GABA interneurones in the PVN are thought to be the substrate for functional integration of anorexigenic and orexigenic pathways of the hypothalamus (Cowley *et al.*, 1999). Since GABA is an inhibitory neurotransmitter, this model is consistent with studies demonstrating an inability to adequately restrain eating following bilateral PVN ablation. Electrophysiological and immunohistochemical studies indicate that NPY/Agrp and POMC/CART neurones converge on GABA interneurones expressing both MC4 and NPY receptors. NPY receptor activation inhibits adenylate cyclase activity via the Gi subunit of the plasma membrane G protein. Reduced availability of intracellular cyclic AMP results in decreased GABA release, which in turn reduces inhibition of feeding. Conversely, MC4 receptors are coupled to the Gs subunit. αMSH therefore stimulates adenylate cyclase, activating GABA neurones. Agrp inhibits GABA activity via prolonged antagonism of MC4 mediated activation of adenylate cyclase. Thus when food intake is restricted, reduced leptin signalling gives rise to increased NPY/Agrp activity and reduced POMC activity which in turn inhibits the activity of GABA interneurones to enhance appetite (see Figure XXIII-3.1). It is not yet known whether CART inhibits or stimulates GABA interneurone activity, but if CART is an orexigenic peptide an inhibitory effect would be predicted.

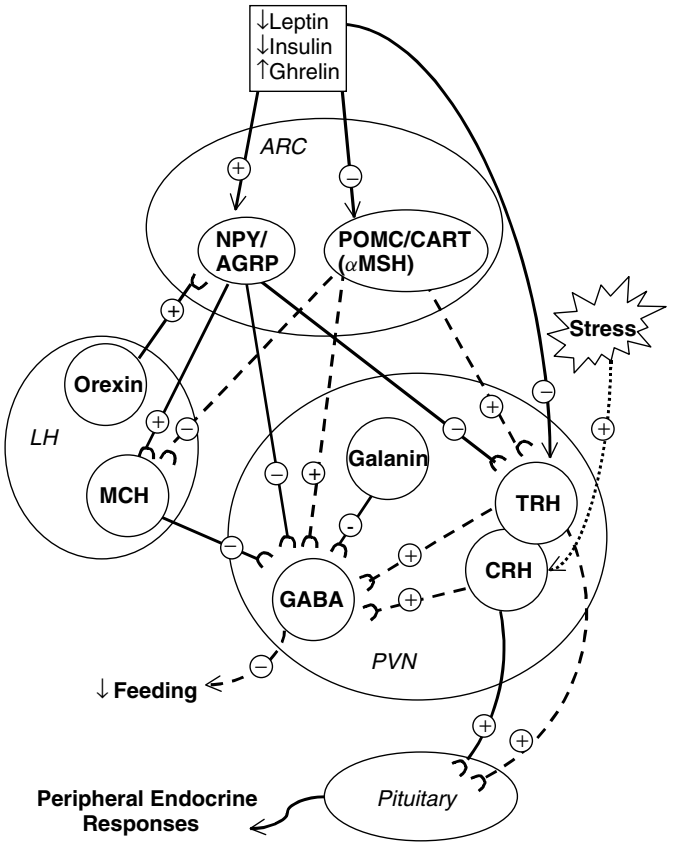

Figure XXIII-3.1 Proposed Model for the Neuroendocrine Response to Starvation. In response to acute food restriction, leptin levels fall below that expected for body fat mass, facilitating an early response to reduced energy availability. If food intake does not increase, falling body mass maintains this low leptin response. Reduced leptin signal to the ARC enhances activity of orexigenic NPY/Agrp neurones, whilst inhibiting anorexigenic αMSH activity. The appetitive effects of CART remain to be clarified. NPY/Agrp and POMC/CART neurones in the ARC project to the PVN and LH where putative second order orexigenic peptides MCH and galanin are up-regulated and anorexigenic peptides such as CRH and TRH are inhibited. Stress-induced CRH release may enhance anorexigenic activity in the PVN. Orexin appears to function upstream of NPY, perhaps providing a link between sleep–wake cycles and feeding behaviour. Orexigenic and anorexigenic signals may be functionally integrated via G protein coupled receptors on GABAergic interneurones in the PVN. When the leptin signal is low, inhibition of GABA activity reduces inhibition on feeding. Additionally, low leptin levels modulate the function of hypothalamic–pituitary endocrine axes such that energy is mobilized from peripheral stores and energy expenditure for growth and reproduction is minimized. In the case of the HPA axis, although fasting may inhibit CRH release in the PVN, a fasting induced increase of NPY expression stimulates CRH release in the median eminence, giving rise to enhanced HPA axis activity. (ARC = arcuate nucleus; LH = lateral hypothalamus; PVN = paraventricular nucleus; NPY = neuropeptide Y; Agrp = agouti related peptide; POMC = pro − opiomelanocortin; αMSH = alpha melanocyte stimulating hormone; CART = cocaine amphetamine related peptide; MCH = melanin concentrating hormone; TRH = thyrotrophin releasing hormone; CRH = corticotrophin releasing hormone. ——— = enhanced pathways; - - - - = suppressed pathways)

The effector neurones upon which GABA interneurones act have yet to be elucidated, but it is likely that at least some of the hypothesized second order neurones function in this way (Schwartz *et al.*, 2000). However, MCH receptors are also coupled to the inhibitory G protein subunit and CRH receptors are coupled to the Gs subunit. It is therefore possible that activity within the proposed second order anorexigenic and orexigenic pathways can also be functionally integrated at the GABA interneurone (Cowley *et al.*, 1999). Further studies are clearly needed to test these hypotheses.

Multiple orexigenic and anorexigenic peptides therefore contribute to the appetitive pathways of the hypothalamus, giving rise to a degree of redundancy within the system. NPY knockout mice, for example, are of normal weight (Erickson *et al.*, 1996), indicating that other neuropeptides, such as Agrp, compensate for this genetic deficit. However, it seems likely that our current model for understanding is an over-simplification of a highly complex network in which the different neuroendocrine systems contribute unique links with important higher functions. For example, the orexin system appears to provide a link between energy regulation and arousal, whilst the CRH system provides a link with stress responsivity. CRH inhibits the expression of NPY (Van Huijsduijnen *et al.*, 1993) and mediates stress-induced anorexia (Krahn *et al.*, 1986; Shibasaki, 1988). Thus even if undernourished, appetite may be impaired in the context of CRH hyperactivity (Schwartz *et al.*, 1995). This hypothesis may be particularly relevant to eating disorders, given their association with premorbid stressful life events and difficulties (Schmidt *et al.*, 1997) and impaired coping (Troop and Treasure, 1997).

Effector Systems

Second order PVN neurones provide a link between leptin and peripheral effectors that mediate adaptations to altered energy availability. One such mechanism involves the hypothalamic–pituitary hormonal axes. In humans, genetic deficits of leptin signalling are associated with widespread neuroendocrine abnormality of the type seen in starvation, including failure of puberty and reduced secretion of thyrotrophin and growth hormone (Clement *et al.*, 1998). Furthermore, if the fall in leptin associated with fasting is prevented by exogenous replacement, changes within the gonadal (HPG), adrenal (HPA) and thyroid hormone (HPT) axes are blunted (Ahima *et al.*, 1996).

Leptin suppresses HPA axis activity at both the central and adrenal level of the axis (Ahima *et al.*, 1996; Bornstein *et al.*, 1997; Heiman *et al.*, 1997), such that cortisol levels are elevated during fasting. Whilst the action of cortisol at high concentrations is catabolic in the periphery, generating glucose and ketone bodies from stored energy, at the central level, cortisol stimulates expression of NPY and is thus anabolic (Strack *et al.*, 1995). In turn, NPY further stimulates HPA axis activity via increased CRH expression in the median eminence, but not other hypothalamic regions (Haas and George, 1987). Thus a feed-forward system is generated in which cortisol and NPY are reciprocally positively regulated in order to maintain a robust central appetite response coupled with mobilization of peripheral energy stores. Schwartz *et al.* (1995) have suggested that persistently dysregulated CRH release in the PVN could impair this feed-forward system via inhibition of NPY expression.

During fasting, low leptin levels suppress prothyrotropin-releasing hormone expression, reducing peripheral thyroid hormone activity (Legradi *et al.*, 1997) and thus reducing energy expenditure. Low leptin levels also suppress growth hormone (GH) secretion during fasting (Carro *et al.*, 1997; LaPaglia *et al.*, 1998) and in genetic leptin deficiency (Clement *et al.*, 1998). This effect appears to be mediated by enhanced expression of NPY (Vuagnat *et al.*, 1998). Interestingly, the fasting induced fall in insulin-like growth factor (IGF-1) levels is not reversed by leptin (Carro *et al.*, 1997; LaPaglia *et al.*, 1998). In contrast to an acute fast, severe starvation is associated with elevated GH secretion, GH resistance and low IGF-1 and insulin levels (Soliman *et al.*, 2000). This pattern of GH-IGF-1 axis activity is thought to promote muscle catabolism, rather than growth, and is therefore adaptive to the starving state.

Leptin regulates gonadal axis activity via stimulation of both hypothalamic and pituitary components of the axis (Yu *et al.*, 1997) and plays a pivotal role in the onset of ovulation at puberty and cessation during starvation (Ahima *et al.*, 1997; Chehab *et al.*, 1996; Miller *et al.*, 1998). The effects of leptin upon gonadal and other anabolic hormone axes may be mediated by NPY (Catzeflis *et al.*, 1993). Since oestrogen enhances leptin production (Mannucci *et al.*, 1998), oestrogen deficiency arising from HPG axis suppression during starvation may amplify orexigenic signalling.

The adaptive response to leptin deficiency may therefore be as important as its role in the regulation of appetite. It is characterized by reduced energy expenditure, via suppression of reproductive and thyroid axis activity, and mobilization of stored energy via the actions of cortisol and altered GH-IGF-1 axis function. Leptin deficiency therefore defends against starvation by both increasing appetite and reducing energy expenditure (see Figure XXIII-3.1).

Similarly, excessive leptin production in the context of obesity may also elicit adaptive changes. POMC/CART neurones project to sympathetic preganglionic neurones in thoracic spinal cord (Elias *et al.*, 1998) suggesting these pathways may contribute to enhanced thermogenesis and energy expenditure when anorexigenic pathways are activated by elevated leptin. Pituitary endocrine axis changes in obesity include reduced GH and elevated cortisol release, which in this context may serve to promote growth and central adiposity. Excess leptin therefore appears to be somewhat less effective in defending healthy body weight than leptin deficiency. Central leptin resistance, perhaps arising from saturation of active leptin transport mechanisms, may contribute (Caro *et al.*, 1996). Indeed, the ratio of CSF to plasma leptin is reduced in obese subjects (Caro *et al.*, 1996; Schwartz *et al.*, 1996). These findings support the hypothesis that the primary role of leptin is to defend against starvation rather than obesity.

SECTION 2: NEUROENDOCRINOLOGY OF APPETITE AND WEIGHT IN EATING DISORDERS

Anorexia Nervosa

Leptin

The wealth of studies examining a putative role for leptin in the aetiology of AN have produced little evidence to support a functional abnormality. In acute AN, leptin levels are low and proportional to BMI and fat mass (Ferron *et al.*, 1997; Grinspoon *et al.*, 1996; Lear *et al.*, 1999; Mathiak *et al.*, 1999) except at extremely low BMI (Balligand *et al.*, 1998; Casanueva *et al.*, 1997; Eckert *et al.*, 1998; Pauly *et al.*, 2000). Even in the severely emaciated state, leptin diurnal rhythm and temporal relationship with insulin and IGF-1 are preserved (Casanueva *et al.*, 1997; Eckert *et al.*, 1998; Herpertz *et al.*, 2000), although the temporal relationship with cortisol is disrupted until weight is restored (Herpertz *et al.*, 2000). During weight gain, plasma leptin levels are relatively elevated for BMI (Hebebrand *et al.*, 1997; Mantzoros *et al.*, 1997) and this could at least partially explain the difficulty achieving full weight restoration during rapid refeeding. Similarly, leptin levels are greater than expected for BMI in those with the purging subtype of AN (Mehler *et al.*, 1999). An elevated CSF : plasma leptin ratio in acute AN (Mantzoros *et al.*, 1997) suggests that enhanced central leptin signalling could contribute to impairment of appetite. However, normalization of both plasma

leptin levels (Gendall *et al.*, 1999; Hebebrand *et al.*, 1997; Polito *et al.*, 2000) and the CSF : plasma ratio (Mantzoros *et al.*, 1997) following full recovery indicates that altered leptin dynamics are a state related phenomena.

Insulin and Ghrelin

Although studies of insulin and glucose dynamics in acute AN have not been entirely consistent, on balance, the evidence suggests that basal and fasting insulin levels are reduced in acute AN (Alderdice *et al.*, 1985; de Rosa *et al.*, 1983; Uhe *et al.*, 1992), consistent with the need to promote gluconeogenesis in the starving state. Delayed absorption and, in chronic cases, impaired pancreatic beta cell function (Nozaki *et al.*, 1994) may contribute to reduced insulin response to nutrients in AN (Alderdice *et al.*, 1985; Blickle *et al.*, 1984). Insulin sensitivity varies greatly between subjects (Kiriike *et al.*, 1990) and there may be a tendency toward increased glucose utilization rather than storage (Franssila-Kallunki *et al.*, 1991). These altered dynamics appear to resolve with full recovery from AN (Casper, 1996). The role of insulin as a central signal of peripheral energy balance has not been investigated in AN. Similarly, ghrelin has yet to be examined in AN.

Hypothalamic Regulation of Appetite and Weight

Several authors have postulated an imbalance between anorexigenic and orexigenic pathways of the hypothalamus in the aetiology of AN (Kaye *et al.*, 1989; Menzaghi *et al.*, 1993). Despite obvious methodological problems limiting the scope of available data, there is some indirect evidence to support this hypothesis. An association between an Agrp gene polymorphism and AN raises the possibility that this variant could be a less effective MC4-R antagonist, conferring susceptibility to AN via reduced ability to inhibit anorexigenic pathways (Vink *et al.*, 2001). NPY levels are elevated in CSF during the acute illness (Kaye *et al.*, 1990), consistent with a reduced leptin signal from the periphery. Levels normalize with full recovery, at which time CSF polypeptide Y (PPY) levels are also reported normal (Gendall *et al.*, 1999; Kaye *et al.*, 1990; Sapolsky, 1992). The NPY Y5 receptor mediates the orexigenic effects of NPY (Schaffhauser *et al.*, 1997) and there is no evidence for an association between receptor gene polymorphisms and AN (Rosenkranz *et al.*, 1998). However, low CSF galanin in women fully recovered from AN (Frank *et al.*, 2001) could reflect a functional impairment of orexigenic pathways of the hypothalamus in those vulnerable to AN.

One recent study found elevated plasma CART concentrations in those with the acute disorder, and normal concentrations in women who had fully recovered (Sarah Stanley, personal communication). This finding perhaps adds weight to the hypothesized orexigenic role of CART in the ARC, LH and PVN (Abbott *et al.*, 2001).

In terms of anorexigenic pathways in AN, there is no evidence of an MC4 receptor mutation or polymorphism associated with AN (Hinney *et al.*, 1999) and no other studies of the melanocortin system have yet been reported. CSF TRH levels are reduced at low weight and are not fully normalized at attainment of target weight (Lesem *et al.*, 1994). This is not inconsistent with an adaptive response to starvation. CSF CRH levels are elevated during the acute illness (Kaye *et al.*, 1987) and this appears to be in contrast to animal models of food restriction in which CRH activity in the PVN is reduced (Brady *et al.*, 1990).

Studies of HPA axis activity in AN suggest that an impairment of feedback inhibition at the level of the hypothalamus gives rise to elevated CRH activity. This is turn is thought to override intact feedback inhibition at the level of the pituitary (Kling *et al.*, 1993), giving rise to the HPA axis hyperactivity associated with AN (Kaye *et al.*, 1987; Licinio *et al.*, 1996). Elevated concentrations of CRH in the CSF (Kaye *et al.*, 1987) and blunting of the ACTH and β-endorphin responses to exogenous CRH (Brambilla *et al.*, 1996; Hotta *et al.*, 1986) are consistent. with this hypothesis. Although HPA axis arginine vasopressin (AVP) activity is up-regulated in the context of chronic stress in animals and depression in humans, there is no evidence of elevated AVP activity in acute AN (Connan *et al.*, 2001a, 2001b). This is significant because AVP modulates CRH release and sensitivity of the axis to feedback inhibition via altered glucocorticoid receptor activity (Felt *et al.*, 1984; Plotsky *et al.*, 1984). An abnormal HPA axis response to chronic stress may therefore contribute to persistently elevated CRH activity in AN. In addition to the inhibitory effect on appetite and feeding, the widespread behavioural and physiological effects of CRH include many of the features of AN including increased locomotor activity, cardiovascular changes, reduced social and sexual behaviour, impaired sleep and increased anxiety behaviours (Dunn and Berridge, 1990).

There is some evidence to suggest that a heightened cortisol response to stress and a blunted cortisol response to a meal may persist even after full recovery (Connan *et al.*, 2001c; Ward *et al.*, 1998). Subtle abnormalities of HPA axis regulation could therefore contribute to susceptibility to AN. Whilst genetic factors are likely to be important, the elevated prevalence of perinatal stress (Cnattingius *et al.*, 1999; Foley *et al.*, 2001) and insecure attachment (Ward *et al.*, 2000) in those vulnerable to AN suggest that early environmental modulation of HPA axis responsivity (Heim and Nemeroff, 1999) may also contribute.

Effector Systems

In acute AN, basal and fasting IGF-1 concentrations are reduced (Argente *et al.*, 1997; Fukuda *et al.*, 1999; Stoving *et al.*, 1999a) whilst GH (de Rosa *et al.*, 1983; Stoving *et al.*, 1999b) and cortisol concentrations are elevated. These findings are consistent with the need to promote gluconeogenesis in the starving state and resolve with weight gain (Casper *et al.*, 1988a; Casper, 1996; Golden *et al.*, 1994), suggesting that they arise as an adaptive response to prolonged negative energy balance.

