocrinological and neuroimaging research, there are a few relevant psychophysiological studies.

ERP

Tuchtenhagen *et al.* (2000) recorded auditory evoked potentials with stimuli of increasing intensity in abstinent 'ecstasy' users with concomitant cannabis use, and in two matched control groups of cannabis users and non-users. 'Ecstasy' users had consumed about 3.5 tablets per month over an average period of 27 months, which is not a very heavy use, and were abstinent for a mean duration of 3 weeks. The intensity dependence of the tangential auditory evoked N100/P200 dipole source activity was assessed. This measure is analogous to the amplitude–intensity (A/I) gradient that we discussed in the section on alcohol. As we saw, alcoholics show increasing VEP responses to increasing stimulus intensities (positive A/I slopes), while non-alcoholic controls do not. This response is typical for so-called augmenters, who tend to increase physiological reactions to increasingly intense stimuli. Furthermore, high-intensity dependence of the VEP and N100/P200 response is thought to reflect low functioning of serotonergic neurotransmission in the primary sensory cortex. Thus, this measure may shed light on the possibility of serotonergic dysfunction in 'ecstasy' users. Confirming this hypothesis, Tuchtenhagen and colleagues found that 'ecstasy' users exhibited an increase of the amplitude of the tangential dipole of the N100/P200 component with higher stimulus intensities, whereas both control groups failed to exhibit this feature. These findings support other evidence for an 'ecstasy'-induced impairment in serotonergic brain function. Another possibility to be considered is that these results reflect pre-existing personality traits such as high novelty-seeking and impulsivity which are typical in drug users. However, several arguments speak against this possibility: high-intensity dependence did not correlate with these personality features. Moreover, not only the 'ecstasy', but also the cannabis control group exhibited higher levels of these personality traits, without showing high-intensity dependence. Finally, the intensity dependence in the 'ecstasy' users was more pronounced than that reported in healthy subjects with high novelty-seeking. In conclusion, high-intensity dependence may be a result of chronic exposure to 'ecstasy', and may possibly indicate central serotonergic dysfunction in 'ecstasy' users.

EEG

Dafters *et al.* (1999) examined eyes-closed resting EEG in moderate recreational 'ecstasy' users abstinent for at least a week. No control group was included, and the analysis was focused on correlations of qEEG variables with variables of drug exposure, mood and cognition. The effects of the use of other drugs were statistically partialled out. 'Ecstasy' use during the previous 12 months was found to correlate positively with absolute power of global alpha and left-posterior beta, and to correlate negatively with relative delta power and with posterior EEG coherence for the 1–20 Hz frequency range. There were no significant correlations with the severity of depression and several cognitive measures of memory and intelligence. The general dose dependence of the EEG findings supports the notion that increasing 'ecstasy' use produces increasing changes in brain function. Dafters and colleagues point out that the pattern of spectral EEG changes is reminiscent of the normal effects of ageing on the EEG. The exposure-dependent decrease of EEG coherence, a measure of the synchronization of firing between paired cortical locations, may indicate dysfunctional brain connectivity as evidenced in studies of dementia, ageing, depression and HIV-related cognitive impairment. Gamma *et al.* (2000) compared moderate-to-heavy 'ecstasy' users and control subjects on measures of mood and resting EEG activity recorded from 31 channels during open and closed eyes. The EEG was analysed by means of conventional power analysis as well as source localization using low-resolution brain electromagnetic tomography (LORETA; Pascual-Marqui *et al.*, 1994; Pascual-Marqui, 1999). While conventional analysis revealed no main effects of group for global absolute power, LORETA indicated increased global power of theta, slow alpha and fast beta. In an analysis of channel-wise absolute power, fast beta power was found to be higher at all recording sites during open, but not closed, eyes. Furthermore, both conventional power analysis and LORETA showed a significant increase in fast alpha power in the right temporo-occipital cortex during both open and closed eyes (Figure XVI-5.8). 'Ecstasy' users had higher levels of depressiveness which highly correlated with increases in beta power (Gamma *et al.*, unpublished data). The elevations of absolute alpha and beta power are in line with the findings of Dafters and colleagues. In contrast to the latter study, however, EEG variables were not correlated with the level of MDMA exposure (unpublished data), while beta changes were related to higher depressiveness. This finding is particularly intriguing in the light of consistent findings of increased beta activity in depressed patients. Together with the fact that increased beta is also common to alcohol and cocaine dependence, these results support the view that beta hyperactivity is a premorbid characteristic of individuals predisposed to substance abuse.

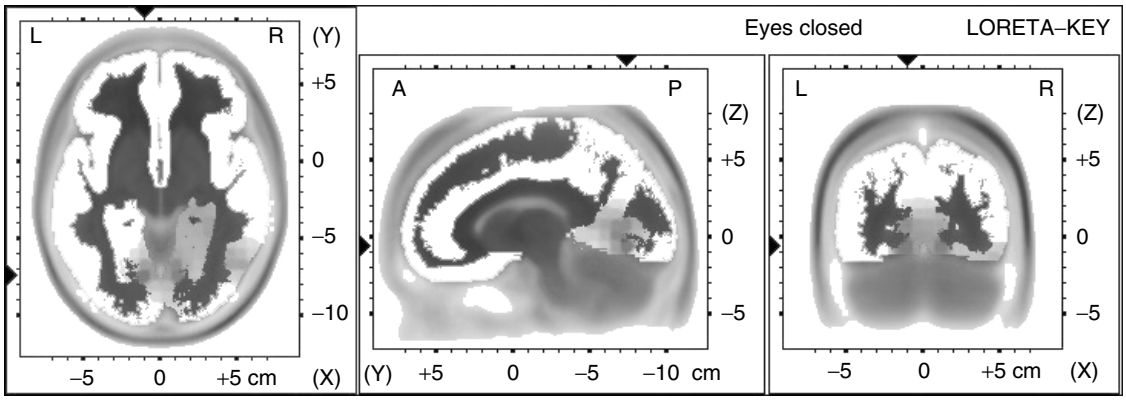

Figure XVI-5.8 Tomographic images displaying differences in fast alpha activity between MDMA ('ecstasy') users and control subjects. 'Ecstasy' users show significant increases (orange colour) in right temporo-occipital fast alpha power during closed eyes. Images have been computed from 31-channel scalp EEG recordings using low-resolution brain electromagnetic tomography (LORETA). Data from Gamma *et al.* (2000) (See Colour Plate XVI-5.8)

OTHER DRUGS

The psychophysiological literature on the chronic use of other widespread psychoactive drugs such as benzodiazepines and hallucinogens is virtually non-existent. Abraham and Duffy (1996) recorded EEG and sensory evoked potentials in LSD users suffering from hallucinogen persisting perceptual disorder (HPPD). HPPD is characterized by chronic visual hallucinations persisting beyond acute drug effects. HPPD subjects evinced faster alpha frequency and shorter visual EP but prolonged auditory EP latencies compared to a matched control group. These differences were most prominent in temporal and left parietal scalp areas. According to the authors, these changes possibly reflect cortical disinhibition and demonstrate differential effects of LSD use on auditory vs. visual systems.

Severely benzodiazepine-dependent patients were assessed during slow withdrawal by Hallstrom and Lader (1981). Heightened levels of anxiety and perceptual disturbances as well as decreases in EEG beta activity occurred during the withdrawal period but subsided after 2 weeks.

CUE REACTIVITY

Studies of cue reactivity in substance users are, to a large degree, conceptually independent of other types of psychophysiological substance use research. Moreover, these studies concern reward and motivational mechanisms that — as evidenced by a growing body of literature (see other chapters in this book) — may operate in a similar fashion across different drugs, owing to a common neurochemical basis. Therefore, we will treat this topic in one place only, integrating the findings from different drugs of abuse.

In the present context, cue reactivity refers to subjective and physiological reactions to visual, auditory or behavioural cues related to the use of a drug. These cues can be photographs, video or audio material, or they may involve the presence of drug paraphernalia or require subjects to engage in drug preparation rituals. It has been proposed that these reactions are conditioned responses in the classical Pavlovian sense, whereby environmental stimuli closely associated with the act of using a drug become capable by themselves of eliciting some of the subjective and physiological changes that normally occur in response to the drug. Such conditioned responses are considered important because it is believed that they constitute a major motivation for readministering the drug and may thus increase the risk for relapse and treatment failure. Although this putative conditioning occurs in the user's natural environment and cannot therefore be directly observed in the laboratory, it is possible to obtain experimental evidence that can be seen as counting towards the conditioning hypothesis. If cue reactivity in fact reflects past conditioning, then drug abusers should show stronger subjective and autonomic responses to drug-related cues than non-drug controls, and should show stronger responses to drug-related cues than to neutral cues or to cues related to substances other than the drug of choice.

The available studies (reviewed in Niaura *et al.*, 1988) have in fact consistently produced these results. With regard to autonomic reactivity, alcoholics frequently showed greater increases in heart rate, skin conductance and salivation in response to drinking-related cues than to other cues or compared to control subjects. Occasionally, increased changes in blood pressure, skin temperature and alpha waves were also reported. Increased autonomic reactivity to drug-related cues has also been found in smokers (Rickard-Figueroa and Zeichner, 1985; Saumet and Dittmar, 1985) and opioid addicts (Childress *et al.*, 1986; O'Brien *et al.*, 1986). Cocaine abusers showed increased skin conductance and heart rate, and decreased skin temperature following exposure to cocaine-related cues compared to non-drug controls (Negrete and Emil, 1992; Robbins *et al.*, 1997). These cues included the presentation of video tapes showing the buying and administering (e.g. 'free-basing' = smoking) of cocaine, audio tapes featuring users talking about their experiences with using cocaine, or even required subjects to engage in the preparation of surrogate cocaine powder for smoking. The same kind of cues related to other drugs, e.g. opiates, as well as neutral cues were not or much less effective in triggering autonomic responses in cocaine abusers (Childress *et al.*, 1988; Ehrman *et al.*, 1992).

With regard to subjective responses, craving or the urge to use the drug of choice as well as withdrawal symptoms are typically observed after cue exposure in substance-abusing or dependent individuals (Rickard-Figueroa and Zeichner, 1985; Ehrman *et al.*, 1992; Powell *et al.*, 1992; Robbins *et al.*, 1997). Reports of emotional or affective alterations are also frequent, although less consistent in nature. Interestingly, both dysphoria or distress (Powell *et al.*, 1992; Negrete and Emil, 1992) and euphoria or 'high' (Kranzler and Bauer, 1992; Robbins *et al.*, 1997) can be elicited by the cues.

While these findings are clearly compatible with a conditioning account of cue reactivity, they do not resolve the controversy that surrounds the issue of whether these cue responses are drug-like (i.e. similar to the actual effects of the drug) or drug-opposite in nature. There are different conditioning models that make different predictions as to the direction of these responses and how they may motivate continued drug-taking behaviour and relapse (reviewed in Niaura *et al.*, 1988).

Wikler developed a model that postulates that, apart from its direct reinforcing effect, a drug also has indirect reinforcing properties by suppressing acute withdrawal symptoms (such as craving) that have arisen from the previous drug ingestion. Since these withdrawal symptoms reliably follow drug ingestion and the environmental cues associated with it, they can become conditioned responses to those environmental cues (which themselves become conditioned stimuli).

A similar model by Siegel proposes that the conditioned responses to drug preparation stimuli are anticipatory compensatory reactions to counteract the pharmacological impact of the drug and maintain a homeostatic balance. In the absence of actual drug ingestion, these reactions will be experienced as drug-opposite changes including craving and dysphoria. Thus, both the 'withdrawal' and the 'compensatory' models have in common that conditioned responses to drug-related cues are not similar to the effects of the drug itself.

A third model favoured by Stewart and others posits that conditioned drug-related stimuli elicit a neural state and a concomitant positive appetitive response that are similar to those elicited by the drug itself. Thus, the drug itself or stimuli that have been paired with its motivational effects stimulate drug craving and drug seeking. This appetitive motivational model does not exclude drug-opposite cue responses, but it postulates that they do not contribute to relapse directly, but by virtue of becoming conditioned stimuli associated with the positive effects of the drug. In Wikler's and Siegel's models, drug-opposite reactions motivate drug use or relapse by a desire to use the drug to overcome these adverse or withdrawal-like effects.

Some studies have directly tested predictions made by these different models. Kranzler and Bauer (1992) have presented video tapes featuring neutral or cocaine-related material to cocaine-dependent male patients. Compared to the neutral material, the cocaine-related film material elicited significantly greater craving and drug-like euphoria, but not withdrawal symptoms. The degree of craving significantly correlated with euphoria but, again, not with withdrawal symptoms. These results clearly support an appetitive motivational model of drug effects. Reviews of the earlier literature focusing on alcohol and smoking (Niaura *et al.*, 1988) and on opiates and stimulants (Stewart *et al.*, 1984) also come to the conclusion that an appetitive conditioning account fits

better with the available data. More recent studies, however, do not unequivocally support this conclusion. For example, Ehrman *et al.* (1992) found much less evidence for a cocaine 'high' than for withdrawal and craving responses. Robbins *et al.* (1997) examined a large sample of male cocaine abusers and observed both withdrawal and high responses to cocaine-related audio and video tapes and to faked drug preparation rituals. Neither response, however, correlated with cue-induced craving, lending support to neither of the conditioning models.

Inconsistencies like these (and perhaps also general reservations regarding behaviouristic explanations) may make it worthwhile to look for alternative, non-conditioning theories of cue reactivity. One such alternative is derived from social learning theory and emphasizes cognitive over conditioned determinants of drug-taking behaviour and relapse (reviewed in Niaura *et al.* 1988). According to this model, there are stressful situations that place abstinent drug users at increased risk for relapse. These high-risk situations may or may not be drug related (i.e. may or may not include symptoms of withdrawal or high). If an individual's resources do not provide for a non-drug-related way of coping with the situation, this will decrease his or her confidence in being able to efficaciously handle the situation. Such negative self-attributions together with positive outcome expectancies regarding drug use (e.g. the expected pleasurable effects and the relief from withdrawal) will increase drug craving and the risk for lapse or relapse.

The data from several studies are in line with this model. Positive outcome expectancies in response to drinking-related cues were found to significantly correlate with increased desire for a drink in alcoholics and social drinkers (Cooney *et al.*, 1987). Moreover, positive outcome expectancies during detoxification correlated with relapse and the amount of drinking in detoxified alcoholics (Brown, 1985). In adolescents, the belief that alcohol would improve social competence was associated with drinking (Christiansen and Goldman, 1983). A more recent study by Powell *et al.* (1992) explicitly compared experimental predictions made by conditioning accounts with those following from a social learning model. These researchers exposed opiate addicts detoxified for at least 1 week to photographs of opiate ingestion and drug paraphernalia, including a fake packet of heroin with either injection equipment (needle and syringe) or foil and matches for smoking, depending on the subjects' preferred route of administration. Self-reports of cue-induced craving, physical symptoms, affect and positive outcome expectancies regarding emotional relief, hedonism, lifestyle, social relations and pain/withdrawal relief were collected. The opiate cues induced significant craving, dysphoria and withdrawal symptoms, but no increase in drug-positive effects. Craving significantly correlated with dysphoria, withdrawal, drug-positive effects and positive outcome expectancies, particularly with emotional relief. When all these variables together were entered into correlational analysis, craving no longer significantly correlated with withdrawal and drug-positive effects. The correlation of craving with dysphoria is consistent with the withdrawal and compensatory conditioning models proposed by Wikler and Siegel. The correlation with positive outcome expectancies, on the other hand, is clearly in accord with social learning models. The appetitive conditioning model received the least support in this study.

We can conclude that social learning models are a valid alternative to conditioning models, but that the final word about which theory is the right one, or whether the truth is not rather a new theory or a combination of existing models, is far from being spoken. These uncertainties stand in marked contrast to the consistency of cue-evoked subjective and autonomic responses in individuals dependent on a variety of substances. This consistency has fuelled the hope that cue desensitization or extinction may be effective complementary strategies in drug treatment, in particular relapse prevention (Childress *et al.*, 1987; O'Brien *et al.*, 1990).

PSYCHOPHYSIOLOGY OF SUBSTANCE ABUSE: FINDINGS, INTERPRETATIONS AND A MODEL

Findings and Interpretations

Table XVI-5.1 presents a qualitative and non-exhaustive overview of the psychophysiological findings among chronic substance abusers. As can be seen, many different measures and paradigms have been used, but few of them have been pervasively employed, making comparisons across substances difficult. Exceptions are P3 paradigms and resting EEG recordings, which reveal consistent decrements in P3 amplitude and increases in EEG beta activity in individuals abusing a variety of substances. Little evidence exists for drug-specific effects, which is in part a consequence of the scattered use of methods and paradigms. One such case is reduced alpha activity that appears to be a specific effect of alcohol not shared by other substances. Rather than further detailing these findings, the remainder of this section will be concerned with the question how these (primarily electrophysiological) findings can be interpreted in terms of their underlying brain substrate and functional significance.

Brain Substrates

Inferences to the brain loci underlying observed scalp EEG/ERP/EP changes are a notorious problem in electrophysiological research. This so-called 'inverse problem' states that it is impossible to unambiguously identify the intracerebral location/distribution of neuroelectrical activity that underlies a given scalp EEG recording. This means, for example, that, although the P3 is typically maximal over parietal leads, we cannot infer that it is generated in the parietal cortex. Likewise, the fact that P3 differences between alcoholics and controls are largest over posterior sites does not mean that this group difference emerges from posterior brain areas. While such inferences may have a certain validity in dense electrode array recordings, they are hopeless in the majority of studies reviewed here that used very few recording sites. Thus (with exceptions noted below), EEG/ERP studies by themselves cannot provide conclusive, only supportive, evidence for the brain location of observed electrophysiological changes. Such evidence could become more conclusive to the extent that other research, e.g. neuroimaging or lesion studies, would independently pinpoint the brain sources of (alterations of) EEG rhythms or ERP components. For example, the conjecture that decreases in P3a amplitude (which shows a frontal scalp distribution) in alcoholics may reflect frontal cortex damage gains substance through the independent finding that P3a amplitude decrements can also be found in patients with prefrontal lesions.

While this situation has looked like an impasse to some researchers, recent progress in EEG source localization techniques may provide a partial remedy. Using biologically plausible assumptions, it has become possible to compute the intensity and distribution of intracerebral neuroelectrical activity from scalp-recorded multi-channel EEG (see, for example, the LORETA method: Pascual-Marqui *et al.*, 1994, 1999). To the extent that methods like LORETA are validated, they allow us to infer, with a given precision, the brain loci generating the brain wave activity we record on the scalp and, consequently, to localize the brain areas underlying EEG/ERP changes observed in substance abusers.

Functional Significance

Assessing the functional significance of the electrophysiological findings in substance abusers has also been problematic. In our

Table XVI-5.1 A selection of psychophysiological findings in chronic substance abusers and individuals with a positive family history of alcoholism

	Alcohol	Cocaine	Opiate	Nicotine	Cannabis	Amphetamines	MDMA/'ecstasy'	Positive FHA
EEG								
Delta activity	↑	↓	–	↑	–		–	—

Beta activity	↑↑	↑	↓[a]	↑	–		↑	↑
ERP								
P3 amplitude	↓↓	↓↓	↓	↓	↓	↓		↓↓
P3 latency	↑	↑	–	–	↑	↑		—
N100 amplitude	↓↓					↓		
N200 latency	↑↑							
MMN amplitude	↑↓							
EP								
P50 suppression		↓			↓			
VEP P100 latency	↑		↑					
VEP N75 latency	–		↑					
A/I slope	↑						↑	
BAER latency	↑							
Other								
Startle amplitude				–				
PPI				↓				
Cue reactivity	↑↑	↑↑	↑↑	↑↑		↑		

Doubled symbols represent robust findings, i.e. reported by the majority of a larger number of studies. Single symbols represent less robust findings, i.e. either positive reports by a small number of studies, or mixed reports by a larger number of studies. ↑ / ↓= increase/decrease; – = no change; empty cell = not reported; A/I = amplitude/intensity; BAER = brain stem auditory evoked response; FHA = family history of alcoholism; MMN = mismatch negativity; PPI = pre-pulse inhibition of the startle reflex; VEP = visual evoked potential.
[a]Beta decreased with increasing duration of use (Bauer, 2001c).

view, the problems originate from the nature of the findings and from confusions in the use of concepts such as 'deficit'. For example, many researchers, possibly aware of the tenuous nature of inferences to brain loci or brain damage, have interpreted electrophysiological changes in terms of some unspecified kind of brain 'dysfunction', 'deficit' or 'impairment'. However, used in this way, such terms are practically void for vagueness, unless we consider any functional change as a deficit, which will render the term meaningless. Further difficulties arise when changes of a given kind and magnitude are interpreted as deficits in some groups, but not others. An example of this are P3 decrements which can be found both in substance abuse populations compared to non-drug controls, and in healthy men compared to women. In the case of substance abusers, these decrements are labelled deficits, but usually not in the case of healthy men and women. Regarding ERP measurements, the problematic use of concepts connects with problems in the nature of the data. ERPs have widely accepted functional interpretations in terms of attentional resource allocation, context updating and the like. Thus the abundant demonstrations of altered ERP characteristics in substance abusers are usually interpreted as deficits of attentional or cognitive information processing. However, very often these alterations are not accompanied by deficits in attentional performance in the task used to elicit the ERP responses. Moreover, in many studies of substance abusers, deficits in attentional and cognitive performance are not even found in neuropsychological tasks that are much more difficult and cognitively demanding than ERP tasks.

A plausible explanation for this seemingly paradoxical situation is that the ERP may be a much more sensitive measure than task performance, and may therefore uncover even subtle, subclinical attentional changes that escape measurements of task performance. But to the extent this is true, the functional significance of such changes becomes more difficult to assess, since then these changes stand isolated from any overt clinical, behavioural or subjective consequences. It further becomes questionable whether we should label such changes 'deficits'. Finally, also the EEG is not spared from interpretive problems. The functional significance of EEG rhythms is still a chapter strewn with question marks. Neither clear nor unique higher-level functions have been identified for the different frequency bands. Alpha rhythms may serve as an example. Increases in alpha activity have been associated with such diverse states and processes as relaxed wakefulness, drug-induced euphoria, normal ageing and HIV brain pathology, to name just a few. Matters are further complicated by the fact that a small percentage of the normal population does not show detectable alpha rhythms — apparently without functional impairments. Unfortunately, the other frequency bands do not fare much better, making functional interpretations of EEG frequency changes fairly speculative.

The foregoing considerations are by no means intended to be a comprehensive treatment, but they point out some important limitations that afflict inferences from and interpretations of psychophysiological data. Currently, EEG/ERP/EP evidence regarding the biological underpinnings (i.e. the nature and location of brain changes) is essentially supportive rather than conclusive, and its functional interpretation is problematic. Ways to overcome these limitations include the use of sophisticated topographical analyses and advanced source localization methods. In addition, other research disciplines must continue to contribute to the elucidation of the brain sources and functional roles of EEG frequency bands and ERP/EP components. These efforts to strengthen and revitalize EEG technologies will be worthwhile, since the EEG has several crucial advantages over other brain-imaging methods, notably its superior time resolution, cheapness, high portability and ease of use.

A Model for Substance Abuse

The fact that certain electrophysiological findings such as P3 decrements and beta hyperactivity in substance abusers persist even with prolonged abstinence, are shared across different drugs (see Table XVI-5.1) and are found in unaffected relatives and offspring of affected individuals supports the view that these are premorbid characteristics not primarily related to the pharmacological effects of a given drug. Low P3 in particular meets the criteria for a psychophysiological endophenotype marking the predisposition for a range of psychopathology, including externalizing and substance-related disorders. Genetic epidemiological studies further support the view of a common heritable predisposition for the abuse of a range of different psychoactive substances, including cannabis, sedatives, stimulants, opiates and psychedelics. The same conclusion is bolstered by a growing body of neuroscientific studies that locates a common neural basis for the abuse of different substances in brain systems for reward, motivation and learning (see later chapters in this book).

Data from large-scale longitudinal family studies such as the Collaborative Study on the Genetics of Alcoholism (COGA) and the Minnesota Twin Family Study (MTFS) have provided invaluable clues regarding the nature of this predisposition. Iacono *et al.* (1999, 2000) have developed a model of substance abuse based on several important findings from the MTFS. The MTFS showed that in both adolescent boys and their fathers higher levels of externalizing disorders (CD in boys, ASPD or ASP features in fathers) are associated with substantially higher levels of substance abuse. Moreover, paternal alcoholism status also had a significant influence on the occurrence of substance use and externalizing tendencies in the boys, in that boys with alcoholic fathers had more externalizing and drug use symptoms than boys with non-alcoholic fathers. The largest increase in these symptoms, however, was seen in those boys whose fathers had an undersocialized form of alcoholism characterized by ASPD or ASP features, comorbid illicit drug abuse and low constraint. What these findings indicate is that the presence of substance use in adolescent boys appears to be largely dependent on the presence of concomitant externalizing features, both in themselves and in their fathers. The common denominator of these externalizing symptoms appears to be a form of behavioural disinhibition which manifests in a spectrum of impulsive, unconstrained, aggressive, but also drug-taking behaviours. Given these findings, and also taking into consideration the ample evidence for the heritability and genetic basis of these deviant behaviours, we arrive at a formulation of the first part of the model endorsed by Iacono and colleagues: *The propensity for substance abuse is part of a heritable predisposition for behavioural disinhibition, which is expressed as a spectrum of externalizing and substance use behaviours*. A similar view regarding alcoholism is held by Begleiter and co-workers from the COGA project (Begleiter and Porjesz, 1999). These researchers equate the inherited predisposition for alcoholism with a premorbid state of CNS disinhibition or hyperexcitability. This disinhibition or hyperexcitability can be temporarily alleviated by the consumption of alcohol, which facilitates the development of chronic alcohol use, and finally, physical dependence. Additionally, this disinhibited CNS state may manifest as disinhibited externalizing behaviours unrelated to substance use.

The second part of the model derives from psychophysiological research indicating that certain heritable psychophysiological changes are associated with substance use and externalizing behaviours as well as with the underlying neuronal/behavioural disinhibition, and may well share a common genetic basis with them. Thus, these psychophysiological changes qualify as endophenotypes marking the genetic risk for disinhibited psychopathology. We have seen that a low P3 is currently the best candidate for such an endophenotype. There are also other, less promising, candidates, including excessive beta activity or a poor modulation of electrodermal responses to predictable aversive stimuli (Taylor *et al.*, 1999; Iacono *et al.*, 2000). We can now formulate the second part of the model as follows: *Certain heritable psychophysiological abnormalities, in particular a low P3 amplitude, are endophenotypes marking the genetic predisposition for the development of substance abuse and externalizing disorders*. The complete model is depicted in Figure XVI-5.9. Figure XVI-5.9 also shows important influences and relations we have neglected so far. Thus, although the major portion of the genetic risk for substance abuse may originate from a common set of genes and may be expressed in a predisposition shared by all forms of substance abuse, there are also unique genetic contributions specific to a given substance. Furthermore, environmental influences, both within and outside the family, are as important as genetic factors in determining the risk for substance abuse. To put it in more popular terms, nature and nurture each contribute equally to the development of substance use, abuse or dependence.

It has also become increasingly clear in recent years that genes and environment interact and that these interactions are essential in understanding the aetiology of many disorders (see chapter XVII-10). A final important consideration is that the model is not intended to apply to all types of substance abuse. There is considerable heterogeneity in substance abuse populations with regard to patterns of abuse, time course and severity of the disorder, as well as gender, socio-economic background, symptom profiles and personality traits of the abusing individual. The scope of the model by Iacono and colleagues presented here is restricted to a type of substance abuse characterized by early onset and undersocialized or antisocial behaviour. This type is based on typologies proposed by Cloninger (1987) and other investigators for alcoholism. Integrating neurobiological and psychosocial data, Cloninger identified two basic types of alcoholism. Type I occurs in both genders, usually begins after age 25 and is entertained by rigid, apprehensive and emotionally dependent individuals with low novelty-seeking, high harm avoidance and high reward dependence. Type II occurs predominantly in males before age 25 and is entertained by impulsive, uninhibited, independent individuals characterized by high novelty-seeking, low harm avoidance and low reward dependence. Type II individuals are prone to antisocial personality features and aggressive acting out. It has been estimated that type II alcoholics make up about 80% of patients presenting for hospital treatment. Furthermore, as asserted by Cloninger, low P3 amplitude may be present only in antisocial type II, but not type I, alcoholics. Thus, the model of alcohol and drug abuse we present here may only be valid for a subset of disinhibited male substance abusers with antisocial tendencies. In women, internalizing rather than externalizing psychopathology, particularly mood and anxiety disorders, is associated with the risk for the development of substance abuse. Also, the genetic and neurophysiological basis of substance abuse may be quite different in women compared to men.

Despite these restrictions, the proposed model is an important step towards integrating our knowledge on the neuronal, genetic, psychosocial, behavioural and psychophysiological processes underlying a major type of substance abuse. This and similar models primarily reflect our advancements in the work based on the second major rationale for psychophysiological research on substance-related disorders, namely to find biological markers that identify individuals at risk for these disorders. Work based on the first rationale, which is the identification of the biological substrates and functional significance of psychophysiological changes in substance abusers, has faced more difficulties, as we have seen in the previous section. Nevertheless, the psychophysiological research into substance abuse and dependence, as reviewed in this chapter, has made significant advancements within the past three decades. Eventually, these advancements will also contribute to the development of more specific and effective treatments for

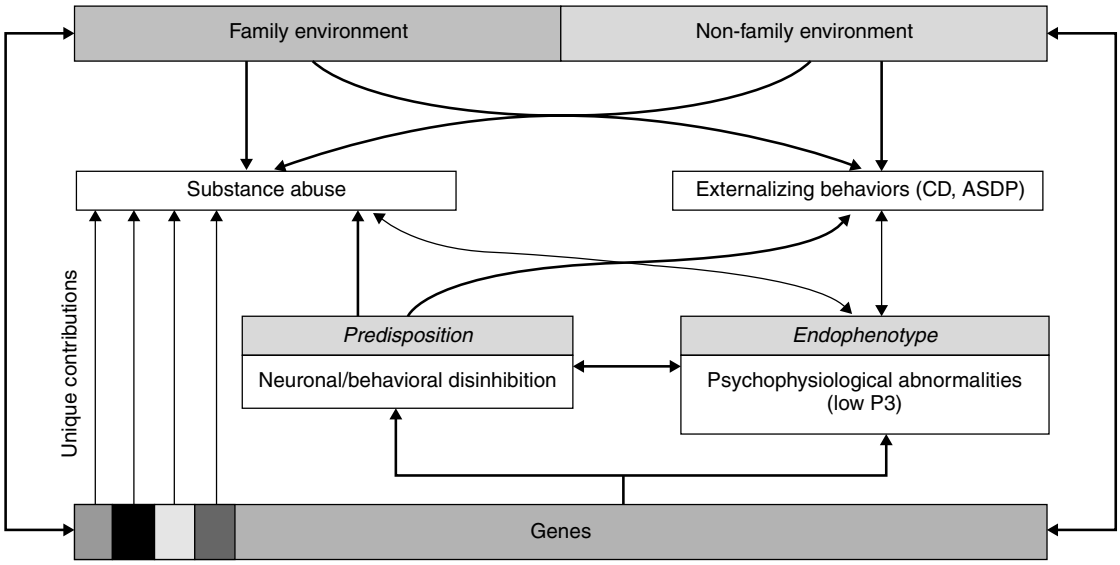

Figure XVI-5.9 A model depicting genetic, environmental and neural influences that jointly determine the risk for developing substance abuse or dependence. A common set of genes produce both a neural/behavioural disinhibition that predisposes for substance abuse and externalizing behaviours, as well as associated psychophysiological changes such as a small P3 amplitude. These changes can be conceptualized as an endophenotype that marks the predisposition for substance abuse and related externalizing pathology. The endophenotype can be used to identify unaffected carriers of high-risk genes, and hence to increase the power of genetic linkage and association analyses. Apart from common genetic factors, the development of substance abuse is also dependent on substance-specific genetic contributions, family and non-family environment and gene–environment interactions. After Iacono, Begleiter and co-workers

adult substance abusers and of prevention programmes that target high-risk children and adolescents before the critical age of substance abuse.

ACKNOWLEDGEMENTS

The authors would like to thank Monica Treve for her invaluable assistance in preparing the manuscript, Shirley Y. Hill for comments on an earlier version, and Jules Angst for providing ample time to A.G. for writing the chapter.

Neuropsychology of Substance Abuse

M. Lacy and L. Sworowski

INTRODUCTION

In this chapter the neuropsychological aspects of substance abuse will be reviewed. The lifetime prevalence rate for any substance use disorder is 16.7% (Regier *et al.*, 1990). The DSM-IV (1994) lists 11 classes of substance-related disorders: alcohol, amphetamines, caffeine, cannabis, cocaine, hallucinogens, inhalants, nicotine, opioids, phencyclidine, and sedatives, hypnotics and anxiolytics. This classification system further breaks down the diagnosis into two categories: substance-induced disorders and substance use disorders. Cognition difficulties thought to be related to substance use are addressed under the category of substance-induced disorders. These include substance-induced delirium, substance-induced persisting dementia and substance-induced persisting amnestic disorder. The substance use disorders must be classified as either substance abuse or dependence conditions. There are no criteria for cognitive dysfunction in either substance use disorder. When cognitive problems are associated with these disorders, the diagnosis of substance-related disorder not otherwise specified may be used. Parsons (1996) has argued that while only 10% of alcohol-using patients have diagnosable organic disorders, another 50–85% of patients have mild to moderate cognitive deficits that do not meet the diagnostic criteria for either substance-induced dementia or persisting amnesia. Thus, the majority of studies in this area, with the exception of some alcohol-related research, have focused on investigating this latter group. Specifically, in the current body of literature most studies address the early neurocognitive effects of abuse and dependence, with few longitudinal studies, and even fewer studies addressing substance-induced disorders. Thus, this chapter will focus on reviewing these studies. As it is beyond the scope of this chapter to review all 11 classes of drugs, the neuropsychological aspects of some of the most commonly abused drugs among adults and adolescents — alcohol, cannabis, cocaine, 'ecstasy', ketamine, opiates and LSD — will be presented in the following sections. The neuroimaging, psychophysiological and functional imaging of substance abuse is reviewed in other chapters of this book and thus will not be addressed here in any detail. Currently, the most research in substance use disorders is directed at understanding the neurocognitive effects of alcohol use.

ALCOHOL

Alcohol is the most commonly used drug (DSM-IV, 1994). According to the National Institute of Alcoholism and Alcohol Abuse (NIAAA www.niaaa.nih.gov/publications), the prevalence of alcohol abuse and dependence is 7.41% for adults, with 18- to 29-year-olds having a prevalence of 15.94% and older adults, aged 65 and older, having the lowest prevalence at 0.64%. Approximately 10–14% of adults abuse alcohol, with at least 6% meeting diagnostic criteria for dependence. Alcohol-related problems begin early in life. Epidemiological studies indicate that over 50% of 14-year-olds in 2000 reported drinking at least once in their life, with 14.1% acknowledging binge drinking, defined as five drinks in the prior 2-week period. Over 71.4% of 16-year-olds acknowledge drinking in the past, with 26.2% admitting binge drinking. Approximately 80% of 18-year-olds acknowledge drinking alcohol, with 30% reporting an episode of binge drinking (NIAAA, 2001).

Given the early abuse and continuous widespread use of this drug, understanding the neuropsychological effects is imperative. While alcohol is involved in numerous medical conditions, this chapter will review the cognitive profiles associated with Wernicke–Korsakoff syndrome, alcohol-related dementia, alcohol abuse/dependence and to a lesser extent the scant research on social drinkers.

Neurocognitive Effects of Wernicke–Korsakoff Syndrome

In DSM-IV, Wernicke–Korsakoff Syndrome (WKS) is typically diagnosed as an alcohol-induced delirium followed by an alcohol-induced persisting amnestic disorder. The term WKS often refers to a two-phase syndrome, with an acute Wernicke encephalopathy (WE) followed by a persisting Korsakoff syndrome (KS). In the acute phase, patients may present with confusion, ocular difficulties (e.g. nystagmus) and cerebellar dysfunction (e.g. gait ataxia), although the sensitivity of this triad is questionable. In 131 WKS cases diagnosed at necropsy, Harper *et al.* (1986) found only 16% displayed this triad and 19% had no clinical symptoms. The prevalence of WE has been difficult to determine. A retrospective study (Torvik *et al.*, 1982) revealed that only 20% of post-mortem confirmed cases (12.5% of all alcoholics) were clinically diagnosed. Harper *et al.* (1995) found the prevalence of WKS to be 0.4–2.8% of autopsies regardless of clinical history. In the past, WKS has been associated with other nutritional conditions, such as self-starvation, intravenous feedings, persistent vomiting, malignancies, and carcinomas of the oesophagus, intestines and stomach. Recently there have been few unequivocal cases of amnestic syndromes from non-alcoholic depletion (see review, Kopelman, 1995). Wernicke patients who die in the acute phase show symmetrical lesions in the paraventricular regions of the thalamus, hypothalamus and mammillary bodies, along with less frequent lesions in the periaqueductal region of the midbrain, floor of the fourth ventricle and superior cerebellar vermis (Kopelman, 1995). Many patients who survive this stage often continue to have significant pathological changes and cognitive deficits (Colchester *et al.*, 2001; Park *et al.*, 2000; Victor *et al.*, 1971). Pathological studies suggest lesions must be present in the mammillo-thalamic circuits, with the anterior thalamic nuclei being the critical area for a resulting amnestic syndrome characteristic of KS (Cole *et al.*, 1992; Harding *et al.*, 2000).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

The prevalence and mode of onset of WE prior to KS are unclear. In the classic 1971 Victor *et al.* pathology studies, 96% of KS patients had histories of WE, with only 10% having an insidious onset. In contrast, Cutting (1978) found more heterogeneity in patients evaluated by a psychiatric service, with more frequent cases of insidious onset especially for females. The portion of patients with a documented history of WE is less frequently documented in the literature than seen previously and recent studies suggest KS may occur without clear history of documented WE (Butters, 1985; Jauhar and Montaldi, 2000). However, autopsy studies suggest that WE is often underdiagnosed (e.g. Harper *et al.*, 1986) and thus the interaction between WE and subclinical episodes prior to KS is unclear.

Clinically, KS is characterized by persistent and disproportionate memory deficits, in contrast to generally intact intellectual functioning (Lezak, 1995) thought to be related to or the direct result of thiamine deficiency, although this latter finding is debatable (Butters, 1985; Molina *et al.*, 1994; Thomson, 2000). To investigate memory processes across dementing conditions, Delis *et al.* (1991) examined the memory performances of Alzheimer (AD), Huntington and KS patients using a 16-item list-learning task. The AD and KS groups did not significantly differ on immediate free recall, learning slope, semantic clustering, primacy–recency effects, delayed free recall, recognition discriminability, false positives and response bias indices. Using percentage of cued intrusion errors and recognition discriminability versus initial learning, discriminant function analysis classified 100% of the KS patients as AD and correctly classified 85% of the AD patients. Thus, KS patients displayed a pattern of memory failure seen in other cortical, rather than subcortical, dementias.

While explicit memory processes are impaired in this population, other aspects of memory may be preserved. The classic studies of amnestics by Warrington and Weiskrantz (1982) revealed adequate speed of access to semantic and phonological knowledge, some degree of improvement on retesting, and differential improvement in retention when tested by cued recall and a prior learning effect. More recently, Heindel *et al.* (1993) compared memory performances of KS, AD, Huntington and Parkinson patients. The KS group performed more similar to the AD group on tests of explicit memory, but displayed normal performances on priming tests, indicative of intact implicit memory abilities. In addition to intact implicit memory performances, KS patients also demonstrate average working memory and average forgetting rates/storage when encoding is equated (Kopelman, 1985).

While explicit memory failure has traditionally been attributed to encoding disruption and diencephalic disruption, several researchers have suggested that the memory disturbance in WKS is at least partly attributable to retrieval failures reflective of frontal lobe dysfunction (Noel *et al.*, 2001). To examine this possibility, Noel *et al.* (2001) presented the case of GS, a patient with prior WE symptoms. The patient completed several tests of verbal memory, which included recognition paradigms. GS displayed primary retrieval deficits on all tests of verbal memory. The authors cite this case as an example of the heterogeneity in this population and the possibility of frontal dysfunction, reflective in retrieval rather than encoding deficits, underlying the memory disturbance in some patients. However, GS performed within normal limits on a demanding list-learning task, raising doubts about the significance of the reported episodic memory deficit in this patient.

Along with anterograde memory loss, KS patients also display a significant retrograde amnesia, steeper than that seen in AD (Kopelman, 1989). These patients have difficulty recalling events prior to the onset of the condition, on a steep temporal gradient. Patients have been noted to confabulate in the presence of this dense amnesia, although this appears rare and more often in the acute phases (Victor *et al.*, 1971). When present in the more chronic condition, several researchers argue that this may reflect inaccurate recall of real memories out of temporal context, reflective of frontal pathology (Kopelman, 1987, 1991a, 1991b). In fact, several studies have shown that KS patients have poor temporal orientation and judgement of time (Mimura *et al.*, 2000; Taylor and O'Carroll, 1995) along with consistent deficits across studies on measures of executive functioning, including problem solving, metamemory, proactive interference and insight (Janowsky *et al.*, 1989; Jacobsen, 1990; see review, Lezak, 1995).

As noted previously, typically KS perform similarly to chronic alcoholics on tests of generalized intelligence. Overall, they display better verbal intelligence, but impaired speeded visuospatial organization and perceptual skills. On simple tests of attention, such as digit span, scores are usually in the average range, but deficits emerge as more complex sustained and divided attention is required (Lezak, 1995).

In summary, the neuropsychological profile of KS includes impairments in recent and remote memory, along with milder deficits in executive functioning. In contrast, KS patients demonstrate relatively intact overall intelligence, implicit memory and rates of forgetting.

Neuropsychological Profile Associated with Alcohol-Induced Dementia

Based on DSM-IV criteria, alcohol-related dementia falls under the diagnosis of substance-induced persisting dementia. To combat the often vague and subjective aspects of the DSM-IV criteria, Oslin *et al.* (1998) proposed a more defined set of criteria (Table XVI-6.1) for alcohol-related dementia (ARD) similar to existing criteria for Alzheimer and vascular dementias. ARD is defined as a syndrome with multiple possible aetiologies, including ethyl alcohol, nutritional deficiencies, metabolic disturbance, immune-related injury, trauma and vascular injury. The use of these more defined criteria may allow for improved validity and reliability of the diagnosis across studies. To date, few published studies have utilized these criteria.

Possibly because of the vagueness in the DSM-IV criteria, the prevalence of ARD is unclear. Most studies list alcohol use as a comorbid condition to dementia, rather than a causative factor. When studies directly address alcohol use and cognition, the issue of dementia is rarely addressed. Despite these methodological problems, it is estimated that 22–29% of dementia cases are related to alcohol dependence. Alcohol abuse or dependence is 1.5 times more common in elderly demented patients. Dementia is 4.6 times more likely to occur in older men with histories of heavy drinking, and increasing alcohol consumption has been associated with a worsening performance on dementia screening scales (Oslin *et al.*, 1998). Finlayson *et al.* (1988) found 23% of elderly patients presenting for alcohol treatment met criteria for dementia. Approximately 29% of institutionalized elderly patients have alcohol-induced dementia. The only longitudinal study to examine the duration of heavy drinking as a risk factor for developing dementia revealed a 5-year history of drinking as a risk factor (Saunders *et al.*, 1991).

The neuropsychological profile in ARD has received much less attention in the literature than the subtler deficits associated with abuse or dependence. Research available suggests deficits in memory functioning, along with visuospatial and executive abilities (Cummings and Benson, 1992). While early studies have suggested deficits in encoding, more recent investigations utilizing recognition paradigms suggest retrieval deficits may underlie the memory impairment. For instance, Saxton *et al.* (2000) compared AD, non-demented elderly alcoholics, ARD elderly and normal controls. The alcoholic patients were matched on liver disease, nutritional status, number of head injuries and number of periods of abstinence. Compared to the AD patients with similar premorbid IQ estimates

Table XVI-6.1 Classification of alcohol-related dementia

A. Probable alcohol-related dementia includes the following:

1. A clinical diagnosis of dementia at least 60 days after the last exposure to alcohol.
2. Significant alcohol use as defined by a minimum average of 35 standard drinks per week for men (28 for women) for greater than a period of 5 years. The period of significant alcohol use must occur within 3 years of the initial onset of dementia.

B. The diagnosis of alcohol-related dementia is supported by the presence of any of the following:

1. Alcohol-related hepatic, pancreatic, gastrointestinal, cardiovascular or renal disease, i.e. other end-organ damage.
2. Ataxia or peripheral sensory polyneuropathy (not attributable to other specific causes).
3. Beyond 60 days of abstinence, the cognitive impairment stabilizes or improves.
4. After 60 days of abstinence, any neuroimaging evidence of ventricular or sulcal dilatation improves.
5. Neuroimaging evidence of cerebellar atrophy, especially of the vermis.

C. The following clinical features cast doubt on the diagnosis of alcohol-related dementia.

1. The presence of language impairment, especially dysnomia or anomia.
2. The presence of focal neurological signs or symptoms (except ataxia or peripheral sensory polyneuropathy).
3. Neuroimaging evidence for cortical or subcortical infarction, subdural haematoma, or other focal brain pathology.
4. Elevated Hachinski Ischemia Scale score.

D. Clinical features that are neither supportive nor cast doubt on the diagnosis of alcohol-related dementia included:

1. Neuroimaging evidence of cortical atrophy.
2. The presence of periventricular or deep white matter lesions on neuroimaging in the absence of focal infarct(s).
3. The presence of the apolipoprotein e4 allele.

The diagnosis of possible alcohol-related dementia may be made when there is:

1. A clinical diagnosis of dementia at least 60 days after the last exposure to alcohol.
2. *Either*: Significant alcohol use as defined by a minimum average of 35 standard drinks per week for men (28 for women) for 5 or more years. However, the period of significant alcohol use occurred more than 3 years but less than 10 years prior to the initial onset of cognitive deficits.
   Or: Possibly significant alcohol use as defined by a minimum average of 21 standard drinks per week for men (14 for women) but no more than 34 drinks per week for men (27 for women) for 5 years. The period of significant alcohol use must have occurred within 3 years of the onset of cognitive deficits.

Mixed dementia

A diagnosis of mixed dementia is reserved for clinical cases that appear to have more than one cause for dementia. The classification of probable or possible should continue to be used to convey the certainty of the diagnosis of ARD. The classification of mixed dementia should not be used to convey uncertainty of the diagnosis or to imply a differential diagnosis.