GH hypersecretion in AN is associated with a disorganized pattern of both basal and pulsatile release (Stoving *et al.*, 1999b). Neuroendocrine challenge studies suggest that hypersecretion is attributable to impaired somatostatinergic inhibition rather than elevated GHRH activity (Ghigo *et al.*, 1994). Low T3 concentrations may also contribute (Valcavi *et al.*, 1990). Peripheral GH resistance, reflected in reduced availability of GH binding protein (GHBP), is characteristic of both AN and other forms of malnutrition (Stoving *et al.*, 1999a, for review). Since IGF-1 mediates many of the anabolic effects of GH, reduced levels in the starving state likely contribute to GH resistance. Reduced central IGF-1 feedback inhibition may also contribute to GH axis hyperactivity (Melmed *et al.*, 1996). It therefore appears that reciprocal interactions between IGF-1 and GH function effectively in AN, generating a feed-forward system of low IGF-1 and elevated GH. A paradoxical increase in the GH response to intravenous glucose in AN could reflect abnormality of hypothalamic appetite and satiety responses (Tamai *et al.*, 1991).

Altered thyroid function in acute AN does not differ from that associated with malnutrition (de Rosa *et al.*, 1983) and normalizes with maintenance of healthy weight and eating (e.g., Kiyohara *et al.*, 1987; Komaki *et al.*, 1992). Specifically, serum total and free thyroxine (T4) are low or normal, tri-iodothyronine (T3) is reduced and reverse T3 (rT3) is elevated (e.g., Boyar *et al.*, 1977; de Rosa *et al.*, 1983; Komaki *et al.*, 1992). Altered peripheral conversion of T4 to T3 contributes to these abnormalities. However, whilst TSH levels are normal, the TSH response to TRH is delayed and prolonged and T3 response to TRH is reduced, suggesting that

central HPT axis dysregulation may also play a role (Casper and Frohman, 1982; Kiyohara *et al.*, 1989).

In terms of the HPG axis, gonadotrophin releasing hormone (GnRH) release is reduced and gonadotrophin secretion exhibits a pre-pubertal pattern (e.g., van Binsbergen *et al.*, 1990), as would be expected in a low leptin state. Leptin levels are predictive of amenorrhoea in eating disordered patients (Kopp *et al.*, 1997) and restoration of normal levels is necessary, although not sufficient, for restoration of menses (Audi *et al.*, 1998). Similarly, leptin levels are positively correlated with HPG function in males recovering from AN (Wabitsch *et al.*, 2001). Although there is a critical BMI threshold for menstruation to return, the presence of anorexic attitudes and behaviours during recovery from AN appears to be more predictive of persistent amenorrhoea than BMI (Falk and Halmi, 1982). Interestingly, CSF NPY levels following weight gain were normal only in those women with return of menses (Kaye *et al.*, 1990), consistent with the hypothesized role of NPY in mediating the effects of leptin deficiency on HPG axis function.

Bulimia Nervosa

Leptin

The fall in leptin levels associated with fasting is blunted in those with BN (Monteleone *et al.*, 2000a). Additionally, although plasma leptin levels are positively correlated with BMI (Monteleone *et al.*, 2000b), leptin levels are lower than those of healthy comparison women, even after adjusting for low BMI (Brewerton *et al.*, 2000; Monteleone *et al.*, 2000b), a finding that persists even after recovery (Jimerson *et al.*, 2000). Duration of illness and severity of disorder are related to the reduced leptin levels in BN (Monteleone *et al.*, 2000a). Amongst obese binge eaters, lower leptin levels are associated with greater dietary restraint (d'Amore *et al.*, 2001) and restraint might similarly contribute to low leptin levels in those vulnerable to BN. These data suggest that whilst the body fat sensing function of leptin is intact, there is a tendency for a lower leptin secretion per fat mass and thus a higher settling point for weight in BN. A degree of restrained eating may therefore be necessary to maintain a healthy low weight in these individuals. The impaired capacity for the leptin system to respond to acute changes in energy intake could contribute to maintenance of disordered eating in BN.

Hypothalamic Regulation of Appetite and Weight

Following short-term abstinence from binge–purge behaviour, CSF levels of PYY and somatostatin are elevated relative to both acute BN and healthy controls (Kaye *et al.*, 1988, 1990). A relative excess activity in the orexigenic pathways of the hypothalamus might therefore be stimulating overeating in BN. However, levels of both PYY and NPY in CSF are normal after full recovery suggesting that this is unlikely to be a trait phenomenon (Gendall *et al.*, 1999). There are currently no published data regarding other orexigenic and anorexigenic neuropeptides in BN.

Effectors

Milder variants of HPG, HPT, HPA and GH axis changes associated with AN also occur in BN (Coiro *et al.*, 1992; Kennedy *et al.*, 1989; Levy, 1989; Pirke *et al.*, 1988). It is likely that these changes reflect undernutrition despite healthy weight, consistent with the hypothesis that women with BN are maintaining weight at a lower level than is necessary to switch off anabolic systems. The finding that a current weight of less than 85% of previous highest weight is predictive of impaired HPG function in BN (Weltzin *et al.*, 1994) further supports this. There is some suggestion of an association between polycystic ovary syndrome (PCO) and BN, but the nature and extent of such an association have been little studied (Michelmore *et al.*, 2001; Morgan, 1999). Raphael and colleagues (Raphael *et al.*, 1995) found a high prevalence of polycystic ovaries on ultrasound scan, but this was not associated with elevated levels of luteinizing hormone or the metabolic features of PCO. The ultrasound findings may therefore reflect multifollicular ovaries rather than true PCO (Treasure, 1988).

Women with BN exhibit reduced cortisol and sympathetic nervous system (SNS) responses to mental stress, relative to healthy comparison women (Laessle *et al.*, 1992), suggesting that in contrast to AN, BN may be associated with stress hyporesponsivity.

Binge-Eating Disorder

At the opposite end of the eating and weight spectrum from AN, binge-eating disorder (BED) is associated with obesity and overeating, in the absence of behaviours to compensate. The biology of BED is therefore likely to overlap with that of BN, but in the absence of the biological consequences of food restriction. When presented with food, those with BED experience a greater subjective desire to eat than women with simple obesity, although the salivary response to food exposure is reduced (Karhunen *et al.*, 1997a). Binge eating may therefore be driven more by emotional cues than hunger in BED.

The few available data examining biological contributions to dysregulated appetite and weight in obese binge eaters can be summarized as follows. This group do not differ from obese non-binge eaters in terms of resting energy expenditure, body composition, serum lipids, insulin and thyroid hormones (Adami *et al.*, 1995; Wadden *et al.*, 1993). Cephalic phase plasma insulin, free fatty acid and glucose levels also do not differ between binge- and non-binge-eating obese people (Karhunen *et al.*, 1997b). Leptin levels are elevated and proportional to BMI in women with BED (Monteleone *et al.*, 2000b), but it remains to be seen whether leptin levels differ between obese binge and non-binge eaters after adjustment for BMI. It is likely that obese binge eaters have a degree of leptin resistance, as occurs in simple obesity, but again, this remains to be demonstrated. Simple peripheral obesity is associated with elevated morning cortisol and high diurnal variability, whilst visceral obesity is associated with low morning cortisol and blunting of the diurnal rhythm, as well as reduced GH and HPG axis activity (Rosmond *et al.*, 1998). These endocrine changes are thought to be responsible for the metabolic and haemodynamic features of visceral obesity as well as reduced fertility in women (Bjorntorp and Rosmond, 2000a). Termed the Metabolic Syndrome by Bjorntorp and colleagues, an interaction between genetic factors, such as an associated glucocorticoid receptor polymorphism, and environmental stress in early and adult life is thought to contribute to aetiology (Bjorntorp and Rosmond, 2000b). Given the association between early adversity and BED (Fairburn *et al.*, 1998), one might predict that those with BED are more likely to exhibit visceral obesity and the associated metabolic syndrome than simple peripheral obesity.

Synthesis and Implications

Eating disorders can be conceptualized as stress related disorders. A severe life event or difficulty can be identified prior to onset in the majority of cases (Schmidt *et al.*, 1997) and there is evidence of abnormal coping (Troop and Treasure, 1997). Additionally, early adversity is a risk factor for each of the disorders, as it is for psychiatric disorders in general (Fairburn *et al.*, 1997, 1998, 1999). The capacity for adverse early life experience to modulate HPA axis development is now well recognized (Heim and Nemeroff, 1999)

and such experience may also affect appetite and weight regulation in adulthood (McIntosh *et al.*, 1999). Interestingly, feeding ameliorates the adverse effect of maternal deprivation upon HPA axis function (van Oers, de Kloet, and Levine, 1999), providing a potential precursor to emotion driven eating in later life. It seems likely that genetic and early environmental factors interact to generate specific vulnerabilities in the systems regulating appetite, weight and stress responsivity. For AN, the phenotype is characterized by impaired appetite and heightened stress responsivity. In contrast, the BN phenotype may be a tendency toward obesity, eating as a strategy to manage emotional experience and reduced stress responsivity.

In terms of the neuroendocrine data, leptin appears to signal low peripheral energy availability to hypothalamic networks effectively in AN, giving rise to elevated NPY expression and appropriate adaptations to the starving state. These include amenorrhoea, and enhanced metabolic efficiency arising from altered thyroid and IGF-1/GH axis function. Relatively elevated central leptin concentrations could play a role in maintenance of the disorder, whilst elevated leptin for BMI during rapid refeeding may contribute to difficulty restoring weight. There is some evidence to support a hypothesized imbalance between anorexigenic and orexigenic pathways of the hypothalamus. Specifically, impaired Agrp function and reduced galanin expression may impair orexigenic pathways, whilst hyper-reactivity of CRH expression may enhance activity in anorexigenic networks. These abnormalities could underlie the association between AN and premorbid tendency toward leanness. An aberrant HPA axis response to chronic stress, characterized by persistently elevated CRH activity, may be one factor that contributes to the onset and pathophysiology of AN. However, it is likely that other neuropeptide and neurotransmitter systems also play an important role. Indeed, the serotonin system may be particularly relevant in this regard because of the well recognized effects on appetite (Blundell, 1986; Dourish *et al.*, 1986) and reciprocal regulatory interactions with the HPA axis (Dinan, 1996; Grignaschi *et al.*, 1996; Lowry *et al.*, 2000). This may underpin some of the response to treatment. Preliminary evidence suggests that olanzepine, which acts on the serotonin system at multiple sites, may improve weight gain during refeeding in AN (Hanson, 1999; La Via *et al.*, 2000; Mehler *et al.*, 2000). There is also weak evidence to support the use of fluoxetine in preventing relapse after weight restoration (Kaye *et al.*, 2001). As in the treatment of depressive disorder, antidepressant modulation of GR levels, and thus HPA axis function, could be as important as serotonergic modulation for efficacy in AN.

In BN, a tendency toward overweight may arise from a variety of constitutional factors, including reduced leptin signalling from stored body fat. Overweight in the context of low self-esteem and emotional dysregulation increases the risk of engaging in weight reduction behaviours. Once initiated, food restriction gives rise to both hunger and dysphoric mood, which are key triggers for binge eating. At the central level, overactivity of orexigenic pathways in acute BN is in keeping with leptin levels that are relatively low for body mass. However, other factors are likely to contribute because orexigenic peptide levels in CSF return to normal after recovery, despite persistence of low leptin levels. The high reward value of food for those with BN may also be secondary to chronic food restriction and low leptin levels, and could serve to both establish and reinforce binge eating as a strategy for emotional regulation. Reduced satiety signalling from peripheral factors such as CCK (Devlin *et al.*, 1997) and the vagus nerve (Faris *et al.*, 2000) may impair the capacity to terminate binges, whilst the rapid fall in serum insulin and glucose associated with purging may play an important role in perpetuating binge–purge behaviour (Johnson *et al.*, 1994). However, there is no evidence currently to suggest that these are primary problems.

Understanding the biological components of appetite and weight regulation is vital if we are to develop better aetiological and treatment models for eating disorders. Functional neuroimaging, neuroendocrine and molecular genetic studies will help to further elucidate the central mechanisms maintaining low appetite and weight in AN, and the drive to overeat in BN and BED. However, emerging differences in the biology of restricting and binge–purge subtypes of AN, as well as between peripherally and centrally distributed obesity, highlight the need for good phenotypic description of study participants. A consensus definition of diagnostic subtypes, stage of illness and recovery is urgently needed.

Peptides that increase appetite and ultimately body weight have potential for the treatment of AN. Agrp analogues may be particularly interesting because of their long-lasting effect in promoting food intake and fat storage in animals. CRH antagonists may also prove fruitful therapeutic options for the treatment of AN. Safe and effective anti-obesity drugs that target central orexigenic pathways are likely to proliferate in the future, providing potentially useful treatments for BN and BED.

Neuroimmunology of Eating Disorders

Jan Pieter Konsman and Robert Dantzer

INTRODUCTION

Eating is a behaviour familiar to all of us. Despite this familiarity, regulation of eating in humans is complex and involves biological, psychological, social as well as cultural factors (Fischler, 2001). Most of our current knowledge concerning the biological factors involved in the regulation of food intake has been gained from investigations of eating behaviour in animals. The results obtained have recently been incorporated into a neurobiological model of the regulation of food intake (see for review Schwartz *et al.*, 2000) that most probably bears important implications for a better understanding of eating behaviour and disorders in humans.

In this paper, we will, therefore, first review the neurobiological basis of the regulation of food intake before addressing two of the most common causes of anorexia in the absence of lesions or dysfunction of the gastro-intestinal tract, namely anorexia associated with infectious diseases and anorexia nervosa. Factors inhibiting food intake will be discussed in more depth than signals promoting eating since the focus of this paper is on anorexia. Besides, our present day understanding of how feeding is initiated is limited and the prevailing model of the regulation of food intake is based on the assumption that ingestion of food generates signals that subsequently inhibit eating.

NEUROBIOLOGY OF EATING

Food intake needs to be regulated to assure the supply of amino acids and energy to cells throughout the body. All macronutrients, carbohydrates, lipids and proteins, can provide usable cellular energy, albeit with different efficiencies. Most cells are, however, capable of using carbohydrates in the form of glucose or lipids in the form of free fatty acids as energy substrates.

The early so-called depletion–repletion model of food intake postulated that organisms start eating when energy substrates, for example glucose levels, are low (depleted) and stop ingesting food as soon as energy substrate levels are replenished. According to this model a relationship should exist between the size of a meal and the time passed since the preceding meal. However, no such relationship is found when measuring meal size and the interval between meals in rats with free access to food (Le Magnen and Tallon, 1966). Instead, a relationship exists between the size of a meal and the time lag before the rat eats its next meal (Le Magnen and Tallon, 1966). These findings indicate that the ingestion of a meal generates satiety signals that suppress food intake.

Cholecystokinin Acts as a Satiety Signal Reducing Meal Size

During the 1970s and 1980s it became clear that the gut peptide cholecystokinin (CCK) constitutes a meal-generated satiety signal. CCK is synthesized in endocrine cells within the mucosa of the proximal small intestine (Buchan *et al.*, 1978) and secreted upon ingestion of food (Liddle *et al.*, 1985). Intraperitoneal administration of a synthetic peptide corresponding to the eight amino acids at the C-terminal portion of CCK (CCK-8) in rats just prior to food presentation causes a dose-dependent decrease in meal size, but not in water intake (Gibbs *et al.*, 1973). CCK-8 administered intravenously to humans also induces earlier satiation without reports or signs of sickness (Geary *et al.*, 1992).

Low concentrations of CCK-8 act on afferent fibres of the vagus nerves to reduce food intake in rats (Smith *et al.*, 1981). Vagal afferent fibres express CCK receptors (Lin and Miller, 1992) and terminate in the brain stem at the level of the nucleus of the solitary tract. Lesioning this brain structure attenuates the satiety effects of CCK-8 (Edwards *et al.*, 1986) indicating that it plays a role in the CCK-induced reduction of meal size. Although forebrain structures most probably influence brain stem circuits activated by CCK-8, it is important to note that brain stem circuits are sufficient to mediate the inhibitory effects of peripheral CCK-8 administration on sucrose intake (Grill and Smith, 1988).

More recently, with the development of CCK receptor antagonists, it has become possible to test the hypothesis that abdominal release of endogenous CCK constitutes a satiety signal. The expected effect of a CCK receptor antagonist would be to increase meal size. Indeed, administration of a CCK_A (CCK type A) receptor antagonist increases meal size by about 25% in rats (Brenner and Ritter, 1995). It is important to note here that these results were obtained with an antagonist that did not enter the brain, since CCK receptors are also present in the CNS. Altogether, these findings indicate that the peripheral release of CCK after ingestion of food constitutes a satiety signal suppressing eating by acting on the vagus nerve and activating hind brain circuits.

Leptin Constitutes an Adiposity Signal Inhibiting Long-Term Meal Size

Although CCK clearly inhibits the ingestion of food during a meal, systematic administration of CCK-8 to rats at the start of each spontaneous meal turns out to have no effect on body weight, since animals eat meals more frequently (West *et al.*, 1984). This indicates that other factors regulate eating over a longer time span to maintain energy stores. The hypothesis that the regulation of food intake is linked to the amount of energy stocked, for example in the form of fat, was first formulated in the 1950s by Kennedy (1953). This so-called lipostatic model of food intake and energy balance postulates that the organism eats to maintain a set point level of body adiposity. This stock of energy in the form of fat is used to meet the energetic demands of the organism. In this model the existence of adiposity signals reflecting the amount of energy stocked in the form of fat was postulated and proposed to act on

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

the brain to inhibit feeding and body adiposity (Kennedy, 1953). These adiposity signals are integrated with other factors regulating food intake, such as satiety signals (see above), energy needs as well as the physiological state of the animal and food properties.

It was not until the mid 1990s that a factor proportional to body fat mass was identified in the form of leptin, also known as ob protein (Frederich *et al.*, 1995; Zhang *et al.*, 1994). Leptin is released mainly by subcutaneous and visceral adipose tissue. Leptin levels increase with feeding and quickly fall after starvation (Ahima *et al.*, 1996; Maffei *et al.*, 1995). Mice carrying mutations in the leptin gene or its receptor are obese (Chen *et al.*, 1996; Zhang *et al.*, 1994) indicating that leptin inhibits feeding and adiposity. Indeed, repeated Intraperitoneal administration of leptin reduces food intake and, in contrast to CCK (see above), induces weight loss in leptin deficient mice, but not in mice lacking the leptin receptor (Halaas *et al.*, 1995). Moreover, repeated subcutaneous administration of a stabilized form of leptin in rats reduces meal size through several days after the last injection and does not induce the compensatory overeating (Kahler *et al.*, 1998) that develops after repeated CCK administration (see above). Interestingly, injection of regular leptin into the lateral brain ventricle of the rat reduces meal size for at least 12 hours and at much lower doses than needed after peripheral injection (Flynn *et al.*, 1998). Moreover, neutralization of leptin in the CNS augments food intake in rats without any subsequent compensatory changes in eating patterns (Brunner *et al.*, 1997). These findings clearly show that leptin acts in the CNS to inhibit meal size in both the short and long term.

The Adiposity Signal Leptin Interacts with the Satiety Signal CCK, but Inhibits Long-Term Food Intake by its Action on the Hypothalamus

One of the predictions of the lipostatic model for the regulation of food intake is that adiposity signals, such as leptin, are integrated with satiety signals, such as CCK (see above). Leptin acts in the CNS to inhibit food intake (Brunner *et al.*, 1997) and its receptors are found at the level of the nucleus of the solitary tract (Elmquist *et al.*, 1998). Given that this brain structure is involved in the satiety effects of CCK (Edwards *et al.*, 1986), leptin might interact with the brain circuits mediating the effects of CCK to inhibit food intake. Indeed, intracerebroventricular administration of leptin at a dose that by itself does not affect food intake, increases the suppression of intake induced by Intraperitoneal injection of CCK-8 (Emond *et al.*, 1999). Moreover, combined leptin and CCK-8 treatment augments the number of activated neurons in the nucleus of the solitary tract compared with either leptin or CCK-8 treatment alone (Emond *et al.*, 1999) indicating that leptin and CCK signals interact at the level of the brainstem (see Figure XXIII-4.1).

However, intracerebroventricular injection of leptin still inhibits food intake in rats lacking the CCK_A receptor (Niimi *et al.*, 1999), the receptor responsible for the satiety effects of CCK (see above). In addition, intracerebroventricular leptin induces activation of hypothalamic structures in these rats (Niimi *et al.*, 1999) indicating that leptin inhibits food intake by acting on the hypothalamus independently from CCK. Strong expression of leptin receptors in the CNS is found in the arcuate nucleus at the basis of the hypothalamus in both humans and rodents (Couce *et al.*, 1997; Elmquist *et al.*, 1998). This hypothalamic structure that regulates long-term food intake and energy balance (Dawson and Lorden, 1981; Morris *et al.*, 1998) is pivotal in mediating the anorectic effects of leptin, since lesions of the arcuate nucleus prevent the inhibitory effects of leptin administered into the lateral brain ventricle (Tang-Christensen *et al.*, 1999). Moreover, intravenously injected leptin is taken up by the arcuate nucleus (Banks *et al.*, 1996) possibly by diffusion from the nearby median eminence which lacks a blood-brain barrier. Taken together, these results indicate that leptin acts as a hormone at the level of the arcuate hypothalamus to reduce food intake (see Figure XXIII-4.1).

The Arcuate Hypothalamus Contains Two Neuronal Populations Exerting Opposite Effects on Food Intake and Fat Tissue and Senses Adiposity Signals as well as Energy Needs

Leptin receptors in the arcuate nucleus of the hypothalamus are found on two populations of neuropeptide-expressing neurons (Hakansson *et al.*, 1998; Mercer *et al.*, 1996). The first population expresses neuropeptide Y and projects to the paraventricular nucleus of the hypothalamus (Baker and Herkenham, 1995). Local injection of neuropeptide Y into the paraventricular nucleus promotes food intake (Stanley and Leibowitz, 1985) and inhibits sympathetic output to fat tissue (Egawa *et al.*, 1991), thus inhibiting catabolic pathways (Schwartz *et al.*, 2000). Conversely, food intake is decreased by damaging arcuate NPY neurons immunologically (Burlet *et al.*, 1995) or by local administration of NPY antigens oligonucleotides (Akabayashi *et al.*, 1994).

The effects of NPY are countered by a second population of arcuate neurons that also project to the paraventricular hypothalamus, but express the neuropeptide alpha-melanocyte-stimulating hormone (α-MSH) (Cowley *et al.*, 1999), a product of the pro-opiomelanocortin gene. α-MSH acts on so-called melanocortin receptors and intracerebroventricular injection of a melanocortin-4 receptor agonist, that mimics α-MSH action, inhibits food intake (Murphy *et al.*, 1998) and increases sympathetic nervous system outflow to adipose tissue (Haynes *et al.*, 1999). Conversely, administration of a melanocortin-4 receptor antagonist into the paraventricular nucleus stimulates feeding (Giraudo *et al.*, 1998).

Feeding increases metabolic rate by 25–40% (Shibata and Bukowiecki, 1987; Sims and Danforth, 1987), and decreases NPY contents in the paraventricular hypothalamus while increasing POMC expression in the arcuate nucleus (Hagan *et al.*, 1999; Kalra *et al.*, 1991). Food restriction, on the other hand, increases NPY, but decreases POMC expression in the arcuate nucleus (Brady *et al.*, 1990; Mizuno *et al.*, 1998; Schwartz *et al.*, 1993) and leads to a reduction in energy expenditure (Leibel *et al.*, 1995).

As might be predicted from its inhibitory effects on food intake, leptin decreases arcuate levels of neuropeptide Y (Stephens *et al.*, 1995; Wang *et al.*, 1997) (see insert Figure XXIII-4.1). Leptin receptors are also found on neurons expressing the pro-opiomelanocortin gene that gives rise to α-MSH in the arcuate nucleus (Cheung *et al.*, 1997) and leptin increases expression of pro-opiomelanocortin (Schwartz *et al.*, 1997). Furthermore, the anorectic effect of leptin directly injected into the brain ventricle is attenuated by administration of a melanocortin receptor antagonist (Seeley *et al.*, 1997) indicating that leptin inhibits food intake by stimulating α-MSH release from arcuate neurons (see insert Figure XXIII-4.1).

In summary, leptin inhibits food intake and promotes fat breakdown by stimulation of an α-MSH containing projection and inhibition of a neuropeptide Y-expressing projection from the arcuate to the paraventricular nucleus of the hypothalamus. In addition to sensing energy supplies via leptin receptors, the arcuate nucleus also contains receptors for growth hormone (Minami *et al.*, 1993), corticosterone (Fuxe *et al.*, 1987) and the pro-inflammator cytokine interleukin-1 (Ericsson *et al.*, 1995). These factors signal energy needs in conditions of growth, stress and disease. The presence of their receptors at the level of the arcuate nucleus indicates that the integration of adiposity signals and factors signalling energy needs, as postulated in the lipostatic model of the regulation of food intake (see above), occurs at the level of the arcuate hypothalamus.

Rewarding and Motivational Aspects of Feeding

In addition to its energetic value, food has rewarding properties. In fact, it has been suggested that the energetic value and rewarding

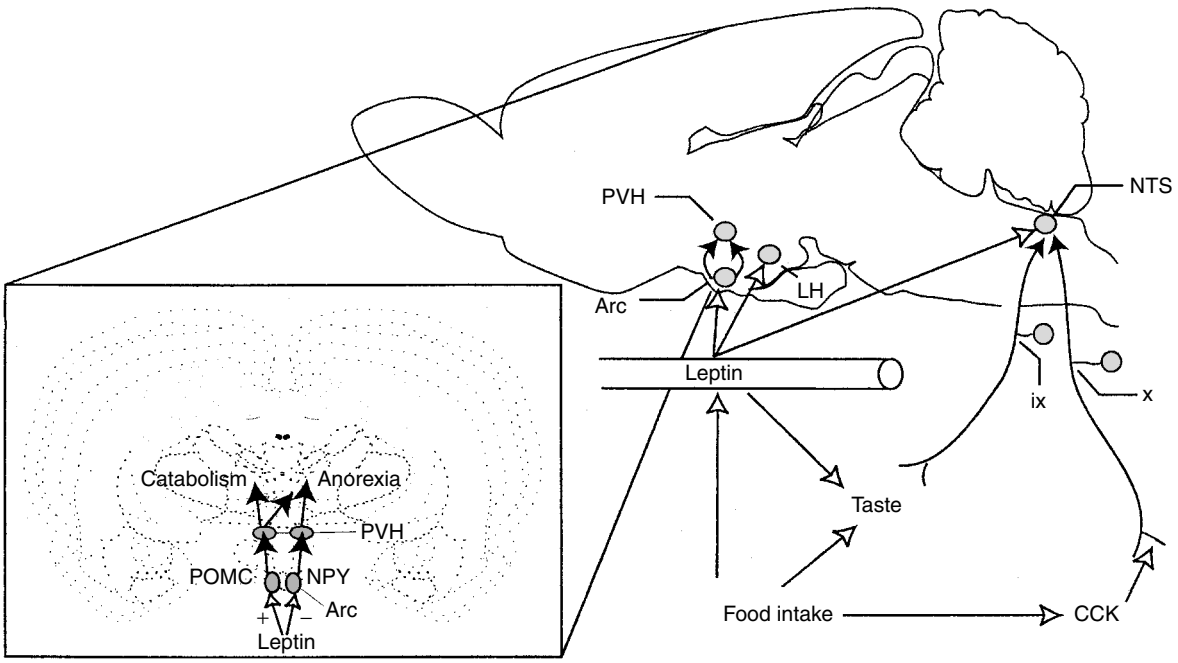

Figure XXIII-4.1 Saggital view of the rat brain to illustrate mechanisms by which leptin reduces food intake. Ingestion of food intake leads to an increase in intestinal cholecystokinin and circulating leptin. At the level of the nucleus of the solitary tract in the brainstem, leptin augments the anorectic signal induced by action of cholecystokinin on the vagus nerve. Leptin also acts at the level of the arcuate hypothalamic nucleus to inhibit the neuropeptide Y containing neuronal projection to the paraventricular hypothalamus which promotes food intake (see insert showing a coronal section at the level of the arcuate and paraventricular hypothalamus). At the same time, leptin increases the synthesis of α-melanocyte-stimulating hormone, a product of the pro-opiomelanocortin gene in neurons of the arcuate hypothalamus. These latter neurons project to the paraventricular hypothalamus to activates anorectic and catabolic pathways. Other mechanisms underlying the anorectic effects of leptin may include modulation of lateral hypothalamic (LH) circuits mediating the rewarding properties of food intake and inhibition of sweet taste sensitivity (see text). Open arrowheads indicate humoral or paracrine action, closed arrowheads neuronal projections. Abbreviations: ix: glossopharyngeal nerve, x: vagus nerve, Arc: arcuate hypothalamic nucleus, CCK: cholecystokinin, LH: lateral hypothalamus, NPY: neuropeptide Y, NTS: nucleus of the solitary tract, POMC: pro-opiomelanocortin, PVH: paraventricular hypothalamus. Drawings of rat brain sections were modified from Swanson (1998)

properties of a food are correlated in that highly palatable foods, such as chocolate, are more energy dense (Drewnowski, 1998). Palatability increases appetite and thus food intake and can be measured as the perceived pleasantness of a food or the intent to eat in humans (Drewnowski, 1998).

The term reward, which connotes pleasure, infers a subjective state and is therefore strictly spoken problematic when referring to animal experiments. Obviously, an animal cannot report the perceived pleasantness of a food or its intent to eat. However, since this term is widely used in the scientific literature, it will also be employed here. Despite this fundamental difficulty, there are ways to measure the rewarding properties of food in laboratory animals. One approach is to electrically activate the brain regions that mediate reward by a micro-electrode when the animal presses an operant lever and to study how natural stimuli like food affect the rate of lever pressing. It is well known that animals work vigorously in the form of lever pressing in order to trigger electrical stimulation of certain brain regions, for example the lateral hypothalamus, as if the stimulation had rewarding properties (Shizgal, 1997). When rats are forced to choose between brain-stimulation reward and a natural reward in the form of a sucrose solution, they choose sucrose when the electrical stimulation is weak. However, at higher stimulation frequencies, rats prefer brain stimulation over sucrose ingestion (Shizgal, 1997).

The rewarding properties of a stimulus also depend on the physiological state of the organism. A hungry animal will choose a more concentrated sucrose solution rather than a less concentrated solution, whereas a sated animal is likely to ingest both solutions with indifference, and an overfed animal chooses not to ingest at all. A hungry animal is also more sensitive to stimulation of the lateral hypothalamus (Abrahamsen *et al.*, 1995; Carr and Papadouka, 1994). Furthermore, mildly food-deprived rats choose to ingest sucrose and stimulate their lateral hypothalamus rather than apply brain stimulation alone (Shizgal, 1997). Since brain stimulation and natural stimuli compete with and add to each other, both signals are likely to activate the same brain circuits that mediate reward.

Interestingly, both food reward and self-stimulation of the lateral hypothalamus increase dopamine release in the nucleus accumbens (Hernandez and Hoebel, 1988). Dopamine containing terminals at the level of the nucleus accumbens are part of the so-called mesolimbic dopamine system that plays an important role in mediating reward (Berridge and Robinson, 1998). Finally, the findings described above are not restricted to the ingestion of sucrose, but also occur when a saline solution is provided to salt-deprived animals (Shizgal, 1997). Altogether, these data are in accordance with the hypothesis that self-stimulation of the lateral hypothalamus is an appropriate model to study reward mechanisms in animals.

From the experiments described above it is also clear that both the properties of a stimulus, such as sweetness, and the physiological state of the organism determine the rewarding properties of that stimulus and the motivational state of the animal. The animal's degree of motivation can be assessed by its capacity to work for a goal, for example by studying the number of times the animal is willing to press a lever in order to obtain a food pellet.

Leptin Modulates Brain Circuits Involved in the Rewarding Aspects of Feeding

According to the lipostatic model of the regulation of food intake, adiposity signals, such as leptin, should interact with the physiological state of the animal and food properties. Intracerebroventricular administration of leptin reduces intake of a sucrose solution from a bottle in rats (Ammar *et al.*, 2000) indicating that leptin is likely to act on those brain circuits that mediate the rewarding properties of food.

However, leptin also inhibits the sensitivity for sweet taste in peripheral taste cells of rodents (Kawai *et al.*, 2000). An alternative explanation would therefore be that leptin does not modulate brain circuits mediating reward, but merely alters the taste of a sucrose solution (see Figure XXIII-4.1). Although the modulation of taste by leptin most probably contributes to the reduction of sucrose intake, evidence exists to indicate that this is not the only factor. As discussed above, food deprivation enhances hypothalamic self-stimulation, an operant model to study reward in animals. Interestingly, intracerebroventricular injection of leptin inhibits the deprivation-induced enhancement of self-stimulation (Fulton *et al.*, 2000) indicating that leptin does indeed modulate brain circuits mediating reward (see Figure XXIII-4.1).

So, in addition to its interaction with brain circuits controlling energy balance at the level of the arcuate nucleus of the hypothalamus, leptin also interacts with CNS circuits mediating the rewarding properties of food. Although the brain circuits that mediate reward are not yet fully unravelled, leptin might act directly on the lateral hypothalamus as its receptors are expressed present in this structure (Elmquist *et al.*, 1998). In contrast to what occurs in the arcuate nucleus which is located close to the median eminence where the blood-brain barrier is absent, circulating leptin does not appear to reach the lateral hypothalamus by diffusion from the blood. Instead, an active transport system involving a shorter form of the leptin receptor might be responsible for leptin action on the lateral hypothalamus (Banks *et al.*, 1996).

ANOREXIA ASSOCIATED WITH INFECTIOUS DISEASES

Suppression of food intake is seen in humans and animals with a variety of systemic diseases as well as with more localized infections (Hart, 1988). By decreasing their food intake the organism reduces the chance of raising plasma concentrations of free iron, which is an essential element that many bacteria need to replicate (Weinberg, 1984). Low iron levels alone do not impair bacterial growth, but proliferation of bacteria is inhibited when iron levels are low and body temperature is elevated (Kluger and Rothenburg, 1979). This is probably due to decreased bacterial synthesis of iron-chelating compounds at temperatures above 37°C (Garibaldi, 1972). So, anorexia together with fever limits bacterial proliferation.

The low incidence of infections in iron-deficient humans is in accordance with this hypothesis. In the late 1970s Murray *et al.*, described a five-fold increase in the incidence of infectious episodes after treatment of iron-deficient nomads with iron (Murray *et al.*, 1978). Based on this finding and their experience with famines in Africa these authors proposed that therapeutic refeeding during infection can be harmful (Murray *et al.*, 1978). When this hypothesis was tested experimentally, it was indeed found that forced feeding of mice during acute bacterial infection reduces survival time and increases mortality (Murray and Murray, 1979), while food deprivation increases survival (Wing and Young, 1980). These findings indicate that anorexia upon acute infection is an adaptive response.

Anorexia during disease has long been thought to be either the consequence of fever or to result from a general weakness of the sick individual. However, hyperthermia alone does not suppress food intake (McCarthy *et al.*, 1984), indicating that anorexia during disease is not a necessary consequence of fever. Since muscle weakness and pain are common symptoms of infectious diseases (Hart, 1988), anorexia during disease might be due to difficulty or pain interfering with hoarding of food. Hoarding of food requires a high locomotor activity, but allows rodents to consume food safely and to anticipate food scarceness. When rats that are dependent for their food intake on the amount of food they hoard are injected with bacterial fragments, food hoarding decreases only by 22%, whereas food consumption drops by 70–75% (Aubert *et al.*, 1997). These findings indicate that the difficulty to move does not play a major factor in anorexia during infectious disease.

During infectious disease anorexia is accompanied by fever as a result of increased heat production in adipose tissue. However, normally when food intake diminishes, adipose tissue metabolism is decreased, a response mediated by the effects of low circulating leptin on the central nervous system (see above). The concomitant occurrence of fever and anorexia suggests, therefore, that the central nervous circuits controlling food intake and energy metabolism are altered during infectious disease.

Interleukin-1β Acts on the Vagus Nerve to Induce Anorexia

Soluble factors secreted by immune cells are proposed to act on the nervous system to induce anorexia during infectious disease (Hart, 1988). One of the soluble factors secreted by tissue macrophages upon detection of bacterial fragments is the pro-inflammatory cytokine interleukin-1β (IL-1β). Intraperitoneal administration of IL-1β induces a reduction in total caloric intake thus mimicking the effect of injection of bacterial fragments (Aubert *et al.*, 1995). To explain its anorectic effects, IL-1β was proposed to act on vagus nerve (Dantzer, 1994). The first evidence indicating that IL-1β affects functioning of the vagus nerve was obtained by Niijima, who showed an increase in firing frequency of the hepatic vagus nerve after injection of IL-1β into the hepatoportal system (Niijima, 1996).