Alcohol as a contributing factor

The designation of alcohol as a contributing factor is used for the situation in which alcohol is used, but not to the degree required or within the time required to meet the classification of probable or possible alcohol-related dementia. This designation should not preclude the use of probable vascular dementia or probable dementia of the Alzheimer type.

and current MMSE scores, the ARD group exhibited significantly more deficits on tasks of executive and visuoconstruction ability. In contrast, the AD group displayed worse semantic memory abilities as displayed on tests of confrontational naming, recall and recognition memory. The ARD group performed worse than the non-demented alcoholic group across the test battery, but were only significantly different on two measures. They performed slower on a measure of fine motor control and on tests of initial learning and delayed free recall, but displayed similar recognition memory compared to normal controls and non-demented alcoholics, indicative of retrieval problems underlying memory impairment. The non-demented alcoholics and controls were only significantly different on immediate and delayed recall of visual material, possibly reflecting the early impact of alcohol on visuospatial functioning (Sher *et al.*, 1997). Data on the performances between these two groups on the recognition paradigm of this memory test were not presented and thus the nature (encoding, storage or retrieval) of the visual memory impairment is unclear.

Neuropsychological Functioning in Alcohol Abuse and Dependence

Over the last 25 years, Parsons and his colleagues have conducted the most extensive research on recently detoxified alcoholics, which they term intermediate-stage alcoholics (Parsons, 1998). Using longitudinal and cross-sectional studies, they have also been able to investigate the long-term effects of alcohol abuse. This extensive body of literature suggests that intermediate-stage alcoholics display deficits across neuropsychological test batteries, with lower scores on tests of memory, learning, abstracting, verbal problem solving, visuoperceptual analysis, perceptual motor speed and mental processing speed (Parsons, 1998). Along with being less accurate, other studies by this group of researchers (i.e. Glenn *et al.*, 1992) have suggested that alcoholics take a longer time to complete these tasks, resulting in deficits in efficiency.

In terms of severity, inspection of scores between the patient and control groups suggests only mild difficulties. For example, in one study (Parsons, 1998) alcoholics obtained the following mean domain T scores: verbal mean 48.5, visuospatial mean 48.8, perceptual motor mean 48.9 and semantic memory mean 48.2; compared to the following scores for the control group: verbal mean 52.2, visuospatial mean 51.8, perceptual motor mean 51.5 and semantic memory mean 52.6. All of these T scores reflect performance within the average range. Parson suggests that intermediate-stage alcoholics display a neurocognitive profile similar to mild brain-injured patients, with scores approximately one half a standard deviation or more below the mean. Thus while recently detoxified alcoholics display lower performance on neuropsychological measures, data suggest only subtle differences. In fact, in a study by a different group of researchers (Horner *et al.*, 1999), examining mild to moderate alcoholics without history of inpatient admissions or withdrawal symptoms, the alcohol group performed in the average range, despite the noted averse relationship between cognition performance and recent drinking. Further supporting the hypothesis of only minimal disturbance with alcohol abuse, Parsons reported significant overlap between

alcoholics and controls on most neurocognitive measures. Thus, the neuropsychological impact of alcohol abuse is subtle and diffuse in chronic alcohol abuse.

In terms of aetiology, despite examining numerous behavioural and medical variables, Parsons and colleagues (e.g. Nixon *et al.*, 1995), along with others (e.g. Ham, 2000), have shown that depression and history of childhood behavioural disorders reliably account for only a portion of the differences between patients and controls on cognitive measures. Nixon *et al.* (1995) found that while alcoholics reported more childhood behavioural disorders and residual attention deficit disorder, regression analysis indicated that alcohol abuse was the best predictor of cognitive efficiency. Ham (2000) found that even subclinical levels of depression and anxiety, along with childhood ADD, may contribute to the magnitude of the obtained impairment in cognition, although differences remain when these effects are partialled out. Thus, while childhood disorders (e.g. ADD) and emotional distress may contribute to the neurocognitive difficulties documented in alcoholics, they do not appear to solely account for these deficits. Parsons (1998) has suggested that individual differences may be related to a vulnerability factor. In fact, Di Scalfani *et al.* (1998) examined this hypothesis, which suggests that individuals with larger premorbid brains may have a later onset or lessened severity of cognitive impairment, which may account for the variability across subjects. They investigated the relationship between brain volume based on magnetic resonance imaging and neuropsychological performance in 28 cocaine–alcohol-dependent individuals, 19 cocaine-dependent only subjects, and 19 controls. Intracranial volume accounted for 20% of the variance in cognitive performance. While this study examined data primarily in cocaine-dependent individuals, it suggests the same may be true in alcoholic-only individuals.

Recovery

Parsons and others have also examined the issue of recovery, by employing cross-sectional and longitudinal studies. In 1983, Fabian and Parsons compared 40 alcoholics, sober for 4 years, 40 alcoholics sober for 1 month and 40 controls on a battery of neuropsychological tests. As seen previously, the recently detoxified patients performed significantly differently from the control group, while the long-term sober group performed similarly to the control group. This finding was replicated by a different group of researchers. Rourke and Grant (1999) found that age, length of abstinence and interim drinking affected long-term neurocognitive outcome. They examined 97 alcoholics shortly after detoxification (mean 29.7 days) and again 2 years later. At 2 years, 62 subjects resumed drinking, while 35 maintained abstinence. These patients were compared to 29 age-, education- and years of drinking-matched long-term abstinent alcoholics (mean years = 4.3) and 49 non-alcoholic controls. Results indicated that the group that maintained sobriety for 2 years displayed improved abstraction abilities, albeit still below long-term abstainers. Furthermore, those over the age of 50 who continued drinking displayed deteriorating abstraction abilities. Also, those patients who continued drinking developed worsening motor skills, regardless of age. In summary, the authors conclude: 'What the results from the current study may suggest is that certain neuropsychological abilities may become more susceptible to the toxic effects of alcohol as a person ages, and that the recovery of certain abilities in chronic alcoholics may require protracted periods of abstinence for normalization as a persons increases in age' (p. 242). Consistent with other investigations (e.g. Yohman *et al.*, 1985; Glenn *et al.*, 1994), it is clear that neuropsychological deficits deteriorate with continued alcohol abuse, but may recover with prolonged abstinence.

Horner *et al.* (1999) examined 69 mild to moderate alcohol-dependent outpatients without any inpatient history screened for other psychiatric diagnosis, medical condition or medication which could affect cognition. Examinations occurred approximately 4 days after abstinence or after withdrawal symptoms subsided. Patients were divided into groups based on recent alcohol consumption. Patients with higher consumption in the last 90 days performed significantly below low-consumption users on tests of delayed verbal memory and conditioned reaction time. Linear correlations using the entire sample revealed negative correlations between alcohol consumption and abstract reasoning, inhibition of automatic responses, condition reaction time and memory. Examination of years of drinking revealed no association with neuropsychological performance. Thus, in this group of high functioning mild to moderate drinking alcoholic outpatients, cognitive performance was related to recent drinking rather than long-term history of abuse.

Social Drinking

Finally, Parson and Nixon (1998) addressed the issue of neurocognitive deficits in social drinkers. In this review, 10 of 17 studies failed to demonstrate cognitive deficits associated with 'social' alcohol consumption. However, the negative study subjects averaged only 16.4 weekly drinks, while the positive studies subjects averaged approximately 42 drinks weekly. Further review suggested that consuming 21 or more drinks per week may result in the emergence of subtle cognitive difficulties.

Summary

In summary, the neurocognitive impact of alcohol abuse/dependence is diffuse, affecting memory, perception, construction, visuospatial, abstraction, executive and motor functioning. Inspection of data comparing normal controls and alcoholics indicate mild to subclinical deficits. This relative impairment is not solely accounted for by premorbid variables such as childhood behavioural disorders, or by current depression. Individual differences may reflect a vulnerability factor. Long-term abstinence may result in almost full recovery, especially in younger patients. Long-term abuse may result in continuing decline, with the possible development of an alcohol-related dementia. However, the amount drunk per week may have a greater impact on outcome than chronicity. Social drinkers who drink 21 drinks per week are at risk for developing cognitive dysfunction.

CANNABIS

Cannabis, the most widely used street drug in the world, contains over 60 cannabinoids. The pharmacological properties of these cannaboids are mostly unknown, although the most potent agent, tetrahydrocannabinol (THC), has been identified and examined in numerous studies. Unfortunately, the increasing THC content in the average marijuana cigarette over the last several decades has made it difficult to compare studies across time. For instance, in the 1970s the average marijuana cigarette contained 10 mg THC, while today the THC level can range from 20 to 300 mg depending on cultivation and other breeding techniques (Aston, 2001). Along with this drastic increase in potency, there has been a significant increase in the prevalence of cannabis use over the last decade. For instance, 30–40% of 15- to 16-year-olds in the UK and the USA reported trying marijuana, with 60% of university students in the UK reporting regular use of marijuana.

Studies investigating the acute impact of cannabis use on cognitive functioning have resulted in mixed results. In their 1995 review, Pope *et al.* concluded that there was significant data to indicate that there were acute, but not residual effects of marijuana on cognition. Since then, there continue to be studies raising questions regarding the reliability of acute effects of marijuana on

cognition. For instance, Fant *et al.* (1998) had 10 male participants smoke a single joint containing high and low doses of THC and then complete various cognitive tasks. In contrast to several earlier studies, results revealed no acute effect on cognition, regardless of potency. In 2001, Pope *et al.* examined 63 current heavy smokers, 45 'former' (abstinent 3 months) smokers and 72 controls at 0, 3, 7 and 28 days after admission. Results revealed that the current smokers performed worse on a list-learning task only on day 7, with performances similar to controls on nine other neuropsychological measures, including tests of attention, visual memory and executive functioning. Thus, recent studies raise questions regarding even reliable acute effects. Differences across studies in terms of study design (e.g. naturalistic versus laboratory), period of abstinence, potency of drug, years of abuse, premorbid intelligence and other substance use may underlie conflicting findings.

In summary, there are conflicting findings regarding acute cognitive effects related to marijuana use. When effects are found they appear to be subtle, affecting attention and memory, and resolving quickly with abstinence. There is no reliable evidence of permanent cognitive impairment in cannabis users.

COCAINE

Cocaine, in the form of cocaine hydrochloride powder, is one of the most frequently used drugs in the world. In 1999, NIDA reported that the rate of use in 17- to 18-year-olds was 9.8%, compared to 5.9% in 1994. In the last year, 6.2% of 18-year-olds reported using cocaine at least once, while 2.6% used it in the last month. Almost 5% of 13- to 14-year-olds have used cocaine at least once, 2.7% in the last year and 1.3% in the last month. In 1995, it was estimated that 1.5 million Americans used cocaine, with half a million using the drug weekly. In 2000, 12.7% of adults over the age of 26 reported trying cocaine in their lifetime.

Cocaine continues to be a widely used drug, with significant central nervous system complications. Cocaine use has been associated with seizures, ischaemic stroke, intracerebral haemorrhage, cerebral vasculitis, vascular spasm and transient ischaemic attacks (Lezak, 1995). Neuroimaging studies, including single photon emission tomography (SPECT) and positron emission tomography (PET), have revealed decreased cerebral metabolism and blood flow in prefrontal cortex associated with cocaine use (Rogers and Robbins, 2001). Given the possible impact on brain functioning, and the frequent complaint of cognitive difficulties among abusers (Washton and Tatarsky, 1984), it is important to examine the current state of the literature examining the neuropsychological impact of cocaine abuse/dependence.

Horner (1999) outlined eight factors to consider in evaluating cocaine studies: (1) specific measures used, (2) sample size, (3) length of abstinence at time of evaluation, (4) monitoring of abstinence, (5) severity and type of use, (6) concurrent abuse of other substances, (7) neuromedical, developmental and psychiatric histories, and (8) comparability of control groups. While not specifically addressed by Horner, it is also important to consider estimates of premorbid intelligence in assessing the comparability of control groups, a factor rarely addressed in this body of literature. Finally, an additional methodological problem, seen in all studies examining abuse variables, is the reliance on self-report regarding such important variables as prior intensity, frequency and duration, along with polysubstance abuse, including nicotine. Over the last several years, while better methodological criteria have been employed, problems still exist that thwart a solid understanding of the neurocognitive impact of cocaine use. The following will review the most recent studies, which employ better research design.

Rosselli and Ardila (1996) compared 61 cocaine-dependent Colombian subjects to 63 controls. Using the conservative alpha level of 0.01, significant differences were seen on measures of WMS Logical Memory Immediate Recall and Mental Quotient. Significant differences were also seen on all measures derived from the Wisconsin Card Sorting Test (WCST), a test of executive functioning. Length and frequency of use correlated with level of impairment. No differences were seen on tests of sustained attention, fluency or naming, with only modest trends ($p < 0.05$) seen on measures of delayed visual and verbal memory, visuoconstruction and working memory. While this study suggests mild difficulties on immediate attention and executive functioning, the drug group had lower IQ scores and higher rates of history of anxiety and suicide attempts, raising questions regarding the comparability of the groups and the aetiology of the impairments.

Gillen *et al.* (1998) compared 19 cocaine-dependent and 16 non-cocaine-dependent men. All subjects were screened for history of other psychiatric or major medical conditions, childhood attentional difficulties, mild head injuries, learning disabilities and recent psychoactive medication. For the both groups, other substance abuse/dependence was also an exclusionary criterion, except current alcohol abuse and alcohol dependence in remission in the cocaine group. Cocaine use during the preceding month had to exceed 4 g, with the average 15.8 g. Comparisons between the groups revealed equivalent age, education, socio-economic status and racial composition. The cocaine group was statistically different on symptoms of depression, alcohol use and family substance abuse history compared to the control group. Cocaine abusers were tested approximately 7–8 days after entering the study and half were taking carbamazepine. No toxicology screens were conducted during the week prior to testing. No differences were found between the two cocaine groups and thus the data were grouped.

Tests results were interpreted as revealing group differences on Information, Vocabulary, and Picture Arrangement subtests of the WAIS-R (Weschler, 1981), with a trend for delayed visual memory and phonemic fluency. However, given that 29 comparisons were conducted, the more stringent criteria for significance would suggest only significant differences on the WAIS-R subtests Vocabulary and Picture Arrangement, with the cocaine group actually performing better on Trails A. As the authors note, the differences on the information and vocabulary subtests may reflect differences in premorbid IQ, as the control group had slightly higher education and socio-economic status and these tests are most resistant to brain changes and are highly correlated with premorbid intelligence. It is also noteworthy that all scaled scores on the WAIS-R were within the average to low average range (8–10) for the cocaine group, again suggesting no significant impairment. Thus, this study again suggested no significant differences between a small group of recently abstinent cocaine-dependent individuals, despite histories of alcohol abuse, mild depression and possibly lower premorbid IQ compared to a slightly better-educated control group.

Selby and Azrin (1998) examined 60 cocaine-abuse/dependent incarcerated felons, abstinent for an average of 36 months, compared to 138 non-cocaine-abusing felons. Cocaine abusers averaged over 8 g per week for longer than 12 months, for an average of 13 years of use and were abstinent for 36 months, although screening of current use was not reported. The groups were similar in age, education, race and intelligence, and screened for comorbid conditions. Overall analysis revealed that the cocaine group performed similar to the control group on tests of short-term and long-term memory, executive and visuomotor functioning. Thus, this study demonstrated that after long abstinence individuals with a history of cocaine abuse/dependence do not display significant neurocognitive deficits compared to well-matched controls.

Robinson *et al.*'s (1999) study compared 30 cocaine abusers, 30 cocaine and alcohol abusers and 30 age-, education-, race- and sex-matched controls on an extensive battery of neuropsychological tests. Cocaine abusers reported using approximately 11.9 g per month over 4 years, with 67% freebasing and 33% inhaling.

Patients reported abstinence for a mean of 146 days. Current alcohol use was unavailable, but patients were excluded if they met diagnostic criteria for abuse or dependence. Neuropsychological data were converted to age-, education- and sex-corrected *T* scores based on Heaton normative data (Heaton *et al.*, 1992), rather than using the control group as a reference. Results indicated that all groups obtained similar full-scale IQ and Heaton Reitan Average Impairment ratings. In contrast, on the Global Deficit Score, reflective of tests on which subjects performed two standard deviations below the mean, a higher percentage of cocaine users (27%) scored in the impaired range. Inspection of tests revealed differences on the Psychomotor, Simple motor and Attention domains, with no differences found on verbal, executive, learning, incidental memory, explicit memory and sensory abilities. Specifically, patients performed significantly worse on digit symbol, picture arrangement, Trails A, Speech Perception and grip strength. Impairment on these four cognitive tasks may reflect attentional difficulties. In contrast, they performed equally as well as controls on the Tactile Performance Test, Object Assembly, Block Design, Digit Span, Arithmetic, Picture Completion, Rhythm and tests of speeded dexterity. Thus, patients reporting abstinence for over 4 months demonstrated only inconsistent deficits on speeded motor-based attention tasks, along with reduced grip strength, with intact overall IQ, memory and abstraction.

While Robinson *et al.*'s study suggests some aspects of attentional processing may be impaired in abstinent cocaine users, consistent with evidence of frontal lobe dysfunction from neuroimaging studies, Horner's (1999) review of the literature on attentional processing in cocaine abusers did not support a consistent attentional deficit in this population. Horner identified seven well-designed studies that tested patients after several weeks of abstinence and controlling for confounding variables (Herning *et al.*, 1990; O'Malley *et al.*, 1992; Berry *et al.*, 1993; Roberts and Bauer, 1993; Bauer, 1994; Beatty, 1995; Van Gorp *et al.*, 1995). Despite improvements in methodology, mixed findings persisted across studies. Including the above-cited studies and others, Horner concluded, 'Thus, based on the evidence accumulated to date, it would be premature either to accept or reject the hypothesis of attentional impairment associated with cocaine dependence' (p. 30).

In one of the few longitudinal studies of cocaine abusers, Van Gorp *et al.* (1999) examined 37 cocaine abusers with a 1-year history of abuse, 13 years of education and almost daily use of cocaine, with recent use over 4 g in the last month. Subjects were compared to age- and education-matched controls within 72 hours of admission, and then 10, 21 and 45 days later on tests of declarative and procedural memory. Patients were monitored for substance use during the course of the study. Results revealed no significant differences on tests of verbal delayed memory at any testing time, although drop-out rates may have influenced this finding. On a measure of non-verbal delayed memory (Rey Complex Figure), the cocaine group performed significantly and consistently worse on the delayed free recall subtest at each test session. In contrast, this group displayed a faster rate of learning on the procedural memory task, even when the positive effect of nicotine was controlled. Thus, in this longitudinal study of relatively 'new' (use < 2 years) cocaine abusers, they were able to learn and recall verbal information in a normal fashion and learned at a faster rate on a procedural memory task, but displayed consistently worse delayed visual memory. One possible explanation for this finding is that patients with a prior history (greater than 6 months) of alcohol abuse were not excluded from this study. Selby and Arzin (1998) found that patients with a history of polysubstance (alcohol plus cocaine) abuse performed worse on the same measure of visual memory, while cocaine-only abusers performed in a similar fashion to controls.

To address the issue of dose-related effects, Bolla *et al.* (1999) compared 30 abstinent cocaine-abusing and 21 non-abusing well-matched controls, screened for past and present psychiatric and neurological illnesses, including other substance abuse. Cocaine subjects used cocaine by any route for at least 1 year, at least four times a month, and were using at the time of admission to the study. The cocaine group was given a comprehensive neuropsychological battery on the 28th or 29th day after entering into the inpatient unit. They received no treatment or medication during their inpatient stay prior to testing and randomly underwent urine screens to confirm abstinence. Controls and subjects were matched on premorbid intelligence, education and age. Multiple regression analyses indicated that the cocaine group performed better than the control group on tests of immediate memory (RAVLT Trial 1) and visuoperceptual/construction problem solving (Block Design), while performing worse on a measure of reaction time (go/no-go paradigm). This is consistent with other findings of other researchers, who have shown better performance on certain neurocognitive tasks in cocaine groups (e.g. verbal fluency, O'Malley *et al.*, 1992; attention, Gillen *et al.*, 1998; visuospatial learning and recall, Manschreck *et al.*, 1990).

Regression analysis revealed dose-related effects on tests of memory, executive, visuomotor, psychomotor speed and manual dexterity. Intensity of use, defined as grams of cocaine used per week, rather than duration or weekly frequency, was the most consistent predictor of performance. Bolla *et al.* hypothesized that neurobehavioural effects would only be seen at high levels of use. High-abusing patients (>2 g per week) were compared to low-abusing patients. Results indicated that the high-use patients performed worse than the low-use patients. However, while there were significant differences between the abusers, analyses comparing the high-dose users and the control group were not discussed. Inspection of available mean data indicated few differences on several of the measures. Specifically, the high-abusing group performed worse on only two tests, with slower reaction times and slower Trails B performance. Thus, these data suggest deficits on speeded cognitive flexibility and reaction time with dose-related effects for heavy cocaine-smoking individuals, but otherwise intact performance on other cognitive domains.

Bolla *et al.* (2000) also examined the impact of dose-related effects of cocaine and cocaine plus alcohol, on cognition. The study examined 29 chronic (mean 8 years) cocaine abusers, without history of alcohol abuse, and 27 cocaine abusers who also reported consistent abuse of alcohol (mean 15 years), in a treatment facility at 1–3 days of abstinence and again after 4 weeks. At time 1, regression analyses revealed dose effects on learning and memory measures for those who used 3 g or more of cocaine per week. Digit symbol also was negatively related to cocaine dose. Performance on the go/no paradigm revealed more false positive errors and less accuracy with higher cocaine use. After 4 weeks, partial variance regression analyses revealed dose-related effects for tests of mental processing speed in those reporting mid-range use of substances. Those who performed better at time 1 showed less of a dose-related effect, supporting a cognitive reserve hypothesis. There was also a dose-related effect for delayed verbal memory, with those that abused more cocaine performing worse at 4 weeks than low-dose users. Thus, this study supports the hypotheses of dose-related effects on certain measures of cognition, consistent with Jasiukaitis and Fein (1999). Those authors also found dose-related effects on cognition, with low-using patients ($22 000 spent per year) performing worse than high-using subjects ($64 000 spent per year). However, the subjects in this study used alcohol along with cocaine. While statistically controlled, this is not a clear assessment of the role of dosage on cognition in a group of cocaine-alone abusers.

Together these recent investigations indicate the impact of recent and long-term abuse of cocaine is minimal when present, though

possibly more likely when high doses are consumed, but may be compounded by the concurrent abuse of alcohol.

'ECSTASY'

'Ecstasy', ±3,4-methylene-dioxymethamphetamine (MDMA), is a ring-substituted amphetamine derivative with both stimulant and low-level hallucinogenic properties that was originally used for potential chemical warfare by the US Army in the 1950s. Psychotherapists later used it in the 1970s as an adjunct to psychotherapy because of its properties of increasing self-awareness and empathy (Rodgers, 2000). At present, the consumption of MDMA is primarily by adolescents and young adults in many Western countries (Bolla *et al.*, 1998; Morgan, 2000; NIDA, 2001). A recent Norwegian survey indicated that more than 3% of adolescents aged 14–17 have used ecstasy, with twice as many boys using the drug than girls, and in the UK between 200 000 and 5 million tablets are taken each weekend (Pedersen and Skrondal, 1999; Rodgers, 2000). In the USA, ecstasy use is associated with 'rave' culture and dance parties, and there are escalating numbers of both high school and college students who use MDMA at increasingly higher doses in other social contexts. For example, the rate of use of MDMA increased from 1999 to 2000 for students ages 13–18 (NIDA, 2000). The National Institute on Drug Abuse review of drug abuse trends among US grammar school and high school students showed that lifetime use of MDMA among 13- to 14-year-olds increased from 1.7% in 1999 to 3.1% in 2000. Similarly, there was a rise in lifetime use for 15- to 18-year-olds from 1999 to 2000 (i.e. 4.4% to 5.4% and 5.6% to 8.2%, respectively). African American high school senior students demonstrate lower rates of MDMA use (1.3%) compared to Hispanic (10.6%) and Caucasian students (7.6%) (NIDA, 2000).

This trend of increased ecstasy use among students and young adults is alarming given that research with laboratory animals has demonstrated neurotoxic effects of MDMA, including serotonergic neurodegeneration, decreases in brain serotonin and reductions in 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (Steele *et al.*, 1994; Morgan, 2000). Specifically, in rats and non-human primates, MDMA produces reduced serotonin levels and lesions in the cingulate, hippocampus, striatum, neocortex and thalamus (Ricaurte *et al.*, 1992, 1993). Investigating the possible long-term effects of MDMA exposure, Hatzidimitriou *et al.* (1999) found that squirrel monkeys exhibit persistent, decreased serotonergic innervation of all neocortices, hippocampal CA1 and CA2 regions (with evidence of some recovery in CA3), dentate gyrus, subiculum, caudate, putamen and the amygdaloid complex (except the central nucleus which fully recovers), 7 years after treatment with MDMA. Functional imaging studies (i.e. PET and SPECT) conducted with humans who use ecstasy have shown reduced glucose metabolism in the hippocampus, parahippocampal gyrus, insula, thalamus, amygdala, posterior cingulate bilaterally and portions of neocortex (i.e. decreased serotonin receptor binding in primary sensory and occipital cortices), as well as hypermetabolism in the ventromedial prefrontal cortex, ventral anterior cingulate, inferior temporal lobe and medial occipital lobe (Reneman *et al.*, 2000; Gamma *et al.*, 2000; Obrocki *et al.*, 1999; Semple *et al.*, 1999). However, some discrepancies exist (e.g. Gamma *et al.*, 2001) such that ecstasy use is not always associated with statistically significant differences in regional blood flow relative to healthy control subjects.

Although the primary focus of the current chapter is to review the possible neuropsychological effects of ecstasy use, it is notable that MDMA has been associated with particular personality variables such as impulsivity, sensation seeking and novelty seeking (for a review, see Morgan, 2000). While inconsistencies exist (e.g. McCann *et al.*, 1994) elevations on various measure of trait impulsivity (e.g. Impulsiveness, Venturesomeness and Empathy Questionnaire) have indicated that heavy ecstasy users demonstrate greater impulsivity than non-drug-using controls (Parrot, 2000). Overall, it appears that specific personality factors such as impulsivity or sensation seeking may be associated with increased risk for heavy ecstasy use, which may subsequently place users at risk for experiencing neurotoxic effects of MDMA.

A number of studies have examined the possible neuropsychological sequelae related to MDMA use given its demonstrable effects on serotonergic systems in animals and indirect effects observed in humans, likely affecting limbic and basal forebrain structures. Perhaps the most reliable finding regarding cognitive functioning among ecstasy users is that memory performance is often somewhat lower when compared with ecstasy-naïve control subjects (for a review see Morgan, 2000; Bhattachary and Powell, 2001; Gouzoulis-Mayfrank *et al.*, 2000; Zakzanis and Young, 2001; Morgan, 1999; Rodgers, 2000). For example, Morgan (1999) examined immediate and delayed recall among polydrug users who use ecstasy (>20 times) ($N = 25$), polydrug users who do not use ecstasy ($N = 22$), and healthy controls ($N = 19$). Polydrug users who also take ecstasy had not used ecstasy for an average of 65 days prior to participating in the study. Results indicated that the ecstasy group recalled fewer details of a story during immediate and delayed recall trials (delayed recall was administered approximately 40 minutes after initial presentation) compared to polydrug users and non-drug-using controls. The verbal recall performance of the ecstasy users was markedly decreased compared to participants in the other two control groups. Cannabis consumption did not differ significantly between the two drug-using groups, and when the two drug-using groups were combined cannabis consumption was significantly negatively correlated with immediate recall scores but not delayed recall. The two drug-using groups did differ on estimated IQ scores and duration of LSD use; however, only duration of LSD use proved to be a significant covariate and group differences on immediate and delayed recall performance remained significant when LSD use was statistically controlled. The author also examined the relationship between time since last use of ecstasy and memory performance and found that individuals who abstained from using ecstasy for more than 6 months had significantly better immediate and delayed recall scores compared to those who had used it within the past 6 months. Degree of memory impairment for individuals who had used the drug within the past 6 months was not reported. It is not clear if those individuals who did not use ecstasy in over 6 months also abstained from other or all drugs, and therefore it is difficult to determine whether the better performance was due to the lack of ecstasy use only or abstinence in general. Nonetheless, these data suggest that there is likely some recovery of memory functioning in moderate ecstasy users who refrain from taking it for a significant amount of time.

In a similar study, Rodgers (2000) compared the performance of 15 regular ecstasy and cannabis users, 15 cannabis users only and 15 non-drug-using controls on a broad battery of memory tests (i.e. Wechsler Memory Scale–Revised). Results indicated that both drug-using groups performed more poorly than the non-drug users on the General Memory Index and immediate and delayed story memory. Although statistically significant, a review of the index scores revealed that the MDMA and cannabis users' performance ranged from low average to average (i.e. not within a clinically impaired range), while the control group was average to high average. Only the ecstasy group demonstrated poorer delayed recall on a verbal-paired associates task and a visual-paired associates task relative to the cannabis and non-drug-using groups. Groups in this study did not differ on a composite index of immediate visual memory scores or subtests assessing attention and concentration. Differences in story recall were found in both the MDMA–cannabis group and the cannabis-only group; thus these results suggest that a deficit in story memory may be due to long-term cannabis use rather

than ecstasy use. However, ecstasy consumption may be associated with additional memory deficits, such as impairment in the ability to remember complex information (i.e. randomly organized material) across multiple cognitive domains (verbal and visual).

Other researchers have also found support for memory deficits among ecstasy users associated with amount of time since last use as well as total lifetime consumption of MDMA (Bhattachary and Powell, 2001; Gouzoulis-Mayfrank *et al.*, 2000; Zakzanis and Young, 2001; Bolla *et al.*, 1998). Compared to non-drug-using controls, Bhattachary and Powell (2001) showed that users of MDMA demonstrated poorer immediate and delayed prose recall compared to non-users. In this study, memory scores were not correlated with cannabis use; the apparent discrepant findings relative to the Rodgers (2000) study may be at least partially attributable to the variability and degree of cannabis use between these studies. Specifically, the cannabis group in the Rodgers (2000) study was using cannabis, on average, 4 days per week for a period of 11 years, whereas Bhattachary and Powell (2001) included individuals who had used cannabis two to four times in the 30 days prior to testing and their entire cannabis history was not reported. Regarding the effects of degree of ecstasy use, Bhattachary and Powell (2001) found that heavier users of MDMA obtained the worst memory performance relative to 'novice' and 'regular' users. Total lifetime consumption of ecstasy was the strongest predictor of memory scores, accounting for 34% and 36% of the variance of immediate and delayed recall, respectively. Time since last use predicated an additional 5% of variance in immediate recall and 10% of variance in delayed recall. When studied longitudinally, verbal memory performance has been shown to decline over a 12-month period with continued MDMA use (Zakzanis and Young, 2001). The authors of this study demonstrated that ecstasy users using the drug at a rate of 2.4 times per month display poorer memory performance on immediate and delayed prose recall tasks, 1 year following their initial baseline assessment. Measures of simple facial recognition memory, object memory and prospective memory were not significantly different over time (Zakzanis and Young, 2001).

None of the studies reporting poor verbal memory performance by ecstasy users employed methods of separating different memory processes. Without such investigation, it is difficult to determine whether ecstasy users exhibit poor encoding and consolidation processes or instead display impaired retrieval strategies that are more closely associated with executive dysfunction implicating a disruption of frontal–subcortical circuits. Some support for the latter hypothesis was provided by the Rodgers (2000) study, which found that ecstasy users show greater memory impairment when recalling complex, randomly arranged information (verbal or visual-paired associates). These tasks place high demands on one's ability to organize information and employ self-generated mnemonic strategies for optimal performance, an ability considered to be mediated by frontal cortical regions. Damage to frontal cortex or its associated connections to other cortical regions and subcortical structures can impair one's capacity for generating learning strategies as well as retrieving information previously learned. Future studies should include a recognition paradigm when assessing memory functioning in order to clarify the type of possible memory impairment and other cognitive deficits in individuals who use ecstasy.

In addition to decreased memory performance, recent research has shown that individuals who use ecstasy demonstrate poorer performance on measures of 'executive functioning' relative to controls. Specifically, some studies have demonstrated that working memory, divided attention, information-processing speed, motor speed and problem-solving skills may be affected by consumption of MDMA. For example, Croft *et al.* (2000) found that users of both MDMA and cannabis demonstrate slower processing speed (Stroop Word Reading), impaired memory span (digit span forward and backward), decreased verbal fluency ('Animals') and decreased manual dexterity for the left hand than individuals who do not use cannabis or MDMA. The authors cautioned that the differences between groups could be attributable to the cannabis use rather than ecstasy, as only processing speed (Stroop Word Reading) differences remained significant when cannabis use was held constant.

Other researchers have demonstrated additional evidence for relative decrements among ecstasy users (after controlling for cannabis use) on measures examining components of executive functioning. Wareing *et al.* (2000) found that both previous (i.e. those who had not used in at least 6 months; time since last use average, 323 days) and current users of MDMA demonstrate difficulty with tasks that place a high demand on cognitive resources. One measure administered in this study was the random letter generation test, a task that requires subjects to speak aloud consonants (i.e. no vowels) in a random sequence, avoiding repetitions of the same letter or using an alphabetical sequence, at different rates for each letter (1 second to 4 seconds). On this task, ecstasy users generated fewer letters and exhibited a greater degree of redundancy during the fastest letter rate presentation. Ecstasy users also had more vowel intrusions compared to non-users at the 1-, 2-, and 4-second letter rates. On a measure of information-processing speed, in which subjects were asked to determine whether two groups of letters were the same or different, the ecstasy groups processed information as quickly as non-users; however, they committed more errors when judging two groups containing nine letters. Increased error rates were not noted on the simpler trials involving three- and six-letter groups. Current users of MDMA reported more anxiety than non-users, while previous ecstasy users did not differ from controls on level of anxiety. The authors conducted covariance analyses to control for the effects of potentially confounding variables (e.g. anxiety, LSD use, physical health) and the results indicated that nearly all group differences on the letter generation task and the processing speed task remained significant. This study lends support for subtle impairments in some aspects of executive functioning among ecstasy users. Based on evidence from the previous ecstasy-using group (average time since last use, 323 days), the cognitive changes identified in this study may persist for almost 1 year following abstinence from MDMA.

In a study comparing ecstasy–cannabis users, cannabis-only users and non-drug-using controls, Gouzoulis-Mayfrank *et al.* (2000) did not find support for decreased accuracy on speeded information-processing measures; however, ecstasy users did exhibit longer response times on a test of selective visual attention (i.e. go/no-go) than the cannabis group or non-drug group. On a divided attention task involving both visual and auditory processing, MDMA users evidenced significantly longer reaction times than the two control groups. Auditory working memory capacity (digit span backward) was also poorer among ecstasy users relative to non-drug-using controls. When assessing the effects of moderate versus heavy ecstasy consumption, Verkes *et al.* (2001) showed that moderate and heavy MDMA use is associated with poorer visual working memory ability on the Corsi Block Tapping Test, although group differences did not reach statistical significance. On a test similar to a Sternberg paradigm (i.e. presentation of six words or figures and subsequent presentation of five new items and one previously presented), both moderate and heavy ecstasy users demonstrated difficulty recognizing previously presented material (working memory deficit). Reaction times on simple and choice attention tests were slowest in the heavy ecstasy-using group; however, these differences were diminished after controlling for level of education and score on the Beck Depression Inventory. Serotonergic functioning, measured by cortisol and prolactin response to dexfenfluramine challenge test, was also examined in this study and results indicated compromised neuroendocrine functioning among both moderate and heavy MDMA users relative to non-using controls. Serotonergic functioning was

significantly related to performance on the Corsi Block Tapping Test such that individuals with higher cortisol responses during the challenge test obtained better scores on the Corsi task. Overall, the effects of heavy ecstasy use may be associated with some slight inefficiency in working memory, processing speed and reaction time, although elevated levels of depression and lower levels of education may also explain or contribute to these findings.

In summary, the literature on the neuropsychology of MDMA consumption is somewhat variable but generally suggests that prolonged, moderate to heavy, regular use of ecstasy may produce subtle cognitive changes that affect one's memory capacity and executive functioning, and the changes may persist after abstinence from MDMA. Importantly, the majority of the studies reviewed above did not indicate individuals using MDMA obtained scores on cognitive tests that were within the very significantly impaired range, but rather scores generally represented low average to mildly deficient performance (e.g. Rodgers, 2000). Based on these results it is difficult to clearly determine to what extent MDMA use affected performance as well as other possible factors such as premorbid functioning, IQ, other drug use, personality traits and alcohol use.

KETAMINES

Ketamine is a non-competitive *N*-methyl-D-aspartate (NMDA) receptor antagonist that interferes with the action of the excitatory amino acids glutamate and aspartate, and its primary medical purpose is for veterinary anaesthesia (Anis *et al.*, 1983; Curran and Morgan, 2000). Anatomically, NMDA receptors are found in regions of the cerebral cortex and hippocampus and are associated with the modulation of dopamine concentration in the striatum (Curran and Morgan, 2000; Smith *et al.*, 1998). Blockade of NMDA receptors is associated with inhibition of long-term potentiation (LTP) in the hippocampus, impairing one's ability to encode new information (Kandel *et al.*, 2000). A functional imaging (PET) study indicated that subanaesthetic doses of ketamine are associated with increased extracellular dopamine concentrations in the prefrontal cortex and striatum (Smith *et al.*, 1998). According to the Drug Abuse Warning Network (DAWN) the recreational use of ketamine is common among young adults and teenagers and is considered a 'club drug' because of its association with 'raves' and dance clubs. Since 1994, use of ketamine has increased dramatically and emergency medical treatment for unexpected reactions or overdoses related to ketamine has also increased. Specifically, in 2000, there were 263 mentions of ketamine-associated reactions or overdoses in emergency room reports across multiple cities (NIDA Advanced Report, 2001). Of the 263 mentions, 70% were individuals under the age of 25.

Studies examining the acute effects of ketamine on healthy subjects have shown that ketamine intoxication is associated with decreased attentional capacity, reduced learning and memory functioning, poor novel-problem solving and impaired working memory ability (Hetem *et al.*, 2000; Krystal *et al.*, 2000; Adler *et al.*, 1998). For example, Hetem *et al.* (2000) showed that individuals learning words before and after infusion of ketamine ($0.5\,mg\,kg^{-1}$) recalled significantly fewer words administered during the ketamine phase than subjects who received a placebo. However, individuals who received the ketamine did not demonstrate deficient recall for words given prior to the drug administration, suggesting ketamine impairs encoding processes but not retrieval processes. During ketamine infusion, subjects also exhibited lower scores on attention tasks, including digit–symbol coding and digit cancellation. In a similarly designed study using the WCST, Krystal *et al.* (2000) found that subjects receiving a ketamine infusion obtained significantly fewer categories (1.5 versus 5.1) and committed more perseverative errors (69.2 versus 46.0) when compared to subjects who did not receive the drug. Individuals who initially received a placebo during the first administration of the WCST did not perform more poorly on the second WCST trial when they were given ketamine, indicating that ketamine likely interferes with the acquisition of functions related to abstract learning. It has also been demonstrated that acute effects of ketamine adversely affect working memory capacity assessed by a one-back and two-back paradigm (Adler *et al.*, 1998).

The possible persistent neurocognitive effects of recreational ketamine use have not been studied in large group investigations involving abstinent ketamine users. One study examining the relatively short-term effects have shown that ketamine-using individuals exhibit impairments in working, episodic and semantic memory 3 days after using ketamine compared to individuals with minimal ketamine histories but otherwise similar drug and alcohol histories (Curran and Morgan, 2000). On day three, ketamine users recalled less information from a prose passage following a 15-minute delay than non-ketamine-using controls. Ketamine users also generated fewer items on a semantic fluency task as well as committed more errors on a speeded task involving judgement of the semantic accuracy of sentences 3 days after ketamine intoxication. Groups did not differ on day three on a digit cancellation task, word-stem completion task, serial sevens or phonemic fluency. Examining the effects of frequent ketamine use, Curran and Morgan (2000) showed that frequent users (more than twice a month) evidence marked impairments in delayed recall of verbal information relative to infrequent users (less than twice a month) 3 days after taking ketamine. Frequent users also obtained significantly lower scores on phonemic and semantic fluency on day three; however, speeded comprehension of sentences, serial sevens and digit cancellation performance between groups did not differ. Although the long-standing effects of ketamine use are not clear, these studies provide evidence for an obvious and dramatic effect of acute ketamine intoxication on cognitive functioning as well as short-term changes in memory capacity.

OPIATES

Heroin use is on the rise, especially in Europe, the USA, and Australia. Along with increased prevalence, there has been a significant increase in the purity and availability of this drug. Subsequently, the rate of heroin non-fatal overdoses in addicts is estimates to be as high as 40%. Polysubstance abuse is also extremely high in this population (Gossop *et al.*, 1996). There are only a few studies examining the neurocognitive effects of opiates on cognition. Hill and Mikhael (1979) found that opiate users, primarily heroin addicts, demonstrated deficits on the Tactual Performance memory subtest and a tapping test, but generally intact executive functioning, consistent with other studies (Bruhn and Maage, 1975; Rounsaville, 1982). However, Ornstein *et al.* (2000) found evidence of executive deficits in heroin addicts. In this study 22 heroin-dependent and 23 amphetamine-dependent subjects were compared to age and premorbid IQ matched controls on several neuropsychological tasks. Results indicated that the heroin group performed significantly worse on the IDS subtest of the CANTAB and on a visuospatial strategy task, suggestive of possible frontal dysfunction. This finding is consistent with the widely held hypothesis that opiates most likely exert their reinforcing effects by increasing the mesolimbic DA system, which projects to the nucleus accumbens, prefrontal cortex and amygdala (Koob and Bloom, 1988). Additional evidence of possible frontal dysfunction comes from SPECT studies that have shown altered cerebral blood flow in the frontal and parietal cortices in patients with chronic opiate dependence. In addition to executive deficits, Darke *et al.* (2000) compared methadone maintenance

patients to a matched sample of non-heroin-using controls and found significant impairments in attention, memory and processing speed. Thus, recent studies examining the effects of heroin and possibly methadone on cognition have found evidence of at least acute effects following short-term abstinence. The impact of other substance abuse and non-fatal heroin overdoses may exemplify some of the findings as found in the Darke study.

Studies examining morphine use have shown little cognitive effects. For instance, Walker and Zacny (1998) examined the cognitive effects of 20–40 mg of morphine on 12 healthy volunteers. The drug did not affect performance on attention, memory and reasoning tests, consistent with other researchers (O'Neill *et al.*, 2000).

LSD

Lysergic acid diethylamide (LSD) is a synthetic ergoline compound that distorts cognitive, sensory and perceptual processes and was accidentally discovered by the chemist Albert Hoffman in 1943 (Hartmann, 1995; Aghajanian and Marek, 1999). LSD has been widely used for its psychedelic properties since the 1960s and its use has continued to rise among teenagers and young adults who are associated with the dance ('rave') scene. A recent survey conducted in Edinburgh, Scotland, showed that approximately 30% of participants (sample $N = 122$) using drugs at dance events use LSD, and its consumption ranks fifth (behind ecstasy, amphetamine, cannabis and cocaine) among the drugs most frequently used by drug-using individuals who attend rave parties (Riley *et al.*, 2001). Riley *et al.*'s (2001) survey also showed that the majority of these individuals use other drugs in addition to LSD and that 37.8% of those who use LSD take the drug at least once a month.

Aghajanian and Marek (1999) reviewed the effects of hallucinogens, including LSD, and their relationship to serotonergic activity within the central nervous system. Specifically, the effects of LSD are related to serotonergic mechanisms, and its hallucinogenic properties in particular are associated with its affinity for 5-HT_{2A} (and 5-HT_{2C}) receptors primarily within areas of the cerebral cortex and locus coeruleus (Aghajanian, 1994; Egan *et al.*, 1998). The locus coeruleus is responsible for maintaining vigilance and responsiveness to novel stimuli (Kandel *et al.*, 2000). It receives afferent input from sensory neurones carrying somatic, visceral and other sensory information and it contains spontaneously active neurones that project diffusely throughout the central nervous system (Aghajanian and Marek, 1999). The administration of LSD decreases the spontaneous activity within the locus coeruleus that ultimately results in increased activation of locus coeruleus neurones due to the stimulation from sensory afferents (Aghajanian and Marek, 1999). Within the cerebral cortex, LSD has a predominantly excitatory effect at 5-HT_{2A} receptors, which are densely located within the region of the medial prefrontal cortex (Aghajanian and Marek, 1999). Aghajanian and Marek (1999) suggest that the prolonged excitation of cortical regions, through glutamatergic transmission by hallucinogens, may contribute to the sensory, perceptual and cognitive distortions produced by drugs such as LSD. At 5-HT_{1A} receptors in the raphe nucleus, LSD is a potent agonist that has a direct inhibitory effect on the raphe neurones. LSD's activity at the 5-HT_{1A} receptors is not correlated with hallucinogenic properties but rather has similar anxiolytic effects to other 5-HT_{1A} agonists (Aghajanian and Marek, 1999).

The extant literature regarding the neuropsychological effects of long-term LSD use is mixed. Halpern and Pope's (1999) review of studies examining the possible residual effects of hallucinogen use indicated that some of the early studies, despite various methodological concerns (e.g. failure to control for current or past use of drugs other than LSD), demonstrated subtle neurocognitive impairments. Specifically, slightly decreased performances on tests of spatial abilities, sustained attention and processing speed, abstraction ability and cognitive flexibility have been indicated among LSD users; however, these results have not been consistently replicated. Culver and King (1974) attempted to control some of the potentially confounding variables such as premorbid intellectual abilities, personality functioning and alcohol history, and their results showed that when compared to non-LSD users individuals who used LSD performed similarly and generally within normal limits on a cognitive battery. However, performance on the Trail Making Test were significantly lower among the LSD group than the control groups' performance, even when alcohol consumption was held constant (as cited in Halpern and Pope, 1999). Overall, Halpern and Pope (1999) concluded that 'the [possible] residual neuropsychological effects of chronic hallucinogen use, if present, are modest'; many findings have not been replicated by subsequent studies and significant methodological concerns limit the interpretability of the majority of results.

Persistent perceptual disturbances associated with LSD use are rare but the consequences of chronic LSD use have included prolonged psychotic reactions, depression, flashbacks, exacerbation of pre-existing psychiatric illness and post-hallucinogen perceptual disorder (PHPD) (Smith and Seymour, 1994). PHPD is a disorder in which individuals reportedly experience trails of light or after-images following hand movement as well as increased psychological difficulties such as anxiety, depression or panic (Smith and Seymour, 1994; Hartmann, 1995). PHPD is a chronic condition that may persist for years following abstinence from LSD. Some cases have been treated successfully with selective serotonin reuptake inhibitors, benzodiazepines and naltrexone (Hartmann, 1995; Lerner *et al.*, 1997).

CONCLUSION

The majority of neuropsychological studies in this area have examined the effect of alcohol use on cognition. In general, these studies have indicated acute and residual cognitive deficits associated with abuse. Research on other drugs has been limited and often hindered by methodological flaws (e.g. failure to address premorbid intelligence and polysubstance abuse). At present, there is some support to suggest acute effects on cognition associated with cannabis, cocaine, ecstasy, ketamine, LSD and opiates, although these deficits are often minimal. The long-term effect on cognition is still unclear and warrants well-designed longitudinal studies.

Functional Anatomy of Substance-Related Disorders

R.A. Wise and E.L. Gardner

For the most part, the functional anatomy relevant to substance abuse disorders remains to be identified. One problem is that the field of substance-related disorders is not yet well defined. For the purposes of the present chapter, the substances under discussion will be drugs of potential abuse. However, the category of 'food' includes at least two classes of substances — sweets and lipids — that can also be abused. The case of food underlines an important principle: substance abuse need not involve the kinds of physiological dependence that have been assumed in the case of drug addiction. Food is 'abused' only when it is taken above and beyond any obvious physiological need. Current evidence suggests significant overlap in the brain circuitry relevant to foraging for food and foraging for drugs of abuse. For the most part, such circuitry has been identified as critical for the substance of interest to serve as a reward or 'reinforcer'. The terms reward and reinforcer are descriptive, not explanatory; they merely identify substances or events that are habit-forming.

The concept of habit is central to the topic of substance abuse. Again, the term is descriptive rather than explanatory. All substance abuse reflects the *habitual* intake of a substance. Some habits are benign, such as the habit of eating a small portion of pastry or ice cream following a meal. We invoke the notion of substance abuse in relation to habits that are pursued compulsively despite negative consequences. The consequences most obviously associated with substance abuse are addiction and obesity. The transition from recreational drug use to addiction is gradual, just as is the transition from overweight to obese, and we have no evidence to suggest that the mechanisms of modest food or drug intake differ in anatomical loci from those of excessive intake. Thus our current knowledge of the neuroanatomy of substance abuse is based largely on our understanding of why individuals take food and drug substances in the first place.

In one sense, the task of identifying the neuroanatomy of drug abuse is an easier one than that of identifying the neuroanatomy of feeding: most drugs of abuse act at receptors that have been identified and localized in the depths of the brain. Unlike foods, drug rewards do not rely on peripheral sensory pathways to reach the brain mechanisms serving motivational function. While addictive drugs act on multiple receptor populations, and while only a fraction of these populations serve motivational functions, by injecting drugs directly into the brain and comparing the effectiveness at different injection sites, we are able to identify chemical trigger zones for the habit-forming actions of several drugs of abuse. These trigger zones and the pathways that connect them can serve as a first step towards identifying the brain structures involved in substance-related disorders.

A classic issue in the field of drug abuse is the role of drug dependence. Clear-cut dependence syndromes can develop with chronic use of opiates, alcohol, barbiturates and benzodiazepines (Kalant, 1977), and more subtle dependence syndromes can develop with use of nicotine (Shiffman, 1979), cannabis (Jones, 1980) or cocaine (Jones, 1984). Addiction theory has, at least until recently, been dominated by the assumption that the self-medication of withdrawal distress differentiates between addiction and the so-called 'recreational' use of drugs. The present chapter thus begins with a discussion of some of the issues and neuroanatomy of drug dependence before turning to the topic of the neuroanatomy of drug reward.

NEUROANATOMY OF DRUG DEPENDENCE

Drug dependence develops with chronic drug use and is revealed in 'withdrawal symptoms' that are seen upon interruption of drug use. There is no common denominator of the range of drug dependence phenomena; the symptoms produced by withdrawal from a given drug depend on the specific actions of that drug. Generally, the withdrawal symptoms associated with a given drug are opposite to the symptoms of intoxication with that drug. Thus withdrawal from stimulants is generally associated with depression and withdrawal from depressants is generally associated with agitation. As a general rule, dependence is seen as resulting from 'compensatory' mechanisms: mechanisms that resist intoxication and tend, over time, to re-establish normal equilibrium. These compensations also result in tolerance (progressive desensitization) to the intoxicating effects of the drug and when the drug is withdrawn the unopposed compensations produce the objective signs of the withdrawal syndrome. If a system has no tonic endogenous input, it is possible to observe tolerance of the response to an exogenous drug in the absence of any overt symptoms when the drug is withdrawn. Usually, however, tolerance and dependence go together.

To the degree that drugs of different classes share common actions, they tend to establish overlapping tolerance and dependence syndromes and they are at least partially effective at alleviating each other's withdrawal symptoms. The ability of one drug to cause tolerance that extends to another drug is termed 'cross-tolerance'; the ability of one drug to alleviate the withdrawal symptoms associated with another drug is termed 'cross-dependence'. Even drugs such as opiates, alcohol and barbiturates, which produce partial cross-tolerance and partial cross-dependence, have some actions — and thus cause some adaptations — that are not shared (Kalant, 1977). There is a good deal of cross-tolerance between depressant drugs (opiates, alcohol, barbiturates and benzodiazepines) but little if any between depressant drugs of abuse and stimulant drugs of abuse (Wise, 1987).

'Somatic' Dependence Signs

Pursuit of the anatomy of drug dependence mechanisms has been fuelled by classic addition theory, which held that the self-medication of withdrawal distress was a central if not a defining

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

property of addiction (Tatum *et al.*, 1929; Himmelsbach, 1943; Lindesmith, 1947; Goldstein and Goldstein, 1961; Collier, 1966; Jaffe and Sharpless, 1968). Inasmuch as the withdrawal symptoms associated with such drugs as opiates and alcohol are unpleasant, and inasmuch as addicts report that they are 'sick' during withdrawal and that they take their drug to get 'well', this theory had obvious face validity. From the perspective of classic addiction theory, the anatomy of drug dependence should be the anatomy of the brain circuits regulating thermoregulation, autonomic function and the other somatic signs of drug withdrawal — the signs that addicts report as aversive and liken to some of the symptoms of influenza.

Our best knowledge of neuroanatomy of such dependence phenomena involves opiate dependence. In part, this is because the opiate withdrawal syndrome has frequently served as the model of other addictions. In part, it is because opiates can be injected directly into the brain sites where they have various actions and where they remain reasonably localized for many minutes. In part, it is because opiate withdrawal symptoms can be precipitated by administration of opiate antagonists, which can also be restricted to localized brain areas. Localization is relative, of course; drugs injected into the brain can diffuse to adjacent structures, to the ventricular system and into the circulation, from which they can reach distant targets of action. Adequate localization of the effects of direct drug injections into the brain requires the demonstration that higher doses are required to produce the same effects when the injections are in adjacent regions, into the ventricles or into the circulation. This is a requirement that is frequently not met in studies involving central drug injections.

Localized brain injections of opiates and opiate antagonists have been used to identify sites at which opiates act to cause the various symptoms of opioid intoxication and subsequent withdrawal, and where opiate antagonists precipitate the various somatic symptoms of the opiate withdrawal syndrome in dependent laboratory animals. The somatic symptoms include diarrhoea, ear blanching, ptosis, teeth chattering, 'wet dog' shakes, seminal emissions and in rats, attempts to escape from the test chamber. The human symptoms are similar: lacrimation, rhinorrhoea, yawning, sweating, restless sleep, dilated pupils, tremor, nausea and vomiting, diarrhoea, increased heart rate and blood pressure, chills, abdominal cramping, muscle spasms and sexual orgasm (both male and female).

The brain mechanism of a given somatic withdrawal symptom is the brain mechanism involved in the normal function that is distorted by intoxication and subsequent withdrawal. The diarrhoea during opiate withdrawal reflects an adaptation in the mechanism responsible for the constipation during opiate intoxication: the mechanism of μ-opioid inhibition of intestinal contractility. During intoxication the intestine relaxes; during withdrawal it contracts and expels the accumulated faeces. In the case of each withdrawal symptom, a mechanism specific to that symptom is involved. The sweats and chills of opiate withdrawal reflect the actions of opiates and opiate withdrawal on the mechanisms of regulation of body temperature. Thus the anatomy of opiate withdrawal is, essentially, the anatomy of opiate action. Not surprisingly, very many brain structures are implicated in the full range of opiate and other drug dependence symptoms.

Among the first opiate withdrawal symptoms to be associated with specific brain regions were the somatic signs of ptosis, teeth chattering, wet dog shakes, and escape behaviour. These symptoms can be precipitated in opiate-dependent rats by injections of opiate antagonists into the ventricular system of the brain (Laschka *et al.*, 1976a). If the cerebral aqueduct is blocked so that antagonists injected into the lateral or the third ventrical do not have easy access to the fourth ventral, it is injections into the fourth ventricle (Laschka *et al.*, 1976b) that are most effective. Injections into the nucleus locus coeruleus, at the lateral floor of the fourth ventrical, are similarly effective (Maldonado *et al.*, 1992). If the opiates themselves are infused locally into the periaqueductal grey matter or into the fourth ventricle, which is fed by the aqueduct, systemic naloxone precipitates the somatic signs of teeth chattering and escape behaviours (Wei and Loh, 1976; Wei, 1981; Bozarth and Wise, 1984). One hypothesis holds that these symptoms are responses to the fluctuations of body temperature that accompany opiate withdrawal and result from opiate-induced disturbance of temperature-regulating mechanisms (Wei *et al.*, 1974).

Of the sites that are readily reached by drug injections into the fourth ventricle, nucleus locus coeruleus and the periaqueductal grey have received most attention. The noradrenergic neurones of the locus coeruleus are inhibited by morphine; this inhibition undergoes tolerance with repeated application (Aghajanian, 1978). In opiate-dependent animals, the opiate antagonist naloxone precipitates accelerated firing of these neurones (Aghajanian, 1978); at least part of this hyperactivity appears to involve adaptations of the locus coeruleus itself (Ivanov and Aston-Jones, 2001). Part of this hyperactivity results from altered neuronal input to these cells (Akaoka and Aston-Jones, 1991). Thus while the cells of the locus coeruleus appear to be one anatomical substrate of dependence, the cells that provide input to the locus coeruleus are another. Presumably, the many cells that receive input from the locus coeruleus are yet other such substrates.

Indeed, most of the brain is involved directly or indirectly in the opiate dependence syndrome. Signs of abnormal activity in opiate-withdrawn animals are seen in the abnormal expression of early immediate genes in a variety of brain areas associated with autonomic function. Among these are the locus coeruleus and the A5 noradrenergic cell group, the nucleus of the solitary tract, the parabrachial nuclei, and the caudal and rostral ventrolateral medulla (Stornetta *et al.*, 1993). Moreover, it is not just autonomic control systems that are altered by opiate dependence. Indeed, studies of early immediate gene expression confirm that opiate withdrawal is accompanied by abnormal neuronal activity in multiple structures and at all levels of the neuraxis. Among additional sites where immediate early genes are activated during opiate withdrawal are the paraventricular nucleus of the hypothalamus, amygdala, ventral tegmentum, nucleus accumbens, neostriatum, cerebral cortex, hippocampus, thalamus, cerebellum and various layers of the spinal cord (Hayward *et al.*, 1990; Stornetta *et al.*, 1993; Beckmann *et al.*, 1995; Rohde *et al.*, 1996).

The fact that opiate withdrawal effects are widespread in the central nervous system makes a general search for an anatomical basis of opiate dependence a questionable enterprise. The problem is confounded when other drugs of abuse are considered, particularly because there is no common denominator to stimulant and depressant somatic dependence signs (Wise, 1987). The affected circuitry is not only widespread; it also differs from drug to drug. Even when we restrict consideration to the opiates, dependence appears to be more easily characterized in neurochemical than in anatomical terms. Opiate receptors are G-protein-coupled, and the exposure of G-protein-coupled receptors to agonists usually results in desensitization of the receptor (Ferguson *et al.*, 1998; Pitcher *et al.*, 1998). Other drugs of abuse also act on (e.g., cannabis) or via (e.g., cocaine, amphetamine and, more indirectly, nicotine) G-protein-coupled receptors. Rebounding supersensitivity of such receptors will, where the receptor usually receives endogenous input, result in withdrawal symptoms. This fact appears to confirm what has already been suggested: every site of opiate action can contribute to the complex phenomenon of opiate dependence. Localization of the mechanisms of opiate or other drug dependence thus requires a symptom-by-symptom characterization that may never be completed. Interest in drug withdrawal symptoms has thus tended to focus on the specific symptoms most likely to contribute to the motivation for drug self-administration.

Classic addiction theory — with its myriad withdrawal symptoms and syndromes — has always had as a primary weakness that it does not explain why non-dependent subjects initiate sufficient

drug intake to *become* dependent, nor does it explain why detoxified addicts are re-addicted so quickly. Broad dependence theory has thus been challenged by workers who hypothesize that it is the generation of drug-induced positive reinforcement and euphoria, rather than the alleviation of withdrawal-induced dysphoria, that motivates compulsive drug-seeking in addicts (McAuliffe and Gordon, 1974; Bijerot, 1980; Wise and Bozarth, 1987; Gardner, 1992; Robinson and Berridge, 1993; Di Chiara, 1998). This view gained support from the fact that stimulant drugs like cocaine, nicotine and cannabis can be taken compulsively despite withdrawal symptoms quite different from and much weaker than those associated with depressant drugs (Shiffman, 1979; Jones, 1980, 1984). Further support came from studies showing that lower animals would learn to take morphine, heroin, amphetamine, cocaine and related drugs compulsively even if they were not first made dependent. Indeed, animals will self-administer opiates in doses and limited access conditions that cause no overt somatic withdrawal symptoms (Deneau *et al.*, 1969; Woods and Schuster, 1971). Confirmation that opiates are strongly habit-forming independent of their ability to induce physical dependence came from the demonstration that rats self-administer morphine into the ventral tegmental area of the brain, a site at which infusions of doses that are effective elsewhere fail to produce somatic signs of dependence, but not into the periaqueductal grey, where infusions do cause somatic dependence signs (Bozarth and Wise, 1984). With the waning influence of dependence theory, interest in the neuroanatomy of somatic dependence signs has also waned, and dependence theory has come to focus on intoxication-induced neuroadaptations within the specific circuitry of drug reward.

Reward-Relevant Dependence Signs

With the realization that opiate dependence was not a necessary condition for compulsive opiate self-administration, the assumption that some form of physical dependence must explain compulsive self-administration of addictive drugs became less attractive and classic addiction theory became overshadowed by theories that focused on the positive reinforcing properties of drugs for non-dependent subjects (Fibiger, 1978; Wise, 1978, 1988; Wise and Bozarth, 1987; Di Chiara and Imperato, 1988; Gardner, 1992; Robinson and Berridge, 1993). The brain circuitry contributing importantly to the positive reinforcing properties of drugs of abuse has been a target of intensive investigation and is discussed in some detail in the next section. With the accumulating evidence as to the neural substrates of drug reward has come a focusing of dependence theory on those specific substrates. In the modern reformulation of dependence theory, neuroadaptations in the reward circuitry itself are posited to account for states of generalized depression and anhedonia and it is hypothesized that it is the self-medication of such states that adds the compulsive dimension to drug self-administration (Solomon and Corbit, 1973; Leith and Barrett, 1976; Kokkinidis *et al.*, 1980; Dackis and Gold, 1985; Kokkinidis and McCarter, 1990; Frank *et al.*, 1992; Koob and Bloom, 1988).

The first suggestion that drugs of abuse might desensitize the mechanisms of reward came from studies of the effects of drugs on rewarding electrical stimulation of the brain. While drugs of abuse usually potentiate the rewarding effects of lateral hypothalamic and related brain stimulation (Wise, 1996b), reward thresholds are elevated following withdrawal from chronic exposure to amphetamine (Leith and Barrett, 1976; Kokkinidis *et al.*, 1980; Wise and Munn, 1995), cocaine (Frank *et al.*, 1988, 1992; Kokkinidis and McCarter, 1990; Markou and Koob, 1991), ethanol (Schulteis *et al.*, 1995) and nicotine (Watkins *et al.*, 2000). The period of elevation lasts, however, only a few days, far short of the period when peak craving for opiates (Shalev *et al.*, 2001) or cocaine (Grimm *et al.*, 2001) occurs.

A variety of neuroadaptations have been found within the mesolimbic dopamine system and its primary terminal field, the nucleus accumbens. These loci are central to current knowledge of brain reward circuitry, and neuroadaptations in these loci are of potential relevance to drug dependence. The known neuroadaptations range from morphological changes (Beitner-Johnson and Nestler, 1991; Beitner-Johnson *et al.*, 1992; Sklair-Tavron *et al.*, 1996) to changes in neurotransmitter sensitivity (Bell *et al.*, 2000; Henry and White, 1991) and changes in intracellular signalling cascades and transcription factors (Cha *et al.*, 1997; Chen *et al.*, 1997; Fitzgerald *et al.*, 1996; Hope *et al.*, 1992; Kelz *et al.*, 1999; Nestler *et al.*, 1990; Terwilliger *et al.*, 1991). Some of these changes are associated with decreased sensitivity — tolerance — to the drug, while others are associated with increased sensitivity — sensitization. Mechanisms of tolerance are consistent with traditional dependence theory, but mechanisms of sensitization are opposite to those associated with dependence theory, and the finding that addictive drugs can sensitize the nervous system to the drug's rewarding action raises another challenge to dependence theory and the question of whether its anatomy is part of the anatomy of substance abuse.

Sensitization in Reward Pathways

Dependence theory is predicated upon the notion that increasing amounts of the drug are needed to ameliorate withdrawal symptoms. Dependence theory thus requires that the effects of repeated drug experience decrease the sensitivity of the brain to the addictive drug, and bias normal brain function in the opposite direction from the acute drug state (Solomon and Corbit, 1973; Koob *et al.*, 1989). Some drug effects — in particular those associated with somatic withdrawal symptoms — do appear to desensitize with chronic drug treatment. The reward-specific effects of amphetamine (Lett, 1989; Piazza *et al.*, 1990; Lorrain *et al.*, 2000), cocaine (Lett, 1989; Horger *et al.*, 1990; Shippenberg and Heidbreder, 1995) and morphine (Lett, 1989; Shippenberg *et al.*, 1996), however, appear to undergo sensitization, at least with intermittent repeated treatment. Thus while it is true that tolerance to the rewarding effects of cocaine can occur within a binge of cocaine self-administration (Emmett-Oglesby and Lane, 1992; Li *et al.*, 1994), sensitization to the rewarding effects of cocaine appear to occur *between* such binges. While tolerance usually decreases within a few days of the last drug administration, sensitization to intermittent psychomotor stimulants is very long lasting (Robinson and Becker, 1986).

The finding that between-session sensitization is much stronger and longer-lasting than any obvious signs of tolerance to the rewarding effects of these drugs has led to yet another positive reinforcement perspective on addiction (Robinson and Berridge, 1993). This perspective has again raised the question of whether drug dependence phenomena play the significant role in addiction that has been suggested by dependence theory. The sensitization-of-reward findings directly challenge all forms of dependence or opponent process theory and raise, again, serious questions about the relevance of the neuroanatomy of dependence to the neuroanatomy of substance abuse. While it is clear that there are drug-induced neuroadaptations within the reward system itself, the importance of drug-opposite or drug-like neuroadaptations for drug self-administration require direct experiments that have only recently begun (Carlezon *et al.*, 1998; Kelz *et al.*, 1999).

NEUROANATOMY OF DRUG REWARD

While it does not make obvious sense to discuss a 'trigger zone' for the rewarding effect of such natural incentives as food or sexual contact, it is well established that food, like the psychomotor

stimulants and a number of other drugs of abuse, depends upon dopamine neurotransmission for its rewarding effects (Wise *et al.*, 1978; Spyraki *et al.*, 1982; Ettenberg and Camp, 1986). The major dopamine systems originate in the midbrain and have long-axon projections to the forebrain. These neurones originate as one embryonic group, but the somata spread laterally from the midline and are somewhat arbitrarily subdivided into a nigrostriatal system, originating primarily in the substantia nigra and projecting primarily to the caudate nucleus, and a mesocorticolimbic system, originating primarily in the more medial ventral tegmental area and projecting primarily to the frontal and cingulate cortices, the septum, hippocampus, amygdala and the nucleus accumbens. Of the various dopaminergic terminal fields, the nucleus accumbens is most clearly seen as serving motivational function (Mogenson *et al.*, 1980). It appears to house trigger zones — regions where the drug binds and initiates its relevant pharmacological action — for the rewarding effects of at least three classes of addictive drug.

Nucleus Accumbens

The nucleus accumbens appears to be the primary site of rewarding action for amphetamine, one of two sites of rewarding action for cocaine and for phencyclidine, and one of two sites of putative rewarding action for addictive opiates. The mechanisms of rewarding action of amphetamine and cocaine are secondary to their actions at the dopamine transporter, by which they elevate nucleus accumbens dopamine levels, whereas phencyclidine and morphine have rewarding actions due to their actions at receptors for the neurotransmitter glutamate or for one or more of the endogenous opioid peptides, respectively. The rewarding action of each appears to result in decreased activity in the medium-sized spiny neurones that comprise the output neurones of the nucleus accumbens. While much less is known about the habit-forming actions of cannabis, alcohol, barbiturates, benzodiazepines and caffeine, there are reasons to suspect that the nucleus accumbens also plays a part in the habit-forming effects of these potentially addictive agents.

Phencyclidine

Phencyclidine (PCP) is a non-competitive antagonist at the NMDA-type excitatory amino acid receptor, where it blocks some of the excitatory effects of glutamate (Chaudieu *et al.*, 1989; Ohmori *et al.*, 1992). It is also, at higher concentrations, a dopamine uptake inhibitor (Gerhardt *et al.*, 1987). It is self-administered compulsively by a small but stable subset of humans (Crider, 1986); it is also self-administered by laboratory animals (Balster *et al.*, 1973), but not with the vigour or reliability that characterizes intravenous heroin or cocaine self-administration (Collins *et al.*, 1984). PCP has mixed rewarding and aversive actions when given systemically (Barr *et al.*, 1985; Crider, 1986; Iwamoto, 1986), but has straightforward rewarding actions when given directly into the shell portion of the nucleus accumbens (Carlezon and Wise, 1996). PCP shares this rewarding action with NMDA antagonists that do not affect dopamine uptake, and the rewarding action of these agents in the nucleus accumbens is not attenuated by sulpiride, a D_2 dopamine antagonist that attenuates the rewarding effects of nucleus accumbens injections of the dopamine uptake inhibitor nomifensine (Carlezon and Wise, 1996). Thus PCP has dopamine-independent rewarding actions at the NMDA receptor, where it binds at 10 times lower concentration than is required for its binding at the dopamine transporter (Chaudieu *et al.*, 1989; Ohmori *et al.*, 1992).

Before accepting the assumption that intracranial injections of a drug identify the systems where it acts, one should require convincing evidence that the drug is not diffusing from the site of injection to a distal site of action. A central drug injection can reach a distant site of action in three ways. First, it may simply diffuse through the extracellular space to adjacent structures. Only if injections into surrounding structures are less effective and occur with greater latency can we conclude that a drug is acting in a given target site. Second, drugs that readily cross the blood–brain barrier can reach distal sites of action via the circulation. The obvious safeguard against this possibility is the demonstration that the same low doses are ineffective when given intravenously. Finally drugs injected under hydraulic pressure can follow the pressure gradient up the cannula shaft, and, if the cannula penetrates a ventricle, to the ventricular pressure sink through which it can reach distal circumventricular organs. This artefact led to misinterpretation of several studies involving the effects of central hormone and neurotransmitter injections on drinking behaviour (Johnson and Epstein, 1975). In the case of intracranial self-administration of PCP, fluid egress up the cannula shaft is the most likely of these possibilities. The lateral ventricle is just above the nucleus accumbens, and a vertical penetration to the shell of the nucleus accumbens usually involves penetration of the ventricle, establishing a pressure gradient from the cannula tip to the ventricular system (where fluid flows naturally from the lateral to the third and fourth ventricles and cerebrospinal aqueduct. The demonstration that PCP is self-administered into the shell of the nucleus accumbens (Carlezon and Wise, 1996) has two controls that increase confidence that the drug's rewarding action is in the nucleus accumbens. First, an angled cannula was used to avoid penetration of the ventricle. Second, rats did not self-administer PCP to a site in the core of the nucleus accumbens, 1 mm dorsal and slightly lateral — along the same cannula track — to the positive reward sites in the shell of the accumbens. Such essential controls (Routtenberg, 1972; Wise and Hoffman, 1992) are lacking in most central injection studies, and this fact leaves interpretation of several central injection studies in doubt.

Amphetamine

Amphetamine binds to and reverses monoamine transporters, causing release of noradrenaline (norepinephrine), dopamine and serotonin. The first evidence of a role for dopamine in drug reward came from studies in which intravenous amphetamine self-administration was disrupted by treatment with dopamine-selective (but not noradrenaline-selective) receptor antagonists (Yokel and Wise, 1975, 1976; Risner and Jones, 1976). Lesions of the nucleus accumbens, like treatment with dopamine receptor blockers, attenuate intravenous amphetamine self-administration (Lyness *et al.*, 1979). Amphetamine is self-administered directly into the nucleus accumbens but not into the lateral ventricles (Hoebel *et al.*, 1983); this self-administration of amphetamine is not evident if amphetamine is co-injected with dopamine antagonists (Phillips *et al.*, 1994). Local injections of amphetamine into this region but not adjacent regions also establish conditioned place preferences (Carr and White, 1983). Thus the nucleus accumbens is a critical site for the habit-forming actions of amphetamine; amphetamine's rewarding action depends on the activation of local dopamine receptors by the extracellular dopamine that accumulates (Zetterström *et al.*, 1981) because of amphetamine's action at the dopamine transporter.

Once a period of amphetamine self-administration has been initiated, extracellular dopamine concentration appears to regulate the frequency of continued responding. Rats tend to respond to amphetamine until their nucleus accumbens dopamine levels are elevated three- to five-fold; they then wait until prior injections are partially metabolized and their dopamine levels have fallen to approximately twice-normal levels before responding again (Ranaldi *et al.*, 1999). Thus dopamine actions in the nucleus accumbens are not only critical for whether or not amphetamine is rewarding; they also appear to determine how long a given injection will satiate an animal.

Cocaine

Cocaine, like amphetamine, is rewarding through its ability to elevate nucleus accumbens dopamine levels (de Wit and Wise, 1977; Risner and Jones, 1980). Whereas amphetamine is a dopamine releaser, cocaine is a dopamine uptake inhibitor (Heikkila *et al.*, 1975a, 1975b). While cocaine appears to be more effective as a reinforcer when injected into the frontal cortex (Goeders and Smith, 1983), if animals are given sufficient exposure they will self-administer it directly into the nucleus accumbens (Carlezon *et al.*, 1995), where dopamine-selective lesions attenuate the rewarding effects of intravenous cocaine (Roberts *et al.*, 1977, 1980). Moreover, frontal cortex injections of cocaine appear to be rewarding because they trans-synaptically elevate nucleus accumbens dopamine levels (Goeders and Smith, 1993). Nomifensine, a more selective (Samanin *et al.*, 1975) and efficacious (Nomikos *et al.*, 1990) dopamine uptake inhibitor, is also rewarding in the shell (but not the core) of the nucleus accumbens, and its effectiveness is blocked by co-administration of the D_2 dopamine antagonist sulpiride (Carlezon *et al.*, 1995). This suggests that it is not the local anaesthetic action of cocaine (Ritchie and Greene, 1985) in nucleus accumbens that accounts for its rewarding actions there. Self-administered doses of cocaine, like self-administered amphetamine, elevate nucleus accumbens dopamine levels (Hurd *et al.*, 1989; Pettit and Justice, 1989) and maintain them at levels two or more times above normal baseline levels (Wise *et al.*, 1995b).

Opiates

It is also thought that opiates trigger rewarding actions in the nucleus accumbens. Morphine (Olds, 1982) and the endogenous opioid met-enkephalin (Goeders *et al.*, 1984) are reported to be self-administered into this region, and morphine injections into this region are reported to cause conditioned place preferences (van der Kooy *et al.*, 1982). Some concern must remain, however, as to whether opiate injections into this brain region have their rewarding actions locally (Wise, 1989). In studies where nucleus accumbens self-administration or conditioned place preference has been reported, anatomical controls that would rule out drug efflux to the ventricular system or adjacent sites have not been reported. This is troublesome because much lower doses of morphine are self-administered or cause conditioned place preferences when injected into other brain sites (Bozarth and Wise, 1981, 1982; Bozarth, 1987; Olmstead and Franklin, 1997). Moreover, some workers have reported nucleus accumbens opiates to be ineffective in each of these reward paradigms (Bozarth and Wise, 1982; Schildein *et al.*, 1998; Zangen *et al.*, 2000).

It is tempting, nonetheless, to suspect that opiates at high enough concentrations can induce rewarding effects at nucleus accumbens opiate receptors. There are several populations of opioid receptors in nucleus accumbens, and μ- and δ-opioids inhibit nucleus accumbens medium spiny neurones (Hakan and Henriksen, 1989; Jiang and North, 1992). There are μ-opioid receptors on the medium spiny output neurones of the nucleus accumbens (Wang *et al.*, 1997). Activation of these receptors is thought to inhibit medium spiny neurone activity much as does dopamine and systemic morphine (Hakan and Henriksen, 1989). In addition, there are both μ- and δ-opioid receptors on the presynaptic terminals of corticolimbic glutamate inputs to the nucleus accumbens. Actions at each of these receptor subtypes appear to inhibit release of the excitatory amino acid glutamate onto medium spiny neurones (Jiang and North, 1992), much as does blockade of NMDA receptors by PCP. The two compounds that have been reported to be self-administered into the nucleus accumbens, morphine and met-enkephalin, each activate both μ- and δ-opioids. There are also κ-opioid receptors in the nucleus accumbens, but κ-opioids are aversive and act at the dopamine transporter to decrease dopamine release (Thompson *et al.*, 2000).

Cannabinoids

While there are no behavioural studies in which local injections of cannabinoids were used to localize a rewarding site of action, there is evidence that cannabinoids can influence the mesolimbic dopamine system. The major psychoactive constituent of marijuana and hashish is Δ^9-tetrahydrocannabinol (THC). Partly for reasons of solubility, this substance appears to have its greatest abuse liability when smoked. Recently, however, intravenous self-administration of THC has been demonstrated in squirrel monkeys (Tanda *et al.*, 2000) and intravenous self-administration of a synthetic cannabinoid has been shown in mice (Martellotta *et al.*, 1998). Systemic treatment with THC can also establish conditioned place preferences (Lepore *et al.*, 1995; Valjent and Maldonado, 2000).

THC elevates nucleus accumbens dopamine levels when given either systemically (Chen *et al.*, 1990) or directly into the nucleus accumbens (Chen *et al.*, 1993), and it enhances potassium-induced dopamine release in much the same way as do dopamine uptake inhibitors (Ng Cheong Ton *et al.*, 1988). Such elevations appear to occur selectively in the shell of the nucleus accumbens (Tanda *et al.*, 1997a). When THC is given in combination with haloperidol, the dopamine release normally caused by haloperidol-induced blockade of dopamine autoreceptors is enhanced, as it is by dopamine uptake inhibitors (Gardner *et al.*, 1990). Finally, THC's effect on nucleus accumbens levels of the dopamine metabolite 3-methoxytyramine resembles the effects of a dopamine uptake inhibitor (Heal *et al.*, 1990) like cocaine or nomifensine (Chen *et al.*, 1994). It would thus seem that at least some part of the habit-forming effects of THC is triggered in the nucleus accumbens or somehow depends on nucleus accumbens dopaminergic function.

Alcohol

Ethanol elevates nucleus accumbens dopamine levels (Imperato and Di Chiara, 1986; Gonzales and Weiss, 1998; Weiss *et al.*, 1993), and intra-accumbens microinjections of the dopamine D_2 receptor antagonist raclopride produce dose-orderly decreases in ethanol self-administration (Samson *et al.*, 1993). Thus it seems likely that alcohol has habit-forming actions mediated in part by the nucleus accumbens. In this case, however, there is no evidence to suggest that alcohol's interface with drug reward circuitry is *within* the nucleus accumbens.

Caffeine

The only links between caffeine and drug reward circuitry are extremely speculative. There is no direct experimental evidence on caffeine's central sites of rewarding action. Indeed, although reports do exist of successful caffeine self-administration in laboratory rats (e.g., Collins *et al.*, 1984), monkeys (e.g., Deneau *et al.*, 1969) and baboons (e.g., Griffiths *et al.*, 1979), the bulk of the existing literature suggests that caffeine self-administration in laboratory animals is inconsistent and sporadic at best (see reviews by Griffiths and Woodson, 1988; Griffiths and Mumford, 1995; Howell *et al.*, 1997). More consistently, caffeine has been reported to augment the reinforcing properties (e.g., Schenk *et al.*, 1994; Shoaib *et al.*, 1999), prolong extinction of self-administration (e.g., Kuzmin *et al.*, 1999) and trigger reinstatement of extinguished self-administration (Schenk and Partridge, 1999) of *other* addictive drugs.

Caffeine is an antagonist at adenosine A_1 and A_2 receptors, and its behavioural effects appear to be mostly mediated by such actions (Fredholm *et al.*, 1999). As adenosine A_1 (Goodman and Snyder, 1982; Fastbom *et al.*, 1987) and A_{2A} (Dixon *et al.*,

1996; Rosin *et al.*, 1998) receptors are densely distributed in the nucleus accumbens, as A_{2A} receptors are extensively co-localized with dopamine D_2 receptors and preproenkephalin mRNA in accumbens medium spiny neurones (Svenningsson *et al.*, 1997, 1998), and as A_{2A} receptors are also co-localized (sparsely to be sure, but significantly above background levels) with dopamine D_1 receptors in the accumbens (Svenningsson *et al.*, 1997, 1998), it may be surmised that adenosine receptor activation in the accumbens modulates meso-accumbens dopaminergic function. Indeed, considerable evidence exists that A_1 or A_{2A} receptor activation inhibits dopaminergic function mediated through either the D_1 or D_2 receptor, and that adenosine antagonism *enhances* meso-accumbens dopaminergic function (e.g., Turgeon *et al.*, 1996; Le Moine *et al.*, 1997; Moreau and Huber, 1999; Svenningsson *et al.*, 1999; Poleszak and Malec, 2000). In a standard drug discrimination assay in monkeys, adenosine antagonism generalizes dose-dependently and completely to eight different dopamine receptor agonists that encompass a variety of mechanisms and sites of action, both pre- and postsynaptic (Holtzman, 1999). Further, the discriminative stimulus properties of the non-selective A_1/A_2 adenosine antagonist CGS-15943 are blocked dose-dependently and completely by the dopamine D_1 antagonist SCH-23390 and the D_2 antagonist eticlopride (Holtzman, 1999). Congruently, caffeine enhances dopamine turnover in the striatum (Waldeck, 1972, 1975; Watanabe and Uramoto, 1986) and enhances striatal dopamine release in freely moving rats as measured by *in vivo* voltammetry (Morgan and Vestal, 1989). Recent evidence suggests that adenosine and dopamine receptors form heterodimers in medium spiny neurones (Franco *et al.*, 2000). All of these interesting findings notwithstanding, it is only by tentative and arbitrary decision-making that we include caffeine with habit-forming drugs having rewarding sites of action in the nucleus accumbens. There is no evidence that caffeine has its rewarding action at trigger zones in the nucleus accumbens, and it is listed here simply because we could suggest no more relevant place for it.

Ventral Tegmental Area

Opiates

A good deal of evidence suggests that the primary site of rewarding action of opiates is in the ventral tegmental area, where μ-opioids disinhibit the mesocorticolimbic dopamine system by inhibiting the GABAergic cells that normally hold their dopaminergic neighbours under inhibitory control (Johnson and North, 1992). First, μ- and δ-opioids are self-administered into the ventral tegmental area but not into an area just dorsal to it (Bozarth and Wise, 1981; Welzl *et al.*, 1989; Devine and Wise, 1994; Zangen *et al.*, 2000). The μ-opioid DAMGO is 100 times more potent than the δ-opioid DPDPE. Ventral tegmental injections of these substances elevate nucleus accumbens dopamine levels (Leone *et al.*, 1991; Devine *et al.*, 1993), and DAMGO is here again 100 times more potent than DPDPE. Opiate antagonists injected into the ventral tegmental area decrease the rewarding effects of intravenous heroin, although there is disagreement as to whether they do so more potently than antagonists injected into the nucleus accumbens (Britt and Wise, 1983; Vaccarino *et al.*, 1985). Opioid doses that are ineffective in the nucleus accumbens establish intracranial self-administration and conditioned place preferences in the ventral tegmental area (Bozarth, 1987; Olmstead and Franklin, 1997; Zangen *et al.*, 2000). Indeed, in other behavioural tests opioids have stronger behavioural effects when injected into the ventral tegmental area than when injected into the nucleus accumbens (Broekkamp *et al.*, 1976; Kalivas *et al.*, 1983; Jenck *et al.*, 1987; West and Wise, 1988; Zangen *et al.*, 2000) unless the nucleus accumbens is pharmacologically or neurotoxically deprived of dopamine (Stinus *et al.*, 1985, 1986).

It is clear that self-administered intravenous doses of heroin are sufficient to activate the mesolimbic dopamine system, as self-administered intravenous heroin elevates nucleus accumbens dopamine much as do self-administered amphetamine and cocaine (Wise *et al.*, 1995a). Thus — since it is unlikely that medium spiny neurones in the nucleus accumbens can discriminate the dopamine overflow that results from heroin's action at the dopamine cell bodies from that resulting from amphetamine's or cocaine's actions at the dopamine transporter — it seems clear that opiate actions triggered in the ventral tegmental area must contribute significantly to the rewarding effects of intravenous heroin. This suggestion is strengthened by the fact that the initiation of the next within-session lever-press for intravenous heroin, like those for intravenous amphetamine and cocaine, can be predicted by the fall of nucleus accumbens dopamine levels to a trigger point about twice the normal dopamine concentration (Pocock *et al.*, 1994).

Nicotine

Nicotine also triggers its rewarding actions in the ventral tegmental area. Here the critical receptors are on the dopaminergic neurones themselves (Clarke and Pert, 1985). Intravenous nicotine self-administration is blocked by dopamine antagonists and neurotoxins as well as by chlorisondamine (Corrigall *et al.*, 1992), a nicotinic channel blocker that is taken up and concentrated within the dopaminergic cell bodies of the ventral tegmental area and substantia nigra (El-Bizri *et al.*, 1995). Nicotine increases dopaminergic cell firing (Grenhoff *et al.*, 1986; Mereu *et al.*, 1987) and elevates dopamine levels in the nucleus accumbens (Imperato *et al.*, 1986). Thus nicotine, like amphetamine, cocaine and morphine, appears to be habit-forming because it elevates dopamine levels in the nucleus accumbens.

Nicotine also elevates dopamine levels when infused directly into the nucleus accumbens, where the cholinergic agonist carbachol is self-administered (Ikemoto *et al.*, 1998a). However, as is the case with ventral tegmental and nucleus accumbens administration of opioids, nucleus accumbens actions of nicotine appear to be weaker than the ventral tegmental actions of nicotine (Benwell *et al.*, 1993; Nisell *et al.*, 1994) and thus seem unlikely to account for the rewarding effects of systemic nicotine (Corrigall *et al.*, 1992).

Cannabinoids

Like morphine, THC has actions in the ventral tegmental area (VTA) as well as in the nucleus accumbens. First, it stimulates dopaminergic cell firing and this effect is not blocked — while at least part of the elevations seen in dialysis studies are (Chen *et al.*, 1990; Tanda *et al.*, 1997a) — by opiate antagonists (French, 1997; Melis *et al.*, 2000). Second, local application of THC to the ventral tegmental area elevates ventral tegmental but not nucleus accumbens dopamine levels (Chen *et al.*, 1993). This effect is tentatively interpreted as a reflection of the inhibition of dendritically released dopamine; it is not known if this local effect of THC in the VTA is naloxone-sensitive. Local injections of cannabinoids into the VTA have not been tested in behavioural paradigms.

Alcohol

Ethanol increases the firing rate of dopamine neurones in the rat VTA (Gessa *et al.*, 1985; Brodie *et al.*, 1990) and it is self-administered directly into the VTA (McBride *et al.*, 1993; Gatto *et al.*, 1994; Rodd-Henricks *et al.*, 2000). This intracranial self-administration of ethanol was seen in selectively bred alcohol-preferring and ordinary Wistar rats, but not in selectively bred alcohol-non-preferring rats. The animals performing

such intracranial ethanol self-administration show lever discrimination, extinction of self-administration when vehicle is substituted for ethanol, and reinstatement of self-administration responding on the active lever when ethanol is once again made available (Rodd-Henricks *et al.*, 2000). Sites dorsal to the VTA do not support ethanol self-administration (Gatto *et al.*, 1994). In a mapping study, posterior ventral tegmental sites were found to support ethanol self-administration; anterior ventral tegmental sites did not (Rodd-Henricks *et al.*, 2000). As noted by McBride *et al.* (1999), intracranial ethanol self-administration may involve brain serotonin (5HT) mechanisms, especially $5HT_3$ receptors. Ethanol potentiates the depolarizing effects of 5HT at the $5HT_3$ receptor (Lovinger and White, 1991), and local $5HT_3$ agonist microinfusion increases somatodendritic dopamine release in the VTA (Campbell *et al.*, 1996), suggesting that activation of $5HT_3$ receptors in the VTA may activate meso-accumbens dopamine neurones. Most provocatively, local $5HT_3$ antagonist microinfusion prevents ethanol-induced somatodendritic dopamine release in the ventral tegmental area (Campbell *et al.*, 1996), suggesting that ethanol's action on meso-accumbens dopamine neurones is mediated via VTA $5HT_3$ receptors. Ethanol's actions on meso-accumbens dopamine neurones may also involve $GABA_A$-(Harris *et al.*, 1995) or NMDA-mediated (Weight *et al.*, 1991) mechanisms.

Barbiturates and Benzodiazepines

Barbiturates and benzodiazepines are self-administered and can be abused by humans. These drugs are also self-administered in animal models, more readily in primates than in rodents (Ator and Griffiths, 1987). Neither self-administration nor conditioned place preferences have been established with intracranial injections; thus notions of the sites of rewarding action for these drugs are largely based on evidence that barbiturates and benzodiazepines act via an interaction with $GABA_A$ receptors (e.g., Korpi *et al.*, 1997; Chebib and Johnston, 1999). Inasmuch as opiates are thought to have rewarding actions by decreasing $GABA_A$ inhibition of dopaminergic neurones in the VTA, one possibility is that barbiturates and benzodiazepines have dopamine-dependent rewarding actions in the VTA. This fits with the finding that dopaminergic lesions of the nucleus accumbens produced by microinjections of the dopaminergic cytotoxin 6-hydroxydopamine block diazepam-induced conditioned place preference (Spyraki and Fibiger, 1988). However, the GABAergic synaptology of the ventral region area is complex, as GABAergic neurones comprise not only afferents to but also efferents from this region. Recent evidence suggests that some GABAergic drug actions are reflected in dopaminergic output and others are reflected in non-dopaminergic output (Laviolette and van der Kooy, 2001).

Non-Dopamine Output from the VTA

The view that rewarding brain stimulation, natural rewards like those of food and sexual contact, and several drug rewards owe their ability to control behaviour to the fact that they elevate mesolimbic dopamine levels is widely but not uniformly accepted (Wise, 1996b; but see Koob and Goeders, 1989; Bechara *et al.*, 1998). Several recent findings suggest that the dopaminergic output of the VTA is not the only contribution of this region to reward function.

First, ventral tegmental microinjections of a D_1-type dopamine antagonist reduce the rewarding effects of intravenous cocaine (Ranaldi and Wise, 2001). D_1-type dopamine receptors are not expressed by the dopaminergic neurones of the VTA or adjacent substantia nigra themselves; rather, the D_1 receptor populations in this brain region are thought to be localized primarily to the terminals of GABAergic inputs to this region (Altar and Hauser, 1987; Beckstead, 1988). The evidence for this localization, however, is based on the adjacent substantia nigra, where D_1 receptor-expressing GABAergic terminals synapse primarily on GABAergic output neurones of the zona reticulata. There is dense expression of D_1 receptors in the zona reticulata of substantia nigra, and sparse expression in the zona compacta and VTA. This density parallels the density of GABAergic cell bodies and of GABAergic input in terminals that co-localize dynorphin, which identifies the D_1-expressing GABAergic medium spiny neurones of the striatum. This evidence suggests, very indirectly, that the D_1 receptors in the VTA and zona compacta are likely to be localized to GABAergic inputs to GABAergic rather than to dopaminergic targets. Ventral tegmental administration of D_1-type agonists causes increased glutamate as well as increased GABA efflux, however, raising the possibility that D_1 receptors may also be expressed on glutamatergic input to the VTA (Kalivas and Duffy, 1995).

The GABAergic anatomy of the VTA and substantia nigra is complex. The substantia nigra, and to a lesser extent the VTA, contains GABAergic neurones with dominant projections to the pedunculopontine tegmental nuclei (Gerfen *et al.*, 1982), and to the superior colliculus and medial thalamus (Williams and Faull, 1988). GABAergic cells of the VTA also project to the nucleus accumbens (Van Bockstaele and Pickel, 1995). GABAergic neurones also project to and inhibit (Johnson and North, 1992) their dopaminergic neighbours; it was originally suspected that this inhibition was accomplished by GABAergic local circuit neurones (Grace and Bunney, 1985), but recent evidence suggests that it is collaterals from GABAergic projection neurones that account for the tonic inhibition of nearby dopaminergic neurones (Tepper *et al.*, 1995).

Three lines of recent investigation suggest heterogeneity of GABAergic participation in reward function. First, Ikemoto *et al.* (1997b) have found that rats will self-inject the $GABA_A$ antagonist picrotoxin into the anterior but not the posterior VTA, and that this behaviour is disrupted by co-infusion of the $GABA_A$ agonist muscimol. However, when injected into the *posterior* VTA, muscimol is rewarding (Ikemoto *et al.*, 1998b). Zangen *et al.* (2000) also found evidence of rostral–caudal differences in ventral tegmental reward; they report that endomorphin-1, the endogenous ligand for the μ-opioid receptor (the rewarding effects of which are thought to be mediated by μ-opioid receptors on GABAergic neurones: Johnson and North, 1992), is vigorously self-administered into the posterior VTA but much less vigorously self-administered into the anterior VTA. Laviolette and van der Kooy (2001) have reported that the rewarding effects of ventral tegmental injections of the $GABA_A$ agonist muscimol are dopamine-dependent whereas the rewarding effects of ventral tegmental injections of the $GABA_A$ antagonist bicuculline are dopamine-independent.