Based on Niijima's initial findings, experiments were performed in our laboratory to study the role of subdiaphragmatic vagal branches in anorexia associated with infectious diseases. A modified Skinner box was used to study the effects of bacterial fragments or IL-1β on food-motivated behaviour in mice of which the vagus nerve was sectioned under the diaphragm. The depressing effects of Intraperitoneal administration of bacterial fragments or IL-1β on a food-motivated lever-pressing response were found to be abolished by subdiaphragmatic vagotomy (Bret-Dibat *et al.*, 1995) and were independent from the well-known anorectic effect of cholecystokinin on the vagus nerve (Bret-Dibat and Dantzer, 2000). These findings indicate that IL-1β acts directly on the vagus nerve to induce anorexia during infectious disease. The discovery of IL-1 receptors on cell bodies of the vagus nerve (Ek *et al.*, 1998) is in accordance with the idea of direct IL-1β action on the vagus nerve (see Figure XXIII-4.2).

The vagus nerve projects to the nucleus of the solitary tract in the brainstem which plays an important role in meal termination (Treece *et al.*, 1998, 2000). Peripheral administration of bacterial fragments (Gaykema *et al.*, 1995) or IL-1β (Ericsson *et al.*, 1994) activates in part the same neurons as the ingestion of a meal (Rinaman *et al.*, 1998) or a physiological dose of cholecystokinin (Rinaman *et al.*, 1993) (see above). However, an additional neuronal population is activated at the level of the nucleus of the solitary tract in response to immunological stimuli. This neuronal population contains the neuropeptide glucagon-like peptide 1 (GLP-1) and seems to mediate nausea during illness (Rinaman, 1999). Moreover, intracerebroventricular administration of an antagonist of GLP receptors attenuates anorexia induced by an Intraperitoneal injection

of bacterial fragments as well as activation of the paraventricular nucleus of the hypothalamus (Rinaman, 2000). This latter structure is important in the control of food intake and energy metabolism (see above), since neuropeptide containing neurons in the paraventricular nucleus of the hypothalamus have been proposed to give rise to pathways that stimulate breakdown of body fat and promote anorexia (Schwartz *et al.*, 2000). In addition to abolishing the anorectic effects of Intraperitoneal administration of bacterial fragments, subdiaphragmatic vagotomy prevents activation of neurons in the nucleus of the solitary tract as well as in the paraventricular nucleus of the hypothalamus (Konsman *et al.*, 2000). Altogether, these findings indicate that during infectious disease IL-1β acts on the vagus nerve to activate GLP-1 neurons in the nucleus of the solitary tract that signal nausea and by consequence induce anorexia.

Although subdiaphragmatic vagotomy prevents the decrease in food-motivated behaviour in response to Intraperitoneal injection of a low dose of IL-1β, it only attenuates the effect of a higher dose (Bret-Dibat *et al.*, 1995). Moreover, vagotomy does not affect activation of neurons in nucleus of the solitary tract and the paraventricular hypothalamus after intravenous injection of LPS or IL-1β (Ericsson *et al.*, 1997; Wan *et al.*, 1994). These observations suggest that still other pathways exist by which IL-1 can act on the central nervous system to induce anorexia during disease.

Interleukin-1β Acts in the Central Nervous System to Induce Anorexia

Observations by several authors show that IL-1 receptors are expressed in the central nervous system (Cunningham *et al.*, 1992; Ericsson *et al.*, 1995; Konsman *et al.*, 2000; Parnet *et al.*, 1994; Yabuuchi *et al.*, 1994), thus raising the possibility that IL-1β acts in the central nervous system to induce anorexia. An experiment was designed in our laboratory to study the role of brain IL-1 receptors in anorexia during infectious disease by infusing an IL-1 receptor antagonist into the lateral brain ventricle of mice after Intraperitoneal injection of bacterial fragments. Intracerebroventricular infusion of the IL-1 receptor antagonist was indeed found to attenuate the reduction in food intake induced by bacterial fragments (Layé *et al.*, 2000).

Although these findings clearly indicate that IL-1 acts in the central nervous system to mediate anorexia during infectious disease, they also give rise to the question as to how IL-1β enters the central nervous system. Blood-borne IL-1β, with its relatively high molecular weight and hydrophilic profile, cannot cross the blood-brain barrier passively. Therefore, circulating IL-1β can only enter the brain by active transport (Banks *et al.*, 1991) or by leakage at the level of circumventricular organs where the blood-brain barrier is non-functional. Circumventricular organs contain fenestrated capillaries that by consequence do not form a functional blood-brain barrier (Gross, 1992). Circulating IL-1β can thus leak from the blood stream into circumventricular organs and possibly into adjacent central nervous tissue. Circumventricular organs also contain phagocytic cells (Murabe *et al.*, 1981) and express receptors for bacterial fragments (Laflamme and Rivest, 2000) raising the possibility that these organs synthesize IL-1β during infectious disease. IL-1β immunoreactivity is, indeed, found in phagocytic cells of circumventricular organs after Intraperitoneal injection of bacterial fragments (Konsman *et al.*, 1999).

One of the circumventricular organs, the median eminence is juxtaposed to the arcuate nucleus of the hypothalamus, a structure involved in the integration of factors signalling energy stocks and needs (see above). The part of the arcuate nucleus of the hypothalamus just adjacent to the median eminence contains capillaries rich in vesicles suggesting transport of molecules through these cells (Gross, 1992). Furthermore, these capillaries are surrounded by perivascular spaces that are thought to be confluent with those around fenestrated capillaries in the median eminence (Gross, 1992), suggesting that circulating molecules reach at least this part of the arcuate hypothalamus. Physiological experiments using intravenous tracer injections in the rat revealed that the capillary and perivascular space available for blood-tissue exchange is four times larger and tissue penetration 34 times greater in the arcuate nucleus proximal to the median eminence compared to the distal arcuate nucleus (Shaver *et al.*, 1992). Since IL-1 receptor mRNA is expressed in the arcuate nucleus of the hypothalamus (Ericsson *et al.*, 1995; Konsman *et al.*, 2000), it is tempting to speculate that IL-1β acts on arcuate neurons to induce anorexia associated with infectious disease. Further research is necessary to establish which neuronal population expresses IL-1 receptors and to what extent IL-1β reaches its receptors in arcuate nucleus of the hypothalamus (see Figure XXIII-4.2).

In summary, IL-1β seems to induce anorexia during infectious disease by provoking nausea via its action on the vagus nerve and possibly by altering central nervous circuits regulating food intake and energy metabolism at the level of the arcuate nucleus of the hypothalamus. In contrast to leptin (see above), IL-1β does not modulate brain circuits mediating reward directly (Anisman *et al.*, 1998). However, both the administration of bacterial fragments and IL-1β do induce a rise in plasma levels of leptin at later time points (Faggioni *et al.*, 1998; Sarraf *et al.*, 1997). The role of leptin in anorexia associated with infectious diseases needs therefore to be addressed in future studies (see Figure XXIII-4.2).

ANOREXIA NERVOSA

Anorexia nervosa is an eating disorder common among teenage girls and characterized by self-starvation and weight loss. This disorder has a very poor prognosis with less than 50% chance of recovery and a mortality rate of 9% (Woodside, 1995). Despite intensive research and numerous hypotheses, the causes of this disorder remain at present unknown.

In view of the anorectic effects of pro-inflammatory cytokines during infectious and probably neoplasic diseases (see above), it was tempting to hypothesize that pro-inflammatory cytokines play a role in the aetiology of anorexia nervosa (Holden and Pakula, 1996; Vaisman and Hahn, 1991). Despite numerous studies aimed at measuring circulating cytokines or *in vitro* cytokine secretion by white blood cells, no clear-cut conclusion can be drawn from these studies (Marcos, 1997). Among the difficulties in interpreting these findings are the fact that cytokines may have paracrine or autocrine effects that do not result in elevated plasma levels and the fact that starvation alters cytokine production (Grimble, 1994). Besides, virtually all reported alternations of immune responses in anorexia nervosa patients improve with refeeding (Marcos, 1997) suggesting that they are a consequence rather than a cause of anorexia nervosa.

A closer look at the symptoms of anorexia nervosa and the non-specific symptoms of infectious disease indicates, however, that it is rather unlikely that pro-inflammatory cytokines play an important role in the aetiology of anorexia nervosa. Anorexia induced by bacterial fragments or interleukin-1 concerns mostly protein intake and not carbohydrates (Aubert *et al.*, 1995). On the contrary, the diet of a typical anorexia nervosa patient is deficient in carbohydrates, while relatively sufficient in protein and fat (Crisp and Stonehill, 1971; Russell, 1967). Another striking difference between anorexia nervosa and infectious diseases is that both infection and pro-inflammatory cytokines provoke depression of behavioural activity (Bluthe *et al.*, 1992), whereas anorexia nervosa is characterized by increased physical activity (Davis *et al.*, 1994). Taken together, these findings indicate that it is unlikely that pro-inflammatory cytokines play a causative role in anorexia nervosa.

Although it seems at first sight counter intuitive that starvation is accompanied by enhanced physical activity, the combination

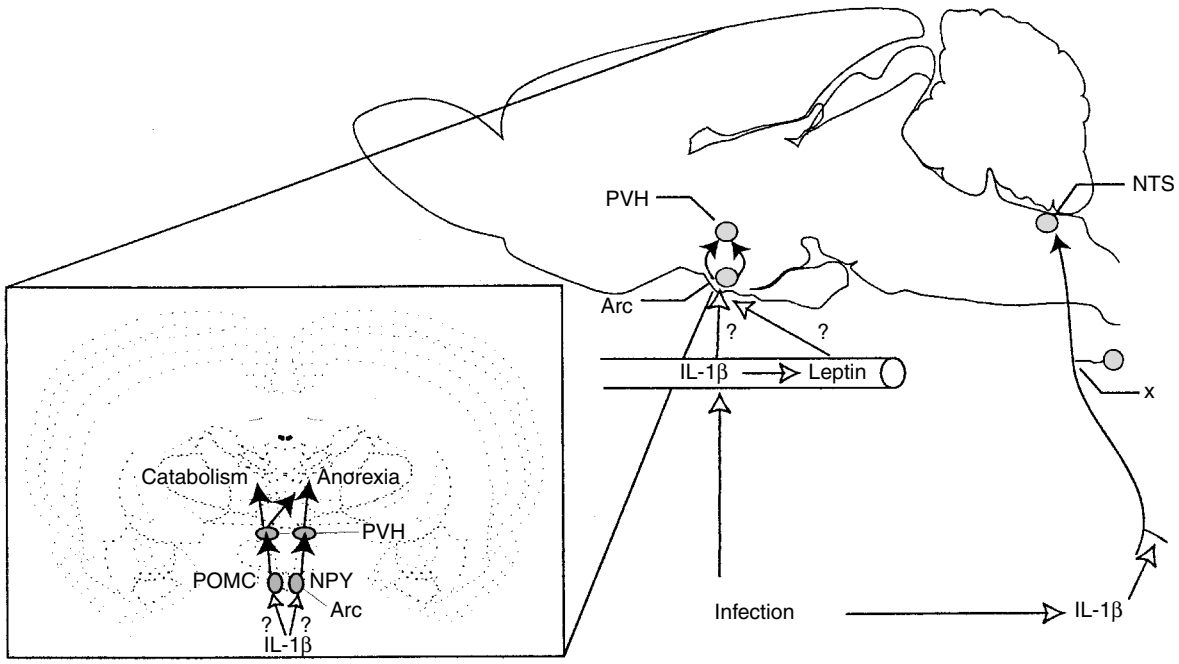

Figure XXIII-4.2 Saggital view of the rat brain to illustrate mechanisms by which interleukin-1β reduces food intake after infection. After detection of bacterial fragments by tissue macrophages, these cells produce interleukin-1β. Interleukin-1β produced by macrophages in the abdominal cavity then acts on the vagus nerve to induce anorexia. Interleukin-1β also acts directly in the brain to induce anorexia after infection. The mechanisms by which interleukin-1β acts in the brain are at present unknown. Circulating interleukin-1β or interleukin-1 produced by phagocytic cells in brain circumventricular organs may act at the level of the arcuate hypothalamus to inhibit the production of neuropeptide Y and to increase that of pro-opiomelanocortin. Interestingly, interleukin-1β induces a rise in circulating levels of leptin, raising the possibility that leptin also plays a role in mediating infection-induced anorexia. Abbreviations and arrowheads see Figure XXIII-4.1

of these two symptoms was considered to be most striking and distinctive in the eyes of Sir William Gull, who coined the disorder anorexia nervosa at the end of the 19th century (Bergh and Sodersten, 1996, 1998). Recent studies in both humans and animals suggest that enhanced physical activity may indeed play an important role in the development and maintenance of anorexia. Analysis of interviews with 32 anorexia nervosa patients revealed that 78% engaged in excessive exercise, 60% were competitive athletes prior to the onset of anorexia nervosa, 60% engaged in sports or exercise before dieting and 75% reported that their physical activity steadily increased during the period when food intake and weight loss decreased the most (Davis *et al.*, 1994). Moreover, earlier studies pointed out that both reducing food intake and exercise are rewarding and agreeable to the patient (reviewed in Bergh and Sodersten, 1996). Interestingly, when rats that have restricted access to food are given access to a running wheel, they also engage in excessive exercise, lose control over body weight and eventually even die (Morrow *et al.*, 1997). The findings both in humans and animals indicate that increased physical activity plays an important role in maintaining and perhaps even in the development of reduced food intake in anorexia nervosa.

The inverse relationship between food intake and energy expenditure indicates that, just like during infectious diseases, the inverse relationship between energy stocks reflected by leptin levels and food intake that normally regulates food intake is overridden in anorexia nervosa. In the case of anorexia nervosa this may be due to an increased release of endogenous opioids or of the neuropeptide corticotropin-releasing hormone. Interestingly, plasma endogenous morphine activities are increased in anorexia nervosa patients (Marrazzi *et al.*, 1997). Furthermore, injections of morphine can reduce food intake when animals are food deprived or have been engaged in intense physical activity (Gulati *et al.*, 1991; Sanger and McCarthy, 1980; White *et al.*, 1977). So, starvation and overactivity might potentate one another through the release of endogenous opioids. In view of the fact that morphine injection increases dopamine release in the nucleus accumbens (Rada *et al.*, 1991) which plays an important role in mediating reward (see above), it can be hypothesized that the rewarding properties of food restriction and exercise in anorexia nervosa are due to activation of brain circuits associated with reward (Bergh and Sodersten, 1996).

Another neuropeptide that may play a role in the association of reduced food intake and increased activity typical of anorexia nervosa is corticotropin-releasing hormone. This peptide controls the activity of the hypothalamus-pituitary adrenal axis, but is also involved in other manifestations of responses to stress (Dunn and Berridge, 1990). Interestingly, corticotropin-releasing hormone is involved in the reduction of food intake after exercise in rats (Rivest and Richard, 1990). In view of the elevated concentrations of corticotropin-releasing hormone in cerebrospinal fluid of anorexia nervosa patients (Kaye *et al.*, 1987), this neuropeptide may indeed play a role in maintaining reduced food intake in anorexia nervosa.

CONCLUSION

There is now ample evidence to suggest that pro-inflammatory cytokines are important mediators of the profound alterations in food intake and energy metabolism that develop during infection and probably during wasting syndromes associated with cancer and AIDS (Argilés and López-Soriano, 1999; Chang *et al.*, 1998). A role for cytokines in other pathological conditions such as geriatric cachexia is also likely especially in view of the increased production of pro-inflammatory cytokines that occurs with ageing (Yeh and

Schuster, 1999). In all these cases, however, the mechanisms of effects of cytokines have not yet been fully elucidated, and their exact targets within the central nervous system remain to be determined. Despite their potent anorectic and metabolic effects, cytokines do not appear to play a major role in anorexia nervosa.

Psychophysiology and Eating Disorders

Patricia P. Sanchez Gomez, Nicholas A. Troop and Janet L. Treasure

INTRODUCTION

For psychiatric disorders such as eating disorders in which psychological conflicts seem to be essentially played out on the body, psychophysiology is an important avenue of exploration. Apparently abnormal behaviours in relation to food and weight may be associated with an abnormal psychophysiological response to such stimuli.

One advantage of taking psychophysiological measures, is that this approach is relatively objective and may therefore overcome some of the characteristic biases of other techniques (Lattimore, Gowers and Wagner, 2000) such as the confounding in self-report measures caused by patients' motivational states (e.g. trying to make sense of the illness or even to punish/reward a therapist) and co-morbidity with mood or personality disorders. For example, several studies have shown elevated rates of alexithymia in individuals with eating disorders (Bourke *et al.*, 1992; Schmidt, Jiwany and Treasure, 1993). Alexithymia is a personality construct denoting difficulties in identifying and expressing feelings, an impoverished imaginative life, and an externally oriented cognitive style with thoughts characterized by pragmatic contents (Taylor *et al.*, 1996; Corcos *et al.*, 2000). Individuals displaying these characteristics may systematically misreport their inner states. Thus an objective assessment of emotional responses to food stimuli by monitoring of indices of autonomic arousal can be informative. Among these indices heart rate, blood pressure, skin conductance, finger temperature, respiration and eye movement variability are the most widely used (Léonard *et al.*, 1998; Parrott and Hertel, 1999).

There has been a relative lack of psychophysiological research in patients with either anorexia or bulimia nervosa. However, eating disorders can be set within a dimensional framework in which the clinical conditions merge on the continuum of eating behaviour from dietary restraint to overeating and on the continuum of body weight from emaciation to obesity. Therefore, in addition to studies using clinical groups of patients, we include in this review those studies that report on the psychophysiological responses of dieters and overeaters and in people of different weight groups.

Studies have generally used two types of provocative stimuli to elicit a physiological response. The first relates directly to the symptoms and includes food and body shapes (either real, pictorial or imagined). The second involves exposing participants to some kind of stressor such as a difficult cognitive task (such as unsolvable anagrams) or speech threat (where participants prepare a talk that they believe they will have to present to a group of judges). Below we review studies that measure psychophysiological responses to both of these kinds of stimuli. These studies are summarized in Table XXIII-5.1.

LIMITATIONS OF PSYCHOPHYSIOLOGICAL ASSESSMENT IN EATING DISORDERS

There are some limitations in using psychophysiological methods to assess the autonomic arousal in patients with eating disorders. In the first place, basal autonomic tone may differ from that of non-eating disordered women, particularly, for example, in those who are emaciated. Leptin levels are lower in those who are in a state of starvation and leptin is known to affect activity in the autonomic nervous system. Research has shown that patients with anorexia nervosa and bulimia report high levels of anxiety and depression (de Zwaan *et al.*, 1996; Phillips, Tiggeman and Wade, 1997; Godart *et al.*, 2000) and these variables should also be taken into account. Any differences in arousal between patients with eating disorders and controls could be partially due to their higher baseline levels of anxiety and depression (Léonard *et al.*, 1998; Staiger, Dawe and McCarthy, 2000).

In addition, it is often difficult to get patients with eating disorders to eat foods that they consider 'forbidden', let alone get them to consume as much as non-eating disordered groups (Williamson, 1988). Simple differences in the amount eaten may directly influence psychophysiological measures independently of any pathology. One way round this may be to ask participants to imagine or to look at pictures of food, rather than consume it. However, even here it is possible that patients with anorexia may use cognitive strategies such as avoidance.

Another variable to take into account is the individualization of food cues. As Staiger and co-workers (2000) suggest, an individual's favourite binge food may elicit a greater activation than a standard food. Although some studies have used individualized favourite foods (e.g. Bulik *et al.*, 1996; Staiger, Dawe and McCarthy, 2000) others have used standardized foods or meals (e.g. Léonard *et al.*, 1998). In studies on psychophysiological responses to stress it can also be questioned whether the stressors used approximate to the type and severity of problems that are associated with eating disorders outside of the laboratory. For example, it is severe events and difficulties (such as the ending of a relationship) that typically provoke the onset of an eating disorder rather than being taxed by mental arithmetic or preparing a brief speech. On the other hand, laboratory studies using tasks such as these have been shown successfully to disinhibit dietary restraint (e.g. Heatherton, Herman and Polivy, 1991).

Any or all of these reasons may account for why there is very little psychophysiological research in patients with anorexia nervosa or bulimia nervosa.

Furthermore, psychophysiological measurement is very complex, involving influences due to both situational and person factors. This creates variability in the data and one of the consequences is that only very salient effects can be established using psychophysiological methods. It is also difficult to control other variables that may influence results, such as the amount of food eaten prior to the

Table XXIII-5.1 Psychophysiological responses to two types of stimuli

Authors	Stimuli	Participants	Psychophysiological measures	Results
Test meal				
Williamson *et al.* (1988)	Test meal	12 BN 12 obese 24 comparison women (12 ate test meal, 12 did not) Mean ages for all the groups ranged from 21.5 to 22.0 yrs. Weight ranges: obese subjects (mean percent overweight = 28%); the two normal groups had weights from −10% to +20% under/overweight of population norms.	Heart rate Vasomotor response Skin temperature Skin resistance Forearm electromyogram	After test meal, increase in heart rate and EMG in BN women. No other significant differences.
Léonard *et al.* (1998)	Standardized test-meal	14 AN women (Age: X = 23.9; BMI: X = 16.2) 10 BN women (Age: X = 27.8; BMI: X = 21.1) 18 comparison women (Age: X = 29.3; BMI: X = 21.1)	Skin conductance Heart rate ECG	Increase in skin conductance during meal in ANs only. No other significant differences between groups.
Food cues exposure and food consumption				
Bulik *et al.* (1996)	Exposure to individualized high-risk binge food	31 BN women (Age: X = 26; BMI<30 kg m^{-2})	Salivation Blood pressure Heart rate	Pre-treatment, no change in salivation after presentation of foods. Post-treatment, increased salivary reactivity. Salivation negatively related to blood pressure, not heart rate.
Vögele and Florin (1996)	Exposure and consumption of individualized binge food	30 female binge eaters (Age: X = 27.5; BMI: X = 23.4) 30 female non-binge eaters (Age: X = 24.3; BMI: X = 22.0)	Heart rate Blood pressure Electrodermal activity Respiration rate	Binge eaters show higher reactivity than comparison women. Heart rate during food exposure predicted amount subsequently consumed.
Overduin *et al.* (1997)	Slides of favourite binge food and subject's own body	11 restrained eaters (non-clinical but disinhibitive) (Age: X = 21.5; BMI: X = 21.8) 13 unrestrained eaters (controls) (Age: X = 20.3; BMI: X = 19.9)	Skin conductance Heart rate Startle eyeblink EMG	No significant differences between groups for any stimuli on any measure.
Nederkoorn *et al.* (2000)	Exposure and consumption of favourite foods	24 healthy students (Age: X = 20.1; BMI: X = 21.5)	Heart rate Blood pressure Peripheral pulse amplitude Electrogastrography Salivation Skin conductance level Temperature	Increases in salivation, temperature, heart rate, skin conductance, diastolic and systolic blood pressure during the exposure. Same changes for saliva, temperature, blood pressure, heart rate and gastric activity during food intake. Blood pressure related to restraint during exposure to food.
Staiger *et al.* (2000)	Sight and smell or sight, smell and taste of individualized binge/favourite and neutral food	17 BN women (Age: X = 21.8; BMI: X = 22.3) 17 comparison women (Age: X = 23.5; BMI: X = 21.1)	Salivation	No significant difference between groups.
Drobes *et al.* (2001) — Study 1	Emotional and food related pictures	105 male and female students	Heart rate Skin conductance Facial EMG	Food deprivation led to greater reactivity (an enhanced startle reflex and increased heart rate) in response to food stimuli but not emotion stimuli.
Drobes *et al.* (2001) — Study 2	Emotional and food-related pictures	76 female students: Binge eaters (Age: X = 19.1; BMI: X = 22.04)	Heart rate Skin conductance	Binge eater and food-deprived groups showed startle potentiation to food cues but not emotional stimuli.

Table XXIII-5.1 (*continued*)

Authors	Stimuli	Participants	Psychophysiological measures	Results
		Restrained eaters (Age: X = 18.5; BMI: X = 21.75) Food deprived (Age: X = 18.3; BMI: X = 21.00) Food non-deprived (Age: X = 18.7; BMI: X = 22.18)		
Stress stimuli				
Cattanach *et al.* (1988)	Interpersonal conflict vignette Audiovisual conflict task Speech delivery Social interaction vignette	15 BN students 15 non-BN students Mean age for both groups: ranging from 17 to 21 yrs.	Blood pressure Pulse	No significant group differences in psychophysiological responses.
Koo-Loeb *et al.* (1998)	Paced auditory task Serial addition task Interpersonal speech task	15 BN (Age: X = 25.3; Weight: X = 130.9 pounds; Height: X = 65.3 inches) 15 comparison women (Age: X = 24.4; Weight: X = 131.5 pounds; Height: X = 64.9 inches)	Blood pressure Heart rate Epinephrine Norepinephrine Systolic time interval Peripheral resistance	Blunted sympathetic activation in BN in response to mental stressors.
Tuschen-Caffier and Vögele (1999)	Achievement challenge Interpersonal conflict	27 BN women (Age: X = 24.5; BMI: X = 20.9) 27 women restrained eaters (Age: X = 26.5; BMI: X = 22.6) 27 women unrestrained eaters (Age: X = 24.6; BMI: X = 21.4)	Heart rate Blood pressure Skin conductance Respiration rate	No significant group differences in psychophysiological reactivity.
Lattimore *et al.* (2000)	Low and high conflict discussion tasks	20 AN (Age: X = 15.7; BMI: X = 17.1) and their mothers 14 psychiatric controls (Age: X = 15.2; BMI: X = 21.8) and their mothers	Heart rate Skin conductance	Higher arousal in AN patients than their mothers and psychiatric controls.

experimental session or the anticipatory anxiety due to participation in the study itself (Williamson *et al.*, 1988).

Another problematic aspect of these studies is that the appropriateness of some parameters to measure autonomic responses (e.g. heart rate, heart rate variability, blood pressure) is still uncertain and we do not exactly know what changes in these parameters mean (Nederkoorn, Smulders and Jansen, 2000). Most of the studies on cue reactivity have used non-specific autonomic responses (e.g. heart rate, blood pressure) that are multidetermined. Changes in these parameters may reflect a range of biological, affective and cognitive events that may or may not be related to the cue exposure (Bulik *et al.*, 1996).

Therefore, and although psychophysiological measures potentially offer an objective measure of emotional arousal, it is in fact likely that, due to the limitations noted above, other types of assessment in addition to psychophysiological measures should be included in the experimental procedure. Direct behavioural observation of participants throughout the experimental session, subjective ratings, and data from self-report inventories may be necessary to support psychophysiological data (Williamson *et al.*, 1988) in order that an overall picture of responses emerges. This is in line with current componential definitions of emotions which emphasize that an emotion includes a cognitive appraisal of the situation, a subjective feeling, an action tendency (or actual behaviour) as well as a psychophysiological response.

CUE REACTIVITY

Notable animal and human research has proved the role of conditioning in the mediation of the appetitive reflex modulation and motivation to eat (Drobes *et al.*, 2001). Classical conditioning models, derived from addiction research have been recently applied to binge eating (Overduin, Jansen and Eilkes, 1997; Overduin and Jansen, 1997).

'Cue reactivity' is defined as a range of physiological, cognitive and emotional responses elicited by cues (conditioned stimuli) that have been repeatedly paired with a specific behaviour such as alcohol, drug administration or binge eating (Staiger, Dawe and McCarthy, 2000). Over a hundred studies have found autonomic responding, such as increased heart rate, skin conductance and salivation, in addicts who were confronted with drug-related cues (Jansen, 1998). However, in contrast to addiction research, relatively few laboratory cue reactivity studies have been carried out in individuals with eating disorders (Overduin, Jansen and Eilkes, 1997; Staiger, Dawe and McCarthy, 2000) and the results are rather contradictory.

Conditioning models of binge eating assume that, through a learning process, cues predictive of binge eating (e.g. feelings of depression, anxiety, loneliness or boredom, or the sight and smell of food) acquire the power to elicit a variety of anticipatory physiological, behavioural, affective and cognitive responses (Bulik *et al.*, 1996; Vögele and Florin, 1996; Overduin, Jansen and Eilkes, 1997). These responses are subjectively experienced as craving, leading to increased food consumption, and play a significant role in dysfunctional eating behaviour (Jansen, 1998; Nederkoorn, Smulders and Jansen, 2000). The reduction of cue reactivity may be an essential part of treatment and continued elevated cue reactivity after treatment could predict relapse (Bulik *et al.*, 1996).

REACTIVITY TO FOOD CUES IN STATES OF NORMAL AND ABNORMAL PHYSIOLOGY OR PSYCHOPATHOLOGY

Now we will review some of the studies that have been carried out to examine the arousal elicited by food cues in individuals

with eating disorders and sub-clinical samples of restrained and binge eaters.

Restrained Eating

Homeostatic drives are thought to lead to periodic phases of disinhibited eating in people who chronically restrain their eating. Both bulimic and restrained subjects are characterized by failed attempts to restrict eating, overconcern with body shape and weight and an elevated frequency of binge eating (Overduin *et al.*, 1997). The conditioning model of binge eating predicts that cue reactivity should be larger in restrained eaters than in normal individuals. However, and contrary to these predictions, psychophysiological studies carried out in restrained and unrestrained eaters (Overduin, Jansen and Eilkes, 1997; Drobes *et al.*, 2001) have not found significant differences in the responses of both groups to food cues.

Binge Eating

Food cue reactivity has been investigated in sub-clinical samples of binge eaters and in individuals with a clear diagnosis of bulimia nervosa. For example, Vögele and Florin (1996) examined reactivity to exposure to favourite foods in non-binge eaters and to binge foods in binge eaters. All subjects responded with increased physiological arousal and feelings of hunger and desire to binge but significant differences between groups were also found. Binge eaters showed higher psychophysiological reactivity (increased blood pressure and electrodermal activity) throughout food exposure relative to controls. Interestingly, heart rate during food exposure predicted the later amount of food consumed in all subjects. This relationship was more marked in binge eaters than in the comparison group. In a later study, Drobes *et al.* (2001) also studied the emotional responding to food cues in binge eaters. Since binge eaters typically report high levels of dietary restraint, these authors predicted that they would show similar responses to food-deprived subjects given that these two groups might have an enhanced approach-oriented bias to food. Their hypothesis was confirmed as both groups showed enhanced startle reflexes while viewing food pictures. The same result was previously reported by Mauler *et al.* (1997) (cited in Drobes *et al.*, 2001) who found augmented probe startle responses to the presentation of food pictures in a bulimic group and in food-deprived normal eaters. Thus it appears that people with bulimia nervosa have arousal of the sympathetic nervous system in response to food cues.

Results from this research therefore suggest that binge eaters show an enhanced overall psychophysiological arousal to the presentation of food cues than do controls. However, the physiological response in terms of parasympathetic reactivity such as salivation to food cues in bulimia nervosa is less clear cut. Staiger and co-workers (2000) examined psychophysiological reactivity to individualized binge/favourite food exposure in bulimic subjects. They hypothesized that increasing cue salience would correlate with augmented reactivity and examined salivation and subjective responses to sensory properties of food (the sight and smell and the sight, smell, and taste of a binge/favourite food) and compared this to the responses elicited by a neutral food. Results confirmed the hypothesis that bulimic subjects would show greater urge to binge, stress and loss of control than the control group and this relationship would be more pronounced when exposed to the sight, smell and taste condition. However, there were no significant differences between groups in salivary reactivity.

In a longitudinal study, Bulik *et al.* (1996) examined salivary reactivity to individualized binge foods in a group of bulimic subjects. Before treatment (eight sessions of cognitive behavioural therapy), there was no evidence of an increase in salivation with the presentation of food. After treatment, however, food cues did lead to greater salivary reactivity. Thus it is possible that, before treatment, arousal of the sympathetic nervous system may have inhibited the parasympathetic response to food cues, namely salivation.

This result contrasts with those of other studies (LeGoff, Leichner and Spigelman, 1988) however, in which a greater increase in salivation was found in individuals with bulimia nervosa compared to controls. It is not easy to suggest a single conclusion for the contradictory results obtained in salivary reactivity in bulimic subjects. It has been hypothesized that variables such as body mass index, anxiety, depression, food restriction, dehydration, volume depletion or parotid gland hypertrophy could influence salivary reactivity and confound the results (Bulik *et al.*, 1996). In order to test this, Bulik *et al.* (1996) correlated all these variables with salivary reactivity but they failed to find any connection between them. Clearly, further research is needed to elucidate the possible variables affecting salivary reactivity in individuals with bulimia nervosa.

Another interesting topic of research in the addiction area has been to experimentally induce negative mood states and observe changes in the response to specific cues. In line with this, Laberg *et al.* (1991) assessed the physiological and subjective response of restrained eaters and patients with bulimia nervosa to slides before and after an experimental induction of negative mood. The slides consisted of pictures of the subject's actual body, food previously identified by the individual as typical binge food and control images of landscapes and houses. Heart rate was recorded continuously and self-reports of mood, craving and self-efficacy were obtained before and after the presentations of the slides. Patients with bulimia nervosa and restrained eaters did not differ in their responses prior to the negative mood induction. All participants had an initial deceleration in heart rate to food slides. After the induction of negative mood, patients with bulimia nervosa showed a greater deceleration in heart rate in response to food and body shape pictures than comparison women. Furthermore, bulimic patients reported an increased craving for food in the negative mood state. These findings suggest that negative affect focuses attention on food and increases craving in patients with bulimia nervosa and are congruent with clinical data suggesting that binge episodes are more likely in negative mood states.

Anorexia Nervosa

Very few studies of cue reactivity have included a group of individuals with anorexia nervosa. As noted above, one difficulty in interpreting the results of such studies is that starvation is associated with changes in autonomic nervous activity, and this may confound the response. One of the first reported studies of cue reactivity in anorexia nervosa was that by Salkind, Fincham and Silverstone (1980). These authors were interested in testing the conceptualization of anorexia nervosa as a fear-based disorder (i.e. fear of weight gain, weight phobia, morbid dread of fatness) and so also included as a control group patients with a specific phobia. The skin conductance changes in patients with anorexia and related feeding disturbances following exposure to food- and weight-related stimuli were either absent or small. This contrasted with the marked responses to the feared stimuli in subjects with specific phobias. Therefore, the hypothesis that anorexia might be considered a phobic disorder was not supported. However, 'fear of weight gain' remains one of the criteria for a diagnosis of anorexia nervosa in DSM-IV (APA, 1994).

Conclusion

Overall we can conclude that abnormal eating behaviours alter physiological and subjective reactivity to food cues. However, responses on some parameters are still uncertain. It is unclear

whether the difference in these results arises from differences in food cues or technology used from the studies or whether the negative results can be attributed to low power or to inappropriateness of some response parameters. Finally, it is not clear whether this reactivity to food cues confirms the conditioning model of binge eating or not. Future research should be aimed to clarify the veracity of this model and its accuracy to explain abnormal eating patterns.

REACTIVITY TO FOOD INTAKE IN STATES OF NORMAL AND ABNORMAL PHYSIOLOGY OR PSYCHOPATHOLOGY

Weight and appetite are regulated homeostatically. Food is more attractive and the drive to eat is increased in states of starvation (Keys *et al.*, 1950). Food intake is governed not only by states of depletion but also by the hedonic properties of food (Pinel, Assanand and Lehman, 2000). The sensory properties of foods influence food choice and intake (Shepherd and Farleigh, 1989). Therefore the physiological and psychological state of the individual as well as salience of the cue will impact on the psychophysiological response.

The anticipation of food or the exposure to the sensory properties of food (visual, olfactory and taste) as well as cognitive processes (such as the thought of food or eating) elicit cephalic phase responses which prepare the body to optimize the digestion, absorption and use of nutrients, and play a role in the amount of food that an individual can tolerate (Jansen, 1998; Nederkoorn, Smulders and Jansen, 2000). Therefore, it is hypothesized that they are also important in eating disorders in which the intake of a large amount of food is a characteristic feature (Nederkoorn, Smulders and Jansen, 2000). Specifically, the cue reactivity model predicts that the frequent large food intake of binge eaters and their chaotic eating pattern (alternating between dieting and binge eating) will induce stronger conditioned responses in binge eaters than in normal subjects, and that these anticipatory responses will be subjectively experienced as craving, making it more difficult for the subject to abstain from eating (Nederkoorn, Smulders and Jansen, 2000; Jansen, 1998). Although this relationship is particularly marked in individuals with eating disorders, food cues also increase feelings of hunger and craving in healthy individuals (Overduin, Jansen and Eilkes, 1997; Vögele and Florin, 1996; Nederkoorn, Smulders and Jansen, 2000).

Animal and human research has found that food exposure increases salivation, gastric activity, and insulin release. Woods and Strubbe (1994) found that the temperature of rats increased prior to a meal. Nederkoorn and co-workers (2000) found a similar increase in temperature of humans during food exposure. The response to eating differs from that of exposure alone. Skin conductance increased during food exposure and decreased during and after the meal. A parallel pattern of change was seen in the low frequency component of heart rate variability.