Medial Prefrontal Cortex

Cocaine

Cocaine is self-administered directly into the medial prefrontal cortex (Goeders and Smith, 1983, 1986). It is difficult to imagine how injections into this area could diffuse to the nucleus accumbens, the other area implicated in cocaine reward. The self-administration of cocaine in this region is dopamine-dependent, as co-infusion of the D_2 dopamine antagonist sulpiride blocks the effect (Goeders *et al.*, 1986). It is not at all clear, however, that cocaine is effective in the frontal cortex — as it is in the nucleus accumbens — because of its ability to block the dopamine transporter. The dopamine transporter is sparsely distributed in the frontal cortex (Garris and Wightman, 1994; Sesack *et al.*, 1998), where it is the noradrenaline transporter that seems to be most strongly implicated in dopamine clearance (Tanda *et al.*, 1997b; Yamamoto and Novotney, 1998;

Morón *et al.*, 2001). The noradrenaline transporter has greater affinity for dopamine than does the dopamine transporter, and in the frontal cortex, unlike nucleus accumbens, it is abundant. Thus it is probably cocaine's ability to block the noradrenaline transporter in the frontal cortex that accounts for its self-administration into this area. Whatever the local site of action, self-administered cocaine in the frontal cortex causes elevation of dopamine levels in the nucleus accumbens, and this presumably trans-synaptic effect is thought to be necessary for cocaine's rewarding effects in the frontal cortex (Goeders and Smith, 1993).

Phencyclidine

Phencyclidine is also self-administered into the medial prefrontal cortex (Carlezon and Wise, 1996), where direct electrical stimulation is also rewarding (Routtenberg and Sloan, 1972; Corbett *et al.*, 1982). In this case the mechanism of action is not well understood, but it should be noted that the prefrontal cortex is intimately linked to the mesolimbic dopamine system. The ventral tegmental dopaminergic neurones project to the medial prefrontal cortex, where they synapse on GABAergic interneurones and on the pyramidal cells that are the cortical output neurones (Goldman-Rakic *et al.*, 1989; Sesack *et al.*, 1995). The prefrontal cortex neurones, in turn, project to both the nucleus accumbens and the VTA (Christie *et al.*, 1985; Sesack *et al.*, 1989; Sesack and Pickel, 1992). The primary neurotransmitter of these neurones is glutamate (Druce *et al.*, 1982; Sandberg *et al.*, 1985), and they co-localize the neuropeptide cholecystokinin (CCK) (Meyer *et al.*, 1982; Hökfelt *et al.*, 1988). These neurones are of interest because the release of CCK in both VTA and nucleus accumbens is more proportional to the strength of rewarding electrical stimulation of the prefrontal cortex than is the release of either dopamine or glutamate in either structure (You *et al.*, 1998).

Conceptual Nervous System of Addiction

While only a portion of the anatomy of substance abuse is known, a preliminary sketch of several important links in the rewarding effects of drugs can be suggested. At its core is the mesolimbic dopamine system with its cells of origin in the VTA and its most important terminals in the nucleus accumbens. The trigger zones for the habit-forming actions of nicotine and opiates are in the VTA; the critical receptors are expressed by dopaminergic neurones and GABAergic neurones, respectively. The endogenous ligand for the μ-opioid receptor in this region is endomorphin-1, which projects to the VTA from the cells in either the hypothalamus or the nucleus of the solitary tract (Martin-Schild *et al.*, 1999); the endogenous ligand for the nicotinic receptor in this region is acetylcholine, which is released in the VTA by projections from the pedunculopontine tegmental nucleus (Oakman *et al.*, 1995).

Trigger zones for the habit-forming actions of amphetamine, cocaine and phencyclidine are in the nucleus accumbens. The binding sites for amphetamine and cocaine are the dopamine transporters on dopaminergic nerve terminals in this region; the trigger zone for phencyclidine seems to be the NMDA receptor on medium spiny neurones. The endogenous transmitter mediating the rewarding effects of amphetamine and cocaine is dopamine; it appears to require synergistic effects (see, e.g., Clark and White, 1987) of both D_1-type and D_2-type receptors for dopamine to be rewarding (Ikemoto *et al.*, 1997a). The endogenous transmitter that, when blocked, accounts for the rewarding effects of phencyclidine would appear to be glutamate; glutamatergic afferents to the nucleus accumbens arise from a variety of cortical structures.

Additional trigger zones for cocaine and phencyclidine effects are found in the medial prefrontal cortex; the receptor mediating the rewarding effects of phencyclidine again appears to be the NMDA receptor. It is not clear what binding site mediates the rewarding effects of cocaine in the medial prefrontal cortex. While the rewarding effects of cocaine in this region appear to be dopamine-dependent, since they are blocked by the D_2 dopamine antagonist sulpiride and are eliminated by dopamine-specific neurotoxic lesions (Goeders *et al.*, 1986; Goeders and Smith, 1986), cocaine does not appear to have its rewarding effects as a result of actions at the dopamine transporter because this transporter is sparsely distributed in this region. Rather, cocaine's ability to elevate frontal cortex dopamine concentration appears to depend on its blockade of the noradrenaline transporter, which apparently takes up dopamine into noradrenergic nerve terminals.

The findings reviewed above suggest a common reward circuitry associated with a broad range of addictive drug classes. At the core of the circuitry are the mesolimbic dopamine system and the descending anatomical cascade of GABAergic neurones that dominate the efferent pathway from nucleus accumbens. While this unifying theme is attractive, the evidence for actions of different drugs in this system is consistent but minimal in several cases. A good deal of additional evidence will be needed, either to tie each of these drugs unequivocally to the suggested circuitry or to establish separate, parallel, reward circuitry for the drug classes for which current evidence remains limited. Moreover, we are hardly closer now than we were 20 years ago (Nauta *et al.*, 1978; Mogenson *et al.*, 1980) to understanding how the activity of these segments of motivational circuitry interfaces with and controls the mechanisms of behavioural action.

Neuroimaging and Substance Abuse

R. Hitzemann, N. Volkow, J. Fowler and G.-J. Wang

INTRODUCTION

Substance abuse has played a prominent role in biological psychiatry. To a large extent, the mechanisms of action of abused drugs are well understood at the molecular, cellular and systems level. This level of understanding has been important to the development of our current hypotheses regarding the regulation of normal and abnormal behaviour. However, until quite recently, it was not possible to directly test (in humans) even relatively simple hypotheses such as whether abused drugs up- or downregulate their target receptors. The information that was available depended on either indirect measures of brain function, e.g. neuroendocrine challenge studies, or post-mortem analyses. While such techniques have provided important data, for a variety of reasons they are not entirely satisfactory. For example, post-mortem analyses depend on opportunistic samples where many critical variables, such as duration, amount and types of drugs abused, can only be partially known. Beginning in the mid-1980s, new techniques became commonly available that allowed the direct measurement of brain receptors and metabolism in the living brain. Two of these techniques — single photon emission computerized tomography (SPECT) and positron emission tomography (PET) — and their use in the study of substance abuse will be the subject of this chapter. PET and SPECT remain the only procedures available to directly measure neurotransmitter receptors in the living brain. Their disadvantage is that anatomical resolution is only moderate, and temporal resolution is poor. Thus, these techniques cannot be used to measure changes in receptor availability in the same temporal way that microdialysis is used to measure neurotransmitter release, nor can these techniques be used to measure receptor availability in some regions that are of interest for substance abuse, e.g. the shell of the nucleus accumbens. SPECT and PET have been, and continue to be, used to measure cerebral blood flow and metabolism. However, newer magnetic resonance-based techniques, such as functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS) and arterial spin perfusion, with much improved spatial and temporal resolution, are now generally preferred for such measurements. Details regarding SPECT and PET methodology are found in Chapter XI.

Figure XVI-8.1 uses a dopamine synapse to illustrate some of the data that can be obtained using PET. In addition to measuring the availability of D_2 dopamine receptors (^{11}C-raclopride) and dopamine transporters (^{11}C-methylphenidate), one can also measure the levels of monoamine oxidase A (MAO-A) (^{11}C-clorgyline), which is localized largely intraneuronally and monoamine oxidase B (MAO-B) (^{11}C-deprenyl), which is localized largely in glial cells and is involved in the metabolism of dopamine. Figure XVI-8.1 also illustrates that measurements of brain metabolism, e.g. with ^{18}F-deoxyglucose (FDG), can be used as a surrogate measure of the downstream postsynaptic events, at least in regions with known connectivity to the striatum. Not illustrated in Figure XVI-8.1, is a strategy used to measure changes in dopamine release, which has been adapted to both the SPECT and PET paradigms (e.g. Mach *et al.*, 1997). The strategy makes use of the competition between endogenously released dopamine and ligands for the D_2 dopamine receptor. When dopamine and the receptor ligands have relatively equal affinities for the receptor, then increases in dopamine release will be associated with a decrease in receptor binding. To increase dopamine release, methylphenidate or amphetamine is administered intravenously. The disadvantage to this technique is that very large increases in dopamine release (e.g. >500%) are required to produce relatively small changes in binding.

ALCOHOL

Given the well-known neuropathology and associated cognitive deficits associated with chronic alcohol abuse, it is not surprising that the first functional neuroimaging studies of substance abuse focused largely on alcoholism. Early studies (e.g. Berglund and Ingvar, 1976; Berglund and Risberg, 1977) used the xenon-133 technique to measure cerebral blood flow in chronic alcoholics. Elderly alcoholics were found to show a decrease in blood flow localized largely to the frontal and temporal cortical regions. The first PET study (see Samson *et al.*, 1986) used FDG to measure brain metabolism and noted only a small decrease in the mediofrontal area of the alcoholics; given the poor resolution of the early PET cameras, a more exact placement of the deficit was not possible. A survey of subsequent PET and SPECT studies of alcoholism follows. In reviewing this information, it is important to note that during the early period of alcoholism imaging research, there was a fundamental paradigm shift in our view of the mechanism(s) of alcohol action. Before the early 1980s, it was the consensus view that alcohol acted by perturbation of membrane structure and, thus, had a mechanism of action not dissimilar from the general anaesthetics (see Kresishman *et al.*, 1985). However, there were problems with this hypothesis that began with the discovery of benzodiazepine binding sites and the subsequent discovery that benzodiazepines acted by potentiating the effects of γ-aminobutyric acid (GABA) at the $GABA_A$ receptor (Braestrup *et al.*, 1978). These findings were problematic (from the perspective of understanding the mechanisms of alcohol action) since it was well known that alcohol and the benzodiazepines exhibited cross-tolerance and cross-dependence (e.g. Chan *et al.*, 1985; Chan *et al.*, 1988; Chan *et al.*, 1991). Thus, it seemed likely that ethanol caused a more specific effect than was originally considered and must interact in some way with the $GABA_A$ receptor. Subsequent research confirmed this hypothesis (Allan and Harris, 1986), and it is now known that ethanol has complex effects on a number of ligand-gated ion channels, including the $GABA_A$, *N*-methyl-D-aspartate (NMDA), Serotonin 5-HT_3, nicotinic acetyl choline (nACh) and glycine receptor arrays (Deitrich *et al.*, 1989). As will

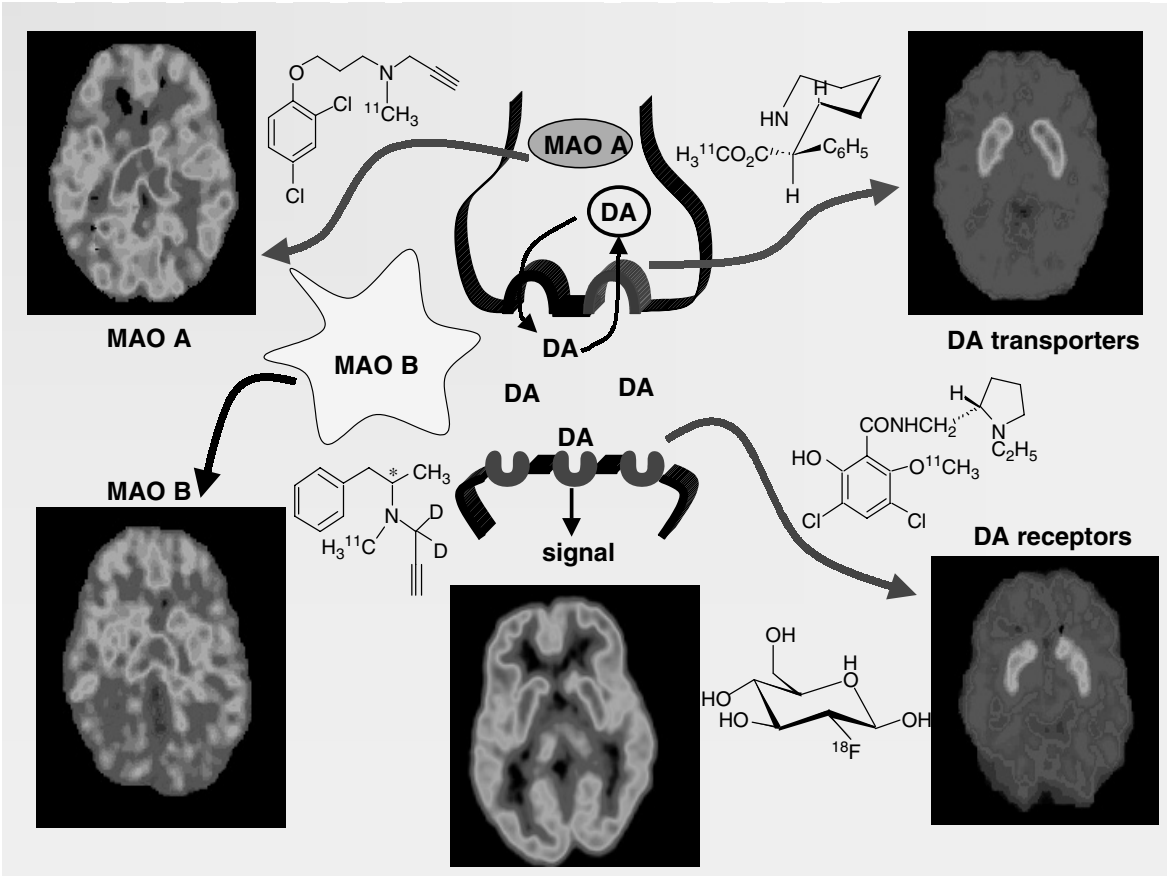

Figure XVI-8.1 Schematic of a dopaminergic synapse, indicating how PET can be used to evaluate dopaminergic function. The various ligands are ^{11}C-methylphenidate (dopamine transporter), ^{11}C-raclopride (D_2 dopamine receptor), FDG (metabolism), ^{11}C-deprenyl (MAO-B) and ^{11}C-clorgyline (MAO-A) (See Colour Plate XVI-8.1)

be noted below, this new information had a significant impact on the direction of imaging research.

Chronic Alcoholism: Cerebral Metabolism and Cerebral Blood Flow

Continuing the theme and direction of the earlier studies showing that brain metabolism and/or regional cerebral blood flow (rCBF) was decreased in chronic alcoholics, Sachs *et al.* (1987) examined a group of ten non-Korsakoff chronic alcoholics using PET and ^{11}C-deoxyglucose; the authors concluded that there were at least suggestive data pointing to lower glucose metabolism in the alcoholic brains, fewer region-to-region functional relationships, and significant impairment in right-hemispheric processing. Wik *et al.* (1988) followed ^{11}C-glucose metabolism in nine alcoholics and 12 controls; the authors observed that age decreased glucose metabolism, that this effect was greater in the alcoholics, and that the parietal cortex seemed to be the region most affected. Gilman (1988) found a significant decrease in cerebellar metabolism (PET–FDG) in patients with alcoholic cerebellar degeneration. In a subsequent study, this group observed that chronic alcoholics showed a decrease in the medial prefrontal region, which was independent of whether there was evidence of cerebellar degeneration with the associated decrease in cerebellar metabolism (Gilman *et al.*, 1990) Using SPECT and ^{133}Xe to measure rCBF, Melgaard *et al.* (1990) reported that blood flow was decreased in chronic alcoholics in both the anterior and posterior parts of the brain, and that the decrements were independent of morphological abnormalities. Using ^{99m}Tc-hexamethyl propylene amineoxime (HMPAO) rather than xenon, Erbas *et al.* (1992) found that 24 of 28 alcoholics showed abnormal rCBF, with most showing a significant decrement in the left hemisphere. Subsequent work (e.g. Adams *et al.*, 1993; Dao-Castellana *et al.*, 1998) illustrated that the prefrontal deficits are associated with significant neuropsychological impairments.

An important conclusion reached from these early imaging studies was that chronic alcoholism could have significant effects on cerebral metabolism and blood flow in the absence of marked anatomical changes (Wang *et al.*, 1993). Interestingly, even in patients with frank Korsakoff's syndrome, the metabolic deficit appears to be somewhat independent of the structural changes (Joyce *et al.*, 1994).

Although the data available suggested that cerebral metabolism was decreased in chronic alcoholics, the studies of Martin *et al.* (1992) and Volkow *et al.* (1992a) illustrated that the situation was not so straightforward. Using essentially identical experimental approaches (PET–FDG), Martin *et al.* (1992) did not detect an effect of chronic alcoholism on cerebral metabolism, while Volkow *et al.* (1992a) noted marked decreases in left parietal and right frontal cortex, including the orbitofrontal cortices and the cerebellum. Although the patients in the Martin *et al.* study had evidence of organic mental disorder attributable to alcoholism, they had been withdrawn for a significantly longer period than the Volkow *et al.* subjects, suggesting decreased metabolism was a state effect. This point was confirmed by Volkow *et al.* (1994) (see also Meyer *et al.*,

1985 and Ishikawa *et al.*, 1986), who examined detoxified alcoholics at 8–15, 16–30 and 31–60 days after the last use of alcohol. Recovery from the initial deficit in brain metabolism occurred primarily during the 16–30-day period. However, it was observed that brain metabolism in the basal ganglia remained persistently low. The clinical relevance of these findings should be interpreted cautiously. The group of alcoholics studied were neurologically intact and were in general good health; the question of whether a similar recovery would be noted in a more representative population of alcoholics is not known. Nicolas *et al.* (1993) examined cerebral blood flow (CBF) (^{99m}Tc-HMPAO–SPECT) in a group of 'healthy' alcoholics and found a significant decrement in CBF during the first week of abstinence, which returned to normal 2 months later. The initial decrement in CBF was correlated negatively with the amount of alcohol consumed during the previous month, but there was no relationship between the decrement in perfusion and performance on a battery of neuropsychological tests. Caspari *et al.* (1993) noted that perfusion (^{99m}Tc-HMPAO–SPECT) increased in the superior temporal cortex during withdrawal (weeks 1–4) but decreased in the basal temporal cortex. A small persistent decrement in basal ganglia perfusion was also noted, similar to the results of Volkow *et al.* (1994). More recently, Tutus *et al.* (1998) reported in recently withdrawn but stabilized alcoholics a persistent decrease of rCBF (^{99m}Tc-HMPAO–SPECT) in the temporal cortex.

Some studies on alcoholism and brain metabolism have examined longer periods of withdrawal. For example, Dupont *et al.* (1996) examined CBF (^{123}I-iodoamphetamine–SPECT) in a group of short-term and long-term abstinent alcoholics (mean abstinence = 25 days and 7.7 years, respectively). CBF and cognitive performance were improved in the long-term compared with the short-term group but remained significantly less than a comparison control group. Johnson-Greene *et al.* (1997) studied six alcoholics who received two scans with an interscan interval of 10–32 months. For four of the subjects who remained abstinent (or nearly abstinent), brain metabolism (PET–FDG) was improved at the second scan in some (but not all) frontal areas; cognitive performance also improved. For the two subjects who did not remain abstinent, brain metabolism decreased. Harris *et al.* (1999) noted a persistent cerebellar perfusion (^{99m}Tc-HMPAO–SPECT) in subjects who had been abstinent on average for >6 years. Finally, Gansler *et al.* (2000) found that in the left inferior frontal brain regions, alcoholics abstinent on average for 1.7 years showed a significant decrement in CBF from both normal controls and a group of alcoholics abstinent for an average of 10.5 years.

Gender appears to differentially influence the behavioural and neurochemical effects associated with chronic alcoholism (Gomberg, 1993), in particular the neurotoxic effects (Roman, 1988). However, Wang *et al.* (1998) did not detect a significant effect on brain metabolism in a group of chronic female alcoholics. The authors suggested that this lack of effect may be associated with the fact that female alcoholics generally consume less alcohol than their male counterparts.

The genetics of substance abuse are well established (see Chapter XVI-9). The question of whether there is a difference between family-history-positive and family-history-negative alcoholics on measures of metabolism and CBF has been examined. Mampunza *et al.* (1995) using ^{99m}Tc-HMPAO–SPECT found greater abnormalities of rCBF in family-history-positive compared with family-history-negative alcoholics. Volkow *et al.* (1995a) observed that family-history-positive (compared with negative) alcoholics had a lower cerebellar metabolism and a blunted response to a 30-$\mu g\,kg^{-1}$ lorazepam challenge (see also below). Adams *et al.* (1998) approached this issue from a different perspective. Noting that in at least some studies there is evidence of a reduced alcohol response in the sons of alcoholics compared with nonalcoholics (Schuckit, 1994), it followed that a positive family history might moderate the effects of chronic alcoholism on brain metabolism. However, no difference was detected in cerebral metabolism between (PET–FDG) family-history-positive and family-history-negative alcoholics.

There is considerable consensus that chronic alcoholism causes both short- and long-term decrements in brain metabolism. Differences between studies are noted in the brain regions affected and the duration of the persistent effects; such differences probably reflect differences in the patient samples and the neuroimaging techniques. However, the data point to persistent changes in brain metabolism and CBF, which are associated with both cognitive and psychiatric deficits. The question arises as to whether the pathology observed is specific to alcohol. As will be shown in subsequent sections, persistently decreased brain metabolism and CBF, especially in cortical areas, is a common feature of chronic drug abuse and is observed not only with alcohol but also with some central stimulants, e.g. cocaine.

Alcohol and Benzodiazepine Challenge Studies

Volkow *et al.* (1988a), following up on the earlier work of Newlin *et al.* (1982) and Mathew and Wilson (1986), measured CBF (PET and ^{15}O-labelled water) before and after an alcohol challenge (0.5 and 1.0 $g\,kg^{-1}$) in a group of social drinkers. At the high dose, alcohol decreased CBF in the cerebellum but increased flow in the right temporal and the prefrontal cortex. Interestingly, when the same group examined cerebral metabolism (PET–FDG), they found that the 1-$g\,kg^{-1}$ challenge decreased metabolism not only in the cerebellum but also in cortical areas, suggesting that in the latter there is an uncoupling between metabolism and flow (Volkow *et al.*, 1990b). It was also noted that recently detoxified alcoholics were more sensitive to the depressant effects of the ethanol challenge. Further, the depressant effects of ethanol were greatest in those regions with the highest density of benzodiazepine–$GABA_A$ receptors. It was suggested that the enhanced metabolic response in the alcoholics might result from an upregulation of benzodiazepine–$GABA_A$ receptors, for which there was some preclinical evidence (Ticku *et al.*, 1983). However, the available neuroimaging data suggest that this is not the case. Litton *et al.* (1993) reported no difference between controls and alcoholics in either the K_D or B_{max} for the binding of ^{11}C-flumazenil binding (a benzodiazepine receptor antagonist). Abi-Dargham *et al.* (1998) examined the receptor distribution volume (a measure of receptor availability) in a group of recently detoxified alcoholics; benzodiazepine–$GABA_A$ receptor availability (SPECT and ^{123}I-iomazenil) was decreased significantly in several brain areas, in particular the frontal, anterior cingulate and cerebellar cortices. Using a similar method, Lingford-Hughes *et al.* (1998) found that alcoholics had decreased receptor availability in the frontal, parietal and temporal cortices, and that some decrements were clearly not associated with grey matter atrophy. This same group also addressed the question of whether the decrement in receptor availability differed between men and women (Lingford-Hughes *et al.*, 2000); in a small sample, the authors observed that women tended to show decrements in the cerebellum, occipital lobes and parietal cortex and not in the frontal cortex. Another approach to examining benzodiazepine–$GABA_A$ receptor function is to challenge subjects with a benzodiazepine agonist and examine the effect on brain metabolism. Volkow *et al.* (1993a) found that alcoholics were less sensitive than controls in some brain regions to a lorazepam challenge (30 $\mu g\,kg^{-1}$ intravenously); the alcoholics showed a significantly reduced response in the thalamus, basal ganglia and orbitofrontal cortex. These data are particularly significant as they point to some components of the limbic-reward circuit as being affected by chronic alcohol administration. The use of the lorazepam challenge also illuminated changes in the thalamus, a region that is not greatly affected by an acute ethanol challenge (Wang *et al.*, 2000).

There are insufficient data to answer the question of whether it is the benzodiazepine–$GABA_A$ receptor system that primarily mediates the neuroadaptive and/or neurotoxic effects associated with chronic alcohol intoxication. Thus, the possibility must be considered that alcohol effects on other ligand-gated ion channels are also important. However, there is a general consensus that from the perspective of receptor binding and brain metabolism, the benzodiazepine–$GABA_A$ receptor system is attenuated in alcoholics, providing evidence of functional tolerance.

Dopamine

The role of brain dopamine systems, particularly the mesolimbic and mesocortical systems, in mediating substance (including alcohol) abuse is well established (Weiss, 2000). In a series of papers, Noble, Blum and colleagues (Blum *et al.*, 1990; Blum *et al.*, 1991; Noble *et al.*, 1991) put forth the proposition that there was an association between alcoholism and a Taq 1 polymorphism in DRD2 that affected D_2 dopamine receptor density. From the genetic perspective, the association between the Taq 1 polymorphism and alcoholism remains controversial (reviewed in Hitzemann, 1998). However, the question of whether there is an association between D_2 receptor density and alcoholism remains unanswered. Hietala *et al.* (1994) were the first to address this issue directly in the living brain. Using PET and ^{11}C-raclopride (a D_2/D_3 dopamine receptor ligand), these authors found that the striatum/cerebellar ratio of binding was lower in alcoholics compared with controls. Essentially, a similar result was found by Volkow *et al.* (1996a), although the magnitude of the decrement was greater (20% *v.* 12%). Repo *et al.* (1999) used SPECT and ^{123}I-epidepride (a D_2/D_3 dopamine receptor ligand, but with higher affinity than raclopride) to measure striatal binding and were unable to detect a difference between alcoholics and controls; however, these data must be interpreted cautiously since the ligand did not reach equilibrium during the experiment. Interestingly, this same group (see also Kuikka *et al.*, 2000) have suggested that extrastriatal D_2/D_3 receptors in the temporal pole are lower in alcoholics. Guardia *et al.* (2000) found no difference in the striatum between alcoholics and normal controls (SPECT and ^{123}I-iodobenzamide, also a D_2/D_3 dopamine receptor ligand). However, when the alcoholics were divided into those who relapsed and those who did not, the non-relapsing group had a significantly lower receptor density.

The question of whether the dopamine transporter (DAT) is altered in alcoholics has also been addressed. Tiihonen *et al.* (1995) found that DAT density (SPECT and ^{123}I 2-beta-carbomethoxy-3-beta-(4-iodophenyl)-tropane) (β-CIT)—a cocaine analogue) was lower in non-violent alcoholics compared with controls; interestingly, violent alcoholics had a DAT density somewhat higher than controls. Volkow *et al.* (1996a), is a small sample, detected no difference in DAT between alcoholics and controls (PET and ^{11}C-threomethylphenidate as the ligand). Laine *et al.* (1999) found that DAT density (SPECT and ^{123}I β-CIT) was lower in alcoholics, but in addition they noted that DAT density normalized as a function of duration of withdrawal. Finally, Gilman *et al.* (1998) found a significant reduction in the vesicular monoamine transporter (PET and ^{11}C-tetrabenazine) in the putamen of severe chronic alcoholics without Wernicke–Korsakoff disease.

Overall, the data are relatively consistent that both D_2 dopamine receptor and DAT density are lower in chronic alcoholics. The normalization of the DAT decrement with abstinence suggests that this is a 'state' effect. At this time, it is unknown whether the decrement in D_2 receptors normalizes with abstinence, or whether lower D_2 dopamine receptor density is a risk factor for alcoholism.

Serotonin

There is considerable evidence to suggest that a Serotonin (5-hydroxytryptamine, 5-HT) dysfunction is associated with alcoholism. For example, low 5-HT turnover has been associated with both alcoholism and impulse control problems (Linnoila *et al.*, 1983; Kruesi *et al.*, 1990; Higley *et al.*, 1992, 1996a; Higley *et al.*, 1996b). From the imaging perspective, interest has focused on the 5-HT transporter (5-HTT), for which there is a known naturally occurring variant with a relatively high gene frequency that is associated with reduced 5-HT capacity (Heils *et al.*, 1996; Lesch *et al.*, 1996). Heinz *et al.* (1998b) used SPECT and ^{123}I β-CIT (which, in the brainstem, measures binding largely to the 5-HTT) and found a reduction in the availability of 5-HTTs (−30%) in alcoholics; further, the reduction was correlated with lifetime alcohol consumption. In a subsequent study, this group found that the reduction was largely in those individuals homozygous for the ll-allele of the 5-HTT (Heinz *et al.*, 2000).

CENTRAL STIMULANTS: COCAINE AND METHYLPHENIDATE

For a variety of reasons, it is useful to compare cocaine and methylphenidate. Both drugs have similar mechanisms of action, although methylphenidate does not block the 5-HTT.

Pharmacokinetics

The synthesis of ^{11}C-cocaine (Fowler *et al.*, 1989) made it possible to determine the relationship between the euphoric effects of cocaine and the occupancy of the DAT. The initial findings pointed to a very high brain uptake (8–10% of the injected dose), a very rapid uptake (peaking 4–6 minutes after injection) and a rapid clearance (half-life in the brain of 20 minutes). These data suggested that pharmacokinetic parameters were the principal cause of the transient euphoric effects associated with cocaine administration. However, it was possible to test this hypothesis directly by comparing the uptake of cocaine with that of methylphenidate. Volkow *et al.* (1995b) compared the uptake of ^{11}C-cocaine and ^{11}C-methylphenidate (Figure XVI-8.2). The results obtained show that both drugs have a similarly rapid and high uptake into the brain; however, the clearance of methylphenidate from the brain is considerably slower (half-life = 90 minutes compared with 20 minutes for cocaine). Since the time course and intensity of the euphoric response were the same for both drugs, these data suggested that the euphoric response was associated with the rapid uptake, but that termination of the behavioural response was due to other factors (e.g. rapid adaptation at the dopaminergic synapse). The data in Figure XVI-8.2 also show the uptake of oral methylphenidate. The time to peak brain level is 60–80 minutes after drug administration; the slow uptake presumably accounts for the lack of euphoric effects from this route of administration.

The data illustrated in Figure XVI-8.2 also posed a new question: would the slow clearance of methylphenidate from the brain prevent the euphoria induced by a second administration of the drug? This was tested in a group of normal controls given two doses of methylphenidate (0.375 mg kg^{-1} intravenously) 60 minutes apart; DAT occupancy was measured using ^{11}C-methylphenidate (Volkow *et al.*, 1996b). The results obtained showed that the second drug administration produced a similar euphoric response to the first administration despite the fact that >80% of the transporters were still occupied from the first dose. Importantly, these data illustrated that a potential therapeutic strategy (DAT blockade) was not likely to be useful unless the transporters were completely or nearly completely occupied. Such a level of occupancy would likely be associated with significant side effects.

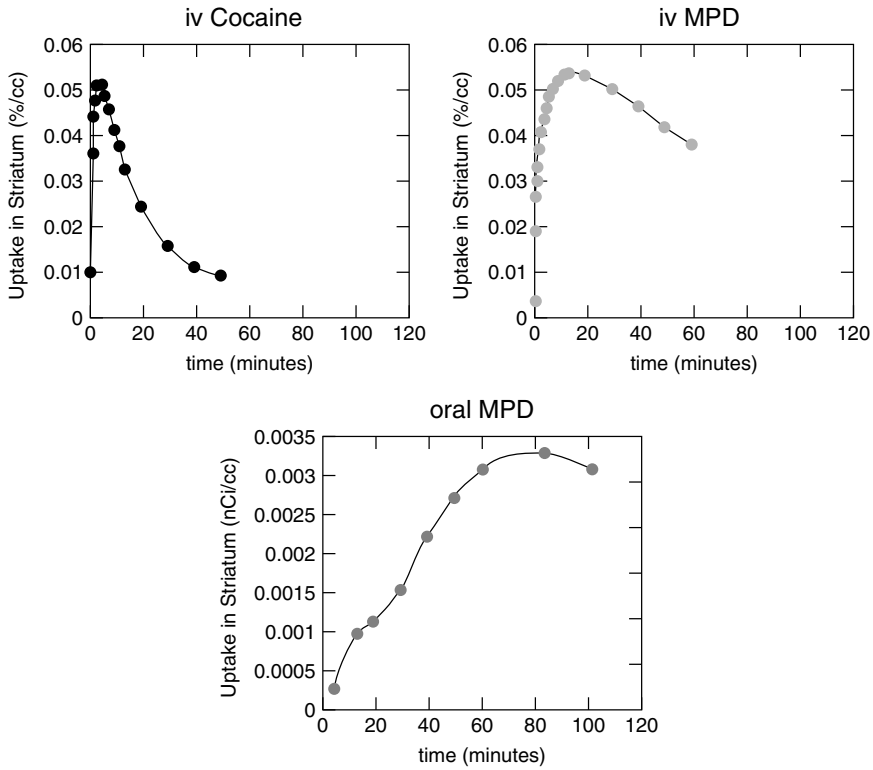

Figure XVI-8.2 Time courses for the striatal uptake intravenously administered ^{11}C-cocaine and ^{11}C-methylphenidate (MPD) and orally administered ^{11}C-methylphenidate. Data adapted in part from Volkow *et al.* (1995a) and Volkow *et al.* (1998)

The availability of ^{11}C-cocaine allows us to determine what is the threshold level of DAT blockade that is sufficient to induce a euphoric response (Volkow *et al.*, 1997a). Intravenous cocaine ($0.3-0.6\,\mathrm{mg\,kg^{-1}}$) blocked between 60% and 77% of DAT sites in the brain. The magnitude of the high was proportional to the level of DAT blockade, and at least 47% of the DAT sites had to be blocked to perceive the effects of cocaine. These data contrast with a subsequent report from this group (Volkow *et al.*, 1999a), in which it was observed that significant blockade (>60%) of DAT sites by methylphenidate was not associated with euphoria in four of eight subjects. The difference between the two studies was that the former used cocaine addicts and the latter used normal controls. The percentage of 'normals' who would not experience a high in response to cocaine, despite a significant DAT occupancy, is unknown. However, these data do point out that DAT occupancy alone is not sufficient to produce a euphoric response. What are the causes of such a marked intersubject variability? Understanding this issue is important not only in determining risk factors for substance abuse but also in developing effective therapies. At least two factors have been identified as important. One is the increase in synaptic dopamine (Volkow *et al.*, 1999a). Subjects were administered methylphenidate over the dose range of $0.025-0.5\,\mathrm{mg\,kg^{-1}}$; the amount of dopamine released was measured indirectly by monitoring changes in ^{11}C-raclopride binding. Methylphenidate-induced changes in ^{11}C-raclopride binding were associated significantly with self-reports of high and rush; importantly, these associations remained significant after accounting for differences in the dose and plasma concentrations of methylphenidate. Volkow *et al.* (1999a) suggested a mechanism to account for the intersubject variability in the reinforcing responses to methylphenidate. It was postulated that for equivalent levels of DAT blockade, the increases in dopamine induced by methylphenidate would be larger in subjects with a high dopamine tone compared with those with a low dopamine tone; this will result in a larger dopamine occupancy of D_2 dopamine receptors and a more intense high. The second factor that appears to be associated with the variability in methylphenidate response is the density of D_2 dopamine receptors. In a study of 23 normal controls administered $0.5\,\mathrm{mg\,kg^{-1}}$ methylphenidate, 12 reported the effects of methylphenidate as pleasant, nine described the effects as unpleasant, and two responded neutrally (Volkow *et al.*, 1999b). The subjects who reported the effects as unpleasant had a significantly higher level of D_2 receptors compared with the group that reported the effects as pleasant (Figure XVI-8.3). The causes of the variation in D_2 receptor density are unknown (see Hitzemann, 1998) but the range of variation is considerable.

Although the mechanism(s) of action of both cocaine and methylphenidate are well understood, it is clear that blockade of DAT sites is not sufficient to predict a euphoric or pleasant response to the drugs. Important variables appear to be the basal tone of the dopamine neurons and the density of D_2 dopamine receptors.

Chronic Cocaine Abuse, D_2 Dopamine Receptors, Dopamine Transporters and Dopamine Release

The obvious expectation from the abuse of central stimulants like cocaine is that dopamine receptors will be downregulated. Surprisingly, the preclinical data are not clear on this issue. Chronic cocaine administration to rats has been reported either to have no effect on D_2 receptor density (Stanwood *et al.*, 2000; Alburges *et al.*, 1993) or to transiently decrease receptor density (Goeders and Kuhar, 1987; Kleven *et al.*, 1990; Maggos *et al.*, 1998). Volkow *et al.* (1990a) using PET and ^{18}F-*N*-methylspiroperidol (NMS) found in a small sample of cocaine addicts that D_2receptor density was reduced after 1 week of abstinence from cocaine and was at

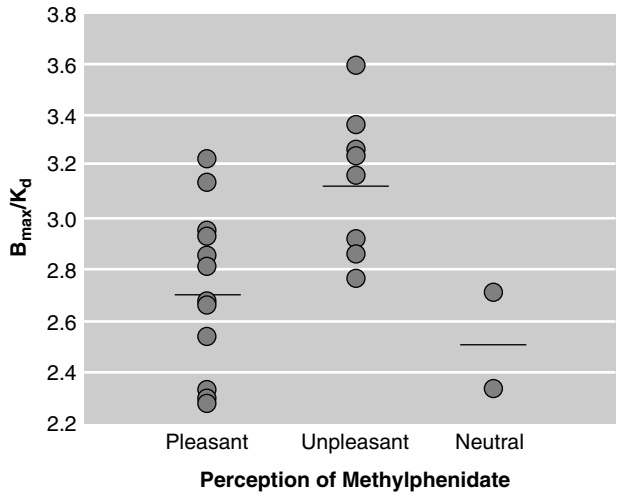

Figure XVI-8.3 Summary of the data illustrating the relationships between D_2 dopamine receptor density and response to methylphenidate. Note the large variation in receptor binding. Reproduced from Volkow *et al.* (1999a)

normal levels within 4 weeks of withdrawal. (It should be noted that NMS will bind with a high affinity to D_2, D_3 and D_4 receptors.) In a subsequent larger study of cocaine addicts ($n = 20$) (Volkow *et al.*, 1993b), significant receptor decrements were again found early in withdrawal. Furthermore, in this study, seven of the 20 addicts remained abstinent for 4 months and were rescanned. Although receptor binding had normalized, it was still significantly below normal levels. It was also noted that the decrements in striatal receptor binding were associated with decreased metabolism (PET–FDG) most markedly in the orbitofrontal and cingulate cortex. The authors suggested that dopamine dysregulation of these areas, which are known to be involved in impulse control, could be important to understanding drug-taking behaviour (see also Volkow and Fowler, 2000). Subsequent studies by this group, using ^{11}C-raclopride, have confirmed the lower receptor binding in cocaine addicts (e.g. Volkow *et al.*, 1997c). The post-mortem data are not clear on whether D_2 receptor binding is lower in cocaine addicts. Meador-Woodruff *et al.* (1993), using *in situ* hybridization, found that neither D_1 nor D_2 receptor expression was changed in the nucleus accumbens, caudate-putamen or substantia nigra of cocaine-exposed subjects. In contrast, Worsley *et al.* (2000), using a quantitative immunoblotting procedure for the measurement of D_2 protein levels in the nucleus accumbens, found a decrease in methamphetamine, cocaine and heroin users, although only the decrease in heroin users reached statistical significance. Segal *et al.* (1997) observed that the expression of the D_3 dopamine receptor is markedly increased (six-fold) in the nucleus accumbens of cocaine abusers. These data are of interest since under certain binding conditions, upregulation of D_3 receptors could obscure a downregulation of D_2 receptors.

Potentially, the DAT could be a site for neuroadaptation during chronic cocaine abuse. The brain uptake of ^{11}C-cocaine is reduced modestly (about 15%) in cocaine abusers, but the availability of DAT sites appears to be normal (Volkow *et al.*, 1996b). Interestingly, cocaine abusers do not show the normal age-related loss of striatal DAT sites, which may suggest that cocaine has some neuroprotective effects for dopamine neurons (Wang *et al.*, 1997).

To determine whether the increase in synaptic dopamine was different between controls and cocaine addicts, Volkow *et al.* (1997b) used a methylphenidate challenge technique which indirectly measures release by monitoring changes in the binding of ^{11}C-raclopride. Addicts showed a reduced release in the striatum and had a reduced high relative to controls. In contrast, the addicts showed an enhanced response in the thalamus, and the extent of the enhanced response was associated with drug-induced craving and was not seen in controls subjects. These results challenge the notion of an enhanced dopamine response in addiction and/or an enhanced induction of euphoria. Moreover, the data point to an important involvement of the thalamus in drug-seeking behaviour.

The data suggest that, at least within the striatal dopamine system, chronic cocaine intoxication is associated with an attenuated response to acute drug administration. Such a functional downregulation appears superficially to be the predicted and appropriate neuroadaptive response. However, for the cocaine addict, the reduction in the euphoric response is likely to trigger an increase in drug craving. In addition, some data point to adaptive changes in the striatal-thalamo-orbitofrontal circuit, which may contribute to increased craving and decreased impulse control (Childress *et al.*, 1999; Volkow and Fowler, 2000).

Other Transmitters

Although their precise role in addiction and drug craving is less clear, other neurotransmitters are affected by chronic cocaine intoxication. Two examples will serve to illustrate this point. Zubieta *et al.* (1996) used PET and the ligand ^{11}C-carfentanil to examine μ opiate receptor binding in a group of cocaine addicts and controls. The addicts showed increased receptor binding in several areas, including the caudate, thalamus, cingulate cortex and frontal cortex. The increase in binding was detected 1–4 days after cocaine withdrawal and persisted for at least 4 weeks. The initial increase in binding was correlated with the severity of drug craving. To determine whether the benzodiazepine–$GABA_A$ receptor system is affected by chronic cocaine intoxication, Volkow *et al.* (1998) challenged cocaine addicts and controls with lorazepam ($30\,\mu g\,kg^{-1}$) and examined both the behavioural effects and the effects on cerebral metabolism (PET–FDG). The results showed that despite significantly lower plasma drug concentrations, the addicts showed significantly greater decrements in brain metabolism, especially in the striatum, thalamus and parietal cortex. The addicts also reported significantly greater drug-induced sleepiness, which was correlated with the decrements in thalamic metabolism. Interestingly, this same group (Volkow *et al.*, 2000) found that cocaine addicts are less sensitive behaviourally and metabolically to an alcohol challenge, suggesting that alcohol and benzodiazepine affect the cocaine abuser's brain in a fundamentally different manner. Overall, these studies point out one of the major problems associated with trying to understand the mechanisms of drug addiction, the likely involvement of multiple neurotransmitter/neuropeptide systems.

Cocaine, Cerebral Metabolism and Cerebral Blood Flow

The initial interest in cocaine and CBF stemmed from the vasoactive properties of the drug and a marked increase during the late 1970s and 1980s in the number of cocaine-related cerebrovascular incidents (Brust and Richter, 1977; Schwartz and Cohen, 1984; Tuchman *et al.*, 1987). In addition, during this period there were an increasing number of reports of seizures associated with cocaine abuse (Baxter *et al.*, 1988). Volkow *et al.* (1988b) (PET–^{15}O-labelled water) found that cocaine abusers showed areas of decreased CBF as evidenced by 'patchy' areas where isotope accumulation was low; the prefrontal cortex appeared to be especially affected. Repeated scans after 10 days of withdrawal did not lead to a significant improvement in CBF. Holman *et al.* (1991) also noted patchy areas of reduced flow (SPECT–^{99m}Tc-HMPAO) in the inferoparietal, temporal and anterofrontal cortex and the basal ganglia; interestingly, there didn't appear to be a relationship between

these deficits and the mode, frequency or duration of cocaine abuse. The 'patchy' hypoperfusion has been confirmed in several studies (Miller *et al.*, 1992; Strickland *et al.*, 1993; Holman *et al.*, 1993; Bell *et al.*, 1994; Levin *et al.*, 1994; Levin *et al.*, 1995; Kosten *et al.*, 1998; Ernst *et al.*, 2000). Associated with perfusion deficits were deficits in cognitive function, including attention, concentration, visual and verbal memory, word production and visuomotor integration (Strickland *et al.*, 1993). The perfusion deficits may be worse in men than in women (Levin *et al.*, 1994), and they appear to be worse in multidrug users (Levin *et al.*, 1994; Kosten *et al.*, 1998). Interestingly, one group has reported improvements in CBF after treatment with buprenorphine (Levin *et al.*, 1995).

Paralleling the data on CBF, brain metabolism is reduced in cocaine addicts (Baxter *et al.*, 1988; Volkow *et al.*, 1991a; Volkow *et al.*, 1992b). Of particular interest is the observation by Volkow *et al.* (1992b) that cocaine abusers had significantly lower metabolic activity in 16 of 21 left frontal regions and eight of 21 right frontal regions. These decreases persisted for 3–4 months after drug withdrawal and were correlated with the dose and duration of cocaine abuse.

Although it is difficult to compare studies directly, the data suggest that for neurologically intact subjects, the decrements in CBF and brain metabolism in cocaine addicts are at least of a similar magnitude to those observed in alcoholics and, perhaps, are even more persistent. Importantly, it must be assumed that these decrements will slow the process of recovery and readaptation of the relevant neural networks.

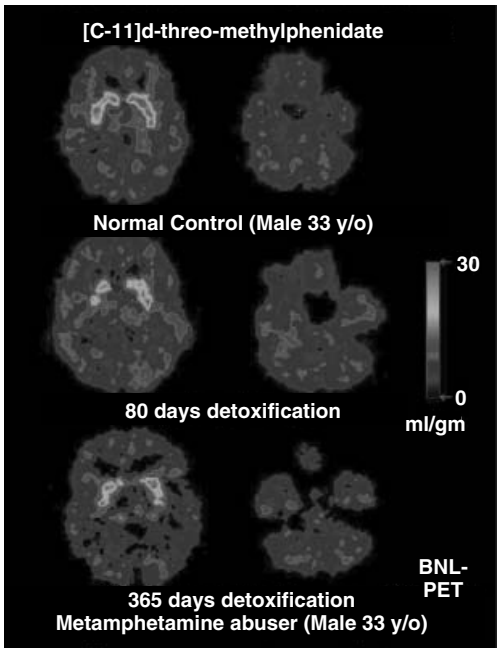

Figure XVI-8.4 Representative PET images showing ^{11}C-methylphenidate uptake to striatal dopamine transporter sites in a normal control and a methamphetamine abuser, scanned twice at 1 month and 4 months into withdrawal. Data adapted from Volkow *et al.* (2001a) (See Colour Plate XVI-8.4)

CENTRAL STIMULANTS: METHAMPHETAMINE

Dopamine Transporter and D_2 Dopamine Receptor

Methamphetamine has been abused for over 50 years. However, in recent years, the abuse appears to be increasing (Lukas, 1997). Methamphetamine and the related compound methcathinone can be made easily with relatively simple equipment, thus control of its production is difficult. Methamphetamine differs from cocaine and methylphenidate in that there is a considerable amount of animal literature showing that repeated high doses of the drug produce long-lasting depletions of both dopamine and serotonin (e.g. Seiden *et al.*, 1976; Ricaurte *et al.*, 1980). In non-human primates, two large doses of methamphetamine (2 mg kg^{-1}, 24 h apart) can reduce ligand binding to striatal DAT sites by >90% (Melega *et al.*, 2000). Although these doses are high, methamphetamine abusers are known to consume up to 10 g per day or approximately 120 mg kg^{-1} per day (Volkow *et al.*, 2001a) and, thus, some neuropathology would not be unexpected. Surprisingly, until recently, there was little human data on this issue. Wilson *et al.* (1996), in a post-mortem study of methamphetamine abusers, found reduced levels of dopamine, tyrosine hydroxylase and DAT sites in the nucleus accumbens, caudate and putamen; however, levels of DOPA decarboxylase and the vesicular monoamine transporter were normal. This type of neuropathology differs from that seen in Parkinson's disease and suggests that methamphetamine does not cause destruction of the dopamine neuron (e.g. see Melega *et al.*, 1997a; Melega *et al.*, 2000). McCann *et al.* (1998b) examined six methamphetamine/methcathinone addicts who had been withdrawn for an average of 3 years; they detected a significant decrement in DAT sites in both the caudate nucleus and putamen. These authors confirmed what had been observed previously in non-human primates: that the decrement was larger in the caudate compared with the putamen, thus differentiating the loss in addicts from that seen in Parkinson's disease patients. Volkow *et al.* (2001a) also noted a persistent reduction DAT availability (Figure XVI-8.4), with significant decrements being detected in subjects withdrawn for up to 11 months. These authors also found that the decrement in DAT availability was associated with deficits in both cognitive (auditory memory) and motor performance (grooved pegboard). A subgroup of these subjects (withdrawn for <6 months) were then retested 6–11 months later (Volkow *et al.*, 2001b); on retest, there was a significant improvement in the availability of DAT sites. Although some improvement was also noted on the cognitive and motor performance, these changes were not significant.

Finally, Sekine *et al.* (2001) examined DAT availability in a group of long-term methamphetamine addicts who also experienced significant psychiatric symptoms. Confirming previous findings, these authors noted a decrease in DAT sites in the methamphetamine users but also noted that the reduction in DAT sites appeared to be associated with positive psychotic symptoms.

Iyo *et al.* (1993) examined D_2 dopamine and serotonin 5-HT$_2$ receptors (^{18}F-NMS and PET) in six methamphetamine addicts who had also experienced psychosis. Five of the six subjects had been withdrawn from methamphetamine for more than 1 year. No difference in binding was detected in either the striatum (D_2 dopamine) or the frontal cortex (serotonin 5-HT$_2$). However, the authors did note a difference (decrease) in the ratio of binding between the striatum and frontal cortex. Volkow *et al.* (2001c) observed a modest but significant reduction in D_2 dopamine receptor availability (^{11}C-raclopride) in the caudate nucleus (−16%) and putamen (−10%). As in cocaine addicts, there was a significant relationship between receptor availability and metabolism in the orbitofrontal cortex.

Methamphetamine abuse differs from cocaine abuse in that for the former there appears to be a persistent presynaptic pathology, as evidenced by the decrease in the availability of DAT sites. The molecular mechanisms responsible for the loss of DAT sites are not clear; however, in non-human primates, the loss of DAT sites can be prevented by the concomitant administration of glial cell-line-derived neurotrophic factor (GDNF) (Melega *et al.*, 2000).

Methamphetamine abuse is similar to alcohol and cocaine abuse in that there is a significant and persistent decrease in D_2 dopamine receptor density.

Methamphetamine, Cerebral Metabolism and Cerebral Blood Flow

Iyo *et al.* (1997) noted marked focal vascular deficits (SPECT–^{99m}Tc-HMPAO) in the cortex of methamphetamine abusers that did not appear to be associated with strokes or cerebral atrophy. Further, these deficits were found in some individuals withdrawn from methamphetamine for up to 4 years. Alhasson *et al.* (2001), also using SPECT, found CBF to be lower in methamphetamine-dependent alcoholics (MDA) compared with cocaine-dependent alcoholics (CDA), who in turn were significantly lower than controls. The CDA group displayed marked regional abnormalities in the superior frontal region, which were not found in the MDA group (where the perfusion defects were diffuse). Volkow *et al.* (2001d) found an overall global increase in metabolism (PET–FDG), which was most notable in the parietal cortex (Figure XVI-8.5). After normalization of the data, significant decrements were detected in the thalamus and caudate nucleus. Pathological causes of increased metabolism have been associated with inflammation and gliosis (e.g. Roh *et al.*, 1998), and preclinical studies have documented that under certain conditions, methamphetamine can induce gliosis. Although there is no direct evidence that methamphetamine induces gliosis in humans, Ernst *et al.* (2000) have obtained MRS data in methamphetamine addicts consistent with this idea.

OPIOIDS

Despite the prevalence of the problem, and the enormous costs associated with treatment, there have been relatively few neuroimaging studies of opiate dependence. Early PET studies showed that the acute administration of morphine (London *et al.*, 1990) or buprenorphine (Walsh *et al.*, 1994) to healthy polydrug abusers decreased brain metabolism. A preliminary study of three post-addicts and two current addicts suggested that chronic heroin abuse produced a persistent decrease in brain metabolism (London, 1989). Van Dyck *et al.* (1994) examined the effects of naloxone-precipitated withdrawal from buprenorphine on rCBF (SPECT–^{99m}Tc-HMPAO) in 11 subjects; no naloxone-specific effects on rCBF were detected, although the severity of withdrawal showed a significant negative correlation with CBF in the anterior cingulate cortex.

Krystal *et al.* (1995) examined the effects of naloxone-precipitated withdrawal in a group of methadone-dependent

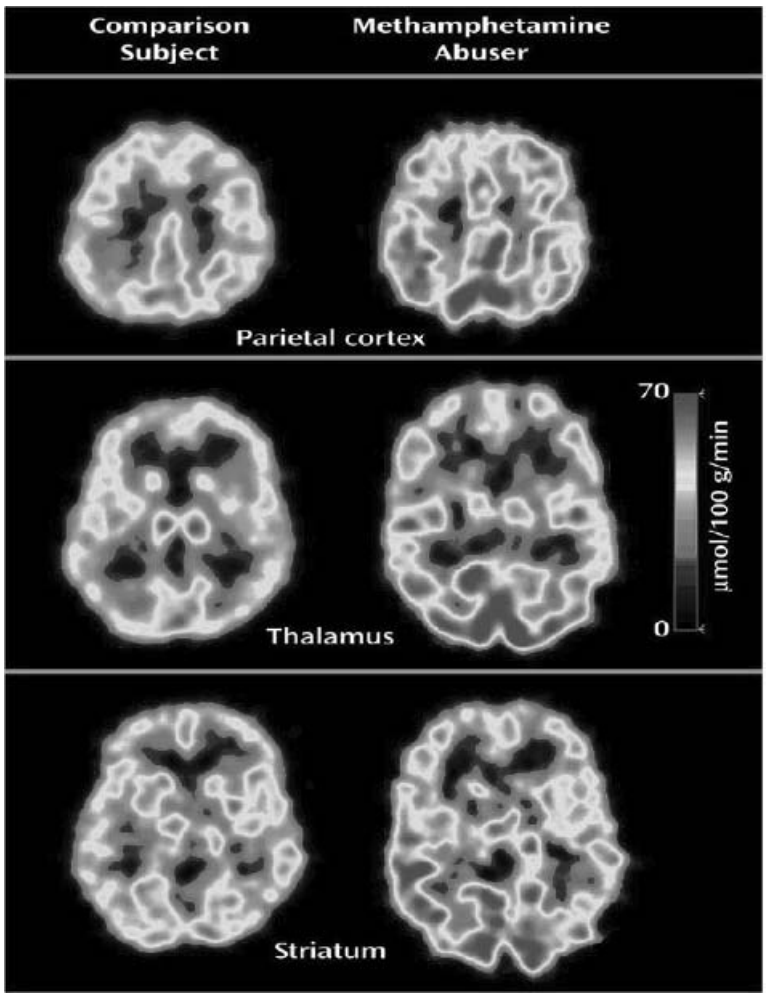

Figure XVI-8.5 Representative comparison of brain metabolism in a normal control and a methamphetamine abuser. Note the increased metabolism in the parietal cortex but decreased metabolism in the thalamus and striatum. Reproduced from Volkow *et al.* (2001b) (See Colour Plate XVI-8.5)

patients, but this study included a control group in double-blind, placebo-controlled study design. The data suggested that there was a decrease in brain perfusion in the frontal and parietal cortex of the methadone-dependent group after saline administration compared with the control group; however, metabolism was increased in the thalamus. Relative to the effects in the normal subjects, withdrawal in the addicts was associated with a decrease in global metabolism and a decrease in rCBF in the right temporal cortex. However, the changes reported were quite small. Rose *et al.* (1996), also using the SPECT technique, examined ten chronic heroin users at 1 week and 3 weeks of withdrawal. The initial scan indicated perfusion deficits in the frontal, temporal and parietal cortices. Two weeks later, improvement in perfusion was noted, suggesting that the deficits were transitory. Hypoperfusion during withdrawal has also been noted by Gerra *et al.* (1998) and Danos *et al.* (1998), although in the former, the hypoperfusion appeared to be related to comorbid behavioural abnormalities, e.g. depression.

Given the availability of numerous opiate ligands suitable for imaging, e.g. ^{11}C-carfentanil and ^{18}F-cyclofoxy, it is somewhat surprising that the question of whether opiate abuse affects opiate receptor binding has not been addressed fully. Post-mortem data (Gabilondo *et al.*, 1994; Schimdt *et al.*, 2000; 2001) indicate that μ and δ opiate receptors are not affected by chronic drug intoxication, similar to earlier preclinical results (Hitzemann *et al.*, 1974). In contrast to these results, Zubieta *et al.* (2000) found substantial increases in μ opiate receptor binding in a small group of dependent subjects maintained on buprenorphine; particularly marked increases were noted in the inferofrontal cortex and anterior cingulate regions. In contrast to these data, Kling *et al.* (2000) found that the binding of the μ and κ opiate receptor ligand, ^{18}F-cyclofoxy, was reduced in a group of dependent subjects maintained on methadone. The measurements were made 22 hours after the last dose of methadone, and the decrements in binding were correlated with the residual plasma methadone levels.

Worsley *et al.* (2000) found that D_2 dopamine receptor density was decreased in a post-mortem sample of heroin abusers compared with controls. Wang *et al.* (1997) noted that receptor availability (PET and ^{11}C-raclopride) was lower in heroin-dependent subjects; further, these authors noted naloxone-precipitated withdrawal did not change binding availability.

Heroin addicts are the fourth group of substance abusers that have a decrease in D_2 dopamine receptor density, the others being alcohol, cocaine and methamphetamine abusers, suggesting the possibility of a common underlying pathology.

CANNABINOIDS

Despite an impressive increase over the past decade in our understanding of the mechanisms of cannabinoid action (e.g. see Chaperon and Thiebot, 1999), including the characterization of the CB1 and CB2 receptors and a number of endogenous ligands for these receptors, there has been relatively little research on cannabinoid abuse from the clinical imaging perspective. Volkow *et al.* (1991b) investigated the effects of acute intravenous administration of 2 mg of Δ^9-tetrahydrocannabinol (THC) on brain metabolism (PET–FGD) in eight normal controls. When compared with baseline measures, the effects of THC were quite variable: three subjects showed a decrease in global metabolism, three showed an increase, and two showed no change. However, all subjects showed an increase in cerebellar metabolism, which was correlated with the subjective sense of THC intoxication and plasma THC. The authors concluded that the cerebellar effect corresponds well with the known high density of THC receptors in the cerebellum. This same group followed with a study in normal controls and chronic marijuana abusers (Volkow *et al.*, 1996c). At baseline, cerebellar metabolism was lower in the abusers compared with the controls. THC increased cerebellar metabolism in both groups but increased metabolism in the orbitofrontal cortex, prefrontal cortex and basal ganglia only in the marijuana abusers. The authors concluded that the activation of the orbitofrontal cortex and basal ganglia by THC in the abusers could be associated with the drive and compulsion to self-administer THC. Amen and Waugh (1998) measured CBF (SPECT–^{99m}Tc-HMPAO) in a group of 30 heavy marijuana users with ADHD and ten attention deficit hyperactivity disorder (ADHD) controls. Both groups showed a perfusion deficit in the prefrontal cortex; however, only the marijuana group showed a marked decrease in activity in the right and left temporal lobes.

3,4-METHYLENE-DIOXYMETHAMPHETAMINE

Although 3,4-methylene-dioxymethamphetamine (MDMA; ecstasy) was first synthesized in the 1960s, its popularity as a recreational drug is relatively recent. Animal models of MDMA neurotoxicity have suggested that in doses similar to those that are abused, the drug produces a loss of serotonergic neurons. Data from non-human primates (baboons) have confirmed that NMDA markedly reduces the density of 5-HT transporters, and that in some regions, these effects can persist for over a year (Scheffel *et al.*, 1998). McCann *et al.* (1998a), using PET and the 5-HT transporter ligand ^{11}C-McN-5652, compared 14 previous users of MDMA with 15 controls. Decreases in transporter binding correlated with the extent of previous drug use (see also McCann *et al.*, 2001 and Ricaurte *et al.*, 2001). Semple *et al.* (1999) found that while MDMA use led to significant decreases in 5-HT transporter binding, there was no change in DAT binding. Reneman *et al.* (2001a, 2001b) have observed that the decrease in 5-HT transporter density is greater in more recent than more abstinent users, and that women may be more be susceptible to the loss of transporters than men. One study has suggested that in response to the apparent loss of 5-HT neurons, MDMA users show an upregulation of cortical 5-HT_{2A} receptors, which appeared to be associated with memory impairments. Several studies have used PET or SPECT to examine rCBF or brain metabolism in MDMA users (Obrocki *et al.*, 1999; Chang *et al.*, 2000; Gamma *et al.*, 2001; Buchert *et al.*, 2001). Some abnormalities in rCBF and metabolism have been observed; however, at present the data do not suggest the same extent or persistence of abnormalities as those seen in cocaine or methamphetamine abusers.

NICOTINE

Arguably, the use and abuse of nicotine-based products, largely cigarettes, has the greatest effect on society from the perspective of both cost and health risk. Each year, about 3 million people die from smoking-associated illnesses (Wald and Hackshaw, 1996). Despite the importance of the problem, neuroimaging studies of nicotine abuse are few. Fowler *et al.* (1996, 1998, 2000) have found that people who smoke cigarettes have a marked inhibition of both brain MAO-A and MAO-B. The two forms of MAO were visualized using ^{11}C-clorgyline and ^{11}C-deprenyl, respectively (Figure XVI-8.6). The smoking-associated decrease in enzyme activity for both forms of the enzyme was about 40–50%. The mechanisms by which cigarette smoking inhibits MAO activity are not clear but apparently are not associated with nicotine *per se* (Fowler *et al.*, 1998). Further, smoking a single cigarette does not decrease MAO activity (Fowler *et al.*, 1999). Thus, it is assumed that the inhibition of enzyme activity is caused by some material in the smoke that accumulates with chronic drug administration. While these data are of interest in their own right, they have particular importance when we consider that nearly all drug abusers also

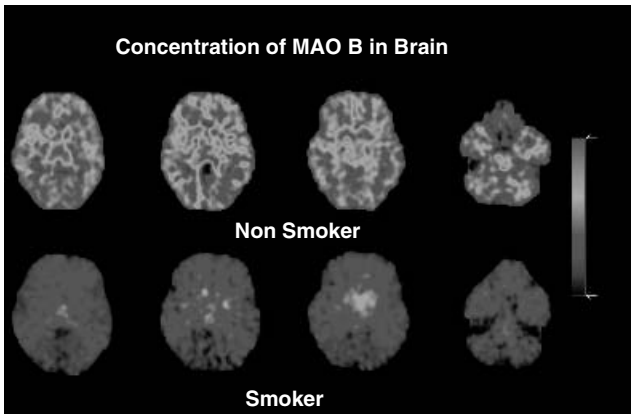

Figure XVI-8.6 Representative comparison of ^{11}C-deprenyl uptake into the brain of a nonsmoker and a smoker. Data are taken to indicate reduced MAO-B activity in the smoker. Adapted from Fowler *et al.* (1996) (See Colour Plate XVI-8.6)

smoke cigarettes. In most imaging studies of substance abusers, smoking is either not controlled for or is controlled for only poorly. These data illustrate that in addition to the substantial effects of nicotine, the smoke contains elements that also affect systems that regulate neurotransmitters.

Domino *et al.* (2000) examined the effects of nicotine on brain metabolism (PET–FDG) in a group of smokers that were abstinent overnight before the study. Three minutes before the scan, a dose of 1–2 mg of nicotine or placebo was delivered by nasal spray. The normalized metabolic data revealed several regions that were activated by nicotine; these included the left inferior frontal gyrus, left posterior cingulate and right thalamus. The authors noted that the increase in the thalamus was consistent with the high density of nACh receptors in that area; however, many areas with a known high density of receptors were not activated, suggesting that the effects of nicotine are more complex than simply receptor activation. Zubieta *et al.* (2001) used a similar experimental design to examine the effect of nicotine on CBF (^{15}O-labelled water–PET). The authors noted decreases in rCBF in the anterior temporal cortex and in the right amygdala. However, nicotine increased rCBF in the right anterior thalamus. Thus, there is agreement between the metabolic and flow data.

CONCLUSIONS

PET and SPECT neuroimaging have both confirmed existing hypotheses and extended our understanding of substance abuse. The most salient points may be summarized:

Individuals who abuse alcohol, cocaine, methamphetamine and heroin all show modest reductions in striatal D_2 dopamine receptor density. The initial interpretation of these results was that of receptor downregulation in response to enhanced dopamine release. However, neuroimaging revealed that the reduction in receptor density is persistent (at least for cocaine addicts), suggesting that lower receptor density may be a risk factor for substance abuse. Of interest is the observation that the subjective response of normal controls to intravenous methylphenidate is associated with D_2 receptor density; those with low receptor density had a 'pleasant' drug response, while those with a higher receptor density had an 'unpleasant' drug response.

Substance abuse is associated with persistent changes (generally decrements) in brain metabolism and rCBF. Although the mechanisms responsible for these deficits are probably drug dependent, there are likely to be common consequences, including cognitive deficits and an extended period of recovery and readaptation of the relevant neural networks.

A common theme that has emerged is the involvement of the striatal-thalamo-orbitofrontal circuit and the development of abnormalities in this circuit that contribute to increased craving and decreased impulse control.

While there has been substantial work on alcohol and cocaine abuse, there is a need for substantially more work on methamphetamine, opiate, marijuana, MDMA and nicotine abuse. Further, there is very little understanding of the interactions between multiple drugs of abuse. However, the preliminary data suggest that the interactions may be substantial.

Neuroimaging of substance abusers is not limited to PET and SPECT. As noted in the introduction, MRI- and MRS-based techniques are used widely and are becoming increasingly popular. The use of these techniques in the study of alcoholism has been reviewed (Mann *et al.*, 2001).

Genetic Epidemiology of Substance-Use Disorders

Kathleen R. Merikangas

INTRODUCTION

The recent announcement that the human genome has now been sequenced has generated widespread excitement about our ability to understand and treat human disease. Many genes have been identified for disorders caused by a single gene with high absolute and relative risk, such as Huntington's disease (Gusella *et al.*, 1983), muscular dystrophy (Kunkel *et al.*, 1986) and cystic fibrosis (Beaudet *et al.*, 1986). However, the application of knowledge derived from the Human Genome Project will be less immediately apparent for complex phenotypes, characterized by high population prevalence, non-Mendelian modes of transmission, and indistinct boundaries between affected and non-affected (Merikangas, in press).

Substance-use disorders are genetically complex disorders that are automatically characterized by gene–environment interaction because exposure to an exogenous substance is necessary for their expression. The tools of epidemiology are suited ideally to examine phenotypes that result from interactions between individual vulnerability factors and environmental exposure.

Figure XVI-9.1 shows the traditional epidemiological triangle of the joint influences of the host, agent and environment in inducing human disease. The methods of epidemiology have been developed to identify the aetiology of particular diseases through simultaneous investigation of each of the three domains depicted in the triangle. This is an excellent model for studying the aetiology of substance abuse: there is a clear *agent*, a drug; numerous characteristics have been demonstrated consistently to confer increased susceptibility of the *host* or individual to drug use, continued use and dependence; and many of the *environmental factors* involved in exposure to drugs have also been identified. The chief goal of the subdiscipline of genetic epidemiology is identification of the genetic and environmental factors underlying human diseases.

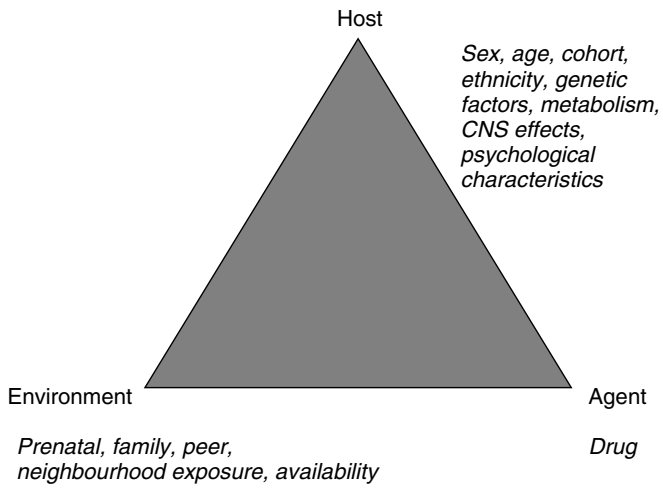

Figure XVI-9.1 Epidemiology of drug abuse

This chapter will: (1) review sources of complexity in identifying genes for complex disorders, (2) review the evidence regarding familial and genetic risk factors for the development of substance-use disorders, (3) review sources of complexity in the aetiology of substance-use disorders, and (4) describe the tools of the discipline of genetic epidemiology that may elucidate the role of genes in the development of substance-use disorders.

CHALLENGES TO IDENTIFICATION OF GENES FOR COMPLEX DISORDERS

Despite advances in characterizing human genotypes, application of this knowledge to human diseases is still limited by the complexity of the process through which genes exert their influence. At present, knowledge of a particular gene does not permit prediction of the phenotype, nor does knowledge of a phenotype permit inferences regarding the genotype, particularly for human behavioural disorders.

A lack of one-to-one correspondence between the genotype and phenotype is clearly the rule rather than the exception for most human disorders. Phenomena such as *penetrance* (i.e. probability of phenotypic expression among individuals with susceptibility gene), *variable expressivity* (i.e. degree to which susceptible individuals express components of genotype), *gene–environment interaction* (i.e. expression of genotype only in the presence of particular environmental exposures), *pleiotropy* (i.e. capacity of gene to manifest simultaneously several different phenotypes) and *genetic heterogeneity* (i.e. different genes leading to indistinguishable phenotypes) have been demonstrated for several human disorders for which susceptibility genes have been identified.

Marfan syndrome is a classic example of pleiotropy. The genetic mutation causing Marfan syndrome has now been identified as fibrillin I, on chromosome 15 (Child, 1997). The diagnostic criteria for Marfan syndrome based on clinical signs require one of the following five conditions: lens dislocation, aortic dilation or dissection, dural ecstasia, skeletal features, plus one other affected system (De Paepe *et al.*, 1996). This single mutation in the genes involved in the production of connective tissue leads to manifestations across multiple organ systems.

Breast cancer provides an illustration of genetic heterogeneity, another major source of genetic complexity. Although family study research is beginning to examine differences in breast cancer among those with and without specific vulnerability genes, the basic breast

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

cancer phenotype has not been adequately differentiated. Patterns of comorbidity with other cancers and sex differences have been valuable in discriminating different genetic forms of breast cancer (King *et al.*, 1993). Whereas families with predominantly affected females, or those with both breast and ovarian cancer are more likely to have the BRCA1 mutation (Miki *et al.*, 1994), families with male breast cancer primarily arise from the BRCA2 mutation (Ford *et al.*, 1994). Thus, sex differences in recurrence risk and comorbidity across cancer types may be used to identify more homogeneous forms of cancer.

Gene–environment interaction characterizes a broad range of human diseases such as cancer and birth defects. The classic examples of gene–environment interaction are the inborn errors of metabolism, such as phenylketonuria, that manifest only when susceptible individuals are exposed to a particular protein or exogenous substance. Glucose-6-phosphate-dehydrogenase (G6PD) deficiency, an X-linked disorder caused by mutation on the long arm of the X chromosome, is another illustration of gene–environment interaction. The expression of this disorder becomes manifest as haemolytic anaemia only when the susceptible individual is exposed to certain drugs or fava beans (Cavalli-Sforza and Bodmer, 1971). Birth defects have also been found to result from gene–environment interaction. For example, Yang *et al.* (1998) found that dietary factors mediate the development of familial adenomatous polyposis among mice with genetic susceptibility. Whittemore (1999) presents several examples of gene–environment interaction underlying human cancers.

Not only is the expression of genes modified by the environment, but also there is now substantial evidence to indicate that numerous environmental factors may actually alter the genotype, as is characteristic of many forms of cancer. Francis and colleagues (1999) have shown that maternal behaviour mediates stress reactivity in adulthood and is associated with future maternal behaviour among offspring. Genes may also be involved in the response or resistance to purely environmental agents such as diet, stress, exercise, drugs and nutritional deficiencies (Omenn and Motulsky, 1987). The methods of genetic epidemiology are designed specifically to identify gene–environment interactions (Ottman, 1995; Yang and Khoury, 1997).

Alzheimer's disease (AD) provides an excellent model of a disease with both genetic heterogeneity and gene–environment interaction. There are some major autosomal dominant genes for early onset familial AD with extremely high relative and absolute risk (Slooter and van Duijn, 1997). However, such genes are very rare in the population and have little public health significance. In contrast, there is increasing evidence that the apolipoprotein E (Apo-E) E4 allele is associated with both late-onset familial AD and the more common sporadic AD (Corder *et al.*, 1993; Mayeux *et al.*, 1998; Tsai *et al.*, 1994). Among families at high risk for late-onset AD, disease risk has been shown to increase with the number of E4 alleles (Mayeux *et al.*, 1998). Finally, environmental risks such as head injuries and anti-inflammatory agents have been shown to interact with the apo-E genotypes to protect against or potentiate development of AD (Slooter and van Duijn, 1997).

EVIDENCE FOR ROLE OF GENETIC FACTORS IN THE AETIOLOGY OF SUBSTANCE-USE DISORDERS

Family Studies

The familial aggregation of alcoholism has been well established (for comprehensive reviews of alcoholism see McGue, 1994; Merikangas, 1990). Although there has been less systematic research on the familial aggregation of drug-use disorders, there is increasing empirical research demonstrating that drug-use disorders are also familial (Merikangas, 2000). The results of numerous family history studies, uncontrolled family studies (Croughan, 1985; Gfroerer, 1987; Hill *et al.*, 1977; Meller *et al.*, 1988; Mirin *et al.*, 1988, 1991; Rounsaville *et al.*, 1991) and controlled studies of first-degree relatives of substance abusers (Bierut *et al.*, 1998; Merikangas *et al.*, 1998b) demonstrate consistently that the rates of substance-use disorders are elevated among relatives of drug abusers. An eight-fold increased risk of drug disorders was found among relatives of probands with drug disorders compared with relatives of psychiatric and normal controls (Merikangas *et al.*, 1998b).

High-Risk Studies

Studies of offspring of parents with substance abuse are a subset of family studies that provide information on the order of onset and patterns of transitions across drug categories, as well as on premorbid risk factors for the development of substance abuse. Although there have been several high-risk studies of children of alcoholics (Sher, 1996; Chassin *et al.*, 1991; Hill and Hruska, 1992; Johnson, 1989; Merikangas *et al.*, 1998a; Reich *et al.*, 1993; Schuckit and Smith, 1996), there have been very few controlled studies of offspring of drug abusers. These studies have yielded consistent findings regarding an increased risk of substance-use disorders among offspring of parents with substance abuse or dependence when compared to those of non-substance abusers (Martin *et al.*, 1994; Merikangas, 1998b; Moss *et al.*, 1994).

High-risk studies are particularly informative for prevention efforts as they aid in the identification of premorbid vulnerability factors that serve as sources of identification for children at risk for particular disorders. Aside from genetic factors, there are numerous other mechanisms through which parents may convey an increased risk of substance abuse to their offspring, including serving as negative role models for the use/abuse of drugs and using drugs as a coping mechanism (Brook *et al.*, 1986). Moreover, adolescents with a family history of substance abuse are more likely to associate with deviant peers than those without familial loading (Kandel and Andrews, 1987).

Likewise, nearly all of the high-risk studies reveal that different risk factors may be involved in the different stages of development of substance-use disorders. Whereas individual characteristics and peer influences strongly influence exposure and initial patterns of use of alcohol and drugs, family history and psychopathology play a more salient role in the transition to problematic alcohol use and dependence (Cadoret *et al.*, 1986).

Twin Studies

There have been numerous twin studies that provide evidence that the strong degree of familial clustering of substance-use disorders can be attributed in part to genetic factors. Studies have examined drug use, abuse and dependence in general (e.g. Grove *et al.*, 1990; Jang *et al.*, 1995; Kendler *et al.*, 1999, 2000; Pickens *et al.*, 1991; Tsuang *et al.*, 1998) as well as a diverse range of specific drugs including nicotine, caffeine, tranquillizers, sedatives, cannabis, cocaine, stimulants, hallucinogens and opiates (e.g. Claridge *et al.*, 1978; Gurling *et al.*, 1985; Heath, 1993; Heath and Madden, 1995; Heath *et al.*, 1993; Kendler and Prescott, 1998a; Kendler *et al.*, 1999, 2000; Pedersen, 1981; True *et al.*, 1997, 1999; Tsuang *et al.*, 1998). As described below, the results of these studies have been highly consistent in demonstrating the role of genes in the aetiology of substance abuse and/or dependence. However, the extent of genetic influence differs according to the definition employed, and the age, gender and source of the sample. Although genetic factors are clearly important in the development of substance-use disorders, environmental factors shared between twin pairs have also been

shown to have substantial impact on the development of substance-use disorders (Tsuang *et al.*, 1998).

One of the strongest sources of evidence regarding the role of genetic factors in the aetiology of substance abuse derives from monozygotic twins reared apart. Grove *et al.* (1990) examined the concordance for alcoholism, drug abuse and antisocial personality disorder among monozygotic twin pairs separated at birth. The heritability estimate of drug abuse was 0.45, far exceeding that of alcoholism (0.11).

Adoption Studies

The classic adoption studies of Cadoret and Colleagues (Cadoret, 1992; Cadoret *et al.*, 1986, 1996) have also been highly informative in elucidating the role of genetic factors in the development of drug use and abuse. Although data on biologic parents are often limited with respect to specific patterns of drug use and abuse, their studies provide the strongest evidence to date that genetic factors play an important role in the liability to drug abuse.

Linkage and Association Studies

Although the research reviewed above demonstrates the importance of genetic factors in the development of substance-use disorders, it only provides evidence for the aggregate influences of genes rather than identifying specific genes and the putative mechanisms through which they exert their influence. The two major classes of genes that have been postulated to convey susceptibility to drug-use disorders include those involved in drug metabolism, and those involved in brain reward systems. There has been increasing interest in the genetic control of drug sensitization and tolerance (Phillips *et al.*, 1997). Associations between genes involved in drug metabolism have been evaluated among probands with opioid dependence, cannabis dependence and nicotine dependence as well as alcohol and/or drug dependence in general (Bergen *et al.*, 1997; Comings *et al.*, 1999b; Kranzler and Leibowitz, 1998). Reviews of candidate genes for substance-use disorders are presented by Crabbe and Phillips (1998), Rossing (1998), Enoch and Goldman (1999) and Uhl (1998).

Genes involved in brain reward systems have been the most frequently studied candidate genes for substance-use disorders. There are numerous reports of a possible association of D_2 dopamine receptor gene polymorphisms and genetic susceptibility to either drug dependence in general or to specific drugs, such as opiates or nicotine (Amadeo *et al.*, 1993; Arinami *et al.*, 1993; Blum *et al.*, 1990, 1991, 1993; Comings *et al.*, 1991; Lerman *et al.*, 1999; O'Hara *et al.*, 1993; Parsian *et al.*, 1991; Smith *et al.*, 1992; Sabol *et al.*, 1999). In contrast to these reports, multiple investigators have found no differences in allele frequencies between abusers and controls (Berrettini and Persico, 1996; Bolos *et al.*, 1990; Cook *et al.*, 1995; Gelernter *et al.*, 1991; Goldman *et al.*, 1992; Schwab *et al.*, 1995; Suarez *et al.*, 1994; Turner *et al.*, 1992). Other candidate genes involving the dopamine receptor or transporter systems have also been examined: DRD3 (Duaux *et al.*, 1998), DRD4 (Bergen *et al.*, 1997; Comings *et al.*, 1999a; Duaux *et al.*, 1998) and DRD5 (Vanyukov *et al.*, 1998). Finally, a variety of other candidate systems have been reported in substance-dependent probands, including the cannabinoid receptor gene (Comings *et al.*, 1997) and the Proenkephalin gene (Comings *et al.*, 1999b). Other systems underlying brain reward will also be important candidates for future studies. For example, the role of substance P in the rewarding properties of morphine has recently been reported (Murtra *et al.*, 2000).

There are numerous methodologic issues that are critical to the interpretation of the significance of the findings of this research. First, the wide variation in the ethnic distributions of these systems, particularly with respect to the dopamine metabolism genes, has rarely been considered in association studies (Barr and Kidd, 1993). This problem of ethnically based allele frequency differences is minimized through application of association studies using parental genotypes and/or unaffected sibling genotypes as controls in the analyses (Falk and Rubenstein, 1987; Kidd, 1993; Risch and Merikangas, 1996). Second, many of the findings implicate genes that do not appear to have functional relevance (Paterson *et al.*, 1999). Third, purported replications have resulted from very different phenotypic definitions (i.e. frequency of use versus ability to quit). Thus, although the genetic epidemiologic evidence (from twin, family and adoption studies reviewed above) is consistent with a heritable component to substance dependence, to date there has been limited success in identifying human susceptibility genes that have been replicated across samples and centres.

Significant progress in animal studies has provided a knowledge base that will ultimately be critical to the identification of human genes for drug dependence. Research using inbred strains, selected lines and recombinant inbred strains provides critical information about the relevance of a particular gene product that may be involved in the pathogenesis of substance-use disorders. Information derived from congenic strains, transgenic mice, knockout and inducible knockout mice could lead to better medical intervention for drug addiction. Reviews of this research are presented by Crabbe and Phillips (1998), Pich and Epping-Jordan (1998), Crabbe *et al.*, 1999. However, the application of information gleaned from animal research is still problematic because few animal models are adequate representations of human patterns of drug use and or dependence. Moreover, these models fail to account for the pervasive human tendency to use multiple drugs both concomitantly as well as historically. Nevertheless, such studies are extremely valuable in providing information regarding the genetic systems underlying metabolism and the effects of specific substances.

SOURCES IN COMPLEXITY OF GENETICS OF SUBSTANCE-USE DISORDERS

Table XVI-9.1 presents some of the key issues that lead to complexity in examining the role of genetic factors in the aetiology of substance-use disorders. Each of these issues is described below.

What is the Phenotype?

Substance-use disorders emerge from a series of complex processes that are difficult to capture using the currently available measurement tools. Different risk factors are associated with different levels of progression of drug use. One of the major impediments to summarizing the results of family and twin studies is the use of different definitions and components of drug-use behaviour. For example, twin studies of smoking have examined diverse components of smoking, including use, frequency, quantity, age at onset,

Table XVI-9.1 Factors related to the complexity of genetics of substance-use disorders

- Polysubstance use/dependence
- Comorbidity with psychopathology

regular use, continued use, current use, current frequency, dependence, severity and ability to quit (Heath and Madden, 1995). Many studies have employed a few items regarding drug use on self-reported questionnaires, whereas others used structured diagnostic interviews that collected full diagnostic criteria for substance abuse and dependence. Van den Bree *et al.* (1998a, b) present a summary of the results of twin studies of drug abuse according to a wide range of definitions. They found that the heritability was greater for clinical diagnoses of abuse/dependence than for use.

In the first twin study using diagnostic criteria for drug abuse and dependence, Pickens *et al.* (1991) reported that approximately 35% of the variance in substance-use disorders was attributable to genetic factors. Moreover, the heritability for drug dependence was significantly greater than that for abuse. Additional analyses of these data by McGue *et al.* (1994) revealed far greater heritability of drug-use disorders among males with early age of onset compared to either those with later age of onset or females. Likewise, Tsuang *et al.* (1998) found that the contribution of genetic factors was greater for frequent use or abuse than for non-problematic use of drugs.

The aggregate twin study data are remarkably consistent in demonstrating that genetic factors play a far greater role in the aetiology of more severe patterns of drug use, particularly that which meets diagnostic criteria for abuse or dependence, than initial use or early stages of use, which appear to be more strongly determined by environmental influences. With respect to specific substances, there is a growing body of literature on the role of genetic factors for tobacco, cannabis and cocaine use and dependence.

Evidence regarding the role of genes in tobacco use has been derived almost exclusively from twin studies. Summaries of twin studies of smoking provided by Heath *et al.* (1993), Heath and Madden (1995), True *et al.* (1999) and Kendler *et al.* (1999) reveal that the proportion of variance in regular tobacco use attributable to genetic factors (i.e. heritability) is about 50%, whereas shared environmental factors explain an additional 25%. Studies of twins reared apart have yielded inconclusive findings. Kaprio *et al.* (1984) found no significant difference between monozygotic (MZ) and dizygotic (DZ) twins reared apart (proband-wise concordance rates of 0.67 and 0.68, respectively), whereas for twins reared together, the concordance rates were greater among MZ twins (0.91) than for DZ twins (0.67). However, these findings differed dramatically among male and female twin pairs, and by definitions of smoking. In a more recent and larger study, Kendler *et al.* (2000) found weak evidence for a genetic effect for lifetime cigarette use in males, but not in females.

Data on female twins from the Virginia Twin Study (Kendler and Prescott, 1998b) revealed that genes had a moderate influence on cannabis use among the female twins, but far stronger impact on heavy use and abuse of cocaine (Kendler and Prescott, 1998a). Likewise, the heritability of cocaine abuse and dependence was greater (MZ and DZ proband-wise concordance rates of 47% and 8%, and 35% and 0%, respectively) than that of cocaine use (proband-wise concordance of 54% and 42%) (Kendler and Prescott, 1998b). With respect to other substances, their results indicated that opiate and sedative use were solely attributable to common genes, whereas hallucinogen and stimulant use resulted from both family environment and genes (Kendler *et al.*, 1999). A recent innovative analysis of the Vietnam Era Twin Registry examined the role of genetic influences in transitions from use to abuse of a range of substances, as well as transitions across particular substances. The rate of transition from use to regular use was greatest for heroin, whereas cocaine had the highest conditional probability for the transition from regular use to dependence.

The adoption study paradigm has been applied to study aggregate drug abuse and its association with antisocial personality. The results of adoption studies also confirm the stronger impact of genes on more severe patterns of substance use. Cadoret *et al.* (1992) found that exposure to a sibling or peer with deviant behaviour appears to contribute to drug use, but not to abuse. None of the adoption studies have thus far been able to detect a gene–environment interaction in drug initiation or in the transition from use to abuse (Cadoret, 1992).

Sex Differences

Substance-use disorders are more common in males than in females. Based on the rates from Epidemiologic Catchment Area Study, men are five times as likely to have an alcohol-use disorder and two to three times more likely to have a drug-use disorder as compared to women (Anthony and Helzer, 1995). Likewise, the National Comorbidity Survey (Kessler *et al.*, 1997) found that substance-use disorders were more prevalent among men than women, with a greater difference for alcohol dependence than drug dependence.

Gender differences in the contribution of familial and genetic factors have also been reported. The results of the Yale Family Study of comorbidity of substance-use disorders and psychopathology demonstrated differential familial transmission of alcohol abuse and dependence among male and female relatives. Whereas female relatives of probands with alcohol dependence had elevated rates of both alcohol abuse and dependence, male relatives of affected probands only exhibited an elevation in rates of alcohol dependence (Merikangas *et al.*, 1998b).

With respect to twin studies, there is little evidence regarding gender differences because of the lack of large-scale twin studies of drug-use disorders in samples with both male and female twin pairs. Pickens *et al.* (1991) found that although both male and female MZ twin pairs had a 1.5-fold increased risk of drug abuse compared to DZ pairs, the concordance for males could be attributed to both shared genes and environmental factors, whereas for females the majority of variance was attributable to the unique environmental experiences of individual twins. Likewise, Van den Bree *et al.* (1998b) found that genetic influences on drug abuse/dependence were generally stronger for males than for female twins. Although the twin studies of Kendler *et al.* are the largest to date, the analyses of the male and female twin samples have been conducted independently. Independent analyses of male and female twin series yielded some sex differences in heritability; there was less genetic influence on cocaine abuse and dependence in males (Kendler *et al.*, 2000) than in females (Kendler and Prescott, 1998a). However, the small numbers of pairs from these population-based samples diminish their value in evaluating the role of genetic and environmental factors in dependence of any one class of drugs.

Age

Twin studies have also begun to examine the role of genetic factors in the development of substance-use disorders in prospective samples of children and adolescents. These studies may inform our understanding of the influence of age and developmental level in the aetiology of substance-use disorders. Since exposure to drugs generally occurs during early adolescence, the above-cited data derived from adult samples is necessarily susceptible to the biases of all retrospective studies. Whereas a study of adolescent twins from the Netherlands (Boomsma *et al.*, 1994) yielded evidence for nearly equal impact of genetic and social influences on smoking among adolescent twins, Maes *et al.* (1999) reported substantial heritability for both lifetime (82%) and current (84%) tobacco use in the Virginia Twin Study of Adolescent Behavioural Development. In contrast, in the latter study, use of other drugs such as cannabis was more strongly attributable to shared environmental factors than

to genes. In the Netherlands sample, the heritability of alcohol use increased with age, whereas shared environmental factors had stronger impact in early adolescence (Boomsma *et al.*, 1994). Follow-up of these samples will elucidate the joint influence of genetic and environmental factors on persistence and dependence as these cohorts pass through the risk period for the development of tobacco dependence.

Recent twin studies of adolescents have also examined the heritability of cannabis use in adolescent twins (Miles *et al.*, 2001). Both genetic and environmental factors were found to contribute equally to cannabis use in both male and female twin pairs.

Cohort and Generation Effects

One key source of complexity in studying the familial transmission of drug abuse is the dramatic changes in patterns of drug use in the general population, as well as within specific subgroups. Rapid shifts in the availability and cultural and geographic patterns of specific drugs impede traditional inspection of vertical patterns of concordance for drug use and dependence. Whereas alcohol has been readily available during the past several decades, and cannabis has been somewhat stable as well, crack cocaine and ecstasy have only been widely available during the past decade. Ironically, nicotine use has been decreasing rapidly in more recent cohorts. These differences in availability and cultural norms make it difficult to discriminate exposed but unaffected relatives from those who were never exposed to a particular drug. Within-generation comparisons are therefore more likely to control for exposure to specific substances. However, siblings are often responsible for the initiation of other siblings to drugs, as well. This could lead to an overestimation in the heritability of drug use.

Evaluation of the family and twin study data by generation of the relative with respect to the proband (i.e. parent, sibling, offspring) reveal that both drug use (Gfroerer, 1987) and abuse/dependence (Bierut *et al.*, 1998; Merikangas *et al.*, 1992, 1998b) are particularly elevated among siblings of drug abusers when compared to parents and offspring. There is also a direct relationship between parental drug use (Gfroerer, 1987) and abuse (Luthar *et al.*, 1992; Merikangas *et al.*, 1992) and use and abuse in offspring.

Environmental Influences

With respect to parental drug use, few genetic epidemiologic studies have considered the effect of foetal exposure to substances on the susceptibility to drug-use disorders. Differences between exposed and unexposed youth could either be a product of the exposure or of genetic or familial factors associated with maternal drug use. For example, Yates *et al.* (1998) reported that foetal alcohol exposure may be associated with an increased risk for later nicotine, alcohol and drug dependence, beyond the effects of genetic factors associated with maternal drug abuse. Although twin studies can distinguish between environmental influences that are common to twins from those that are unique, they do not provide information on specific environmental exposures without being specifically designed to identify sources of discordance.

Spouse Concordance

The tendency for spouses to be concordant for substance use is another issue that must be integrated in evaluation of genetic evidence. Several studies have shown high levels of spouse concordance for drug use (Merikangas *et al.*, 1992; Price *et al.*, 1982). For example, Merikangas *et al.* (1992) reported that more than 90% of opioid-dependent proband's spouses had a history of opioid dependence themselves. Furthermore, these investigators showed that there is a strong association between rates of drug abuse in adult siblings of opioid abusers and the number of parents with substance abuse. It is therefore critical that spouse concordance be incorporated in genetic analyses of substance abuse.

Polysubstance Use

Another important factor in examining the role of genetic factors in drug-use disorders is the tendency for substance abusers to abuse multiple substances, both simultaneously as well as longitudinally (Merikangas *et al.*, 1998b; Mirin *et al.*, 1991). One twin study of substance use revealed a moderate degree of heritability for the frequency of use and the tendency to use numerous illicit substances ($h^2 = 0.32$) (Jang *et al.*, 1995).

Surprisingly, there is little evidence for the cross-transmission of drug disorders and alcoholism (Merikangas *et al.*, 1998b). The results of several uncontrolled family studies suggest that alcohol and drug dependence aggregate independently in families (Hill *et al.*, 1977; Luthar *et al.*, 1992; Meller *et al.*, 1988; Mirin *et al.*, 1991; Rounsaville *et al.*, 1991). Likewise, a controlled family study of both drug abuse and alcoholism found that alcoholism did not modify the association between drug disorders in probands and relatives and vice versa (Merikangas *et al.*, 1998b). In contrast, the results of a large twin study of males revealed common genetic vulnerability to nicotine and alcohol dependence (True *et al.*, 1999).