Léonard *et al.* (1998) also assessed the emotional response to food intake in patients with anorexia nervosa, bulimia nervosa and in a comparison group using three measures of psychophysiological response (skin conductance, heart rate and electroencephalogram). The results showed that meal intake did not lead to significant changes in skin conductance in controls or in people with bulimia nervosa. However, in people with anorexia nervosa there was a significant increase in skin conductance during eating. No changes were found on other physiological variables in any of the groups. It is possible that the negative finding in bulimia nervosa may be because the study was underpowered (there were only 10 women with bulimia) and also the cue may have been less salient for women with bulimia than for women with anorexia.

In an early study, Williamson *et al.* (1988) assessed sympathetic arousal following eating. Four groups were included in this study: bulimia nervosa, obese and a normal control group who all ate a test meal and another normal control group who did not eat the test meal. Results showed that both the bulimic and obese groups responded with increased heart rate after eating the test meal, differing from the normal control group who showed a deceleration in heart rate after eating. All groups had vasoconstriction immediately after eating but this rapidly reversed within 20 minutes in the bulimia nervosa group. All groups responded with decreased skin temperature. The bulimic group also differed from all other groups because subjects with bulimia nervosa responded to eating with an immediate augment in skin resistance followed by a subsequent decline. Contrasting to both normal groups, the obese group responded to food intake with decreased skin resistance. Finally, results for forearm EMG suggested that bulimic and obese groups responded to eating with enhanced EMG, whereas both normal groups showed a decrease in this response. Therefore, some of these physiological responses were congruent with a higher level of sympathetic arousal, whereas others showed opposite results, especially in bulimia nervosa. A possible explanation for these mixed results is that vomiting may produce reduced autonomic arousability and therefore it may be particularly hard to find a global sympathetic arousal response in individuals with bulimia nervosa.

Overall it is difficult to draw a general conclusion from these studies due to the different methodologies used in them. For example, the type of food and caloric content of the test meals, the amount of food the subjects were allowed to eat, sample characteristics and previous exposure of food cues were different for each study. Further research characterized by the use of a single methodology and similar groups of subjects is needed to clarify differences in psychophysiological responses to eating in individuals with and without an eating disorder.

STRESS AND BULIMIA NERVOSA

Stress, in particular interpersonal stress (Cattanach, Malley and Rodin, 1988; Polivy and Herman, 1993; Leal, Weise and Dodd, 1995; Koo-Loeb *et al.*, 2000), plays an important role in the aetiology and maintenance of eating disorders. Eating disorder patients subjectively report high levels of perceived stress as well as the presence of objectively determined severe life events and difficulties both concurrently (Soukup, Beiler and Terrell, 1990; Troop, Holbrey and Treasure, 1998) and at onset (Schmidt *et al.*, 1997; Welch, Doll and Fairburn, 1997). In addition, patients with eating disorders show poorer coping in terms of individual coping strategies (such as cognitive and behavioural avoidance of problems), lower confidence in coping and increased helplessness (e.g. Soukup, Beiler and Terrell, 1990; Neckowitz and Morrison, 1991; Troop *et al.*, 1994, 1998; Yager, Rorty and Rossotto, 1995). It is thought that the abnormal eating behaviours arise from a maladaptive response to stress and that individuals with eating disorders, therefore, will respond to stress with a greater psychophysiological reactivity relative to non-eating disordered controls.

In an early study that tested this hypothesis, Cattanach and co-workers (1988) assessed cardiovascular and affective responses to achievement challenge and interpersonal stress in women with bulimia nervosa. Strong cardiovascular responses and negative mood states were seen in both groups but, relative to the comparison group, bulimic individuals did not show significant differences in blood pressure, pulse rate or affective responses to the stressors. Subjective responses were significantly different between both groups. Individuals with bulimia reported a higher desire to binge than controls (particularly during interpersonal stress) and more

global stress, lower self-esteem, and lower mastery than the normal control group. Consistent with these results, Tuschen-Caffier and Vögele (1999) did not find significant differences in heart rate, blood pressure, respiration rate, and electrodermal activity between patients with bulimia nervosa, restrained eaters and controls during achievement challenge and interpersonal stress. However, subjective ratings did show substantial differences between groups since bulimic patients responded to the stressful tasks with enhanced desire to binge and hunger.

In contrast, however, Tuschen *et al.* (1995) found lower cardiovascular reactivity during achievement challenge in the bulimic group relative to the normal comparison group. Koo-Loeb, Pedersen and Girdler (1998) also found elongated PEP intervals, blunted blood pressure and heart rate in response to mental stressors in individuals with bulimia nervosa relative to a normal comparison group. Psychosocial responses of bulimic individuals also suggested that the bulimic group perceived more stress and were more anxious and depressed than the comparison group.

Overall, subjective ratings from these studies suggest that individuals with bulimia nervosa show higher levels of distress to mental stressors than control subjects and this is accompanied by an increased desire to binge. However, psychophysiological data are confusing. This dissociation between emotional responses and physiological reactivity could be due to a variety of factors. For example, the low power of the studies or the type and range of the stressors used through the different studies (see Table XXIII-5.1). Therefore, and as we suggested above, more studies using a similar methodology should be carried out to clarify physiological reactivity in response to stressors. It is also important to discern what kind of stressors may be important for stress-induced eating.

SUMMARY AND CONCLUSION

Research on psychophysiological factors and eating disorders has provided limited and confusing results (Laberg *et al.*, 1991). The psychophysiological reactivity to food cues remains unclear (Nederkoorn, Smulders and Jansen, 2000). As Nederkoon and coworkers (2000) suggest, deriving a global conclusion from these studies is problematic due to the diversity of groups (restrained eaters, bulimic patients, obese), cues (standardized food, individualized favourite food, pictures of food, real food) and psychophysiological measures (salivation, heart rate, skin conductance) used in these studies. Besides this, most of the studies present methodological problems, such as inadequate test stimuli, small sample size, inappropriate control groups and limited analysis of psychophysiological reactivity (Laberg *et al.*, 1991). Results from studies on psychophysiological responses to stress are similarly inconsistent. While some studies report no difference in psychophysiological responses between patients with bulimia nervosa and non-eating disordered women, others do find differences. More consistently, however, self-reports of urge to binge are greater in patients than in comparison women.

So what are we to make of the results reviewed? What are the implications for the theory and therapy of eating disorders? For the cue reactivity to food- and body-related stimuli, if not for responses to stress, the weight of evidence suggests there are differences in physiological arousal to food when people are in a state of deprivation. This is seen in normals who have missed a meal, in restrained eaters and in women with bulimia and anorexia nervosa.

It is uncertain as to whether the psychophysiological abnormalities that have been found represent aetiological risk factors for eating disorders or whether they are consequences of the illness or even factors that may maintain the illness. The psychophysiological differences found in the normal controls as a result of food deprivation suggest that it may be a maintaining factor.

Regardless of any possible role in the development of eating disorders, the use of psychophysiological measures in response to food-related stimuli may provide a useful marker of improvement and recovery. Measures of outcome tend to rely on objective behavioural indicators as these are relatively unequivocal in terms of making diagnoses (notwithstanding debates about the validity of particular criteria or diagnostic categories). However, there is considerable debate as to what constitutes 'recovery' rather than simply 'abstinence' from eating disordered behaviours. Perhaps it is here, potentially, that psychophysiological measures may be of greatest value in identifying differences between asymptomatic rather than recovered patients. One study has explored changes across treatment (Bulik *et al.*, 1996) but not specifically addressed whether 'normal' psychophysiological reactivity to food and food cues can be used as a marker of recovery. Future research on this possibility might be a useful line of enquiry.

Neuropsychological Findings in Eating Disorders

Christoph J. Lauer

INTRODUCTION

Neuropsychological research in eating disorders initially was driven by the observation that anorexic patients with evidence for perinatal brain injury showed a poor treatment outcome; particularly, a smaller weight gain was found to be associated with more frequent complications in pregnancy and delivery. Such complications were suggested to increase the susceptibility to subtle cerebral damage, which then may lead to a poor clinical prognosis. Hereby, neuropsychological testing was thought to comprise the advantage of favouring identification of cortical dysfunctions caused by these subtle brain damages below anatomically or physiologically detectable levels. The general hypothesis formulated proposed that the pattern of neurocognitive deficits might be suggestive of dysfunction of relative specific brain systems (Braun and Chouinard, 1992). In following these assumptions, most of the early neuropsychological investigations applied formal test batteries such as the 'Luria-Nebraska Neuropsychological Battery' or the 'Wechsler Intelligence Scales' (WAIS). However, while such test batteries are useful in making general conclusions about the presence of impairments in individuals with a given brain injury, they are not flexible enough to allow the investigator to assess the variety of functions that may underlie a performance deficit on a complex cognitive task in patients with, for example, an eating disorder. Poor performance may be the result of a broad range of possibilities, including damage to one of several areas, the accumulative effect of mild deficits in multiple areas, or factors unrelated to specific brain dysfunctions (see: Keefe, 1995). Therefore, neuropsychology should provide more than a window into the everyday mental processes of psychiatric patients; it should provide an objective description of what areas of behaviour and cognition are likely to be a problem for the patient and — more important — what areas are not.

This paper is divided into five sections. First, a short overview of neurocognitive observations in non-eating disordered subjects (e.g. dieters) will be provided; thereafter, the findings obtained during the acute state of an eating disorders will be summarized, followed by the presentation of neurocognitive changes after treatment, the attempt to identify neuropsychological predictors of the treatment outcome and a short section aiming at the neurocognitive-based identification of patients dropping out of therapy. Finally, the significance of various factors mediating the neurocognitive deficits in eating disorder patients will be discussed.

Because little scientific effort has so far been undertaken to evaluate the neurocognitive function in overweight and obese subjects not suffering from an additional disease known to affect neuropsychological task performance (such as the Prader–Willy syndrome, the sleep apnoea syndrome, the Down syndrome), these types of eating disorders will not be considered in this paper.

NEUROPSYCHOLOGICAL FINDINGS IN FORMER PRISONERS OF WAR AND IN NON-EATING DISORDERED, NORMAL WEIGHT DIETERS

In the following the suggestion that severe starvation and weight loss may cause sustained impairments in brain morphology and cognitive functioning, Sutker and co-workers (1987, 1990) evaluated the neuropsychological task performances in former prisoners of war (POW) who had experienced severe weight loss during captivity due to biological and psychological stress. Compared to combat veterans not captured and interned, the high weight-loss POW (loss of more than 35% of preconfinement weight) were deficient on the 'Attention-Concentration' Factor of the WAIS-R and on measures of immediate and delayed memory as assessed by the Wechsler-Memory-Scale (WMS); on the other hand, no significant impairment was obvious on the WAIS-R subtests 'digit symbol' (sustained attention), 'block design' (visuospatial construction) and 'digit span' (span of attention, working memory). The authors concluded that their findings of deficits on measures of immediate recall combined with lowered 'Attention-Concentration' factor performances raises the possibility that memory problems cited frequently in POW self-reports may be more attributable to deficiencies in attention, concentration and perhaps organizing functions than to memory storage or retrieval processes.

In healthy normal weight non-dieting females, various degrees of 'acute' food deprivation (miss one meal, miss two meals and miss all food for 24 hours) did not result in obvious effects on neurocognitive functions such as sustained attention, attentional focus, simple reaction time or immediate memory, except for a significant slower psychomotor speed performance (finger tapping) after 24-hour of food deprivation (Green, Elliman and Rogers, 1995). However, the same group reported that normal weight female *dieters* displayed poorer vigilance performance, slower reaction times and poorer immediate recall of words when they were dieting compared to a period of normal food intake. Performance on psychomotor speed was not impaired (Green and Rogers, 1995). Because self-reported dietary restraint, but not anxiety and depression, was increased during dieting, the authors related their findings to an association between dieting behaviour and high levels of distractibility; they proposed that impaired cognitive performance is closely related to dieting or the perceived need to diet *per se*. An increased distractibility (reduced capacity to inhibit responding to task irrelevant information and to facilitate responses that are goal-directed; assessed by the Stroop Colour Naming Task) was also reported in restrained eaters after a 'high-caloric' preload (single Twix bar) compared to a 'low-caloric' preload (cream cracker) and to unrestrained eaters (Odgen and Greville, 1993); the restrained females took longer to colour name active state words, food words and body size words after the high-caloric preload than unrestrained eating females. Interestingly, not only do acute food deprivation and prolonged periods of dieting affect some facets of neurocognitive

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

performance but also the micro-composition of the nourishment *per se*. Investigating the acute effects of isocaloric lunches differing in fat and carbohydrate content Lloyd and colleagues (1994) observed a slower reaction time following the fat- as well as the carbohydrate-rich lunches compared to the fat- and carbohydrate-balanced meals. However, because the subjects reported themselves as more drowsy and muddled after the fat- and carbohydrate-rich lunches, the reported limited attentional capacity might simply reflect the well-known phenomenon of a 'post lunch dip'.

Thus, the findings reported so far in non-eating disordered *dieters* demonstrate that various manipulations of individual eating habits result in a mild impairment of attention and concentration, as indicated by a slower reaction time, an increased distractibility and a slightly reduced capacity of the working memory. However, in non-eating disordered and non-dieting subjects such manipulations failed to provoke any changes in their neurocognitive task profile.

NEUROPSYCHOLOGICAL FINDINGS IN THE ACUTE STATE OF THE EATING DISORDER

One of the initial studies that investigated a broad range of neurocognitive test performances in patients with anorexia nervosa was conducted by Hamsher and colleagues about 20 years ago (1981). The authors followed the concept that at least some forms of anorexia nervosa may occur in the context of subtle brain dysfunction. Applying the cut-off scores that were known to differentiate well between patients with brain lesions and patients with other clinical disorders, the authors reported 45% of their anorexic patients to show impaired performances on two or more of the applied tasks; most frequently a retarded reaction time on a forced-choice task (35% of the patients) was observed, followed by an impairment on mental arithmetic tasks (15%; sustained attention), short-term visual memory (30%) and long-term information retrieval (20%; long-term memory). Other neurocognitive abilities assessed were more or less well preserved (percentage of affected patients $<15\%$; e.g. psychomotor speed, perceptual-analytic ability, spatial orientation and verbal fluency). The rather non-specific and sporadic nature of the test failures was described by the authors as being most characteristic of an attention-concentration deficit or cognitive inefficiency. The assumption of a reduced attentional capacity in eating disorder patients, along with other but sporadic reported difficulties, was underlined in most of the subsequent studies in anorexic and in bulimic patients (*vigilance and sustained attention*: Laessle *et al.*, 1989, 1990; Green *et al.*, 1996; Kingston *et al.*, 1996; *divided attention*: Lauer *et al.*, 1999; attentional capacity necessary for *response execution/inhibition*: Fairburn *et al.*, 1991; Cooper and Fairburn, 1992; Kingston *et al.*, 1996; *attentional flexibility*: Pendleton Jones *et al.*, 1991; Szmukler *et al.*, 1992; *speed of information processing*: Pendleton Jones *et al.*, 1991; Kingston *et al.*, 1996). Because psychomotor speed and reaction time are among the critical variables on almost all tasks assessing the various aspects of attention, one might simply attribute these findings to the general slowing of motor responses associated with starvation (Maxwell, Tucker and Townes, 1984; Green *et al.*, 1996). Alternatively, the poor performances on these tasks may be related to an increased susceptibility to interference and an increased distractibility (Ben-Tovim *et al.*, 1989; Fairburn *et al.*, 1991; Perpina *et al.*, 1993; Long, Hinton and Gillespie, 1994). In other words, most of the attentional deficits in patients with eating disorders seem to depend on an insufficient functioning of selective and flexible processing of more than one piece of relevant information.

In a number of studies, working (immediate) memory capacity, learning abilities, as well as short-term and long-term memory, were found to be impaired to a similar extent in both anorexia and bulimia nervosa (Touyz, Beumont and Johnstone, 1986; Pendleton Jones *et al.*, 1991; Green *et al.*, 1996; Kingston *et al.*, 1996; Mathias and Kent, 1998). In contrast to the rather 'unspecific' impairments of attention, these findings of mnemonic disabilities are suggestive of a 'specific' deficit and have been primarily discussed in terms of an impaired working memory that, according to Baddeley (1992), is formed by the phonological loop and the visuospatial sketch-pad in conjunction with a central executive component. However, other studies failed to demonstrate a significantly reduced capacity of either the phonological loop (e.g. Digit Span) or the visuospatial sketch pad (e.g. Block/Corsi Span) (see Hamsher, Halmi and Benton, 1981; Szmukler *et al.*, 1992; Lauer *et al.*, 1999), implying that the central executive component was dysfunctional; however, this component is particularly dependent on preserved attentional processes. Of interest here are also the findings of Beatty and colleagues (1990). These authors reported the process of learning to be deficient in their patients; however, the delayed recall (short- and long-termed) of that previously learned material was not. Thus, whereas the acquisition period of the new material was affected probably due to impaired attentional demands and information processing, the final encoding and the memory retrieval processes were undisturbed. Interestingly, Strupp and colleagues (1986) reported the effortful information processing (conscious learning) to be quite normal in their patient sample; however, the automatic information processing (learning without conscious intent) was found to be impaired. The authors discussed their finding in terms of heightened arousal (for example, anxiety and preoccupations concerning food and body weight) and attentional focusing. According to Bacon (1974), they suggested that arousal both narrows attentional focus and reduces overall cognitive capacity; therefore, an aroused subject might be expected to have sufficient cognitive capacity to perform well on the designated (effortful) aspect of the task, but to have insufficient capacity to automatically process additional information. Again, the suggestion of an insufficient attentional capacity allowed a satisfactory explanation without dealing with more complex neurocognitive functioning such as working memory or the ability to appropriately encode, store and retrieve information from the memory.

In only a few studies were higher order cognitive skills such as problem solving capacity, categorization and abstraction evaluated (Palazidou, Robinson and Lishman, 1990; Szmukler *et al.*, 1992; Lauer *et al.*, 1999). The performances of tasks measuring such skills depend on complex neurocognitive functioning (for example, to solve the Wisconsin Card Sorting Test, at least auditory attention, visual attention, motor skills, learning, abstraction, categorization, working memory, short-term memory and executive control are needed). No obvious impairments could be ascertained in two investigations applying the WCST (Palazidou, Robinson and Lishman, 1990; Lauer *et al.*, 1999), while Szmukler and co-workers (1992) reported a poor performance in the Austin Maze, which assesses complex serial learning, error utilization, flexibility, planning and adaptive behaviour abilities.