The *specificity* of familial aggregation of particular types of substance dependence has been examined in both family and twin studies (Bierut *et al.*, 1998; Merikangas *et al.*, 1998b; Tsuang *et al.*, 1998). The results of these studies yield remarkably similar trends towards specificity of aetiologic factors for particular drugs. Data from the Yale Family Study of Comorbidity of Substance Abuse and Psychopathology examined the specificity of familial aggregation of the predominant drug of abuse among adult relatives of probands classified likewise. The results revealed a remarkable degree of specificity for familial aggregation of opiates, cannabis and alcohol, and to a lesser extent for cocaine (Merikangas *et al.*, 1998b); there was an 8-fold increase in opioid dependence among relatives of opioid-dependent probands, and a 2-fold increase in cocaine dependence among relatives of probands with cocaine dependence (Table XVI-9.2). In a study of siblings of alcohol-dependent probands, Bierut *et al.* (1998) found an approximately 1.8-fold increase in rates of nicotine, cocaine and cannabis dependence, respectively, among relatives of probands with each of these types of dependence. Patterns of concordance for specific drugs in twins from the Vietnam Era Twin Registry (Tsuang *et al.*, 1998) also revealed a significant degree of specificity. In summary, the aggregate findings of the twin and family studies provide evidence for common familial and genetic factors underlying substance-use disorders in general, as well as substantial components that are unique for specific drugs.

Table XVI-9.2 Yale family study of comorbidity of drug-use disorders: specificity of familial aggregation of predominant drug-use disorder

	Relatives (%)			
Probands	Opioid	Cocaine	Cannabis	Alcohol
Opioid	10	4	6	20
Cocaine	2	8	5	22
Cannabis	6	2	13	20
Alcohol	2	3	4	29
Controls	1	1	2	11

Comorbidity with Psychopathology

The comorbidity between substance use and psychiatric disorders has been well documented by numerous studies. Ross *et al.* (1988) found that 78% of their treatment sample of patients with substance-use disorders met DSM-III criteria for a lifetime comorbid psychiatric disorder. Specific non-drug related disorders suffered by substance abusers include affective illness, anxiety disorders, antisocial personality disorder, and attention deficit disorder (Khantzian, 1983; Khantzian and Treece, 1985; Kleber and Gold, 1982; Mirin *et al.*, 1984, 1988; Quitkin *et al.*, 1972; Rounsaville *et al.*, 1982; Weiss *et al.*, 1985).

The adoption studies of Cadoret and Colleagues (Cadoret, 1992; Cadoret *et al.*, 1986, 1996) also examined links between antisocial personality in biological parents and drug abuse in offspring. Their findings identify two major biological/genetic pathways to the development of drug abuse in adoptees: one which is driven by substance abuse in the biological parent and is limited to drug abuse and dependence in the adoptee, and another which appears to be an expression of underlying aggressivity and related to criminality in the biological parent (Cadoret *et al.*, 1995, 1996). A study of separated twins confirmed these findings by demonstrating that a large proportion of the heritability of substance abuse in adulthood can be attributed to shared genetic factors that underlie the development of behaviour problems in childhood (Grove *et al.*, 1990).

Several family studies of drug-dependent probands have also examined the effects of comorbid disorders on familial aggregation of both substance-use disorders and other psychiatric disorders. Most of the family studies have found increased rates of all major disorders among relatives of substance abusers; however, most have been uncontrolled, and few have accounted for comorbid disorders within the probands (Croughan, 1985; Mirin *et al.*, 1991; Rounsaville *et al.*, 1991). The results of the family studies have demonstrated consistently that there is independent familial aggregation of antisocial personality disorder and drug-use disorders (Rounsaville *et al.*, 1991). A controlled family study designed specifically to study the co-aggregation of substance-use disorders and psychopathology also demonstrated independence of familial aggregation of most disorders, including affective, anxiety, antisocial personality and other substance-use disorders (Merikangas and Stevens, 1998).

Twin studies may provide information on the extent to which familial correlations between disorders result from shared genetic or familial factors. For example, Lin *et al.* (1996) compared the familial versus non-familial links between major depression with alcohol-use disorders and drug-use disorders. They concluded that whereas comorbidity between major depression and alcohol-use disorders resulted from common familial factors, comorbidity with drug-use disorders was attributable to non-familial factors. The most widely investigated disorder associated with the familial association with substance abuse is antisocial personality disorder. The results of family studies concur that the two disorders aggregate independently in families, despite the high magnitude of comorbidity at the individual level (Merikangas *et al.*, 1998c). Scherrer *et al.* (1996) and True *et al.* (1999) found that antisocial personality disorder and cannabis abuse were not genetically related.

The sources of complexity described above will require substantial research integrating numerous disciplinary approaches. Rapid advances in human neuroscience, pharmacology, pharmacogenetics and preclinical research should be integrated into the genetic epidemiologic research summarized herein. Below is a description of the future directions in the field of genetic epidemiology that are likely to advance our understanding of the role of both genetic and environmental factors and their interaction in producing substance-use disorders.

GENETIC EPIDEMIOLOGY: MOVING INTO THE COMMUNITY

> Although experimental species are of great value for the initial identification and functional analysis of complex disease genes, final evidence for the involvement of these genes in human diseases must come from extensive epidemiological studies, preferably in different populations.
>
> (Peltonen and McKusick, 2001)

In a recent editorial in *Science*, these two prominent geneticists conclude that the best strategy for gene identification will ultimately be large epidemiologic studies from diverse populations. The importance of epidemiology in the future of genetics has also been described by others such as Risch (2000) and Khoury and Yang (1998), who predict that population-based association studies will assume increasing importance in studying the role of genetic risk factors in human complex diseases. The concept of *heritability*, a purely statistical phenomenon, will be replaced by the concepts of relative risk to individuals and attributable risk in populations. Population-based epidemiological studies will be necessary to calculate the attributable, relative and absolute risk of genetic risk factors identified in family-based linkage and association studies. Moreover, they anticipate that population-based case-control studies will have an increasing role in the genome-wide search for susceptibility genes for complex human disorders.

The chief goal of the subdiscipline of genetic epidemiology is identification of the genetic and environmental factors underlying human diseases. There is increasing interest in regenerating the field of genetic epidemiology, which is distinguished from its parent disciplines in three specific ways: (1) its focus on population-based research, (2) its goal of detecting the joint effects of genes and environment, and (3) the incorporation of underlying biology of a disease into conceptual models (Thomas, 2000). Unfortunately, the field of genetic epidemiology has become almost exclusively focused on statistical methods for identification of genes, as witnessed by recent trends in the journal *Genetic Epidemiology*. As such, epidemiology has been detached from the field; in fact, the majority of scientists who perceive themselves as genetic epidemiologists have never had any formal training in epidemiology, since they often equate epidemiology solely with community-based sampling.

The major applications of genetic epidemiology in order to advance our understanding of mental disorders are: (1) establishment of *population-based registries* of mental disorders that will be increasingly valuable in validating the numerous genetic tests that will emerge from advances in human genetic research and the Human Genome Project (Yang *et al.*, 2000), (2) identification of *more homogenous subtypes* of mental disorders through family and high-risk research investigating both biologic and contextual factors, (3) investigation of familial patterns among affected and unaffected probands to *estimate strength and mode of genetic transmission*, (4) *quantification of risk* at the levels of the individual and population (i.e. absolute risk, relative risk, attributable risk), and (5) development of a richer conceptualization of *environmental factors* that may be important mediators of expression of genetic risk for mental disorders through integration of the tools of genetic epidemiology, behavioural neuroscience, developmental psychology and neuroscience.

SUMMARY

This review has summarized the results of family, twin, adoption and high-risk studies that concur in concluding that both drug use and abuse are highly familial. In fact, a family history of alcohol or

substance-use disorder is the most potent and consistent risk factor for the development of substance-use disorders in offspring. The results of twin and adoption studies demonstrate that genetic factors underlie a substantial component of the familial clustering of drug-use disorders. However, in contrast to twin studies of numerous other disorders, the common family environment appears to have a significant impact on the development of drug-use disorders. Drug dependence is far more heritable than either drug use or abuse, and genetic factors appear to be more important in the transmission of problematic drug use rather than drug use *per se*. Comparisons of twin studies of youth with those of adults suggest that heritability is far greater among adults with established patterns of substance use than during its early stages of development. With respect to comorbidity, the results of family studies suggest that drug-use disorders aggregate independently from the affective, anxiety, behaviour, and other substance-use disorders. However, there may be independent pathways to the development of substance-use disorders through psychopathology.

Additional genetic epidemiological research is critical for elucidating the role of genetic and environmental factors in the transmission of substance abuse, validating phenotypic definitions of substance use/abuse, and identifying sources of heterogeneity in the aetiology of substance abuse, particularly with respect to the role of comorbid psychiatric disorders and polysubstance abuse.

The Human Genome Project is expected to facilitate identification of genes and, more importantly, understanding of their role in human diseases, with the ultimate goal of developing successful approaches to prevention and treatment (Collins *et al.*, 1988). This may be relevant to the field of substance abuse in several ways. First, application of genetic case-control studies may identify malleable environmental risk factors that may inform prevention efforts. Second, genetic research on drug metabolism may assist in the development of drugs that block craving or rewarding effects of drugs. Third, closer collaboration between basic research and the fields involved in the research described in this review will enhance our ability to understand the pathophysiology of drug abuse and hence to develop more informed prevention and cessation programmes.

Gender Issues in Substance Abuse

W.R. Yates

INTRODUCTION

Both men and women share a significant risk for the development of substance abuse. Although men and women share many common features in vulnerability, natural history and outcome, gender-specific issues play an important role in the clinical features of substance abuse (Valliant, 1983). An example of a unique gender issue is the diagnosis, treatment and adverse fetal effects of substance abuse in pregnant women. Another unique gender-specific clinical issue would be the effect of specific illicit substances on spermatogenesis.

This chapter will focus on some of the important clinical issues related to gender in substance abuse. Although the level of scientific knowledge in women trails that in men for a variety of reasons, this review will focus on well-designed studies where gender-specific information is available. Since alcoholism is the most widely studied of the substances of abuse, this chapter will have a predominance of information related to alcohol. This reflects only the state of knowledge and should not be interpreted as minimizing potential gender issues for nicotine or illicit substances of abuse.

EPIDEMIOLOGY: PREVALENCE RATES

Environmental Catchment Area Study (US)

The ECA study conducted in the early 1980s was the largest population-based estimate of the prevalence of psychiatric illness in the USA (Regier *et al.*, 1990). Gender comparisons for alcohol and drug diagnoses confirmed a male predominance in both categories. The 6-month prevalence rate for alcohol abuse or dependence ranged from 8.2% to 10.4% for men compared to 1.0% to 1.9% for women. For drug abuse or dependence, the 6-month prevalence rates ranged from 2.5% to 3.0% for men and 1.2% to 1.6% for women.

National Comorbidity Study (NCS) (US)

The NCS examined a population-based sample of adults between 15 and 54 in the USA (Kessler *et al.*, 1997). Lifetime and 12-month prevalence rates for drug abuse and dependence (DSM-IIIR) were compared. Additionally, data regarding drug use was collected for gender comparisons. A significant cohort effect for both genders was noted in this study — cohorts of both men and women born later had higher rates of drug use, and higher rates of drug dependence diagnosis. Twelve-month prevalence rates for alcohol abuse among men was 3.4% (SE 0.4%) and among women was 1.6% (SE 0.2%), the alcohol dependence rate among men was 10.7% (SE 0.9%) and among women was 3.7% (SE 0.4%), the rate for drug abuse was 1.3% (SE 0.2%) for men and 0.3% (SE 0.1%) among women; for drug dependence the rate among men was 2.3% (SE 0.4%) and for women was 1.3% (SE 0.8%). This study confirms others noting the rate of alcohol diagnoses is 3–6 times higher in men than women and the rate of drug diagnoses is 1.5–3 times higher.

EPIDEMIOLOGY: RISK FACTORS

Genetic

Some early studies of the role of genetic influences on the risk of developing substance abuse suggested genetic factors were more important for men than for women. However, later more sophisticated studies using large samples have shown strong genetic influences for alcohol abuse and dependence in both males and females. In a twin study of over 9000 male and female twins, genetic influences were felt to account for between 55% and 66% of the liability for alcohol abuse and dependence in women and for between 51% and 56% of the liability for men. Women and men appear to share some genetic sources of risk, although there do appear to be some gender-specific genetic risks also in play.

Depression prevalence rates are higher in women and alcohol abuse/dependence prevalence rates are higher in men. This sex-specific prevalence pattern produced speculation that a common genetic vulnerability could be expressed as depression in women and as alcohol abuse or depression in men. However, a recent twin study focusing on this issue did not supported this hypothesis (Prescott *et al.*, 2000). This study found that depression and alcoholism appear to have some common genetic and environmental risks. However, these risks appear sex-specific and the factors that predispose to depression in women do not appear to be the same factors increasing the risk for alcoholism in men.

ENVIRONMENTAL FACTORS

Psychiatric Comorbidity

Antisocial personality disorder appears to have a strong relationship with the development of alcohol and drug use problems in both men and women. Since antisocial personality disorder includes conduct disorder symptoms before age 15, this psychiatric illness is one likely to predate significant alcohol or substance abuse diagnoses. A family study of alcoholism examined the risk of alcohol dependence based on latent class analysis of antisocial personality symptom data (Bucholz *et al.*, 2000). Conduct disorder symptom severity strongly correlated with risk for alcohol dependence in both men and women. This study supports identification of conduct

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

disorder symptoms in both boys and girls and may identify a high-risk group appropriate for substance abuse/dependence prevention interventions.

The ECA study documented a strong association between alcoholism and antisocial personality for both men and women. Prevalence ratios for psychiatric comorbidity were calculated for a variety of psychiatric disorders. The prevalence ratio is the prevalence of a psychiatric condition in those with alcoholism versus those without. For women, the prevalence ratio for antisocial personality disorder was 29.6, more than twice the prevalence ratio for men at 12.0. Women and men with alcoholism demonstrated comparable prevalence ratios for a variety of other DSM-III disorders in the ECA. The prevalence ratios for women were: mania 9.3, drug abuse/dependence 8.8, schizophrenia 5.6, panic disorder 4.4, major depression 2.7, dysthymia 2.2 and obsessive compulsive disorder 2.1.

Similar associations between drug abuse/dependence and psychiatric illness were noted in the ECA study. Antisocial personality disorder had a prevalence ratio of 26.6 for women with drug abuse or dependence compared to 10.6 for men. Prevalence ratios for other psychiatric illnesses were comparable between men and women. For women, the prevalence ratios for psychiatric comorbidity were mania 11.1, alcohol abuse/dependence 9.0, schizophrenia 6.4, major depression 3.6, obsessive compulsive disorder 3.5, dysthymia 3.1 and panic disorder 2.9.

These associations underscore the need for psychiatric assessment and treatment for substance abuse treatment populations for both men and women. Additionally, the ECA findings support assessment and treatment of substance abuse problems for women in forensic and correctional settings.

NATURAL HISTORY

Differences in drinking patterns appear consistently in cross-cultural study of the effects of gender (Wilsnack *et al.*, 2000). The rates of current drinking versus abstinence from alcohol are similar between men and women. However, men drink more frequently, drink larger quantities of alcohol, have more heavy drinking days and suffer more total number of adverse consequences from drinking. However, when quantity of alcohol consumed corrected for body weight is controlled, the difference in severity of drinking consequences between male and female drinkers often disappears.

Table XVI-10.1 summarizes some of the clinical features of alcoholism for women compared to men. In studies of clinical populations, women report a later onset of regular and heavy drinking. However, despite this later onset of drinking, women drinkers report a shorter period of time from heavy drinking until the first alcohol problem. This phenomenon has been described as telescoping and has been reported for drugs other than alcohol.

Figure XVI-10.1 demonstrates this telescoping phenomenon in a series of men and women referred from a medical service for alcoholic cirrhosis. This clinical study examined 100 patients with a clinical or biopsy-proven diagnosis of alcoholic cirrhosis. Alcohol histories showed that women with cirrhosis reported a later age of onset for first episode of intoxication and regular drinking. Age of first alcohol problem was reported earlier in women compared to men. The period of time from regular alcohol use until first alcohol problem was shorter in women (12.6 years vs. 18.0 years).

The ECA study documented a trend for fewer women to report alcohol abuse or dependence symptoms than men. Additionally, women with alcohol symptoms tended to have fewer numbers of symptoms compared to men. Ninety per cent of women in the ECA study reported no alcohol symptoms, compared to only 40% of men. Only 3% of women reported three or more alcohol symptoms, compared to approximately 9% of men in the study.

Table XVI-10.1 Clinical features of alcoholism in women compared to men

Women with alcohol problems demonstrate:
Later age of onset of regular and heavy drinking
Shortened time from onset of drinking to problem drinking
Greater rates of drinking at home alone
Variability in drinking related to menstrual cycle (greater use in premenstrual period)
Greater likelihood to use alcohol to regulate emotions
Higher rates of eating disorder comorbidity
Higher rates of history of physical and sexual abuse
Higher risk for development of alcoholic cirrhosis
Higher risk for fibrosis and cirrhosis from hepatitis C virus
Greater disruption in family life function
Greater rates of divorce and separation
Higher rates of referral to treatment by physicians due to medical problem
Greater rates of liver disease corrected for alcohol unit exposure
Higher short-term treatment response rates
Lower long-term treatment response rates
Higher correlation of outcome with outcome of drinking spouse

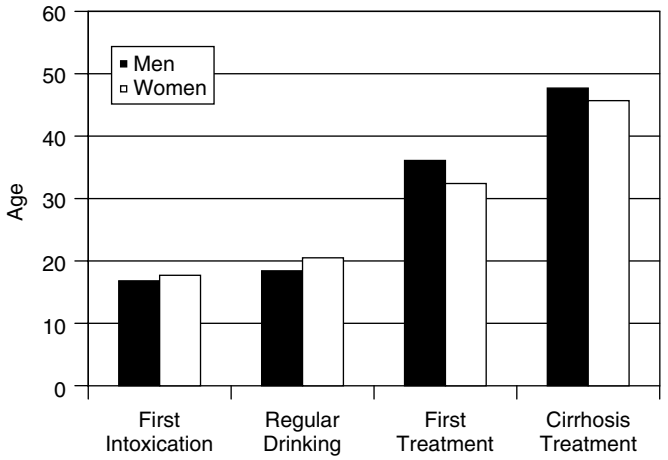

Figure XVI-10.1 A series of men and women with alcoholic cirrhosis were interviewed on the chronology of their alcoholism. This figure demonstrates a later onset of drinking but earlier treatment for alcoholism and cirrhosis

COMPLICATIONS

Alcohol

Many of the medical consequences of chronic alcohol appear very similar between men and women. However, women appear to be more sensitive to the effects of alcohol on the liver. Rates of alcoholic cirrhosis are higher for women than for men with similar drinking histories corrected for body weight. Women significantly increase their risk for cirrhosis by consuming 7–13 beverages per week. To assume a similar increase in risk for men requires 14–27 beverages per week. This gender difference is recognized by a variety of guidelines that have been published for safe drinking limits based on gender.

Table XVI-10.2 Gender-specific recommended daily and weekly standard drink units guidelines for moderate drinking

	Daily		Weekly	
Agency/Author	Men	Women	Men	Women
AHC	6	4	28	14
UKRC			21	14
NIAAA			7	7
Sanchez-Craig	4	3	16	12

AHC, Australian Health Council; UKRC, United Kingdom Royal College; NIAAA, National Institute on Alcoholism and Alcohol Abuse. Sanchez-Craig *et al.* (1995).

Table XVI-10.2 summarizes some of the major published guidelines for moderate drinking for men and women. These guidelines have taken several factors in to account. Since blood alcohol concentrations are proportional to body weight, it would be expected that drinking guidelines for men would exceed those for women by 20–30%. However, due to the specific hepatic sensitivity of alcohol for women, most guidelines recommend a 30–50% reduced quantity for women. The guidelines vary by significant amounts, pointing to the need for further study of this issue. The Australian Medical Council supports the most liberal definition of moderate drinking, supporting a limit of 28 drinks per week for men and 14 drinks per week in women. The National Institute for Alcoholism and Alcohol Abuse in the USA supports the most stringent guidelines, with a recommendation for a seven drinks per week limit for both men and women.

Most guideline recommendations have developed by expert consensus after comprehensive literature review. Sanchez-Craig *et al.* (1995) completed one of the few empirical studies of the quantity of drinking and specific problems for men and women. This study support gender-specific guidelines. Based on an analysis of positive and negative predictive value, sensitivity and specificity, the Sanchez-Craig *et al.*, study found 16 weekly drinks for men and 12 week drinks for women to be the best cut-off.

Several of the drinking guideline recommendations endorse daily drinking limits as well as weekly consumption. Although weekly consumption frequently best approximates the potential medical complications of drinking, daily drinking quantities approximates the highest blood alcohol concentrations associated with behavioural complications from drinking. Daily drinking limits approximate the quantities of alcohol required to reach the legal limits of intoxication. In the Sanchez-Craig study, four drinks for men and three drinks for women were recommended as daily limits.

Hepatitis C is a common viral illness that effects the outcome of alcoholic liver disease. Alcohol use in conjunction with hepatitis C increases the risk and rate for the development of fibrosis and cirrhosis. Some studies suggest that women are particularly sensitive to the effects of alcohol on progression of hepatitis C infection (Logueriicio *et al.*, 2000). Additionally, it appears that women may be more sensitive to the toxic effects of ethanol on peripheral nerve fibres.

Menstrual Cycle Factors

Women face a unique clinical feature: the effect of menstrual cycle on substance use and substance effects. Premenstrual symptoms and premenstrual dysphoric disorder may influence the risk of substance use. A study of 2912 women serving in the military examined the relationship between premenstrual symptoms and substance use (Kritz-Silverstein *et al.*, 1999). Premenstrual symptoms and menstrual irregularities correlated with current cigarette smoking. Current smokers were more likely to report problems with severe menstrual cramps and bleeding irregularities. Alcohol consumption did not correlate with menstrual problems.

Pregnancy-Related Morbidity

Female alcohol and drug use during pregnancy represents a gender-specific public health challenge. A US survey of 4 million women who gave birth found that 757 000 women drank alcohol during pregnancy and 820 000 women smoked cigarettes. Other drug use was reported by an additional 221 000 women. Marijuana was the leading drug, being used by 119 000 women, with 45 000 women reporting cocaine use. Fetal effects of drug use relate to the dosing and timing factors. Heavy daily use is likely to represent the largest risk. Heavy use during the first trimester of pregnancy may increase the risk of developmental abnormalities. Heavy use during the last trimester of pregnancy may result in a neonatal substance withdrawal syndrome.

One effect of pregnancy-related alcohol or drug use may be an increased risk for adult substance abuse in the exposed fetus. A study of adoptees examined the role of fetal alcohol exposure on later development of the adult symptoms of nicotine, alcohol and drug dependence (Yates *et al.*, 1998). In this study, maternal alcohol consumption resulted in a lower birth weight (−377 g). Possible genetic confounding effects were controlled in this study by comparing mothers with and without an alcohol dependence diagnosis who did and did not consume alcohol during the index pregnancy.

Alcohol exposure during pregnancy in this study produced a unique added risk for adult symptoms of nicotine, alcohol and drug dependence. This increases the importance of public health efforts to identify and reduce alcohol consumption during the course of pregnancy.

The effect of substances other than alcohol on the developing fetus is less clear. Early studies of the effects of prenatal cocaine exposure on the fetus suggested significant teratogenic and developmental effects. However, a recent review (Frank *et al.*, 2001) failed to find specific effects of cocaine on physical growth, cognition, language skills or motor skills. Prenatal cocaine may have subtle effects on later attentiveness and emotional expressivity. Studies of the prenatal effects of specific drugs of abuse are hampered by the need to control for confounding variables such as prenatal exposure to alcohol and nicotine. Confounding effects of environmental deficits following birth are also important.

MORBIDITY AND MORTALITY

Accidental Mortality

Women are less likely than men to drink and drive. This may be related to lower tendencies to engage in a variety of risk-taking behaviours. Additionally, women are less likely to view driving after the consumption of one or two drinks of alcohol as acceptable (17% vs. 27%). However, women appear to be involved in higher percentages of fatal alcohol-related motor vehicle accidents over the last few decades. The proportion of alcohol-related fatal accidents for women increased from 12% in 1980 to 16% in 1996 in the USA.

Medical

Medical complications related to alcohol consumption may be influenced by unique metabolic factors in women. Women appear to achieve higher blood levels of alcohol when equivalent quantities of alcohol are consumed. However, women eliminate alcohol from the blood at a faster rate than men. This effect may be due to women demonstrating a higher liver volume per unit lean body mass (Kwo *et al.*, 1998).

Although women have lower rates of heavy drinking, alcohol abuse and alcohol dependence than men, their rates of medical complications frequently approach that for men. Women have high rates of alcohol-related cardiomyopathy (Urbano-Marquez *et al.*, 1995) and alcohol-related liver disease (alcoholic hepatitis and alcoholic cirrhosis).

PSYCHIATRIC COMPLICATIONS

Psychiatric Comorbidity

Multinational studies of the epidemiology of psychiatric illness confirm higher rates of mood and anxiety disorders for women. For clinical substance abuse treatment populations, this finding holds true. Women in treatment demonstrate higher rates of major depression, dysthymia, panic disorder and generalized anxiety disorder. Longitudinal studies of treatment populations note that women are much more likely to have a primary (chronologically first) mood or anxiety disorder. This finding underscores the importance of treatment for a primary mood or anxiety disorder in conjunction with substance abuse treatment. For men, depression or anxiety symptoms commonly emerge after a period of heavy and chronic substance use. Abstinence from alcohol or other substances frequently induces a remission of mood or anxiety symptoms in men. Women are more likely to continue to exhibit a significant mood or anxiety disorder following abstinence from alcohol or drugs. There is also some evidence that women with substance abuse histories are more vulnerable to prescription sedative/hypnotic misuse, abuse and dependence. Clinicians should carefully screen for prior substance abuse histories in those being considered for sedative/hypnotic use. For women, a strong family history of alcoholism should also be considered a risk factor for prescription drug problems.

This comorbidity suggests women are more likely to use alcohol and drugs to self-treat a mood or anxiety disorder. Alcohol, benzodiazepines and other sedative/hypnotics reduce anxiety symptoms in the short term. However, with physiological withdrawal, underlying anxiety symptoms re-emerge. This re-emergence or rebound anxiety problem can facilitate continued self-administration.

Suicide

A large study of over 18 000 drinkers examined the relationship of alcohol to suicidal ideation in men and women (Grant and Hasin, 1999). Men and women with suicidal ideation shared many features including higher rates of unmarried marital status, higher rates of major depression, higher rates of alcohol dependence and higher rates of recent physical injury. However, in a comparative logistic regression model analysis, only women demonstrated an additional risk of suicidal ideation for drug use or a drug use disorder in the past year. This study supports additional vigilance for suicidal ideation among women with alcohol and drug problems.

OUTCOME: TREATMENT RESPONSE

Psychological Treatments

Few studies comprehensively study the effect of psychological treatment response for women. Studies that have examined the effect of gender have tended to find few differences in treatment outcome. Alterman *et al.* (2000) followed 145 men and 149 women receiving a variety of treatment interventions. Patients in this study received treatment through fee-for-service programmes or a managed care model. Outcomes compared by treatment and gender failed to find significant differences on seven Addiction Severity Index Scores.

Although few treatment studies suggest a specific gender response, clinical differences in gender groups may contribute to specific treatment needs. Women in treatment report high rates of previous physical and sexual abuse (Rice *et al.*, 2001). Additionally, women in treatment for substance abuse report significant eating disorder comorbidity (Sinha and O'Malley, 2000). Whether treatment focusing on abuse or eating disorder comorbidity improves outcome is unknown.

Women in treatment are more likely to have a spouse who also abuses substances (Westermeyer and Boedicker, 2000). Their substance abuse outcome is more closely linked to the outcome of substance abuse for their spouses. Studies that have found trends in alcoholism outcome for women tend to note good short-term response rates, often higher than males in treatment with similar levels of substance abuse severity. However, longer-term studies often fail to support this advantage. Several studies have demonstrated that long-term outcome for substance abuse may be worse for men and women. There is some evidence to support gender-specific effects on relapse risk for alcoholism. Some studies suggest women may have a high risk of relapse in response to either a positive or negative emotional event.

Brief interventions have been developed to reduce problem drinking in several target populations including heavy drinkers without a substance use diagnosis. A brief intervention study in a group of pregnant women found that brief intervention improved rates of abstinence among women abstinent prior to the study (Chang *et al.*, 1999). However, those with significant prenatal alcohol consumption did not reduce drinking during pregnancy with a brief intervention approach.

OUTCOME: PSYCHOPHARMACOLOGICAL TREATMENTS

Pharmacological treatment options continue to increase for a variety of substance disorders. Disulfiram, naltrexone and acamprosate are agents that appear to be effective in reducing the rates of relapse for alcohol abuse and alcohol dependence (Garbutt *et al.*, 1999; Myrick *et al.*, 2001). Nicotine replacement and bupropion appear to significantly increase abstinence rates among smokers. Few studies have compared the gender-specific effects of pharmacological treatments for substance abuse. It appears that from the few studies available pharmacological treatments are equally effective for both men and women.

CONCLUSION

Gender issues influence the prevalence, risk factors, natural history and outcome for substance use disorders. Limited empirical studies of the effect of gender on clinical issues in substance abuse hamper understanding of the substance use disorders. Clinicians need to be aware of gender-specific issues that can present in clinic practice. Further basic science and clinical research is likely to focus on the specific effect of gender on substance use disorders.

Therapeutic Armamentarium in Substance-Related Disorders

A. Lingford-Hughes

Pharmacotherapies available for treatment of substance misuse are used for substitution, withdrawal and increasingly for maintaining abstinence. It must be remembered that many patients with drug or alcohol problems also experience concurrent mental health problems that need treating. Pharmacotherapy should be seen as an adjunct to psychosocial treatments delivered in group therapy or on a one-to-one basis. This chapter will describe pharmacotherapeutic approaches used rather than exact protocols or associated psycho-socio-economic benefits. It cannot be exhaustive due to limitations of space, but will aim to acquaint the reader with key themes, concentrating on nicotine, alcohol, opiate and cocaine abuse.

Despite the large numbers of people who suffer from alcohol or drug dependence, compared with many other neuropsychiatric disorders, there is very little research performed in this area. Not only is the dearth of studies of concern, many studies suffer from poor design (e.g. small numbers, lack of placebo, lack of randomization, other therapies (psychological) uncontrolled for) which hinders interpretation or generalization (Moncrieff and Drummond, 1997). This is not to sound gloomy but to emphasize that compared to many neuropsychiatric disorders pharmacotherapeutic approaches for alcohol or drug dependence are in their infancy. As recently remarked by Kranzler (2000) 'consistent interest and high levels of industrial support for medication development internationally are essential for a more rapid development of the field'.

GENERAL PRINCIPLES

Pharmacotherapeutic strategies include blocking the effects of the drug of abuse or substituting it with a similar acting drug but with a longer duration of action, which is then gradually reduced. As the neurobiology of substance misuse is characterized, more novel approaches are likely. McCance (1997) has described properties of ideal pharmacotherapy for cocaine dependence, but the principles can be extrapolated to any substance misuse:

- convenient route of administration: oral, intramuscular, transdermal;
- long acting;
- medically safe with few side effects;
- acceptable to patients presenting for treatment;
- ideally, little abuse liability;
- useful for more than one class of drug since substance abusers tend to be polydrug abusers;
- used in conjunction with behavioural treatments that target the drug abuse and psychosocial problems related to the drug abuse.

NICOTINE

Nicotine is a highly addictive substance, as evidenced by the difficulty in quitting. The health consequences of smoking are legion and are at great cost to both the individual and society. There are several reviews of pharmacotherapy available to help people quit smoking (see Hughes *et al.*, 1999). Nicotine substitutes and antagonists have both been tried, and alternative strategies use drugs active on other neurotransmitter systems, particularly dopamine and noradrenaline.

Substitute therapy is the most commonly used treatment via a nicotine patch, nicotine gum, sublingual tablet, lozenge, nicotine nasal spray or nicotine inhaler. A Cochrane review reported that such substitute therapy increases abstinence rate 1.5- to 2-fold, but the rates remain only around 5–15%, even with psychological/behavioural programmes (Lancaster *et al.*, 2000). A comparison between nicotine gum, patch, inhaler or spray revealed no differences in the abstinence rates at 12 weeks (Hajek *et al.*, 1999). Notably, although the patch was initially the most popular, with gum the least favoured, all products became equally liked (West *et al.*, 2001). Receiving your favoured product did not improve outcome, but women may do better with an inhaler and men with gum.

A nicotine antagonist, mecamylamine, has also been tried since it was hypothesized that it may block the rewarding effect of nicotine and thus reduce the urge to smoke. A Cochrane review found promising results from two small studies of mecamylamine compared to nicotine alone (Lancaster *et al.*, 2000).

Nicotine acts via nicotinic receptors that increase dopamine release in the nucleus accumbens — part of the mesolimbic reward system (Stolerman and Shoaib, 1991). Therefore antagonists of the dopamine D_2 receptor, such as haloperidol, have been used to reduce smoking. These, not surprisingly given their side-effect profile, have not been especially successful.

Bupropion is a weak reuptake blocker of noradrenaline and dopamine. It has been shown in a number of randomized controlled trials to be effective in achieving and maintaining abstinence, even if the first attempt is not successful (Hurt *et al.*, 1997; Jorenby *et al.*, 1999; Gonzales *et al.*, 2001). Bupropion also reduces craving and attenuates withdrawal. While the side effects of bupropion are relatively mild (e.g. dry mouth, insomnia), it has been shown to increase the risk of seizures. Its use is not recommended with epilepsy, or where risk of seizures is increased (e.g. head injury, alcohol abuse) (Ascher *et al.*, 1995). The risk appears less with the slow-release form and more akin with other antidepressants. Bupropion can also be used in combination with nicotine substitute therapy.

ALCOHOL

Alcohol is a widely abused legal drug. As with nicotine, the effects on an individual and society are immense. Pharmacotherapy is currently used during detoxification, and its use in maintaining abstinence is increasingly accepted. Misuse of alcohol commonly occurs with psychiatric problems (depression, anxiety) and treatment of co-morbid conditions is often a challenge.

Alcohol Withdrawal

A commonly accepted regimen prescribed to prevent complications of alcohol withdrawal includes a benzodiazepine (chlordiazepoxide or diazepam), and vitamins, particularly vitamin B_1 or thiamine (see Williams and McBride, 1998). Chlordiazepoxide has advantages over chlormethiazole, since it is safer if alcohol is drunk and has a lower addictive potential. Chlormethiazole cannot be recommended for outpatient alcohol detoxification but does play an important role in inpatient settings, particularly its intravenous preparation. It is derived from the thiazole moiety of the vitamin B_1 molecule and its exact pharmacology is not clear, but it does enhance GABAergic function. The reader is directed to standard texts regarding suitable protocols for management of alcohol withdrawal. A reducing benzodiazepine regimen typically over 5–10 days is commonly used for uncomplicated withdrawal. Another method requiring more monitoring involves giving the patient diazepam, 10–20 mg every 1–2 h, to result in light sedation. Most patients require 100 mg or less (Salloum *et al.*, 1995).

Although withdrawal for most patients is uncomplicated, recurrent detoxification is associated with 'kindling' whereby the risk of seizures increases (Ballenger and Post, 1978). Benzodiazepines used in detoxification are active on the GABAergic system whose function has been reduced by alcohol. However, increased NMDA glutamatergic function is likely to play a key role in alcohol withdrawal (Tsai *et al.*, 1995). Targetting this system may be important since animal studies have suggested that benzodiazepines are not sufficient to prevent the kindling effect or cell damage (Mhatre *et al.*, 2001). The potential role for NMDA antagonists has recently been reviewed but notably some drugs that affect this system are already been studied or used, e.g. acamprosate and amantadine (Bisaga and Popik, 2000).

The question of whether or not to prescribe anticonvulsants continues to arise either to prevent seizures in those that are at high risk or for those who have already suffered from a seizure. If anticonvulsants are started at the same time as detoxification, then therapeutic levels will not be established until after the period of high risk (24–48 h post alcohol). However, there is no empirical evidence to support the use of anticonvulsants, even if they are started a week prior to detoxification. Carbamazepine itself has been proposed as an alternative to benzodiazepines for alcohol withdrawal and appears to be effective (Williams and McBride, 1998). Anticonvulsants may offer advantages over benzodiazepines in the outpatient treatment of alcohol withdrawal since they lack abuse potential, have minimal interactions with alcohol and are not necessarily contraindicated for patients with alcoholic liver disease.

In alcohol withdrawal, noradrenergic hyperactivity is likely to be present (Nutt, 1999). In opiate withdrawal, adrenergic α_2 agonists that reduce this activity, such as clonidine or lofexidine, ameliorate the consequences of this so-called noradrenergic storm. These drugs are, however, ineffective either alone or as an adjunct to benzodiazepines in alcohol detoxification (Adinoff, 1994; Keaney *et al.*, 2001).

Prescribing thiamine is crucial in any alcohol detoxification. Its deficiency, caused by poor diet and absorption in alcoholism, can result in Wernicke–Korsakoff syndrome, with its associated high mortality and morbidity. For uncomplicated alcohol withdrawal, oral supplementation is required (100–300 mg per day). Since absorption of oral thiamine is variable and potentially low, however, thiamine must be administered parenterally to any patient with suspected thiamine deficiency to increase brain levels (Cook *et al.*, 1998; Thomson, 2000). The use of parenteral formulations has previously been associated with adverse reactions including anaphylaxis, but the benefit:risk ratio for malnourished at-risk alcoholics is still in favour of administration. Newer preparations are less associated with such a reaction. No placebo-controlled studies have been performed to determine the dose or duration of vitamin B complex supplementation required. A suggested regimen delivers at least 500 mg thiamine, three times a day, for 3–5 days or more until the patient shows no signs of Wernicke–Korsakoff syndrome (Cook *et al.*, 1998). A recent study has shown the benefit of thiamine in improving working memory in alcoholics admitted for an inpatient alcohol detoxification who received intramuscular thiamine (200 mg once per day) (Ambrose *et al.*, 2001).

Maintaining Abstinence

Although the use of pharmacotherapy to maintain abstinence from alcohol is increasing, not everyone benefits from such adjunctive therapy and currently there are no clear predictive guidelines to direct prescribing. Alcoholism and vulnerability to alcoholism involve altered function in many different neurotransmitter systems. Consequently, where studies or trials show limited efficacy, is this a result of this complex neurobiology, or the type of alcoholism, the patients chosen, or other treatments offered/experienced? The pharmacotherapy of alcoholism has recently been extensively reviewed (Litten and Allen, 1998; Garbutt *et al.*, 1999; Swift, 1999a, 1999b; Kranzler, 2000). In addition, any co-morbid disorder requires treatment in its own right.

Disulfiram

Disulfiram inhibits aldehyde dehydrogenase (ALDH), an enzyme that catalyses the oxidation of acetaldehyde to acetic acid. The build-up of acetaldehyde that results when alcohol is drunk produces aversive effects such as nausea, flushing, headache and palpitations. Disulfiram is one of the oldest available treatments and the reader is directed to recent reviews (Wright and Moore, 1990; Hughes and Cook, 1997).

In an initial study, Fuller and Roth (1979) compared disulfiram (1 mg (non-aversive) or 250 mg (typical dose)) with placebo and found that although either dose resulted in higher rates of abstinence, the result was not statistically significantly different from placebo. A later study which included psychological therapy rather than 'counselling' found no advantage of disulfiram (either dose) over placebo, although in those that relapsed, patients taking 250 mg of disulfiram drank less (Fuller *et al.*, 1986). These studies illustrate that it is the fear of the adverse reaction that is a significant part of disulfiram's efficacy. While some patients need in excess of 1 g per day (Brewer, 1984) to produce an aversive reaction, others may experience it after applying products containing alcohol such as perfumes.

Patients must be aware of the risks of taking disulfiram and drinking or absorbing alcohol. Disulfiram is probably most effective over the first few months of treatment and it is commonly prescribed for about 6 months. Patients may want to take it on an 'as required' basis, i.e. prior to a social function. Often disulfiram is seen as a 'last resort' in treatment, and for some patients it is very effective.

It is clear that supervision is key in maximizing the efficacy of disulfiram. Chick *et al.* (1992) reported that 'supervised disulfiram with counselling enhanced treatment outcome'. Since compliance is important, disulfiram implants were developed. Studies have not been promising and it seems that insufficient blood levels of disulfiram were achieved to act as a deterrent (see Hughes and Cook, 1997).

Disulfiram cannot be used in everyone, limiting its availability. Neuropsychiatric complications resulting from disulfiram include psychosis, confusional states, peripheral neuropathy and optic neuritis. A history of psychosis is therefore seen as a contraindication to prescribing disulfiram but nevertheless has been used successfully in the presence of psychosis (Larson *et al.*, 1992). Due to previous fatal cardiac complications resulting from the disulfiram–alcohol interaction, patients with cardiac disease are generally contraindicated. Rarely (1 in 25 000 treated per year) disulfiram can cause liver hypersensitivity that is fatal. Despite these adverse effects, it must be remembered that alcoholism itself has a high rate of morbidity and mortality.

Acamprosate

Acamprosate is an amino acid derivative which primarily acts as an antagonist of the glutamatergic NMDA receptor, though it can also modulate GABAergic function (Daoust *et al.*, 1992; Zeise *et al.*, 1993). Its use stemmed from an observation from animal studies that calcium bis-acetyl homotaurine (acamprosate) reduced self-administration of alcohol (Boismare *et al.*, 1984). It has been used for a number of years in Europe and a multi-centre study has recently been completed in the USA. The reader is directed to a number of reviews (Swift, 1999a, 1999b; Kranzler, 2000).

There have been several randomized placebo-controlled trials performed in Europe that have shown acamprosate to be approximately twice as effective as placebo in maintaining abstinence. The first study showed that acamprosate in addition to monthly outpatient appointments doubled the rate of abstinence to ~60% over a 3-month period (Lhuintre *et al.*, 1985). Paille *et al.* (1995) studied two doses of acamprosate (1.3 g per day or 2 g per day) compared to placebo over a 12-month period and thereafter for 6 months on placebo. This study began to address many critical questions such as what dose of acamprosate should be prescribed, for how long and what happens after acamprosate is stopped. Acamprosate resulted in longer abstinence, improved clinic attendance and γ-glutamyltransferase (GGT) levels at 6 and 12 months. Patients who drank alcohol on the higher dose of acamprosate drank less frequently. Six months after acamprosate withdrawal, abstinence was associated with clinic attendance and the higher dose. The results for the low-dose acamprosate were intermediate between high dose and placebo.

Pelc *et al.* (1997) also reported that a higher dose of acamprosate (1998 mg per day) was more efficacious than a lower dose (1332 mg per day) on a similar range of parameters over 6 months. Sass *et al.* (1996) reported greater abstinence from acamprosate (45%) compared to placebo (25%) for those that remained in a controlled trial over 48 weeks. This benefit was maintained in the follow-up period and has similarly been reported in other studies (Whitworth *et al.*, 1996; Poldrugo, 1997; Tempesta *et al.*, 2000).

A recent a UK multi-centre study conducted over 6 months was not so positive about acamprosate (Chick *et al.*, 2000b). Absolute abstinence was only achieved in 12% of patients taking acamprosate, compared to 11% in the placebo group. The most likely explanation for this poor response was that 5 weeks was permitted between detoxification and starting acamprosate, and about one third of patients had already relapsed. Generally in other studies, acamprosate was begun within 2 weeks of detoxification (range 2 days to 28 days). This suggests that acamprosate should be started as soon as possible after detoxification. There is preliminary evidence that acamprosate might have a neuroprotective effect and therefore some clinicians advocate that it should be started with detoxification.

Acamprosate is a safe drug with few side effects, most commonly diarrhoea and headache. Its use is not restricted by liver dysfunction unless very severe. Acamprosate has also been found to be effective in medical and neurological settings rather than just psychiatric or addiction services (Tempesta *et al.*, 2000). Acamprosate combined with disulfiram has also been found to be more effective in some patients than acamprosate alone (Besson *et al.*, 1998).

Craving receives a lot of attention since it is implicated in causing relapse, and acamprosate has been labelled as 'anti-craving' (Littleton, 1995). The evidence from randomized controlled trials, however, is less than robust. Paille *et al.* (1995) reported that craving, as rated by the clinician, improved for all patients but somewhat more so in the acamprosate group. Chick *et al.* (2000b) reported a reduction in craving with acamprosate in weeks 2 and 4 and 1 month after the end of the study. More studies are required not only to elicit the effect of acamprosate on craving but also to further define this complex phenomenon and its neurobiology.

Given that many patients do not respond to acamprosate, are there any characteristics that predict efficacy? Lesch and Walter (1996) reported that acamprosate is more likely to benefit a 'pure' alcoholic (Lesch types I and II) rather than those with a psychiatric (affective) or organic disorder (Lesch types III and IV). Acamprosate was more likely to be beneficial to stop drinking alcohol to overcome withdrawal or anxiety. In the UK study, there were small numbers of the type I and II patients which may have contributed to the lack of efficacy (Chick *et al.*, 2000b).

In conclusion, acamprosate does help some patients maintain abstinence, an effect that can be sustained after the drug has been stopped. It appears that acamprosate should be started near to detoxification for maximum efficacy and continued for up to 1 year. If patients drink while taking acamprosate, consumption is reduced. All the trials include at the very least psychosocial support; consequently acamprosate alone has not been shown to be effective. It is not clear whether any particular form of psychological treatment is best combined with acamprosate. Patients experiencing symptoms of anxiety may derive more benefit from acamprosate.

Naltrexone

Evidence from animal studies supports the hypothesis that opiates are involved in mediating rewarding effects of alcohol. Opiate antagonists were shown to reduce self-administration of alcohol. In addition, some alcohol-preferring strains of animals have high endogenous opioid activity (see Froehlich and Li, 1994). Consequently, naltrexone, a non-specific opiate antagonist, was first introduced in the USA in 1994. Its use has been more limited in Europe.

Volpicelli *et al.* (1992) reported that naltrexone (50 mg) compared to placebo in a randomized controlled trial reduced craving for alcohol, resulted in fewer drinking days and lower rates of relapse for alcohol-dependent patients aiming for abstinence. Importantly, in those patients who did drink alcohol, naltrexone reduced binge drinking. All patients had been abstinent from alcohol for at least 1 week before receiving naltrexone as an adjunct to standard psychotherapy over 12 weeks. Naltrexone is probably effective by blocking the effects of opiates, released by alcohol, that increase dopaminergic function in the mesolimbic system mediating reward (Volpicelli *et al.*, 1992). It was therefore hypothesized and later shown that naltrexone was efficacious in those patients who are likely to 'sample alcohol', leading to further consumption since less euphoria was experienced (Volpicelli *et al.*, 1995).