According to the cited findings, no definite conclusion can be drawn as to which neurocognitive functions are impaired in the acute state of the eating disorder. However, as already proposed by Hamsher and colleagues (1981) there is fairly good evidence that the most characteristic failure is a cognitive inefficiency in the form of attentional deficits irrespective of the type of eating disorder (restricting anorexics, bulimic anorexics, and bulimics). Although this conclusion sounds rather non-specific, most of the investigations revealed that especially the selective processing of information is affected in eating disorder patients. This results in a general slowing not limited to specific types of mental decision-making processes. However, this deficiency apparently seems not to diminish the final encoding, storage and retrieval of the information — as long as the information was subjected to conscious learning. In more popular terms, patients with an eating disorder need a bit more time than healthy subjects for sufficient

information encoding, because their overall attentional capacity is limited by additionally processing a certain amount of task irrelevant (disease related?) information. However, this conclusion does not refer to all eating disorder patients; as far as explicitly indicated in the respective reports, only about 38% of the patients presented with more or less obvious neurocognitive impairments (see: Lauer *et al.*, 1999).

RECTIFICATION OF THE NEUROPSYCHOLOGICAL MEASURES AFTER TREATMENT

A number of investigations followed the hypothesis that the neurocognitive deficits assessed at hospital admission might ameliorate in parallel with improvement of the primary and secondary eating disorder symptomatology (weight gain, decreased frequency of bingeing and purging episodes, rectification of the abnormalities in brain morphology and neuroendocrinology). A second, and probably more important point was to identify cognitive deficits predictive for a good but also for a poor clinical prognosis. Such identification would allow the development of additional and specific treatment strategies to increase the likelihood of a favourable outcome.

In addressing this question, two investigations applied a cross-sectional design. In the first study (Strupp *et al.*, 1986), which mainly focused on effortful versus automatic information processing, there were no obvious differences between acute underweight and weight-recovered anorexic patients. Pendleton Jones and colleagues (1991) found a poorer performance on tasks corresponding to attentional focusing, verbal memory and visuospatial reasoning in their underweight anorexics compared to weight-restored anorexics; however, these differences were subtle and nonsignificant.

In contrast, all the prospective studies (Hamsher, Halmi and Benton, 1981; Small *et al.*, 1983; Szmukler *et al.*, 1992; Kingston *et al.*, 1996; Lauer *et al.*, 1999) reported a rectification of the impaired neurocognitive skills, in particular of the attentional capacity, when the patients had successfully completed the respective therapeutic schedules (weight gain, reduction in the frequency of bingeing and purging). In one study, however, the mnemonic disabilities observed in the acute state of anorexia nervosa, continued to persist after a weight gain of at least 10% of the body mass index (Kingston *et al.*, 1996); the authors related their finding to an insufficient weight gain (incomplete nutritional rehabilitation) at the time of re-testing; but they also speculated that the mnemonic disability might have antedated the onset of the illness, although a relationship with the history of perinatal injury could be excluded.

Because one methodological problem is inherent to all neuropsychological prospective study designs — that is the repeated application of the same tasks at different time points — one might argue that the neurocognitive rectifications observed after clinical remission of the eating disorder simply are due to practice effects. However, in most of the studies, methodological attention had been paid to choose measures for which acceptable alternative forms were available, in order to minimize this effect. In addition, the time interval between pre- and post-treatment sessions lasted between 70 days (Szmukler *et al.*, 1992) and seven months (Lauer *et al.*, 1999), a timely length that further lowers the probability of significant practice effects. Therefore, it is certainly possible that the improved attentional abilities are, in part, related to a decrease in susceptibility to interferences and an increase of the flexibility/inhibition functions, as was reported by Kingston *et al.* (1996). This is further supported by the finding of Lauer and colleagues (1999) that the percentage of eating disorder patients who were able to resolve a Daily-Living Problem Task without any cues had increased from 73% at pretreatment to about 90% at post-treatment.

Thus, the neurocognitive deficits that had been present in eating disorder patients before the onset of a specific treatment schedule appear to vanish in parallel with the amelioration of the eating disorder symptomatology, irrespective of whether the patients suffered from an anorexic or a bulimic disorder. However, as will be outlined in more detail in the following section, this conclusion sounds too optimistic, because it refers to only 11% of the eating disorder patients (see below).

DO NEUROPSYCHOLOGICAL MEASURES PREDICT THE CLINICAL OUTCOME?

In four investigations, the authors attempted to identify neurocognitive predictors of the clinical outcome. However, the results reported were conflicting. Hamsher and colleagues (1981) found their anorexic patients who showed impaired performance on two or more neuropsychological tasks at *post*-treatment examination to be more likely to exhibit an unfavourable outcome (weight loss) after one year of follow-up than patients with very mild or no cognitive deficits at hospital discharge. Regarding the task performances at pretreatment examination, however, no such predictions could be confirmed. Small and colleagues (1983) reported the performance in the digit span task, which measures immediate (working) memory capacity, to be a powerful predictor of weight gain in their anorexic patients. In contrast, Szmukler and co-workers (1992) as well as Lauer and colleagues (1999) failed to identify any valuable predictors for the clinical outcome (either just prior to or eight weeks after hospital discharge), although they had applied a broad range of neuropsychological tasks.

NEUROPSYCHOLOGICAL FINDINGS IN PATIENTS DROPPING THE TREATMENT

In one study, the authors aimed at the neuropsychological identification of those patients who dropped out of the therapeutical schedule (Lauer *et al.*, 1999). However, the neurocognitive task performances as well as the personal and clinical characteristics of these patients were fairly good comparable to those patients who completed the programme. Again, the type of the eating disorder appeared not to be of importance.

Percentage of Patients with Neuropsychological Deficits

At present, one would suggest that certain cognitive deficits are evident in anorexic and bulimic patients, but disappear when the eating disorder patients recover. However, when looking at an *individual* level, this suggestion is not reasonable. Considering two or more impaired task performances as a cut-off, only 38% of patients are reported to be cognitively affected in the acute episode of the eating disorder (38 patients out of a total of 101 patients; Hamsher, Halmi and Benton, 1981; Szmukler *et al.*, 1992; Kingston *et al.*, 1996; Lauer *et al.*, 1999) and this figure drops to 27% at post-treatment. In other words, 62% of the patients with an acute eating disorder have well-preserved cognitive skills, while in the remaining patients displaying cognitive deficits (38%) a rectification can be observed in only 11%. Therefore, it appears not surprising that the reports on the cognitive abilities in eating disorders published so far do not provide a very consistent picture, especially as 'positive' findings depend not only on the severity of cognitive deficits but, more importantly, on the number of patients displaying such deficits. It is important to note also that the attempt to distinguish 'poor' and 'good' performing eating disorder patients on a personal (e.g. age, years of education) and a clinical level (e.g. Beck Depression Inventory, BDI; Eating Disorder Inventory, EDI) yielded completely negative results (Hamsher, Halmi and Benton, 1981; Lauer *et al.*, 1999).

FACTORS MODULATING NEUROCOGNITIVE PERFORMANCE IN EATING DISORDER PATIENTS

Eating Disorder Symptomatology

Interestingly, in only a few studies was the performance on neurocognitive tasks directly related to the degree of underweight, the frequency of bingeing and purging, and the severity of the psychopathology in the eating disordered patients (e.g. as measured by the EDI) and their ameliorations during treatment, respectively. The results reported, however, are somewhat disappointing. Correlations calculated between task performances and eating disorder symptomatology were all far from reaching statistical significance. In addition, group comparisons of 'good' performing and 'poor' performing patients revealed no obvious differences in the severity of the eating disorder. And finally, although in all prospective studies the rectification of the cognitive deficits had run in parallel with that of the eating disorder symptomatology, little evidence was found that the two processes are closely interrelated (Strupp *et al.*, 1986; Laessle *et al.*, 1990; Green *et al.*, 1996; Lauer *et al.*, 1999).

'Secondary' Psychopathology

It can also be speculated that the impaired cognitive functions in eating disorder patients are due to secondary psychopathological symptoms, in particular of depression. However, in almost all of the studies performed so far no evidence was found that the severity of depressive symptomatology had influenced the respective cognitive findings in these patients (Hamsher, Halmi and Benton, 1981; Beatty *et al.*, 1990; Pendleton Jones *et al.*, 1991; Szmukler *et al.*, 1992; Cooper and Fairburn, 1993; Green *et al.*, 1996; Kingston *et al.*, 1996; Lauer *et al.*, 1999). Occasionally, however, an association was reported between level of vigilance and severity of depression (Green *et al.*, 1996), a finding that closely matches that generally observed in patients with affective disorders (see further papers in this chapter). In addition, the actual level ('state') of anxiety at neuropsychological examination appeared not to affect task performances (Szmukler *et al.*, 1992; Kingston *et al.*, 1996; Green *et al.*, 1996; Mathias and Kent, 1998). However, the more enduring level of anxiety ('trait'; as measured by the MMPI) was closely associated with the neuropsychological task performances at pretreatment (Hamsher, Halmi and Benton, 1981) and accounted for nearly all of the neuropsychological deficits, though rather subtle ones, reported in the study by Pendleton Jones and colleagues (1991). Therefore, it could be argued that the neurocognitive deficits observed in eating disorder patients reflect simply the effect of more enduring anxiety (this chapter).

Unspecific Stress due to Hospital Admission

In 1981, Hamsher and colleagues had speculated that stress due to hospital admission might obscure task performance in eating disorder patients. A comparable effect also could be expected in those investigations evaluating the neurocognitive status of their patients two to three weeks after admission, that is, during the re-feeding/treatment period. To control for such a bias, Lauer *et al.* (1999) had investigated their patients four weeks *before* admission. However, the profile of cognitive deficits they observed was surprisingly similar to that usually found at or shortly *after* hospital admission. Therefore, it is rather unlikely that the level of performance in patients with eating disorders is affected by unspecific stress due to hospital admission.

Sleep Disorders

Recent observations in sleep research provide fairly good evidence for a relationship between learning and sleep states, particularly rapid eye movement (REM) sleep or dream sleep (Smith, 1996). Furthermore, patients suffering from severe insomnia were found to perform poorly on tasks measuring the capacity of attention and working memory (Pedrosi *et al.*, 1995; Hauri, 1997), observations that are comparable to the neurocognitive task profile in eating disorder patients. The initial electroencephalographic (EEG) sleep studies in patients with anorexia nervosa reported a decreased sleep maintenance caused by frequent awakenings associated with a prolonged wake time during the night, while the amount of REM sleep was unaffected (Crisp, Stonehill and Fenton, 1970); thus, the attentional deficits present in anorexia nervosa might be attributed to a disturbed nocturnal sleep profile. However, the sleep of bulimic patients, who display similarly impaired task performances, was quite undisturbed (Walsh *et al.*, 1985). Moreover, subsequent EEG sleep studies failed to replicate a definite disturbance of the sleep profile (increased numbers of arousals and wake time, decreased amounts of slow wave sleep or REM sleep) in both anorexic and bulimic patients (see: Lauer and Krieg, 2002). Therefore, it appears unlikely that disturbances in the regulation and the maintenance of nocturnal sleep account for the impaired neuropsychological performance in eating disorder patients.

Morphological and Functional Brain Alterations

As already mentioned, neuropsychological research in eating disorder patients initially was driven by the assumption that neurocognitive impairments might be due to subtle cerebral damage acquired by complications in pregnancy and delivery. However, Hamsher and co-workers (1981) were not able to confirm this initial hypothesis by using their patients' case records. One might also speculate that the cognitive deficits depend on morphological and functional brain alterations that are present in the acute episode of an eating disorder, but tend to normalize with clinical recovery (Krieg *et al.*, 1988, 1989; Herholz, 1996; Delvenne *et al.*, 1996; Kingston *et al.*, 1996). Palazidou and co-workers (1990) reported on a significant association between *morphological* brain alterations (size of the cortical sulci) and the performance on the digit symbol test; however, Laessle *et al.* (1989) and Kingston *et al.* (1996) failed to replicate such associations indicating that crude morphological measurements are too insensitive for matching with cognitive deficits. A more conclusive picture can be expected from studies in which neuropsychological assessments are combined with *functional* brain imaging. Several investigations have revealed a relative hypermetabolism in the caudate nuclei and the inferior frontal cortex associated with a relative hypometabolism in the parietal and superior frontal cortex in both anorexics and bulimics (Herholz *et al.*, 1987; Delvenne *et al.*, 1996, 1997; Naruo *et al.*, 2000; see also this chapter). After weight restoration, the parietal hypometabolism and the inferior frontal hypermetabolism tended to persist, whereas the remaining changes had normalized (Delvenne *et al.*, 1996). These findings appear to coincide with the assumption that the capacity of the working memory, which is functionally 'localized' in the frontal and parietal lobes (Shallice, 1982), is particularly affected in eating disorder patients (Green *et al.*, 1996), but also agree with the assumption that primarily the attentional capacity is deficient in these patients (Hamsher, Halmi and Benton, 1981; Pendleton Jones *et al.*, 1991; Lauer *et al.*, 1999).

Neurochemical Changes

Finally, one has to consider several neurochemical substances as the factors mediating the neurocognitive impairments. For example, steroid hormones are known to be specifically altered in the acute eating disorder but normalize with clinical remission (Pirke, Vandereycken and Ploog, 1988; Schweiger, 1991). In addition, these steroid hormones obviously influence human cognitive functions

(Wolkowitz *et al.*, 1990, 1993; Squire, 1992; Sapolsky, 1992). To date, two studies have demonstrated that patients with elevated cortisol concentrations performed poorer on tasks assessing vigilance, attentional demands and memory (Laessle *et al.*, 1992; Seed *et al.*, 2000). However, a direct correlation between the neurocognitive deficits and the cortisol measures could not be established. In a further investigation, Laessle and colleagues (1990) determined the association between β-hydroxybutyric acid (BHBA; elevated levels indicate metabolic adaptation to starvation) and vigilance performance in patients with bulimia nervosa. Interestingly, only the patients with pathologically high BHBA values performed worse on that vigilance task. The authors concluded that biological adaptation to (acute) starvation might be associated with alterations in CNS transmitter systems that regulate and allocate information processing capacity. Thus, although direct evidence is scarce at present, several neurochemical substances appear to be potential candidates that may serve as factors mediating between eating disorder symptomatology and neuropsychological deficits.

SUMMARY

The most robust neurocognitive finding in patients suffering from an eating disorder — and also but to a lesser extent in non-eating disordered dieters — can be characterized by a non-specific attention-concentration deficit. In particular, the selective information processing (enhanced distractibility) and the flexibility/inhibition functions (response selection) appear to be affected. These neurocognitive failures tend to vanish in parallel with the amelioration of the eating disorder. However, there is little evidence that any neuropsychological deficit assessed before the onset of a therapeutical regime might predict the clinical outcome. In addition, eating disorder patients with impaired task performances do not differ in their personal and clinical characteristics from patients presented with well-preserved neurocognitive functioning. Nevertheless, there is some evidence that elevated and enduring anxiety, neurochemical disturbances and, probably, metabolic brain alterations might mediate neuropsychological task performance. Finally, the fact that only fewer than 40% of eating disorder patients show obvious neurocognitive impairments should not limit our efforts to improve therapy by adding specific neuropsychological training programs that aim to ameliorate the attentional deficits. With this, a better clinical prognosis for *all* eating disorder patients might be achieved.

Neuroanatomical Bases of Eating Disorders

Rudolf Uher, Janet Treasure and Iain C. Campbell

INTRODUCTION

There are several lines of evidence that may eventually converge to provide an integrated model of brain dysfunction in eating disorders (ED). In this section we have combined current knowledge and have constructed a neuroanatomically based explanation of ED. The picture is far from clear; and consequently, much of what is written contains suggestions and hypotheses rather than established explanations.

Diagnostic categories of ED span a spectrum of heterogeneous conditions, ranging from anorexia to obesity, in which maladaptive eating habits constitute a major symptom and which are thought to arise from primarily psychological disturbance. The inclusion of simple obesity in ED is controversial (Bruch, 1973; Treasure and Collier, 2001). Restrictive anorexia nervosa (RAN), one of the extreme conditions at the end of the ED spectrum, constitutes probably the most clear-cut syndrome, and is therefore a useful model for research. Much more knowledge has been collected for anorexia nervosa (AN) than for other ED. Therefore, this chapter will be substantially based on AN research and bulimia nervosa (BN) will be discussed to a lesser extent.

In the second part of this paper (Symptoms and Physiology) four groups of ED symptoms and their neural correlates are examined (eating and hunger/satiety perception, body image, pain perception and cognitive functions). A third part (Direct evidence of neural disturbance in ED) summarizes evidence from lesions, electrophysiological and neuroimaging studies. Finally, the fourth part provides a conclusion.

SYMPTOMS AND PHYSIOLOGY

Given the heterogeneity of symptoms and syndromes within the spectrum of ED (Treasure and Collier, 2001), it is unlikely that a particular neuroanatomically defined disturbance will match on to DSM IV or ICD10 diagnostic categories, rather it may be helpful at this stage to examine brain function in relation to individual symptoms. However, a question may be raised: can these diverse symptoms be considered as separate disturbances or do they (all or some of them) represent several facets of a common psychopathological mechanism? For example, the apparent insensitivity of AN patients to hunger, pain and physical fatigue could be attributed to a general impairment or inhibition of signalling coming from the body. Moreover, as body image representation is dependent on interoceptive and exteroceptive sensory information, its distortion in ED may also be caused by primary or secondary sensory insensitivity (Smeets and Kosslyn, 2001). The concept of a 'proto-self' (Damasio, 1999) as a representation of bodily awareness that constitutes a basic level of consciousness can be considered as a model which links these various symptoms. The proposed neuroanatomical substrate for this representation of body physical status is comprised of brainstem nuclei, hypothalamus, basal forebrain, insular, secondary sensory and medial parietal cortices.

Four groups of ED symptoms and their neural correlates are examined in this section: eating and hunger/satiety, body image, pain perception and cognitive functions. Although not clinically apparent, the insensitivity to pain is dealt with in detail, because considerable research has been carried out on this topic and it may provide a useful link in the pathophysiology of ED. Other constituents of ED symptomatology: affective and emotional disturbance, impulsivity and obsessive–compulsive symptoms are shared with other psychiatric disorders (affective disorders, personality disorders, obsessive–compulsive disorder) and their description and neural mechanisms can be found in other sections of this book.