A criticism of many trials is that they last a limited time — here only 12 weeks. O'Malley *et al.* (1996) showed that, 6 months after stopping taking naltrexone, improved rates of drinking behaviour were maintained, but do eventually diminish with time. Unsurprisingly, abstinence during the study period was associated with better outcome at 6 months. It is not clear how long naltrexone should be prescribed for maximum efficacy.

Unsurprisingly, compliance is critical to outcome and strategies to improve this will increase naltrexone's efficacy. In a 'more

naturalistic' study Volpicelli *et al.* (1997) reported that the more compliant a patient was in completing the 12-week programme, the better they did. Overall, however, naltrexone only showed modest efficacy compared to placebo. A belief in the efficacy of naltrexone is important but the number and severity of side effects (e.g. nausea) early in treatment predict poorer compliance (Rohsenow *et al.*, 2000). O'Malley *et al.* (2000) reported the risk of nausea was greater in younger, female patients with a shorter duration of abstinence and in lighter drinkers. Therefore, increasing the length of abstinence before starting naltrexone and at a lower dose, e.g. 12.5 mg, might improve compliance. It is not clear whether 50 mg is the therapeutic dose for abstinence.

Naltrexone is always given alongside a psychosocial programme, ranging from a daily programme for 1 month to once-weekly psychotherapy. O'Malley *et al.* (1992) examined the interaction of naltrexone with coping skills therapy/relapse prevention or supportive therapy in patients who wanted to remain abstinent. After 12 weeks of treatment, both psychotherapies were equally effective. Cumulative abstinence rates were, however, better in those who received supportive therapy, but in those who began drinking coping skills reduced the risk of a full relapse. Anton *et al.* (1999) found that naltrexone combined with cognitive-behavioural therapy over a 12-week period resulted in a modest improvement compared to placebo. It is therefore not clear whether there is an optimum psychosocial intervention, though those receiving less intensive support appear more likely to relapse.

A multi-centre double-blind randomized placebo-controlled trial has been performed in the UK (Chick *et al.*, 2000a). Naltrexone was not shown to be superior to placebo in a number of drinking variables, including 'time to first drink'. Compliance was an issue, but even in those who completed the study the 'time to first heavy drinking episode' was no different for naltrexone compared to the placebo group. Nonetheless, the total amount of alcohol consumed was less for those who were compliant with naltrexone, corroborated by greater improvements in liver function tests and scores in the obsessive-compulsive drinking scale.

In the studies so far described, naltrexone has been used in patients with alcohol dependence to help them remain abstinent, having stopped drinking. Sinclair (2001), by contrast, suggests that naltrexone can be started while drinking alcohol. He argues that the primary mechanism of this drug involves 'extinction of drinking behaviour' since naltrexone will block the rewarding effects of alcohol. While Sinclair reports beneficial outcomes, this has yet to be replicated.

Another opioid antagonist, nalmefene, has recently been studied as a treatment for alcohol dependence. Compared to placebo, nalmefene (>10 mg per day) has been shown to reduce relapse rates (Mason *et al.*, 1999).

Lastly, since naltrexone and acamprosate act via different mechanisms, their combination has been tried to see if abstinence rates were improved. Stromberg *et al.* (2001) reported in rats that the combination was no more effective than monotherapy. Equivalent studies in man are awaited.

Drugs Active on Serotonergic Neurotransmission

Animal models suggest that the serotonergic system plays a key role in alcohol-related behaviours and vulnerability to alcohol-seeking behaviour (see McBride and Li, 1998). Consequently, drugs that are active on the serotonergic system have been investigated as a treatment for alcoholism. In addition, common co-morbid disorders such as depression and anxiety are also effectively treated with specific serotonergic reuptake inhibitors (SSRIs).

In heavy or 'problem' drinkers (e.g. drinking at least 380 g alcohol per week), various SSRIs (zimeldine, fluoxetine, citalopram), often at higher doses than those used in depression (e.g. fluoxetine, 60 mg per day), have been shown to moderately (10–17%) reduce alcohol consumption (Naranjo *et al.*, 1990; see Kranzler, 2000). The subjects were recruited since they were concerned about their drinking, treated for 1 month, but treatment goals were not clear. The reduction in consumption was due to either an increase in the number of abstinent days (citalopram) or decrease in amount drunk per session (fluoxetine). Although this suggests that SSRIs can improve problem drinking, use of these drugs for this purpose cannot be recommended.

In non-depressed alcohol-dependent patients, there have been a number of trials investigating the effects of SSRIs, with conflicting results. While fluoxetine (20 mg per day) in detoxified alcoholics has been shown to increase abstinence rates, other studies conducted in inpatient 'severe' alcoholics reported no reduction in relapse rates (Janiri *et al.*, 1996; Kabel and Pety, 1996). Fluoxetine (40 mg per day) has been shown to reduce the number of drinks consumed but only in those with a family history of alcoholism (Gerra *et al.*, 1992). Gorelick and Paredes (1992) reported a reduction in alcohol consumption by alcoholics treated with fluoxetine ($\leq$80 mg per day) for 28 days, which, however, only lasted 1 week. Fluoxetine ($\leq$60 mg per day) has been shown to confer no advantage over placebo when combined with relapse prevention over 12 weeks (Kranzler *et al.*, 1995).

Citalopram has also been extensively studied. Naranjo *et al.* (1992) reported that citalopram decreased 'desirability, liking and consumption' of alcohol in alcohol-dependent patients after 1 week's treatment. However, the diagnosis of dependency relied on amount and frequency of alcohol drunk. A placebo-controlled trial of citalopram (40 mg per day) combined with brief psychosocial intervention over 12 weeks replicated the initial beneficial effect, but by 12 weeks there was no advantage over placebo (Naranjo *et al.*, 1995). By contrast, Tiihonen *et al.* (1996) reported that citalopram doubled the rate of abstinence at 12 weeks (19%) in outpatient alcoholics aiming for long-term reduction or abstinence. This was associated with improved GGT levels. Citalopram and fluvoxamine have been compared to placebo as an adjunct to cognitive-behavioural therapy over a 16-week period in alcohol-dependent patients (Angelone *et al.*, 1998). The rates of abstinence were doubled in both drug groups ($\sim$60%) compared to placebo (30%), but once patients had relapsed no benefit from continuing the SSRI was apparent. Citalopram, but not fluvoxamine, reduced craving.

What might contribute to these mixed results? In the majority of clinical studies, both men and women are studied. Naranjo *et al.* (2000) has reported that men benefited more from citalopram (40 mg per day) than women. Kranzler reanalysed the data from the study where fluoxetine was no better than placebo (Kranzler *et al.*, 1995, 1996). The subjects were clustered into type A (low risk or severity, later age of onset) and B (high risk or severity, early age of onset). Interestingly, in type A patients, fluoxetine resulted in no improvement, but in type B patients fluoxetine resulted in poorer outcome. Pettinati *et al.* (2000) reported a similar effect with sertraline (200 mg per day for 14 weeks), with type A alcoholics showing a more favourable outcome from sertraline compared to placebo and sertraline in type B alcoholics showing no effect. These studies raise the possibility that SSRIs may be inappropriate for some alcoholics and that a greater understanding of the neurobiology of alcoholism could have a direct impact on treatment. The serotonergic system has been a focus of research since it was shown that in alcoholism associated with early onset, predominantly males, and impulsive behaviour (type II or B) there is reduced serotonergic function (Heinz *et al.*, 2001). By contrast, increased serotonergic function is proposed to be present in alcoholism associated with anxiety, both genders and later onset (type I or A).

SSRIs have also been used to treat depressed alcoholics. Cornelius *et al.* (1997) reported that fluoxetine (20–40 mg per day) resulted in

improved depression and drinking behaviour compared with placebo over a 12-week period in depressed suicidal alcoholics. Notably in the placebo group there was a correlation between improved depression and drinking that was not seen in the fluoxetine group. When followed up at 1 year, those who had received fluoxetine in the trial continued to show less depression and better drinking behaviour than those who received placebo. The authors suggested that antidepressants in this population should be continued for 1 year. Other studies of fluoxetine in less severely depressed alcoholics are less positive (see Kranzler, 2000).

Sertraline (100 mg per day) has also been shown to improve depression in alcoholics after 6 weeks of treatment who remained abstinent (Roy, 1998). However, a previous history of depression or a positive family history did not result in greater response to sertraline (200 mg per day) in improving drinking behaviour (Pettinati *et al.*, 2001).

More recently nefazodone, a weak SSRI and $5HT_2$ antagonist, has been shown after 12 weeks in depressed alcoholics to result in greater improvement in depression but not in drinking behaviour (Roy-Byrne *et al.*, 2000). In a non-depressed group of alcoholics, nefazodone was similarly shown not to be effective in improving abstinence rates (Kranzler *et al.*, 2000).

Serotonergic receptor antagonists have also been used to treat alcoholism. Although ritanserin, a $5HT_2$ antagonist, moderated alcohol intake in animal models, it has shown no such efficacy in relapse prevention in man (Johnson *et al.*, 1996; Wiesbeck *et al.*, 1999). Ondansetron, a $5HT_3$ antagonist, has also been studied since $5HT_3$ receptors are known to modulate dopaminergic activity in the mesolimbic system. Ondansetron attenuates some of the positive reinforcing effects of alcohol (Johnson *et al.*, 1993). In a placebo-controlled trial in alcohol-dependent patients seeking treatment towards abstinence or reduced drinking, odansetron resulted in improved drinking behaviour, particularly in those drinking fewer than 10 drinks per day (Sellers *et al.*, 1994). Johnson *et al.* (2000b) have reported that ondansetron ($4\,\mu g\,kg^{-1}$ twice a day) reduces alcohol consumption and abstinence rates in early-onset but not late-onset alcoholics. Based on the hypothesis that both ondansetron and naltrexone modulate the dopaminergic reward system differently, the effect of these drugs together was studied. Only early-onset alcoholics were studied and ondansetron plus naltrexone (50 mg) for 8 weeks resulted in reduced alcohol consumption (Johnson *et al.*, 2000a). The authors have put forward hypotheses to explain this effect; however, the results require replication before the implications for clinical practice can be determined.

Buspirone, a partial agonist at the presynaptic $5HT_{1A}$ receptor, is used to treat generalized anxiety, and its efficacy at treating co-morbid anxiety with alcohol dependence has been investigated. Buspirone has been shown to improve both anxiety and alcohol consumption (Tollefson *et al.*, 1992; Kranzler *et al.*, 1994), but not consistently (Malcolm *et al.*, 1992). A meta-analysis revealed that buspirone results in improved treatment retention and anxiety rather than necessarily effecting alcohol consumption itself (Malec *et al.*, 1996). George *et al.* (1999) examined whether the response to buspirone varied in non-anxious early-onset and late-onset alcoholics due to their presumed low and high levels of 5HT. Regardless of medication, late-onset alcoholics took longer to relapse.

Other Antidepressants

Both imipramine and desipramine have been shown to reduce depressive symptomatology in an outpatient group of depressed alcoholics but not necessarily to improve drinking behaviour (Nunes *et al.*, 1996; Mason *et al.*, 1996; McGrath *et al.*, 1996). This also serves to reinforce that depression and alcohol abuse do not necessarily go hand in hand. The side-effect profile of tricyclic antidepressants, particularly when taken with drugs and/or alcohol, and the risk when taken in overdose, prevents recommendation of their widespread use.

Drugs Active on the Dopaminergic System

Since dopamine is critically involved in reinforcement, dopamine antagonists have been used to treat alcohol dependence (see Swift, 1999a, 1999b). While some studies do show that D_2 antagonists such as haloperidol, tiapride and olanzapine reduce drinking and craving, they are not widely used clinically.

Benzodiazepines

The use of benzodiazepines in maintaining abstinence from alcohol is controversial and should not be undertaken without expert advice and monitoring (see Ciraulo and Nace, 2000). Abstinent alcoholics may be at greater risk of benzodiazepine abuse and dependence due to greater rewarding effects. Despite the level of concern, there is evidence to suggest that a history of alcohol abuse/dependence does not necessarily result in greater use of benzodiazepines, particularly for those who are less severely dependent. Characteristics of patients who are most at risk of abusing benzodiazepines include severe dependence, antisocial personality disorder and polysubstance abuse. For some people, maintenance benzodiazepines can be indicated to maximize abstinence and minimize morbidity from alcohol.

OPIATE ADDICTION

From a pharmacotherapeutic perspective, treatment of opiate addiction often involves first substituting their illicit use with a prescribed opiate, followed by a period of stabilization and then detoxification. The reader is directed to a number of sources available describing issues around managing opiate addiction (Department of Health Guidelines (UK); NIH Consensus Conference (USA)). It is clear that our lack of understanding about the neurobiology of opiate addiction and the effects of treatment may be contributing to the lack of efficacy of some treatments.

Methadone

Methadone is the most widely used substitute drug for treatment of opiate addiction. It is a full opioid agonist with a half-life of about 24 h. Before a script is issued, opiate abuse should be confirmed by testing, e.g. urinalysis. The initial starting dose of methadone is calculated from the amount of illicit heroin abused. There is evidence to suggest that 40–60 mg methadone in opiate-naïve people is non-fatal. It would therefore be reasonable to use this as a maximum starting dose, and titrate upwards if needed until withdrawal symptoms are absent (Drummer *et al.*, 1992). There is evidence to suggest that illicit opiate use produces less euphoria in addicts on methadone (Kreek, 2000).

Substitution

Several studies support the use of 'high'-dose methadone to prevent illicit opiate use. Ling *et al.* (1996) showed that 'high'-dose methadone (80 mg per day) over 1 year was superior to low (30 mg per day) dose with improved retention rates, opioid use and opioid craving. Interestingly, buprenorphine (8 mg per day; see later) was no different to low-dose methadone. Other studies have also reported that doses around 80–100 mg are more effective, improving retention in treatment, and also that flexible dosing

and patient participation in dose decisions improved retention (Maddux *et al.*, 1997). Treatment programmes using 'low' doses of methadone may contribute to poor outcomes.

Maintenance

Methadone maintenance as a therapy (MMT) was first proposed in the 1960s and became the basis for many treatment programmes in the USA during the 1970s (Dole and Nyswander, 1965; Courtwright, 1997). The harm minimization strategy that grew in the late 1980s out of a worldwide drive to reduce premature deaths in opiate users from infectious disease such as hepatitis C and AIDS also relied on MMT. Such a strategy has been shown to be effective in improving health, and reducing illicit heroin use, infectious disease transmission, death from overdose and criminality (Ward *et al.*, 1999).

The risks associated with MMT include diversion of methadone to other addicts or accidental consumption by others, e.g. children. These risks can be reduced by daily prescribing or supervised consumption where methadone is taken at either the drug team base or pharmacy.

The Cochrane Collaboration has recently provided reviews of treatment of opioid dependence and protocols, including MMT (Mattick *et al.*, 2001). In the USA, the National Institutes of Health (NIH) convened a Consensus Panel on Effective Medical Treatment of Heroin Addiction (1997). The recommendations included increased access to methadone maintenance treatment programmes and noted that substance abuse counselling and psychosocial therapies enhance retention and successful outcomes in MMT programmes (http://consensus.nih.gov.).

Detoxification

Detoxification from methadone can occur at a variable rate depending on the initial starting dose and time available, but usually reduction takes at least a minimum of 7–10 days, if done with no adjunctive treatment (see below).

Other Substitute Drugs

Availability of alternative substitute drugs offers addicts an important choice of treatment since methadone treatment can be stigmatized, reducing the number of addicts seeking help and its acceptability. In many countries methadone can only be prescribed by specialized services, unlike buprenorphine, increasing its availability. Buprenorphine in some parts of the world, however, has had a significant history of abuse (e.g. Scotland).

LAAM

L-α-Acetyl-methadyl (LAAM) is a full opioid agonist at the μ-opioid receptor, with a longer half-life (2–3 days) than methadone. The metabolites of LAAM, nor-LAAM and dinor-LAAM, are active as parent LAAM. The FDA approved LAAM in 1993 for use in the treatment of opiate addiction. At the time of writing, LAAM is still under consideration in many countries. Recently it has become apparent that LAAM is associated with QT prolongation and severe arrhythmia, which has led to cardiovascular screening and to restrictions of its use.

Compared to methadone, addicts typically require 1.2–1.3 times more LAAM and can take longer to stabilize. Rapid induction in those who need a higher dose can lead to opioid agonist adverse effects and drop-out (Jones *et al.*, 1998). Due to its long half-life, LAAM need be taken only every other day or less to prevent opiate withdrawal, and addicts requiring supervised consumption need attend less frequently than if they were receiving methadone. This may not be an advantage if the patient does require more intensive support and monitoring.

LAAM is equally or more effective than methadone (see Finn and Wilcock, 1997; Rawson *et al.*, 1998; Jones *et al.*, 1998). LAAM has been shown to control opiate craving and block the euphoric effects of additional opiate use. Higher doses appear to be more effective, as with methadone. Eissenberg *et al.* (1997) compared thrice-weekly (Monday/Wednesday/Friday) oral LAAM dose regimens of 25/25/35 mg, 50/50/70 mg, and 100/100/140 mg with non-mandatory counselling. While there was no significant difference in the retention rates, self-reported heroin use and opiate-positive urinalysis, the greatest reductions occurred in patients receiving the highest dose.

Buprenorphine

Buprenorphine is a partial agonist at the μ-opioid receptor and a κ antagonist (Jasinski *et al.*, 1978). It can be used for maintenance treatment and detoxification. Two formulations are available: buprenorphine alone and combined with naloxone (buprenorphine:naloxone, 4 : 1 ratio). Both preparations are taken sublingually, and if taken in this manner the naloxone is not active. However, if the formulation with naloxone is injected the naloxone is effective, thus blocking any effects of buprenorphine and inducing withdrawal of varying intensity. This has been shown to prevent significant intravenous abuse (Robinson *et al.*, 1993). Lastly, the bioavailability of buprenorphine in tablet form is about half of the liquid form which was used in early studies, leading to different recommended doses.

Buprenorphine has particular advantages over methadone, with its longer duration of action, more limited withdrawal syndrome, and less propensity to cause respiratory depression and sedation (Bickel *et al.*, 1988; Fudala *et al.*, 1990). Buprenorphine has a slower rate of onset than heroin, resulting in less of a 'high'. Its longer half-life also results in precipitating less withdrawal. The dose–response relationship of buprenorphine is that of a partial agonist. By definition, partial agonists result in lower levels of response at maximal occupancy compared to full agonists. In addition, when a partial agonist occupies all the receptors, no receptors are available to a full agonist (e.g. heroin) to effect a response. The partial agonist is therefore acting like an antagonist. Consequently buprenorphine will stimulate the μ-opioid receptor, but not maximally (hence less risk of respiratory depression) and also prevent effects of heroin taken 'on-top'. Therefore, while the peak effects from 8 mg are much greater than from 2 mg, differences between 8 mg and higher doses are smaller. The duration of effect from these higher doses is longer, however, due to its storage in fatty tissue and slow off-rate from the μ-opioid receptor. Thus higher doses of buprenorphine result in increased duration but not magnitude of effect.

Substitution and Maintenance

The clinically effective dose range for buprenorphine in treating opiate addiction is 4–32 mg per day. Addicts leaving treatment in the induction phase with buprenorphine has been reported (Fischer *et al.*, 1999). Adequate doses of buprenorphine to prevent withdrawal are therefore important. There have been a number of reviews and meta-analyses which suggest that the efficacy of buprenorphine and methadone is similar (West *et al.*, 2000; Barnett *et al.*, 2001). The doses of buprenorphine ranged from 2 mg daily to 16 mg daily and of methadone from 20 mg to 120 mg daily. Patients who had previous methadone treatment preferred buprenorphine.

Buprenorphine can be given less frequently than daily due to its long pharmacological half-life. Thrice-weekly compared to daily dosing of buprenorphine (total = 56 mg per week) was

shown to result in equivalent retention in treatment but was less effective in reducing illicit opioid use and opiate craving (Perez de los Cobos *et al.*, 2000). A negative relationship was found between plasma levels of buprenorphine and positive urinalysis and opiate craving. Perez *et al.* therefore concluded that a dose of >8 mg daily equivalent of buprenorphine tablets should be used. Schottenfeld *et al.* (2000) reported that there were no differences with respect to retention or reductions in illicit drug use between daily dosing of 16 mg buprenorphine tablets or thrice-weekly as 34/34/44 mg (16 mg daily equivalent). More recently, a thrice-weekly dosing regimen of the buprenorphine:naloxone (8 : 2 mg) combination has been shown to be superior to daily dosing, with improved medication compliance and higher patient satisfaction (Amass *et al.*, 2001).

κ-Opiate receptors are proposed to mediate dysphoria. As a κ antagonist, buprenorphine should induce less dysphoria than other substitute drugs. Improved depression ratings have been reported in patients treated with buprenorphine (Kosten *et al.*, 1990). However, a lifetime history of depression has not been shown to predict better retention in treatment with buprenorphine compared to methadone (Schottenfeld *et al.*, 1998).

Detoxification

The role of buprenorphine in detoxifying patients from opiates has been a subject a Cochrane review (Gowing *et al.*, 2000). Most (4/5) of the studies compared buprenorphine with clonidine ($\leq$0.9 mg per day in divided doses) and in all but one study patients were withdrawing from heroin. It was concluded that buprenorphine showed potential to overcome withdrawal from heroin but that further study was required.

Comparative Studies

Methadone (low 20 mg, high 60–100 mg daily), LAAM (75–115 mg, three times a week) and buprenorphine (16–32 mg, three times a week) have been compared (Johnson, R.E. *et al.*, 2000). While only half the patients completed the 17-week study, high-dose methadone, LAAM and buprenorphine all resulted in longer periods of time in treatment, fewer opioid-positive urines, and lower self-rating of 'severity of drug problems' compared to low-dose methadone. LAAM did, however, result in higher drop-out rates than high-dose methadone, which was attributed to the longer time taken to achieve the targetted maintenance dose.

Injectable Opioid Scripts

Although reducing injecting behaviour is a goal of many treatment programmes, some services and countries have supported injectable formulations (e.g. opiates or amphetamines) for some addicts. Many ethical considerations are raised by such a prescription, particularly around maintaining injecting behaviour that is implicated in drug-related deaths. The reader is directed to a recent debate concerning prescribing of injectable heroin or methadone to addicts (Zador, 2001) and the following comments. Zador (2001) argued that in the UK there is almost no evaluation of this practice and that its availability is more reliant on a personal view of the clinician than on any patient characteristics. However, there is evidence, particularly from Switzerland, that it can be a beneficial strategy for some patients, but at greater financial cost than methadone (Perneger *et al.*, 1998).

Opiate Detoxification

Non-Opiate Protocols

While methadone or buprenorphine can be reduced gradually, non-opioid drugs are equally able to cover detoxification and are increasingly used (Mattick and Hall, 1996). In addition to administering medication to ameliorate withdrawal symptoms such as stomach cramps or insomnia, many symptoms can be treated with α_2-adrenergic receptor agonists such as clonidine or lofexidine. These drugs reduce the hyperactivity of the ascending noradrenergic system projecting from the locus coeruleus seen in opiate withdrawal.

A Cochrane Review of the use of α_2-adrenergic receptor agonists for the management of opioid withdrawal reported on the results of 24 randomized controlled trials. Although the intensity of withdrawal symptoms was greater, the symptoms resolved more quickly with α_2-adrenergic receptor agonists than with methadone (Gowing *et al.*, 2001). Clonidine was associated with adverse effects such as low blood pressure, dizziness, dry mouth and lack of energy. A similar picture for lofexidine was reported except for less hypotension, which responded to a reduction in lofexidine dose. Clonidine should now only be used in an inpatient setting, but lofexidine can be used safely in outpatients. Strang *et al.* (1999) recently reviewed randomized and open controlled trials of lofexidine for opiate detoxification compared with clonidine or methadone. Importantly, lofexidine appeared more acceptable to patients than clonidine but may not be preferred over methadone.

In a series of studies of inpatient, Bearn *et al.* (1996, 1998) showed that lofexidine compared favourably with methadone for detoxification and that an accelerated lofexidine regimen (5 days) compared to a 10-day regimen was associated with a faster resolution of withdrawal responses. The 10-day regimen of lofexidine was superior to methadone. Lastly, adding in naltrexone led to an even more rapid resolution of withdrawal symptoms.

More Rapid Protocols

While most detoxification occurs over days to weeks, faster regimens exist. Rapid and ultra-rapid opioid detoxification has been recently reviewed (O'Connor and Kosten, 1998). Ultra-rapid detoxification is a treatment that has courted controversy with advocates and protagonists since it was first reported by Loimer *et al.* (1989) (Strang *et al.*, 1997; Brewer, 1997; Kleber, 1998). The procedure typically involves using propofol as an anaesthetic or midazolam for heavy sedation and precipitating withdrawal by an opiate antagonist (naltrexone), together with benzodiazepines, an α_2-adrenergic agonist and drugs to treat gastrointestinal symptoms (ondansetron, anti-diarrhoeal) over 4–6 h. There is only limited literature available with variable protocols, but some have concluded that currently the risk/benefit ratio is still on the side of too much risk (Kleber, 1998). Such accelerated detoxification regimens are appealing to patients who want to minimize the length and discomfort of this process. However, detoxification is only the first step to achieve abstinence and patients are unlikely to maintain abstinence without further support.

Maintaining Abstinence

Use of an antagonist to treat addiction has been developed from the classical behavioural concept of 'extinction' since the positive effects (e.g. euphoria) of opioids that drive further use are blocked when the patient is treated with an antagonist. Naltrexone was approved by the FDA in 1985 for treatment of opiate dependence. While its use is not ubiquitous, it is more widely used in some highly motivated patient populations, e.g. medical or criminal, with some success. A recent Cochrane Review reported that the methodology of many studies were poor, permitting limited conclusions about naltrexone, except in the populations above (Kirchmayer *et al.*, 2000).

Concerns have been raised about increased dysphoria or depression with naltrexone since it will block endogenous opioids released

in pleasurable circumstances. A review of naltrexone in opiate addicts reported that depression appeared to improve with naltrexone treatment (Miotto *et al.*, 1997). Nevertheless, there are a number of case reports suggesting an association between naltrexone and depression or suicide, so careful monitoring is required.

PSYCHOSTIMULANTS

All psychostimulants result in increased synaptic levels of noradrenaline, serotonin and dopamine by inhibiting uptake of released neurotransmitter (cocaine) or stimulating release (amphetamine). Enhanced levels of dopamine are thought to be key in mediating positive reinforcement which drives further use of these drugs (Koob, 2000). The exact attribution of specific behavioural consequences to particular dopamine D_1-like (D_1, D_5) or D_2-like (D_2, D_3, D_4) receptors remains to be elucidated. This group of drugs results in increased sympathomimetic activation, leading to behavioural arousal. After experiencing the 'high' or 'rush' from psychostimulants, users experience withdrawal consisting of dysphoria or depression, hypersomnia, hyperphagia and craving for more drug. Treatment has therefore been targetted at reducing positive reinforcement or ameliorating withdrawal symptoms to reduce the drive for further drug use. Pharmacotherapy has been developed particularly for cocaine misuse, since standard psychosocial treatment packages appeared to have limited effect, but the principles can be applied to other psychostimulants. There are no medications currently available to treat cocaine addiction specifically; however, several are showing promise and are in development.

COCAINE

The range of pharmacotherapeutic options for cocaine misuse has been reviewed (Mendelson and Mello, 1996). Many different types of treatment have been investigated in the treatment of cocaine misuse, some with promising results that unfortunately do not necessarily hold up in randomized placebo-controlled trials. These can be broadly grouped into those that alter dopaminergic function, antidepressants, mood stabilizers and drugs to treat other substances of abuse.

Altering Dopaminergic Activity

Cocaine is a potent inhibitor of the dopamine transporter, resulting in increased synaptic levels of dopamine. Increased dopamine levels have been shown to be associated with euphoria and 'high' (Volkow *et al.*, 1999) and hence blockade of this effect may reduce drug use. Dopamine D_2 receptor blockade can be achieved with typical antipsychotic medication such as haloperidol or flupenthixol. Use of such drugs has not been shown to help cocaine addicts achieve abstinence. These drugs would block the 'natural pleasure' system which may lead to unacceptable side effects, since dopaminergic hypofunction has been shown to be associated with dysphoria.

Ecopipam, a D_1/D_5 antagonist, has been shown in animal studies to reduce cocaine self-administration. In cocaine addicts, ecopipam has been shown to attenuate the euphoric and stimulating effects of cocaine and reduced the drive for further use (Romach *et al.*, 1999). However, in inpatient cocaine addicts, ecopipam failed to attenuate either the effects of or craving for cocaine (Nann-Vernotica *et al.*, 2001). Furthermore, in cocaine smokers, ecopipam actually increased smoking, craving and the effects of cocaine (Haney *et al.*, 2001). Currently it seems unlikely that ecopipam or D_1/D_5 antagonists will be useful in treating cocaine misuse.

Since psychostimulants increase dopamine levels, dopamine agonists (acting as a substitute) have been tried to treat cocaine misuse. Although bromocriptine initially showed promise in pilot studies, no benefit over placebo was subsequently shown (Eiler *et al.*, 1995; Handelsman *et al.*, 1997). The results of using amantadine are mixed (Alterman *et al.*, 1992; Handelsman *et al.*, 1995; Kampman *et al.*, 1996). Kampman *et al.* (2000) recently suggested that amantadine might be of particular use in those patients who experience more severe withdrawal from cocaine, hypothesizing that increased levels of dopamine from amantadine ameliorate the hypodopaminergic state seen in psychostimulant withdrawal.

Partial agonists are currently in development for treatment of psychostimulant misuse. BP-897 is a partial agonist at the dopamine D_3 receptor which has been shown in animal studies to reduce cocaine self-administration from cue exposure (Pilla *et al.*, 1999). However, once cocaine had been taken, there was no reduction in the total amount consumed. It is currently in Phase I trials (Preti, 2000).

Since cocaine is a dopamine reuptake inhibitor, drugs that also block this site have been developed as pharmacotherapy for cocaine misuse (Howell and Wilcox, 2001). Although in non-human primates such drugs have been shown to reduce cocaine self-administration, they also have some reinforcing potential. Nevertheless, they are less reinforcing than cocaine and altering the pharmacokinetics of these drugs for a slower onset and longer duration of action may make these drugs therapeutically useful.

Vaccination

Another strategy has been to develop a vaccine to cocaine. This raises a number of ethical issues including loss of privacy, use of the antibodies to identify patients, or mandatory vaccination (Cohen, 1997). Currently vaccines are in development and results in humans are awaited.

Antidepressants

Cocaine withdrawal is associated with a 'crash' consisting of depressive and anxiety symptoms. While generally it does not require treatment, it can drive further use. Desipramine, a tricyclic antidepressant which is predominantly a noradrenergic reuptake blocker, has been extensively studied as a treatment for cocaine dependence. A double-blind placebo-controlled randomized study found no advantage of desipramine, though a low dose was used (40 mg per day) (see Mendelson and Mello, 1996). No advantage of desipramine over placebo was found when combined with relapse prevention or clinical management (Carroll *et al.*, 1994). Desipramine only showed greater effectiveness in the first 6 weeks and thereafter only in patients with a lower level of abuse (1–2.5 g per week), and those with co-morbid depression. This emphasizes the heterogeneity of such patients and the need to develop specific tailored treatments.

Other antidepressants investigated include fluoxetine, which has been shown to acutely reduce subjective pleasurable effects of cocaine and show some potential in treating cocaine dependence. Batki *et al.* (1996) found that fluoxetine (40 mg daily) over a 12-week period resulted in increased length of abstinence and better retention in treatment.

Mood Stabilizers

Carbamazepine has been shown in animal models to block cocaine-induced kindling, a mechanism thought to underlie craving. Several studies have not shown that carbamazepine reduces cocaine use in humans (see Kranzler and Bauer, 1993).

Drugs used for Other Addictions

Disulfiram has been used to treat cocaine misuse alone, but it is also efficacious in reducing cocaine misuse complicating either opiate or alcohol dependence. In addition to inhibiting aldehyde dehydrogenase, disulfiram also blocks a key enzyme in the synthesis of dopamine, dopamine β-hydroxylase. It is not yet clear whether this inhibition plays a role in the efficacy of disulfiram in treating cocaine misuse, or whether reduction in alcohol drinking is associated with less opportunity for or more control over taking cocaine. Carroll *et al.* (1998) reported that disulfiram in co-morbid alcohol and cocaine abuse or dependence resulted in improved treatment retention and longer duration of abstinence from both substances. At 1 year follow-up, the benefits from this 12-week trial were still apparent (Carroll *et al.*, 2000).

In opiate addicts maintained on buprenorphine, cocaine dependence also responded to disulfiram with increased rates of abstinence (George *et al.*, 2000). Similarly in a methadone-maintained population, Petrakis *et al.* (2000) recently showed that addition of disulfiram reduced cocaine use. However, almost one-fifth of patients were unable to tolerate disulfiram and cautious use is required due to risk of hepatoxicity in a population with a high prevalence of viral hepatitis. Another concern is cardiotoxicity of disulfiram given the effects of cocaine on the heart.

Since opioids are known to modulate dopaminergic activity (see above), naltrexone has been used in cocaine misuse. Naltrexone does not appear consistently to acutely alter the subjective effects of cocaine (Kosten *et al.*, 1992; Walsh *et al.*, 1996). In patients also diagnosed with alcohol abuse, naltrexone had no effect on cocaine or alcohol use.

CONCLUSION

Pharmacotherapy will continue to play a central role in the treatment of substance misuse alongside psychosocial interventions. Their use in maintaining abstinence is likely to increase. Currently robust evidence to guide use of pharmacotherapy is often lacking for a specific substance disorder at a particular stage of addiction. Increased knowledge about the neurobiology of substance misuse and the effects of drugs and our treatments is urgently needed to inform future pharmacotherapeutic developments.

Animal Models for Schizophrenia

B.A. Ellenbroek and A.R. Cools

INTRODUCTION

'Schizophrenia is arguably the worst disease affecting mankind, even AIDS not excepted' (Nature Editorial, 1988). Nevertheless, and in spite of more than a century of research, the exact aetiology and pathology still elude us (Jablensky, 1997). Moreover, there is still an urgent need for improving treatment, especially for the more negative or defect symptoms. Although there are a number of reasons why our knowledge of schizophrenia is still so limited, one of the main reasons is undoubtedly the lack of adequate animal models (Ellenbroek and Cools, 2000a). Studying the function of the animal brain rather than the human brain has a number of clear advantages. First of all, its accessibility is much higher. Using microdialysis or *in vivo* voltammetry techniques, it is possible to detect changes in very small brain areas (<0.5 mm) in very short periods of time (in minutes with microdialysis, and with voltammetry even in seconds). Moreover, the detecting methods have improved so much that quantities as low as 20–50 fmol of a given neurotransmitter or metabolite can be detected. Another great advantage of animal research is the use of drugs which are not (yet) allowed in humans. These include highly selected receptor agonists or antagonists, but also drugs with a broader working profile. As discussed in a previous paper the reintroduction of clozapine, after the agranulocytosis incident in the 1970s, was no doubt due to the continued use in animals, showing its unique profile (Ellenbroek and Cools, 2000a). However, more important than these advantages is the possibility to alter the brain of animals and directly study changes in behaviour. Whereas in human research one is often limited to studying correlations between activity in neurotransmitters or brain regions and certain behavioural or cognitive parameters, in animal research one can actively enhance or decrease the neurotransmitter activity and directly study the functional consequences. This allows us to directly study the causal relationship between brain and behaviour.

AN INTRODUCTION TO ANIMAL MODELS

Unfortunately, when developing animal models for schizophrenia, it is quickly evident that no animal model will ever be able to completely cover the entire range of symptomatology. Patients with schizophrenia typically suffer from perceptual aberrations such as hallucinations and delusions. By definition, such symptoms cannot be modelled in animals since these rely on an interview with the patient.

The inability to model the entire disease has led to a plethora of animal models, each addressing different aspects of the disease, and each limited in its own right. In general, models for a human disease can be subdivided into two broad categories, depending on the specific goals pursued in the model. When the principal aim is to investigate the pharmacology, and evaluate new pharmacological treatments the models are generally referred to as screening tests. Such models have also been referred to as animal models with predictive validity (Willner, 1984) or animal models with pharmacological isomorphism (Matthysse, 1986). When, however, specific aspects of the disease are being investigated, the models are generally termed simulation models (Willner, 1991; Ellenbroek and Cools, 2000a). These models have also been referred to as animal models with face and construct validity (Willner, 1984) or animal models with cross-species psychological processes (Matthysse, 1986). Although these models generally assess very different aspects of the disease, and will be dealt with separately in the remainder of the chapter, it is important to realize that each of the models can be used for more than one purpose. Thus screening models are not only used for detecting new antipsychotic drugs, but can also be used to investigate the neuronal mechanisms of existing drugs. Likewise simulations models, although predominantly developed to study the neuropathology of the disease, can also be used to develop new treatments.

SCREENING TESTS FOR SCHIZOPHRENIA

Screening tests are primarily developed to test potential new therapeutic drugs. For that purpose, such tests should be quick and simple, and should have unequivocal parameters (Willner, 1991). In general, screening tests are developed following a standard scheme, which is depicted in the flow diagram in Figure XVII-1.1. Generally, the model's starting point is a very effective known clinical compound, generally referred to as the '*gold standard*'. This drug usually has a long clinical tradition and its effects in patients are very well described. Although not absolutely necessary, it would be beneficial if this drug has only limited side effects. In screening tests for schizophrenia the gold standard is generally haloperidol, although chlorpromazine is also often used. Both drugs have been used in clinical practice for well over 40 years now and their clinical effects are very well known. Unfortunately, the drugs have some quite severe side effects, most notably extrapyramidal side effects, which has been a serious limitation in developing a good screening test. As a result of that, in recent years models have been developed with other gold standards such as clozapine. Clozapine is almost completely devoid of extrapyramidal side effects, and it seems effective in therapy-resistant patients.

The second step in animal modelling is devising the right parameter. Theoretically any parameter could be used provided it can be assessed unequivocally. Sertindole, a novel antipsychotic that has been removed from clinical practice because of its ECG side effects, was primarily selected on the basis of a differential influence on dopamine cell firing in the substantia nigra versus the

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

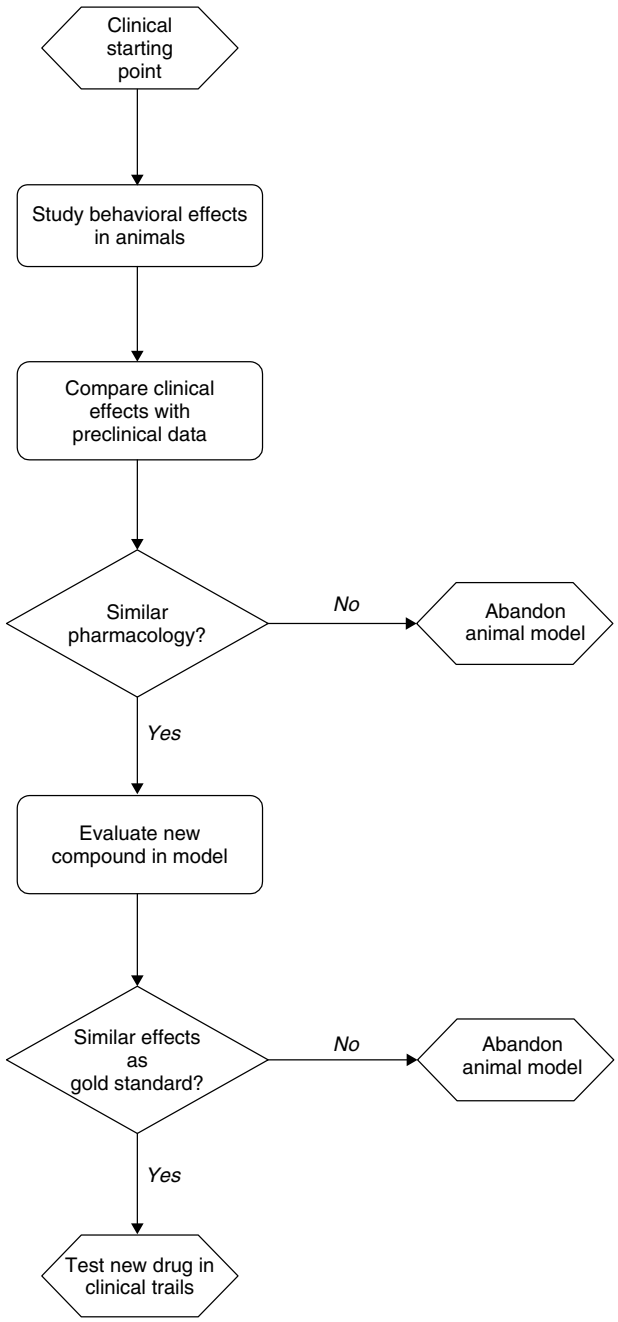

Figure XVII-1.1 A flow chart for developing screening tests for schizophrenia

ventral tegmental area (Skarsfeldt, 1992). Like clozapine, sertindole selectively reduced dopamine cell firing in the ventral tegmental area upon repeated treatment (White and Wang, 1983; Chiodo and Bunney, 1983). Likewise, biochemical data or binding profiles have been used to select novel (potential) antipsychotics. For instance, a number of selective dopamine D_4 receptor antagonists have been developed based on the suggestion that clozapine binds strongly to this receptor (Seeman, 1992). So far, however, these D_4 selective ligands appear to show very little antipsychotic-like efficacy (den Boer and Korf, 2000). Most screening tests are based on behaviour, which offer a number of advantages. Just as the symptoms of schizophrenia, behaviour is the final outcome of a number of alterations in brain activity. Therefore, behavioural studies take into account all the possible integrative and compensatory activity of the central nervous system. Moreover, it takes into account pharmacokinetic aspects, such as the blood–brain barrier penetration of a drug and possible active metabolites. In this respect *in vitro* experiments are severely limited (Willner, 1991). There are quite a number of antipsychotics which produce active metabolites, most notably thioridazine (which leads to mesoridazine) and risperidone (which is rapidly metabolized to 9-OH-risperidone). Although domperidon is a powerful dopamine D_2 antagonist like most other antipsychotics, it fails to be active in any behavioural screening test, since it does not pass the blood–brain barrier. Many different behavioural tests have been developed and the selection is only limited by the fact that the behaviour should be clearly identifiable and altered by the gold standard. They may include spontaneous behaviour, drug-induced behaviour or learned behaviour (Janssen *et al.*, 1965; Arnt and Skarsfeldt, 1998; Ellenbroek, 1993).

The third step in developing a screening test is the most crucial one, which is, unfortunately often underestimated, or only rarely investigated to its full extent. In this step the behaviour under study is compared with the known clinical features. This is the validation step, in which as many criteria as possible are investigated. Scrutinizing the clinical literature has led to a number of criteria based predominantly on pharmacological experiments (Ellenbroek, 1993; Ellenbroek and Cools, 1990). These criteria (see Table XVII-1.1) can be subdivided into general validation criteria (applicable to all screening tests) and specific criteria (applicable only to screening tests for antipsychotics). The general criteria aim to investigate the specificity of the model. Thus in screening tests all antipsychotics should mimic the gold standard (i.e. no false negatives should occur) and none of the non-antipsychotics should mimic the gold standard (no false positives should occur). Moreover, there should be some correlations between the potency in the model and the potency in the clinic. This correlation, however, depends strongly on pharmacokinetic aspects, and since these can differ between species this criterion does not need to be very strictly fulfilled (Ellenbroek and Cools, 2000a). On the other hand, since some drugs (like benzamide sulpiride) do not pass the blood–brain barrier as rapidly as other drugs (like other benzamides such as remoxipride or raclopride), one would expect that much higher doses of the former drugs are needed to obtain similar behavioural effects.

In contrast to the general criteria, the specific criteria have been developed to distinguish between different clinical effects of antipsychotics. As discussed above, in the ideal situation one searches for a gold standard which has virtually no side effects.

Table XVII-1.1 The criteria for validating screening tests for schizophrenia

Criteria	Description
General	
1	No false positives should occur
2	No false negatives should occur
3	A relationship should exist between potency in the model and that in the clinic
Specific	
1	Anticholinergic drugs should not ameliorate the effects of antipsychotics
2	Chronic treatment should not ameliorate the effects of antipsychotics
3	Benzodiazepines should enhance the effects of antipsychotics.

However, such drugs do not exist. Most of the antipsychotics induce extrapyramidal side effects (with the notable exception of clozapine). Therefore, a screening test with haloperidol or chlorpromazine as a gold standard might model the extrapyramidal side effects rather than the therapeutic efficacy, even if it fulfils most of the general criteria. Indeed a number of the classical screening tests, including catalepsy and reversal of apomorphine-induced gnawing, are now generally considered to be models for extrapyramidal side effects rather than for antipsychotic potential (Ellenbroek, 1993). However, careful analysis of the literature has led to the identification of a number of differences in the clinical pharmacology of extrapyramidal side effects and antipsychotic effects (Matthysse, 1981). Most notably, whereas the extrapyramidal side effects are reversed by anticholinergic drugs, the antipsychotic efficacy seems much less affected by this class of drugs. Likewise, with repeated treatment the therapeutic effect generally increases, whereas tolerance develops against the extrapyramidal side effects. The final criterion is based on the findings that benzodiazepines, although not very effective when given alone, have repeatedly been reported to enhance the effects of antipsychotic drugs (Ellenbroek, 1993).

This validation procedure is basically the final step in model building. Once a model fulfils a number of these criteria (or all of them in the ideal situation) it can be used to its full extent, i.e. new therapeutic agents can be tested, and the evaluation of the mechanism involved in the behavioural action of these antipsychotics can be studied. Given the high predictive validity of such models it is assumed that studies into the neuronal mechanism might also help us understand the mechanism of the therapeutic action of antipsychotics.

As mentioned above, a large number of different screening tests have been developed over the last 40 years, basically starting with the seminal papers by Janssen and his colleagues (Janssen *et al.*, 1965, 1966, 1967). Since then, many more tests have been developed. Arnt, in a recent review, clearly showed that of all the models currently available only a few have been extensively validated according to the criteria as delineated in Table XVII-1.1 (Arnt, 2000). These include blockade of the conditioned avoidance response, reversal of amphetamine-induced locomotor activity and the paw test. Nevertheless even these three models are not without limitations. Thus, the conditioned avoidance response, although popular for over 25 years now, has only a limited selectivity, as opiates and benzodiazepines show up as false positives (Ellenbroek, 1993). Moreover the effects of antipsychotics in this test are reversed by anticholinergic drugs (Arnt and Christensen, 1981). With respect to the reversal of dopamine agonist-induced hyperlocomotion, it is important to ensure that the drugs are effective at doses which do not block spontaneous locomotor activity. Moreover, there are quite a number of different dopaminergic drugs that can induce hyperlocomotion, such as amphetamine (Arnt, 1995), methylphenidate (Koek and Colpaert, 1993) and 6,7-ADTN (Arnt, 1983), each having a different pharmacological profile. Moreover, to complicate matters further, Arnt found that there is a difference in the pharmacology between hyperactivity induced by low ($0.5\,mg\,kg^{-1}$) and high ($2.0\,mg\,kg^{-1}$) amphetamine (Arnt, 1995). Thus, whereas haloperidol was about 10 times more effective in reversing the higher dose of amphetamine, clozapine showed about a 10-fold higher selectivity for the low dose of amphetamine (see Figure XVII-1.2a). This selectivity for the low dose of amphetamine seems to be a characteristic of all antipsychotics with limited extrapyramidal side effect liability. The notable exception is remoxipride, which seems to show hardly any selectivity at all.

The paw test was developed many years ago as an animal model based on two rather than one gold standard (namely haloperidol and clozapine). In previous electrophysiological experiments we had found that the dorsal and the ventral striatum play a differential role in regulating forelimb and hindlimb muscular activity (Ellenbroek *et al.*, 1985, 1988). Given the fact that antipsychotics with and without extrapyramidal side effects had been proposed to differentially affect these two structures, we reasoned that measured fore- and hindlimb activity might be a simple method of detecting differences between these antipsychotics (Ellenbroek *et al.*, 1987). Indeed we found that all classical antipsychotics (i.e. those with extrapyramidal side effects) affected both the forelimb and the hindlimb whereas atypical antipsychotics (i.e. those with very little or no extrapyramidal side effects) preferentially affected the hindlimb (see Figure XVII-1.2b). In a large series of experiments we evaluated all criteria and it appears that the paw test fulfils all of the criteria in Table XVII-1.1 to a large degree (Cools *et al.*, 1995;

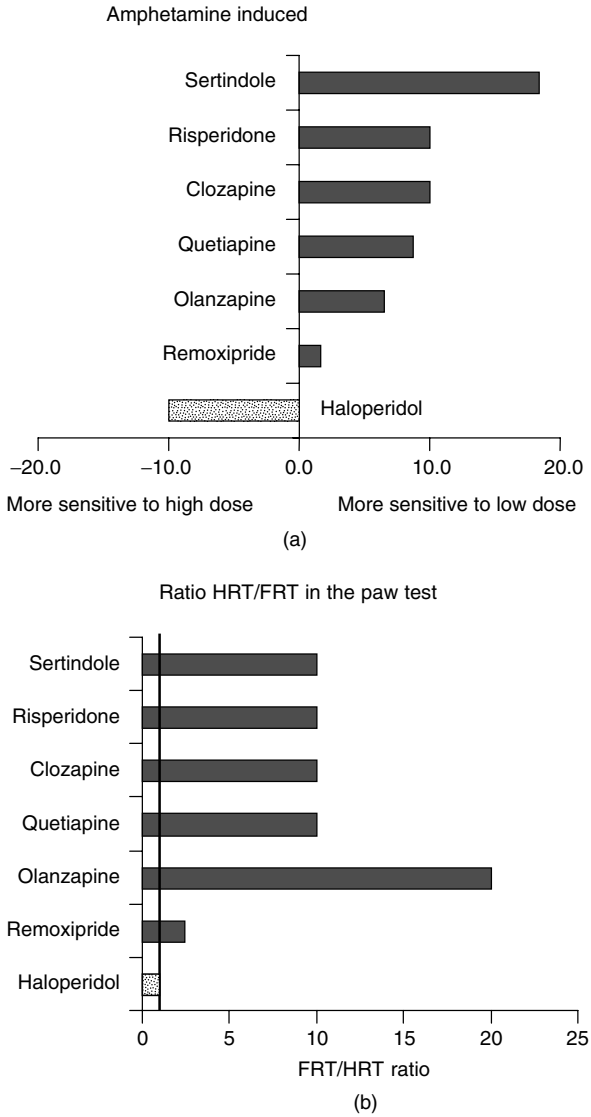

Figure XVII-1.2 (a) The effects of several antipsychotics on amphetamine-induced hyperlocomotion. Haloperidol shows a preference for blocking the high dose of amphetamine ($2\,mg\,kg^{-1}$), whereas all other drugs have a preference for the low dose ($0.5\,mg\,kg^{-1}$). (b) The effects of several antipsychotics on the paw test, represented in the ratio between the minimal effective dose necessary to influence the forelimb and the hindlimb retraction time. Haloperidol is equally effective on both, whereas all other drugs have a preference for increasing the hindlimb retraction time

Ellenbroek and Cools, 1988). Interestingly, as in the amphetamine experiment (see Figure XVII-1.2a), remoxipride also failed to show a clear 'atypical' picture in the paw test.

The paw test has also been used to investigate the mechanism of action of antipsychotics. The data clearly show that even though all antipsychotics effectively increase hindlimb retraction time, they do so via different mechanisms. Thus the haloperidol-induced increase could be reversed by the D_2 agonist quinpirole, whereas the effects of clozapine on hindlimb were sensitive to the D_1 agonist SKF38393 (Ellenbroek *et al.*, 1991). Table XVII-1.2 lists a number of clear differences in the pharmacology between haloperidol and clozapine as observed in the paw test (Ellenbroek *et al.*, 1994; Prinssen *et al.*, 1994a, 1994b). From these data it is evident that there are quite some differences between the two drugs, even in their effects on the hindlimb retraction time. This can also be ascertained when observing the rats: haloperidol-treated rats are rigid with extended toes, whereas clozapine-treated rats show an inability to withdraw the hindlimbs without concomitant rigidity. From the pharmacological studies summarized in Table XVII-1.2, a 'minimal' profile for a clozapine-like antipsychotics was determined, namely a blockade of α_1 adrenoceptors, a blockade of 5-HT_2 and a blockade of D_1 receptors. When selective antagonists of these three compounds are combined, a clozapine-like profile in the paw test was indeed observed. Combinations of any two out of these three, on the other hand, were ineffective (Prinssen *et al.*, 1994a). The differences in the pharmacological profile between the two drugs, especially in relation to hindlimb retraction time, is interesting in view of the finding that clozapine is therapeutically effective in haloperidol-resistant patients.

In spite of the fact that screening tests have been used to detect novel antipsychotics for over 35 years, and have been instrumental in understanding our knowledge on the working mechanism of antipsychotics, they have one inherent disadvantage. Since they are developed according to the analogy model (Figure XVII-1.1), they will produce in the ideal situation only a drug that is similar (or indeed identical) to the gold standard. Although such drugs may have a higher potency, or a longer duration of action, they will most likely work via similar mechanisms, having similar therapeutic and side effects. Whereas there is a need for drugs similar to clozapine, there is an even greater need for drugs with an entirely different mode of action. Only such drugs have the potency of creating a breakthrough in the therapy of schizophrenic patients. As discussed recently, there is a multitude of potential candidates, including glutamate agonists, certain neuropeptides and neurotrophic factors (Stahl and Shayegan, 2000). How such novel therapeutic drugs should be detected, however, is not yet clear, but it seems unlikely that the current generation of screening tests will be very useful.

Table XVII-1.2 The differential effects of selective monoaminergic agonists and antagonists on the effects of haloperidol and clozapine in the paw test

	Haloperidol		Clozapine	
	FRT	HRT	FRT	HRT
D_1 agonist	–	–	–	↓
D_2 agonist	↓	↓	–	–
5-HT_{1A} agonist	↓	↓	↑	↑
5-HT_2 agonist	–	↑	–	↓
5-HT_2 antagonist	↓	–	–	–
α_1 agonist	↓	↓	–	↓
α_1 antagonist	–	↑	–	↓
α_2 agonist	↑	↑	–	↓
α_2 antagonist	–	↓	–	–

↑, effect is significantly increased; ↓, effect is significantly reduced; –, no effect.

SIMULATION MODELS: A GENERAL INTRODUCTION

In contrast to screening tests, simulation models are designed to model specific (when possible all) aspects of the disease. Such models are particularly useful in investigating the neuronal substrate involved in the disease, and develop more rational therapeutic approaches. Indeed, such models might be much more useful in finding a therapeutic breakthrough. Unfortunately, in the case of schizophrenia it has proven very difficult to develop a simulation model. As we will see in the remainder of this chapter, a number of new approaches have recently been developed, which have not yet been extensively investigated and validated, but which might be potentially very relevant.

There are basically two reasons why simulation models have proven to be so difficult in schizophrenia. They are evident once we have studied the flow chart of Figure XVII-1.3, which describes the process of designing a simulation model. As in designing screening tests, simulation models have to have a clinical starting point, and its validation also critically depends upon the interaction between clinical and preclinical research. Depending on the knowledge one has about the disease to be modelled, different approaches can be taken. The best available approach is to mimic the aetiology. Unfortunately, for many diseases, including virtually all diseases involving the central nervous system, the aetiology is unknown. One exception is Huntington's chorea. This severe neurological disease, accompanied by uncontrolled choreatic movements, disturbed speech and deteriorating cognitive capacities, results from a loss of cholinergic and GABAergic cells in the caudate putamen complex. Huntington's disease is one of the few autosomal dominant disorders of the central nervous system which follows a classical Mendelian pattern. Molecular genetic techniques have shown that the aberrant gene is located on the short arm of chromosome 4 and normally contains a small number of CAG repeats in exon 1. When the number of repeats increases above 35 the disease becomes apparent. Moreover, the larger the number of repeats the more severe the disease. Recently, transgenic mice have been created which have CAG repeats in the Huntington's disease gene. It was shown that mice having 48 or 89 CAG repeats manifested progressive behavioural and motor dysfunction (Reddy *et al.*, 1998). Most diseases, however, are presumably due to a combination of genetic and non-genetic factors, most of which are virtually unknown. As we shall see later on, in spite of the fact that the aetiology of schizophrenia is still largely unknown, some of the most interesting and innovative simulation models are based on aetiological theories.

When the aetiological approach fails, because of lack of knowledge in this area, it has been customary to develop models on the basis of the pathology. Again Huntington's disease can be taken as an example. As described above, in Huntington's disease there is a degeneration of acetylcholine and GABA-containing neurones in the caudate–putamen. There have been several approaches to selectively destroy these cells in animals, using for instance local application of quinolinic acid (Beal *et al.*, 1986, 1991; DiFiglia, 1990). More recently, it has been reported that systemic application of 3-nitropropionic acid (an irreversible inhibitor of succinate dehydrogenase) also causes selective degeneration of striatal neurones (Beal, 1994; Borlongan *et al.*, 1995). The pathology approach has also been very successfully applied to Parkinson's disease, a disease in which the dopaminergic cells innervating the basal ganglia undergo degeneration. Using drugs such as 6-hydroxydopamine or

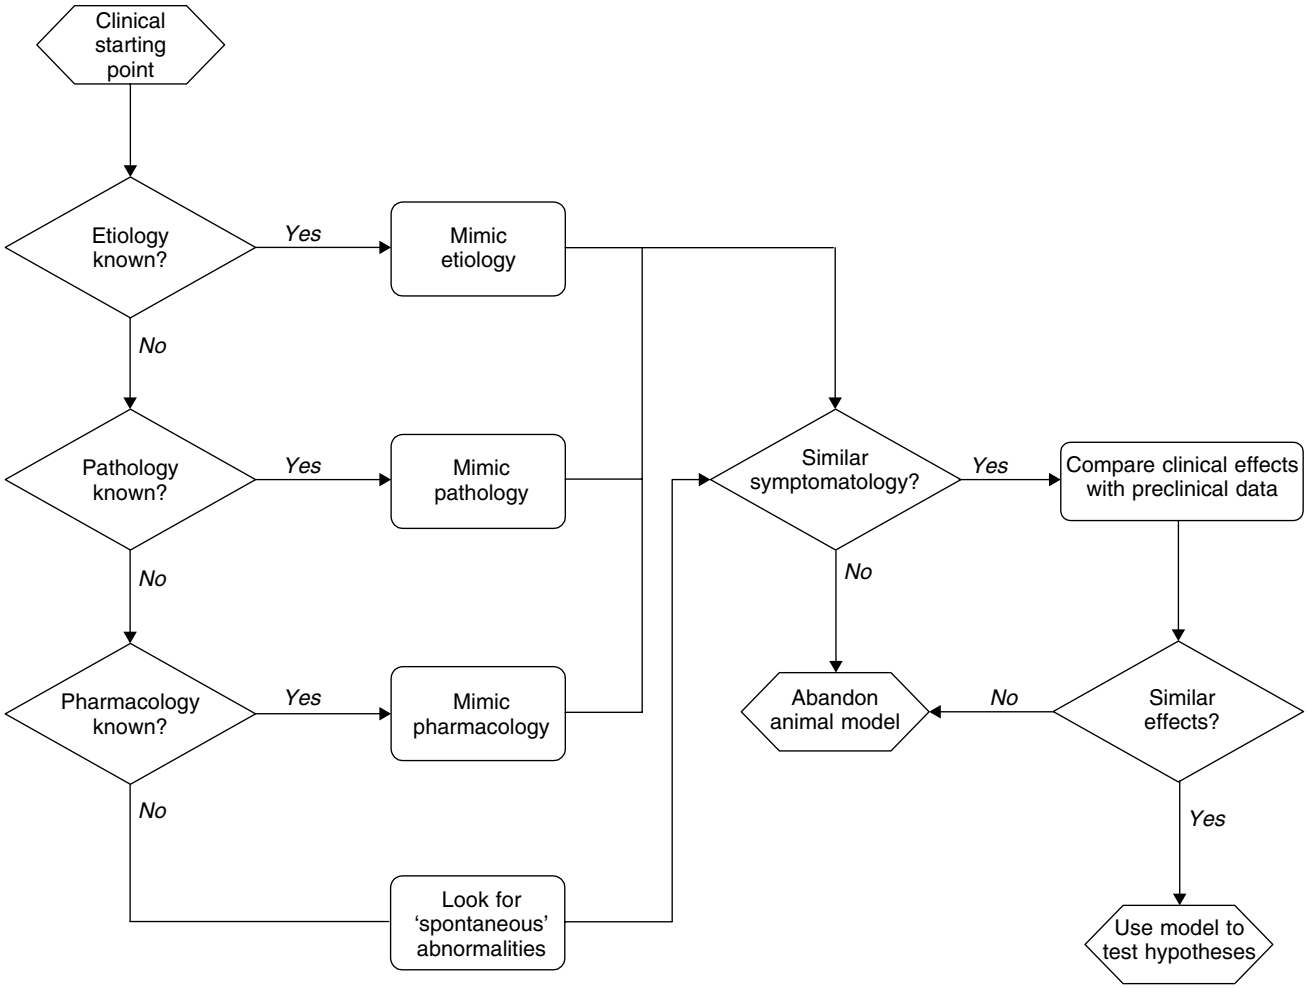

Figure XVII-1.3 A flow chart for developing simulation models for schizophrenia

MPTP a selective lesion of these cells can be achieved (Ungerstedt, 1971; Davis *et al.*, 1979; Andringa and Cools, 2000). In contrast to these neurological disturbances, the pathology of most psychiatric diseases, including schizophrenia, remains largely unknown, thus limiting the possibilities to model this aspect of the disease.

The third approach is based on pharmacological tools. If neither the aetiology nor the pathology is sufficiently known, one can use drugs to induce symptoms characteristic of the disease under study. Although this approach is sometimes used to model neurological diseases (for instance, antipsychotics can induce parkinsonian symptoms; Goldstein *et al.*, 1975), it is most often used in mimicking psychiatric symptoms. For instance, reserpine and yohimbine can induce symptoms of depression (Willner, 1984; Sanghvi *et al.*, 1969). Likewise certain β-carbolines, such as FG7142, can induce severe symptoms of anxiety in man (Dorow *et al.*, 1983) and CCK-4 can induce panic attacks in normal healthy volunteers and increase the existing symptomatology in patients (Bradwejn *et al.*, 1991; Bradwejn *et al.*, 1990; Koszycki *et al.*, 1991).

A final approach to develop simulation models could be termed the 'serendipity approach'. In this non-systematic approach one looks for 'spontaneous' abnormalities that may be related to a disease. This can be done by screening a large number of rat or mouse strains for a specific trait, or it may be a serendipitous finding. For instance, it was discovered by coincidence that olfactory bulbectomy in rats leads to disturbances reminiscent of depression (Cairncross *et al.*, 1978). Likewise, the spontaneously hypertensive rat shows some of the abnormalities seen in patients suffering from attention deficit/hyperactivity disorder (Sagvolden, 2000; Sagvolden *et al.*, 1992). Often, such initial screening is followed by selective breeding, such as the Flinders Low Sensitive Line of rats, originally bred for differences in acetylcholine sensitivity and now generally regarded as an interesting model for depression (Overstreet *et al.*, 1998; Tizabi *et al.*, 1999; Zangen *et al.*, 1999). Likewise, the recognition of differences in behaviour in the elevated plus maze has led to selective breeding for high and low levels of anxiety (Liebsch *et al.*, 1998a, 1998b).

Using any of these different approaches can lead to interesting simulation models of the disease. The next step in the simulation modelling approach is to investigate whether one observes similar symptomatology after mimicking either the aetiology, the pathology or the pharmacology. Purely theoretically, one does not necessarily have to observe similarities in symptomatology, given the species differences between animals. It is quite possible that an identical disturbance in a specific part of the brain may lead to different behavioural changes in humans and in rats or monkeys. However, given the relative lack of knowledge of the underlying aetiology and pathology, it would be very difficult to develop a convincing simulation model without some similarity in symptoms. As discussed below, we agree with Sarter and Bruno (Chapter III) that the clinical symptoms which contribute to the face validity of the

model are less important than symptoms reflecting impairments in underlying processes (such as attentional deficits), which contribute more to the construct validity of the model.

With respect to this modelling, it is important to realize that many aspects of psychiatric diseases cannot be assessed in animals. The key abnormalities observed in neurological patients are generally motor disturbances, like akinesia and rigidity in patients with Parkinson's disease, or abnormal clumsy movements in patients with Huntington's chorea. However, in psychiatric patients the symptoms are generally of a perceptual (like hallucinations), emotional (lack of interest, general anxiety) or cognitive (disturbed thinking, delusions) nature. As these symptoms can only be assessed through a psychiatric interview, they are beyond the realm of animal study. This implies that it is impossible to encompass an entire psychiatric disease in an animal model. It also means that one has to search beyond these symptoms for aspects of the disease which can be measured objectively and quantitatively in humans and animals, where possible using the same methods (Ellenbroek and Cools, 2000a). These may include specific behavioural alterations such as social isolation, specific cognitive phenomena (such as various aspects of memory or executive functioning) or more psycho-physiological aspects (such as abnormalities in information processing).

Another disadvantage is the lack of pathognomic parameters for any of the psychiatric disorders. For instance, chronic mild stress is known to reduce sucrose intake in rats (Papp *et al.*, 1991), which is often considered a model for anhedonia. Since anhedonia is a key symptoms of depression, the chronic mild stress model is often regarded as a simulation model for depression (Willner, 1997). However, anhedonia is also a key symptom of schizophrenia (Andreasen and Olsen, 1982). Likewise, a reduction in pre-pulse inhibition (see below) is often regarded as an animal model for schizophrenia. However, many patients, including those suffering from Gilles de la Tourette (Swerdlow, 1998), obsessive compulsive disorder (Swerdlow *et al.*, 1993) or Huntington's disease. (Swerdlow *et al.*, 1995), also show pre-pulse inhibition deficits. This lack of specificity means that a good animal model should not be based on mimicking one specific symptom, but rather as many aspects of the disease as possible (Willner, 1984).

In the case of schizophrenia, a number of different behavioural, cognitive and psycho-physiological parameters may be used in developing a simulation model (Ellenbroek and Cools, 2000a). With respect to the symptoms, only a few can be objectively assessed, and few of them have been investigated in any detail. The symptoms which can be assessed are anhedonia (see above), social withdrawal and stereotyped behaviour (Ellenbroek *et al.*, 2000). However, in recent years, attention has shifted from investigating the clinical symptoms of schizophrenia to investigating more fundamental deficits, such as disturbances in information processing and attention. These include pre-pulse inhibition, P_{50} gating and latent inhibition. Pre-pulse inhibition refers to the reduction in startle amplitude when the startling stimulus is preceded by a weak prepulse (Graham, 1975). This phenomenon has received much attention since it can be measured in humans and animals with virtually identical methods (Braff and Geyer, 1990). Moreover, pre-pulse inhibition is significantly reduced in schizophrenic patients (Braff *et al.*, 1978; Kumari *et al.*, 2000; Parwani *et al.*, 2000). P_{50} gating also refers to a reduction in response to an acoustic stimulus when this stimulus is preceded by a prepulse. However, there are some clear and important differences between the two paradigms. First of all, in pre-pulse inhibition the interval between the two stimuli is usually around 50–100 ms, whereas in P_{50} gating the optimal interval is longer (500–1000 ms). Another difference is that in P_{50} gating the two acoustic stimuli are identical and do not induce a startle response. In pre-pulse inhibition the pre-pulse is much smaller in amplitude than the stimulus eliciting the startle response. A final important difference between the two paradigms is that in pre-pulse inhibition a behavioural response is measured, whereas in P_{50} gating an electrophysiological (EEG) response is measured. In spite of these differences, it has been found that, like pre-pulse inhibition, P_{50} gating is diminished in schizophrenic patients (Adler *et al.*, 1982, 1985). It was shown recently that in humans (Schwarzkopf *et al.*, 1993) and in rats (Ellenbroek *et al.*, 1999) P_{50} and pre-pulse inhibition are two distinct phenomena with differences in neuronal substrate and pharmacology. Another modification of the acoustic startle response is the habituation which occurs upon repeated exposure. Like pre-pulse inhibition, startle habituation is also reduced in schizophrenic patients (Geyer and Braff, 1982; Geyer and Braff, 1987), but it has received much less attention in animal research.

Latent inhibition refers to the detrimental effect of prior stimulus pre-exposure upon the subsequent conditioning of that stimulus (Lubow, 1989). Although there is controversy about the underlying psychological mechanism, it has been suggested that it depends on the ability to learn to ignore irrelevant stimuli. Since schizophrenic patients have clear deficits in this area, it was expected that latent inhibition was disrupted in these patients. Unfortunately, the data in this respect are far from clear. Baruch and colleagues were the first to report that latent inhibition was disrupted in schizophrenia patients (Baruch *et al.*, 1988). However, the effect was only seen in acute patients and was very transient. When the patients were re-tested 2 months later, latent inhibition was normal again. In a replication study a similar transient phenomenon was reported (Gray *et al.*, 1995). However, disruption in latent inhibition is not found in all studies (Swerdlow *et al.*, 1996). Moreover, in a recent paper it was suggested that the deficit in latent inhibition observed in schizophrenia may be secondary to treatment (Williams *et al.*, 1998). Therefore, it seems difficult to confirm that schizophrenia is accompanied by an impairment of latent inhibition. Moreover, there is evidence that the neuronal mechanism involved in latent inhibition depends on the learning paradigm involved (Killcross *et al.*, 1994; Ellenbroek *et al.*, 1997), and since the learning paradigms differ between humans and animals, the relevance of latent inhibition for schizophrenia is at present questionable.

Apart from these information-processing deficits, there are other phenomena which could be assessed in animals with nearly identical techniques, but which have not been studied in great detail yet (at least not in relation to simulation models for schizophrenia). These include certain types of memory processing (more specifically working memory), aspects of executive functioning and planning, and preservation. With respect to the latter, it was found that schizophrenic patients suffer from an increased tendency to persevere when confronted with a two-choice guessing task (Frith and Done, 1983; Lyon *et al.*, 1986). Such guessing tasks can also be modelled in animals (Evenden and Robbins, 1983). However, these more cognitive symptoms of schizophrenia have so far received little attention.

As in the case of the screening models, simulation models also need to be validated on the basis of a specific comparison between known clinical facts and preclinical results. So far, this step has not received much attention, and therefore criteria have not been developed in any great detail. However, most of the criteria used in screening models also can be applied to validating simulation models. Moreover, some specific criteria may be deduced from a more detailed analysis of the disease. For instance, depression occurs about three times more often in women than in men. Therefore, if we are building an animal model for depression it would improve the validity of the model if the disturbances would occur more often in females than in males. Other features which may prove relevant validity criteria may be increased susceptibility to specific drugs, or abnormalities in specific biochemical processes, preferably extending beyond the central nervous system. In this respect it

has been found that the olfactory bulbectomized rat shows abnormalities in the immune and endocrine system reminiscent of those seen in depression (Leonard and Song, 2000; Kelly *et al.*, 2000). It should be realized that the border between symptom similarity and validation criteria is not always easy to draw. One might argue that abnormalities in the endocrine or the immune system add to the symptom similarity of the model. However, in the present paper we have decided to include only behavioural and psycho-physiological features in the symptom similarity. Biochemical or pharmacological similarities are considered validation criteria (see Tables XVII-1.3 and XVII-1.4).

There is evidence that schizophrenia is a neurodevelopmental hypothesis (see below), due to a combination of genetic and early environmental factors. However, the disease does not present itself until around or after puberty. If, in an animal model, the abnormalities also do not develop until after puberty, it would greatly strengthen the validity. Moreover, if the consequences of such an early disturbance were different between different strains of rats, this would further add to the validity of the model. Many studies have shown that schizophrenic patients are much more susceptible to dopaminergic drugs such as amphetamine and apomorphine (Lieberman *et al.*, 1987; Muller *et al.*, 1998), but also to drugs such as ketamine (Lahti *et al.*, 1994). These increased sensitivities can be used as validation criteria for simulation models. There is also a host of data with respect to alterations in the endocrine and immune system in schizophrenia. With respect to the latter, schizophrenic patients have increased basal levels of cortisol (Altamura *et al.*, 1989, 1999), show an increased cortisol response upon a challenge (Lammers *et al.*, 1995) and show a reduced dexamethasone suppression (Saffer *et al.*, 1985; Altamura *et al.*, 1989), suggesting a marked increase in stress sensitivity (Walker and Diforio, 1997). With respect to the immune system, schizophrenic patients are characterized by increased levels of interleukin (IL)-4 and IL-10, but decreased levels of IL-2 and Interferon-γ. This is characteristic of a shift in the TH_1-TH_2 balance in favour of TH_2. Moreover, schizophrenic patients generally have low plasma levels of natural killer cells (Muller *et al.*, 1999). Even though the data are not uncontroversial, they do suggest abnormalities in the immune system, which might explain the negative association between schizophrenia and autoimmune diseases such as rheumatoid arthritis (Vinogradov *et al.*, 1991). A careful scrutiny of the literature will, no doubt, lead to the identification of other criteria which can be used. Table XVII-1.4 summarizes the main aspects which can be used to validate screening models. These may include abnormalities in the neurochemistry in specific brain regions, preferably findings which have been replicated. Obviously, some of these criteria might be impossible to investigate, depending on the model used. In a recent review Weinberger summarizes the neurochemical alterations observed in the hippocampus in schizophrenia (Weinberger, 1999), but if the simulation model is based on a lesion of the hippocampus (see below) most of these subtle biochemical alterations cannot be assessed. Using these criteria, we can now turn to the various approaches used to build simulation models of schizophrenia.

Table XVII-1.3 The criteria for validating simulation models for schizophrenia

Criterion	Description
1	The model should have a genetic basis
2	The model should lead to alterations in the HPA axis activity
3	The disturbances should occur after puberty
4	The model should show immunological alterations similar to schizophrenia
5	The model should show biochemical alterations similar to schizophrenia
6	The model should show pharmacological alterations similar to schizophrenia

SIMULATION MODELS FOR SCHIZOPHRENIA: PHARMACOLOGICAL APPROACHES

The classical way of producing a simulation model for schizophrenia has been the pharmacological approach. It has long been known that drugs which increase dopamine neurotransmission such as amphetamine (Connell, 1958) or drugs which decrease glutamate neurotransmission such as phencyclidine (Greifenstein *et al.*, 1958) can induce psychotic symptoms in normal healthy volunteers and, more importantly, can worsen the existing symptomatology in schizophrenic patients (Lieberman *et al.*, 1987; Lahti *et al.*, 1994). For that reason these two classes of drugs have most often been used to develop simulation models for schizophrenia.

Dopamine agonists, as expected, induce a number of abnormalities in animals also observed in schizophrenic patients. These include reduced pre-pulse inhibition (Mansbach *et al.*, 1988), reduced latent inhibition (Weiner *et al.*, 1984), reduced P_{50} gating (Adler *et al.*, 1986), increased stereotypy and social isolation (Miczek and Gold, 1983; Ellenbroek, 1991; Ellenbroek *et al.*, 1989). With respect to this latter phenomenon it is important to realize that the effects of amphetamine on social behaviour have not been replicated in rat studies (Sams Dodd, 1998), which may be due either to a species difference, or to differences in methodology. Although dopamine agonists are usually grouped together there is evidence that differences exist between, for instance, amphetamine

Table XVII-1.4 Evaluation of the most important simulation models for schizophrenia

	Symptomatology							Validation					
	anhedonia	Soc iso	Stereo	PPI	P_{50}	LI	Startle Hab	1	2	3	4	5	6
DA ag	−	+	+	+	+	+	(−)	+	+	−	+	0	0
Glu antag	−	+	+	+	+	+	+	−	+	−	+	(+)	(+)
Apo-sus	+	0	+	+	−	+	0	+	+	0	+	+	(+)
NVH	0	+	0	+	0	+	0	+	(+)	+	+	0	+
Isol rear	(+)	(+)	0	+	0	−	−	+	(+)	0	+	0	(+)
MD	0	0	0	+	+	+	+	+	+	+	+	0	+

For a description of the validation criteria see Table XVII-1.3. Abbreviations: Soc iso, social isolation; Stereo, stereotyped responding; PPI, pre-pulse inhibition; P_{50}, P_{50} gating; LI, latent inhibition; Startle Hab, startle habituation; DA ag, dopamine agonists; Glu antag, glutamate antagonists; NVH, neonatal ventral hippocampal lesion model; Isol rear, isolation rearing; MD, maternal deprivation; −, the model does not comply; +, the model complies; 0, not known. If the symbol is in parentheses the effects are not completely clear or consistent.

and apomorphine. Thus, in the latent inhibition direct agonists such as apomorphine were found to be ineffective (Feldon *et al.*, 1991), although using the conditioned taste aversion paradigm some disruption was found (Ellenbroek and Cools, 1996). Recently we also found that some differences exist in the pharmacology between amphetamine- and apomorphine-induced disruption (Ellenbroek *et al.*, 2001).

With respect to the validation criteria (Table XVII-1.3), it has been reported that the effects of apomorphine in pre-pulse inhibition are strain dependent (Rigdon, 1990; Kinney *et al.*, 1999; Swerdlow *et al.*, 2000). In agreement with criterion 2, amphetamine increased cortisol release in humans (Grady *et al.*, 1996) and corticosterone in rats (Abdel *et al.*, 1997; Budziszewska *et al.*, 1996). However, the model fares less well with the puberty criterion, as amphetamine already disrupts pre-pulse inhibition in prepubertal rats (Martinez *et al.*, 2000). There is some evidence that amphetamine can induce some abnormalities in the immune system resembling those found in schizophrenia, including a reduction in IL-2 (House *et al.*, 1994) and in natural killer cells (Nunez-Iglesias *et al.*, 1996). As the effects of amphetamine on schizophrenia-like behaviour are usually observed after acute administration, very few studies have looked into biochemical or pharmacological aspects (criteria 5 and 6). For an overview of the model's validity see Table XVII-1.4.

Like dopamine agonists, NMDA antagonists such as phencyclidine and ketamine induce a number of behavioural abnormalities also observed in schizophrenia. These include a disruption of pre-pulse inhibition (Mansbach, 1991; Mansbach and Geyer, 1991; Mansbach and Geyer, 1989) and in P_{50} gating (Adler *et al.*, 1986). Although it was originally reported that phencyclidine does not affect latent inhibition (Weiner and Feldon, 1992), more recent studies did observe deficits (Turgeon *et al.*, 1998, 2000). Phencyclidine has also been reported to induce social isolation and stereotypy both in monkeys (Schlemmer *et al.*, 1978) and rats (Sams Dodd, 1998, 1999). Moreover, in contrast to amphetamine, phencyclidine also reduces startle habituation (Geyer and Braff, 1987). There is some controversy about the effects of NMDA antagonists on P_{50} gating. Adler and colleagues originally described a reduction similar to that observed after amphetamine (Adler *et al.*, 1986). On the other hand, we recently reported that ketamine did not affect P_{50} gating (de Bruin *et al.*, 1999). Although methodological differences cannot be excluded, it seems more likely that the difference depends on the differences between phencyclidine and ketamine, as phencyclidine has an additional dopamine reuptake-inhibiting effect.

The validity of the phencyclidine effects as a simulation model for schizophrenia have not been investigated as extensively as that of amphetamine (see Table XVII-1.4). In a recent paper, phencyclidine, in contrast to apomorphine, appeared equally effective in disrupting pre-pulse inhibition in several different strains (Kinney *et al.*, 1999). Moreover, phencyclidine was already effective in very young animals. (Martinez *et al.*, 2000), thereby violating both criteria 1 and 3. On the other hand, phencyclidine is know to stimulate the HPA axis, leading to strong increases in ACTH and corticosterone (Pechnick *et al.*, 1986, 1989, 1990) and suppresses IL-2 production (Thomas *et al.*, 1993; Dornand *et al.*, 1987). As with the effects of amphetamine, relatively little research has been performed with respect to criteria 5 and 6, though it has been reported that phencyclidine enhances the sensitivity of rats for amphetamine (Turgeon and Case, 2001; Turgeon and Roche, 1999), which would be in agreement with criterion 6. Moreover, (sub)chronic treatment with phencyclidine can lead to pathological changes in the brain, which may have relevance for schizophrenia (Ellison *et al.*, 1999; Martinez *et al.*, 2000). However, a much more detailed analysis will be necessary before criteria 5 and 6 can be properly evaluated.

SIMULATION MODELS FOR SCHIZOPHRENIA: PATHOLOGICAL APPROACHES

Although there has been a tremendous amount of research using both standard post-mortem analysis as well as more modern *in vivo* imaging techniques, the neuropathology of schizophrenia still eludes us. Moreover, the observed disturbances are often so small and diffuse that they cannot be modelled in animal research. For instance, the most replicated neuropathological finding in schizophrenia is a small increase in the size of the lateral ventricles (Harrison, 1999). Likewise, very subtle neuronal displacements have been described in the hippocampus (Kovelman and Scheibel, 1984), the entorhinal cortex (Jakob and Beckmann, 1986), the cingulate cortex (Benes, 1993) and the prefrontal cortex (Lewis, 2000). However, all these pathological findings are too subtle to be mimicked in an animal. Therefore, very few pathological models have been developed. One possible exception is the kainic acid model. In this model rats are injected with kainic acid into the ventricular space. Since kainic acid is an excitotoxic compound, this leads to relatively widespread cell death. However, as originally described by Nadler and colleagues, the hippocampus is much more vulnerable than other structures to the effects of kainic acid (Nadler *et al.*, 1978). According to some, this model has the advantage that a more subtle pathology in the hippocampus can be induced, compared to focal injections of kainic acid directly into the hippocampus (Csernansky and Bardgett, 1998). Kainic acid also induces intense axonal sprouting, which may lead to axonal disarray, similar to that observed in the brain of schizophrenic patients. Moreover, this treatment leads to increased density of D_2 receptors in the nucleus accumbens and reduced density of kainic acid binding sites in the hippocampus (Bardgett *et al.*, 1995; Csernansky and Bardgett, 1998). Similar changes have also been observed in post-mortem brains of schizophrenic patients, and thus add to the validity criterion 4. Unfortunately, this model has not been evaluated behaviourally to any great extent. Neither pre-pulse inhibition, latent inhibition nor startle habituation have been investigated, although the model seems to fulfil a number of the validation criteria described in Table XVII-1.3. Thus kainic acid-treated animals show an increased response to novelty, suggestive of an enhanced response to stress, and the animals are much more sensitive to both dopamine agonists and NMDA antagonists (Bardgett *et al.*, 1997; Csernansky and Bardgett, 1998).

SIMULATION MODELS FOR SCHIZOPHRENIA: AETIOLOGICAL APPROACHES

The most interesting category of animal models comprises those in which one tries to mimic the aetiology of the disease. Even though we still have only a limited knowledge of the aetiology of schizophrenia, there is now ample evidence that schizophrenia is a neurodevelopmental disorder in which genetic and early environmental factors interact (Pilowsky *et al.*, 1993; Weinberger, 1996; Ellenbroek and Cools, 1998). This has led to a large number of animal models in which the long-term consequences of early manipulations are investigated. These include prenatal treatments with the mitosis-inhibiting drug methylazoxymethanol (Talamini *et al.*, 1998, 2000; Ellenbroek *et al.*, 2000). or with corticosterone (Diaz *et al.*, 1995, 1997). A relatively new strategy has been to selectively alter the genes involved in growth and development. A potentially interesting model in this respect is the NCAM-180 knockout mouse. This mouse, lacking one of the neural cell adhesion molecules, shows, among others, enlarged ventricles and reduced pre-pulse inhibition (Wood *et al.*, 1998). However, most of these models have not been investigated to any great extent. Four animals models have been more extensively studied,

namely selective breeding for dopamine hypersensitivity, early hippocampal damage, isolation rearing and maternal deprivation.

Selective breeding for dopamine (hyper)sensitivity was originally performed to study differences in personality (see Chapter XXVI-1). Wistar rats were divided on the basis of their gnawing response to apomorphine as susceptible (APO-SUS, showing a strong gnawing response) or unsusceptible (APO-UNSUS, showing a very weak gnawing response). Using a special pharmacogenetic breeding strategy which prohibits inbreeding (at least in the short run) these APO-SUS and APO-UNSUS rats were selectively bred. Since dopamine hyper(re)activity has been implicated in the pathophysiology of schizophrenia for a very long time, it is not unexpected that APO-SUS rats show a number of schizophrenia-like behavioural deficits, including stereotypy, disrupted pre-pulse inhibition and latent inhibition (Ellenbroek *et al.*, 1995; Cools *et al.*, 1990). So far startle habituation has not been evaluated in these rats, and P_{50} gating seems to be normal (De Bruin *et al.*, in preparation). Interestingly, APO-SUS rats also drink significantly smaller quantities of sucrose than APO-UNSUS rats, suggesting they show a certain degree of anhedonia (Cools and Gingras, 1998). Moreover, the model seems to fulfil a number of the validation criteria described in Table XVII-1.3. Obviously, it has a genetic basis (criterion 1) and the APO-SUS rats are much more sensitive to dopamine agonists such as apomorphine and amphetamine (Cools *et al.*, 1990, 1997). APO-SUS rats are also much more sensitive to stress, showing an increased ACTH and corticosterone response (Rots *et al.*, 1995). In addition, APO-SUS rats show immunological alterations resembling schizophrenia, including reduced numbers of natural killer cells and a relative dominance of T_{H2} cells (Cools and Gingras, 1998; Kavelaars *et al.*, 1997), which may in part explain their resistance in animal models for autoimmune disease such as rheumatoid arthritis (van de Langerijt *et al.*, 1994). Finally there is some evidence that APO-SUS rats show biochemical alterations similar to those observed in schizophrenia, including increased mRNA levels of tyrosine hydroxylase in the substantia nigra and of D_2 receptor binding in the neostriatum (Rots *et al.*, 1996a).

As discussed above, there is a large literature pertaining to the involvement of the hippocampus in the pathology of schizophrenia (Harrison, 1999; Weinberger, 1999). This extensive literature, combined with the neurodevelopmental hypothesis, has led Lipska and Weinberger to investigate the long-term effects of neonatal lesions of the hippocampus (Lipska *et al.*, 1993). In behavioural studies it was subsequently shown that lesioning the hippocampus at postnatal day 7 leads to a reduction in pre-pulse inhibition in adult rats (Lipska *et al.*, 1995), as well as to deficits in latent inhibition (Grecksch *et al.*, 1999) and in social behaviour (Becker *et al.*, 1999; Sams Dodd *et al.*, 1997). This latter effect was also observed in monkeys (Bachevalier *et al.*, 1999). Unfortunately, neither startle habituation nor P_{50} gating have so far been investigated.

The model seems to fulfil a number of the criteria from Table XVII-1.3. Thus the effect seems to depend on the strain of rats used, suggesting an interaction with the genetic background (Lipska and Weinberger, 1995), and most of the effects do not develop until after puberty (Lipska *et al.*, 1993, 1995). In agreement with criterion 6, rats with neonatal hippocampal lesion are more sensitive to amphetamine (Lipska *et al.*, 1993) and to apomorphine (Schroeder *et al.*, 1999). Whether the model fulfils criterion 2 is not completely clear. Although the hippocampally lesioned rats show an increased locomotion to novelty (Lipska *et al.*, 1993), to our knowledge the ACTH and corticosterone response has not been measured. Moreover, immunological parameters have not yet been measured in this model. Nevertheless, the model seems to be one of the most promising simulations to date (see Table XVII-1.4). A distinct disadvantage of the model is that it involves the virtually complete destruction of the hippocampus. Although some reductions in the volume of the hippocampus have been reported in schizophrenia, the effects are much more subtle (Harrison, 1999). On the other hand, in monkeys the neonatal hippocampal lesion leads to significant reduction in *N*-acetyl aspartate in the prefrontal cortex (Bertolino *et al.*, 1997), a finding also reported in schizophrenia (Bertolino *et al.*, 1998).

An environmental simulation model for schizophrenia is the isolation rearing model. In this model rats are isolated upon weaning (typically postnatal day 21). When the isolation period is long enough (usually 8 weeks or more), abnormalities in pre-pulse inhibition are observed (Geyer *et al.*, 1993; Wilkinson *et al.*, 1994; Varty and Higgins, 1995), though there is a discussion about the robustness of the effect (Domeney and Feldon, 1998; Weiss *et al.*, 1999). Unfortunately, most of the other behavioural parameters seem normal, including startle habituation (Varty and Geyer, 1998) and latent inhibition (Wilkinson *et al.*, 1994). Moreover, sucrose consumption is even increased in rats reared in isolation (Hall *et al.*, 1998). On the other hand, in a recent paper a reduced incentive value for sucrose was observed in rats isolated from postnatal day 21 to 28 (Van den Berg *et al.*, 1999). This same group also reported reduced social interaction in rats after juvenile isolation. (Hol *et al.*, 1999), suggesting this model might be more related to the negative than the positive symptoms of schizophrenia. In agreement with criterion 1, the effects of isolation rearing on pre-pulse inhibition appear to depend on the strain of rats being used (Hall *et al.*, 1997; Varty and Geyer, 1998; Weiss *et al.*, 2000). Moreover, the isolated rats are more sensitive to the locomotor-activating properties of dopaminergic drugs (Phillips *et al.*, 1994; Jones *et al.*, 1990). Isolated rats generally show an increase locomotor activity upon a novelty challenge (Wilkinson *et al.*, 1994; Phillips *et al.*, 1994). It is, however unclear whether they also show an increase in HPA axis activity. Moreover little is known about the effects of isolation rearing on immunological parameters.

The last simulation model is based on the long-term consequences of an early severe stressful life event, namely maternal deprivation. When analysing this model, it is important to realize that there are many different forms of maternal deprivation, including repeated short-term separations (1–3 h). However, the model most relevant to schizophrenia consists of a single 24 h period of maternal deprivation, shortly after birth. Depending on the timing of the deprivation, this maternal deprivation leads to a significant reduction in pre-pulse inhibition (Ellenbroek and Cools, 2000b; Ellenbroek *et al.*, 1998), although some people have been unable to replicate this (Lehmann *et al.*, 2000). The reason for this failure to replicate these findings is unclear, but methodological differences may be partly responsible. Maternal deprivation also leads to a reduction in latent inhibition (Ellenbroek and Cools, 1995), startle habituation and P_{50} gating (Ellenbroek *et al.*, in preparation). So far the effects on social behaviour and sucrose consumption have not been investigated. With respect to validation, the model of maternal deprivation seems to be quite successful. The maternal deprivation effect seems to depend on the genetic background. Thus, whereas maternal deprivation leads to a reduction in pre-pulse inhibition in Wistar rats, it has no effect in Fischer 344 or Lewis rats (Ellenbroek and Cools, 2000b). The insensitivity of Lewis rats is particularly interesting, since this strain also seems to be much less sensitive to isolation rearing and neonatal hippocampal lesioning as well as dopamine agonists (Lipska and Weinberger, 1995; Varty and Geyer, 1998). Moreover, maternal deprivation leads to an enhanced sensitivity to amphetamine (Zimmerberg and Shartrand, 1992) and apomorphine (Rots *et al.*, 1996b; Ellenbroek and Cools, 1995). In agreement with criterion 2 there is a large body of evidence that maternal deprivation leads to alterations in the HPA axis (Levine, 1994; van Oers *et al.*, 1998, 1999), although it should be realized that the exact effect depends upon the maternal deprivation paradigm and the time of measurement (Workel *et al.*, 1997). We recently showed that the effects of maternal deprivation on pre-pulse inhibition are only seen after puberty, in agreement with criterion 3.

So far very little work has been done on the effect of maternal deprivation on immunological processes. Moreover, few biochemical alterations after maternal deprivation relevant to schizophrenia have so far been published. Nevertheless, reductions in hippocampal levels of PSA-NCAM (Foley *et al.*, 2000; Riva *et al.*, 2000) and BDNF have been reported, similar to those observed in schizophrenia (Weinberger, 1999). Finally maternally deprived rats show an increase in mRNA for tyrosine hydroxylase in the substantia nigra (Rots *et al.*, 1996b).

EPILOGUE

Developing animal models for schizophrenia has proven to be extremely difficult because there is a great lack of knowledge on the aetiology, pathology and pharmacology of this disease, which is essential for model building. Moreover, most of the symptoms used in the diagnosis of schizophrenia-like hallucinations, delusions and thought disorder are virtually impossible to measure in animals. For that reason most animal models for schizophrenia belong to the class of screening tests and are more relevant for the pharmacology and for our understanding of the mechanisms of action of antipsychotic drugs. Although these models have been very useful in the past, they do not help us in our understanding of the disease itself, nor are they likely to produce a therapeutic breakthrough.

The notion that schizophrenia is likely due to an interaction between early stressful life events and genetic factors has led to a number of novel models which aspire to simulate the disease. In the present chapter we have discussed the process of developing and validating such simulation models and have evaluated the most relevant models known today. The most promising ones seem to be APO-SUS rats, the neonatal hippocampal lesion model and the maternal deprivation model (see Table XVII-1.4). However, it is important to realize that none of the models fulfils all the criteria laid out in Table XVII-1.3. Moreover, most of the models have not been evaluated to any great extent. Nevertheless, models such as maternal deprivation and neonatal hippocampal lesioning have shown that early alterations can have retarded but persistent effects on brain and behaviour. It is to be expected that such models will help us understand how the organism deals with such environmental insults and may also help us understand how the neuropathology of schizophrenia develops. In the end this may even lead to novel therapeutic approaches aimed more at preventing the development of the disease rather than treating the symptoms once the disease has emerged.