Eating, Hunger and Satiety

Deleterious eating behaviour, the most obvious manifestation of ED, is associated with an abnormal perception of hunger and satiety. People with AN seem to lack the feeling of hunger, whereas those with BN have diminished feelings of satiety and still feel hungry after having eaten a large meal (Owen *et al.*, 1985; Halmi, 1988; Halmi and Sunday, 1991; Hetherington and Rolls, 1991, 2001). The complementarity between hunger and satiety states seems to disappear in ED and people with AN of the bingeing–purging subtype (BPAN) may report feeling both full and hungry at the same time (Halmi and Sunday, 1991). In response to provocation by insulin or 2-deoxy-D-glucose the subjective rating of hunger by AN patients paradoxically decreases (Nakai and Koh, 2001). Despite this subjective absence of hunger, when AN patients were shown palatable food, they responded by increasing insulin secretion to an even greater extent than did healthy controls, but then chose not to eat the food (Broberg and Bernstein, 1989). This suggests that although their body is preparing for meal ingestion, people with AN do not follow this with appropriate behaviour (eating the food). In summary, hunger/satiety sensing is apparently disrupted in people with eating disorders and the subjective experience and behaviour are disconnected from the body's needs and autonomic functions. Several important questions remain unresolved: Do patients with AN not feel hunger or do they just not admit feeling it? Is this disturbance in hunger/satiety sensing primary (and possibly causative) or is it acquired during the course of the illness? Hetherington and Rolls (2001) in a recent review have argued in favour of a secondary, learned disturbance in ED.

Neural mechanisms involved in the response to food and its modulation by hunger and satiation have been extensively investigated with single neuron activity mapping in primates (Rolls, 1999). It has been established that taste, olfactory and visual pathways which process food-related stimuli converge to the amygdala and the caudal orbitofrontal cortex, where their

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

reward value is appraised and a choice is made whether to engage in action aimed at ingesting the potential food. Whereas the amygdala provides a relatively slow and rigid mechanism of learned stimulus-reinforcement associations, the hierarchically superior orbitofrontal cortex adds the flexibility necessary to rapidly adapt the behaviour to a changing environment. Information on the organism's energy needs is conveyed from the hypothalamus and in both the caudal orbitofrontal cortex and in the lateral hypothalamus, the representation of food-related stimuli depends on whether the organism is hungry or satiated. The ventral striatum is implicated in the representation of reward value of food-related stimuli and also constitutes a link to the motor system. In the head of the caudate nucleus, which receives a direct input from the orbitofrontal cortex, an appropriate behavioural (motor) response is selected, once the decision is made. (For a detailed review of findings in primates, see Rolls, 1999.)

Human neuroimaging studies suggest that the neural circuitry involved in eating might be more widespread than suggested by primate studies. In the human amygdala, parahippocampal gyrus and anterior fusiform gyrus, neural activity in response to visual food-related cues was found to be hunger-dependent (LaBar *et al.*, 2001). Several loci in the orbitofrontal and medial prefrontal cortex are activated by food stimuli in a sensory specific manner — i.e. they are activated only to food that has not been eaten to satiety (O'Doherty *et al.*, 2000). A positron emission tomography (PET) study in healthy men identified hypothalamus, posterior orbitofrontal cortex, anterior cingulate cortex and insular cortex, but also hippocampus, precuneus, caudate nucleus, putamen and cerebellum as being activated in a hungry state (36 hours fasting) compared to the state of satiety (Tataranni *et al.*, 1999). Satiation on the other hand was associated with increased neural activity in the dorsolateral and anterior ventromedial prefrontal cortices and left inferior parietal lobule, whereas the activity in the hypothalamus, orbitofrontal cortex and insula decreased (Tataranni *et al.*, 1999). The influence of satiety on eating-related brain processing has been further investigated in a study, where chocolate was eaten to satiety and beyond, so that its reward value gradually diminished and even became negative. The activity (measured as regional cerebral blood flow — rCBF — with $H_2{}^{15}O$-PET) in response to eating another piece of chocolate gradually decreased in subcallosal and medial orbitofrontal cortex, insula, striatum and midbrain, whereas lateral orbitofrontal, prefrontal and parahippocampal regions became activated with increasing satiety (Small *et al.*, 2001). The human central appetite control system apparently is comprised of an orexigenic network and an inhibitory control (or anorexigenic) circuit and the balance between these two subsystems determines eating behaviour (Tataranni *et al.*, 1999). The orexigenic network (consisting of orbitofrontal and insular cortices, hypothalamus, parts of striatum and hippocampal formation) activates with fasting and it promotes feeding behaviour. The inhibitory anorexigenic circuit consists of anterior ventromedial and dorsolateral prefrontal cortices and acts to terminate eating, probably by direct inhibition of the orexigenic system (Karhunen *et al.*, 1997; Tataranni *et al.*, 1999; Gautier *et al.*, 2000; Small *et al.*, 2001), see Figure XXIII-7.1.

Little is known about neural correlates of the feeling of hunger. This subjective feeling is not separable from the biological state of acute negative energy balance (fasting) in the available studies on healthy volunteers but in AN the sensation of hunger and the energy balance status are dissociated. Furthermore, most but not all (Karhunen *et al.*, 1997; Gordon *et al.*, 2000), human studies have been performed on male volunteers, whereas the majority of ED patients are females. A PET study of food stimuli perception in females yielded results that were rather inconsistent with other studies; no increase of brain activity was recorded in the fasted state in this study and only parietal deactivation was seen (Gordon *et al.*, 2000). The question of gender differences in the neurophysiology of eating has however not yet been addressed.

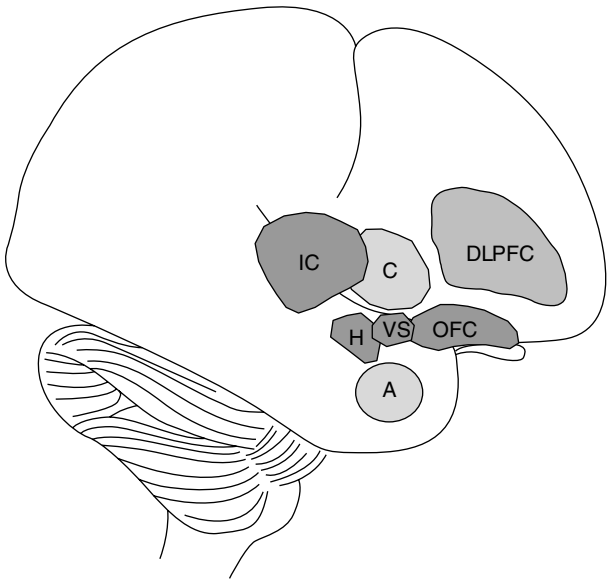

Figure XXIII-7.1 Brain circuits controlling eating behaviour: components of the **orexigenic circuit** are shown in dark shading (OFC — orbitofrontal cortex; VS — ventral striatum; H — hypothalamus; IC — insular cortex); other structures important for eating behaviour in light shading (A-amygdala, C — head of the caudate nucleus); and dorsolateral prefrontal cortex (DLPFC) is shown in medium shading as a structure inhibiting feeding and thus constituting the anorexigenic circuit

Body Image and Anosognosia

Patients with both AN and BN commonly believe their objectively thin bodies or body parts to be fat and large even though their perception of the bodies of other people is usually not distorted (Bruch, 1962; Slade, 1988). Furthermore, any subjective concern about emaciation and its consequences is conspicuously absent (Bruch, 1962), contrasting with their general concern for health and healthy eating in particular. The degree of abnormal body perception and/or conception in ED is akin to neurological disorders such as asomatognosia, microsomatognosia or neglect syndromes or indeed frank delusions or hallucinations. AN is not usually mentioned in writings on anosognosia, but the striking denial of being ill and the body image disturbance are in many ways reminiscent of neurological descriptions of anosognosic patients. As the disturbance in body image is an important constituent of ED psychopathology, we will review the concepts of body representation and its possible contribution to a neuroanatomically based theory of ED.

The body scheme (representing spatial aspects of size, shape and posture) and body image (including also the emotional and cognitive attitudes towards it) depend on multimodal sensory input including proprioception, visual, and haptic tactile sensations (Cumming, 1988; Damasio, 1999; Smeets and Kosslyn, 2001). Unlike early concepts localizing body representation to brain structures in a form of a homunculus, body image is currently viewed as a complex function of a widely distributed network spanning structures from the brainstem to associative cortices (Damasio, 1999). The importance of some of these structures has been highlighted by lesion studies. Considerable evidence implicates the associative parietal cortices, especially in the right hemisphere, and their connections to the thalamus, as lesions in

these areas often produce gross alteration of body perception such as asomatognosia and anosognosia (Cumming, 1988; McGlynn and Schacter, 1989). Anosognosia — unawareness of an obvious deficit is a common phenomenon in many neurological conditions: hemiplegia, cortical blindness (Anton's syndrome), hemianopia, visual agnosia, dementia, amnesia and aphasia, poriomania but also in personality disorder and personality change due to a head injury. In most cases, these disturbances are associated with extensive right parietal lesions (especially in somatic conditions like hemiplegia) or with prefrontal lesions (personality changes) (McGlynn and Schacter, 1989). It has been suggested that the right parietal cortex is the dominant locus for body scheme representation and the proximal prefrontal cortex is important for self-monitoring of the cognitive processes (McGlynn and Schacter, 1989). Thus, damage to these structures would prevent the somatic or cognitive deficits respectively from entering the consciousness. Furthermore, an association of temporal epilepsy with such experiences as micro- or macro-somatognosia (perceiving one's body as smaller or larger) (Trimble, 1988) provides evidence for the participation of temporal lobes in body image representation.

The laterality aspect of body image representation in AN has been examined in a recent study, where body images were morphed to various proportions (thicker and thinner than the real person) and projected separately to the left or right hemisphere in a divided visual field experiment. The left hemisphere tended to identify the subject's own (but not other's) body image with the falsely fatter morphed pictures more often and more quickly than the right hemisphere. The authors suggest that the memory of the subject's own proto-image in the left hemisphere is distorted, whereas the concrete examples represented in the right hemisphere are more accurate (Smeets and Kosslyn, 2001).

In summary, body image representation appears to be a widely distributed and complex function of the CNS with associative cortices of parietal, and possibly frontal and temporal lobes playing important roles; their functioning is nevertheless dependent on multimodal sensory information processing. A pathological disturbance of these structures may be suspected in ED but no particular evidence has been given.

Pain Perception

BN and AN patients have been reported to be less sensitive to pain but the mechanism of this insensitivity is not known (Lautenbacher *et al.*, 1990, 1991). In AN patients, the pain threshold correlates significantly negatively with the local skin temperature, which is suggestive of a primary thermoregulation deficit in AN. In BN patients, the pain threshold tends to correlate positively with body weight (Lautenbacher *et al.*, 1991). The decreased pain sensitivity in ED is not influenced by administration of naloxone and therefore an opiate mechanism seems unlikely to be an important factor. As the pain threshold correlated with the height of patients, it has been hypothesized that a subclinical neuropathy could be the cause (Lautenbacher *et al.*, 1990). The clinical observation that a large proportion of AN patients frequently complain of neuropathic symptoms such as paraesthesias and diminished position sense, also supports the notion of a peripheral neuropathy in AN. Nevertheless, a study aimed at identifying features of a peripheral neuropathy in AN found a selective deficit in pain perception with preserved warmth, cold and vibration recognition in both AN and BN. There was no difference between pain perception from proximal and distal loci, which is considered as an argument against a peripheral neuropathic cause, and therefore the authors concluded that a neuropathy is unlikely to account for elevated pain threshold in ED (Pauls *et al.*, 1991). An autonomic nervous system imbalance has also been suggested as a possible mechanism (Yamamotova and Papezova, 2000).

Decreased pain sensitivity appears to be state dependent in anorexia, because people recovered from AN have normal thresholds (Krieg *et al.*, 1993). Normal pain sensitivity was also found in healthy females after severe food restriction for three weeks (Lautenbacher *et al.*, 1991).

As both BN and AN patients often indulge in self-injurious behaviours, it is interesting that an elevated pain threshold (measured by the cold-pressor test) has also been found in people with borderline personality disorder who reported that they do not experience pain during self-harm (Russ *et al.*, 1992).

Neural mechanisms underlying decreased pain sensitivity in ED are unknown and no relay on the pain pathway can be pinpointed or excluded: receptors, afferent nerve fibres, spinal, medullar, thalamic or cortical mechanisms may be involved. Contrary to earlier views, cortical representation is also essential for pain perception. Neocortical areas surrounding the lateral sulcus (Sylvian fissure), notably the parietal operculum and anterior insula, have been identified as playing a crucial role (Treede *et al.*, 2000). Lesions of the anterior insular cortex produce asymbolia for pain (pain is recognized but not accompanied by negative emotions), which implicates this region in the affective underpinning of pain (Berthier, Starkstein and Leiguarda, 1988; Greenspan, Lee and Lenz, 1999). The anterior cingulate cortex performs the integration of a painful affect and behavioural response selection (Devinsky, Morrell and Vogt, 1995).

In summary, people with eating disorders have an elevated pain threshold, which may be a consequence of starvation as it is not present after weight recovery. Most authors consider primarily peripheral causes of this pain insensitivity, but a central mechanism cannot be excluded. While a peripheral mechanism would probably be restricted to pain perception, a central mechanism may be shared with other disturbances found in ED, such as cognitive impairment, hunger insensitivity and emotional dysregulation.

Cognitive Deficit

Neuropsychological examination of cognitive functioning is a valuable tool for detecting and localizing brain dysfunction and Lauer provides a comprehensive review of ED neuropsychology in Chapter XXIII-6 of this book. In this section, these findings will be summarized according to the neuroanatomical correlates of the cognitive functions impaired in ED.

Both deficits in attention and in visuospatial and tactile spatial processing have been consistently found across studies in AN patients (Fox, 1981; Hamsher, Halmi and Benton, 1981; Kingston *et al.*, 1996; Lauer *et al.*, 1999; Maxwell, Tucker and Townes, 1984; Rovet *et al.*, 1988; Szmukler *et al.*, 1992). Patients with anorexia nervosa are particularly impaired in tasks of spatial abilities which require them to copy a complex figure, complete missing parts of a picture or analyse spatial constructions. The right parietal associative cortex is considered to be central in visuospatial processing and spatial attention and several authors raised the suggestion of right parietal dysfunction in AN (Kinsbourne and Bemporad, 1984; Maxwell, Tucker and Townes, 1984; Braun and Chouinard, 1992; Neumarker *et al.*, 2000; Grunwald *et al.*, 2001). As further evidence for right-rather than left-hemispheric neural disturbance in AN, non-verbal and numeric processing have been reported to be more impaired in AN compared to relatively preserved verbal functions and often excellent language-based academic performance (Fox, 1981; Maxwell, Tucker and Townes, 1984; Strupp *et al.*, 1986; Neumarker *et al.*, 2000). Other studies do not however support this distinction (Jones *et al.*, 1991; Kingston *et al.*, 1996).

Deficits in executive functions, which are mainly attributable to the prefrontal cortices, have also been reported in AN. Problem solving (Szmukler *et al.*, 1992; Lauer *et al.*, 1999), working

memory (Green *et al.*, 1996; Kingston *et al.*, 1996), and cognitive and perceptual set shifting (Kingston *et al.*, 1996; Tchanturia *et al.*, 2001, 2002) have all been reported to be impaired in AN.

As cerebral atrophy is a common finding in AN, several studies combined neuropsychological tests and MRI (magnetic resonance imaging) structural measurements to address the question of whether there is a relationship between structural atrophy and cognitive deficits, but the correlations were generally insignificant (Kingston *et al.*, 1996; Neumarker *et al.*, 2000).

Neuropsychological studies in BN are scarce, but the available evidence indicates cognitive impairments similar to those in AN, with the addition of increased impulsivity (Ferraro, Wonderlich and Jocic, 1997; Lauer *et al.*, 1999, Tchanturia *et al.*, 2001).

In conclusion, there appears to be widespread cognitive impairment in AN. Deficits in attention, visuospatial and numeric processing, problem solving and set shifting are established (see Table XXIII-7.1). This pattern of cognitive impairment is suggestive of a predominantly parietal and prefrontal cortical dysfunction but this association has not been demonstrated in the available morphological neuroimaging studies. As the degree of cognitive disturbance is relatively mild, a rather subtle deficit can be expected, perhaps detectable by functional neuroimaging.

Table XXIII-7.1 Cognitive deficits in AN and their possible neuroanatomical correlates

Function	Evidence	Anatomical correlate
Attention, concentration	Hamsher, 1981 Szmukler, 1992 Laessle, 1989 Jones, 1991 Kingston, 1996 Lauer, 1999	Right frontal, Right parietal, Thalamus
Visuospatial	Fox, 1981; Hamsher, 1981 Szmukler, 1992 Jones, 1991 Kingston, 1996	Right parietal
(Haptic perception)	Grunwald, 2001

DIRECT EVIDENCE OF NEURAL DISTURBANCE IN ED

In this section we provide an overview of the evidence from brain lesions and from electrophysiological and neuroimaging studies in ED patients.

Due to the ethical limitations of human studies, most of the knowledge on ED neuroanatomy *in vivo* derives from functional neuroimaging and surface electrophysiology studies. The fact that both these methods appear to be relatively more sensitive to the changes in cortical activity than to those occurring in deep subcortical structures, may have contributed to focus the attention on neocortical functions. The relative importance of some subcortical structures implicated in eating behaviour by the primate single neuron recording studies, e.g. hypothalamus and ventral striatum, cannot be adequately assessed by these methods. There is a relative dearth of the electrophysiological studies compared to the rapidly expanding neuroimaging research.

While functional neuroimaging simply implicates a region as active under certain conditions, the lesion studies provide valuable information on the indispensability of a structure for physiological eating behaviour. In human lesion studies it is however not possible to differentiate between cellular and fibre damage and between acute effects and subsequent adaptation.

Given these methodological differences and limitations, a careful comparison between results of various studies is necessary and only findings replicated by different methods should be taken into account, when constructing an integrated model of brain dysfunction in ED.

Disorders of Eating Associated with Brain Lesions

Although primarily genetic and psychological explanations for ED are prevalent in the recent literature, there is also evidence that relates disordered eating to specific brain lesions and neurological disease. Cases with an obvious somatic cause constitute a small minority of ED, but they are helpful in understanding neural mechanisms underlying eating and its disorders.

Lesions of prefrontal and temporal cortices, mesiotemporal structures and the hypothalamus have all been reported to produce the clinical manifestations of ED, notably AN (Chipkevitch, 1994; Griffith and Hochberg, 1988; Regard and Landis, 1997; Signer and Benson, 1990; Ward *et al.*, 2000). Lesion studies also provide evidence for a right-hemispheric dominance for eating physiology and pathology. Tumours causing anorexia were found to be predominantly located in the right anterior quadrant (Griffith and Hochberg, 1988) as were lesions causing the so-called 'gourmand syndrome', a benign preoccupation with fine eating (Regard and Landis, 1997). Both right temporal and right frontal lesions are associated with eating-related symptoms. Fisher (1994) reported a case where a sudden feeling of hunger was a first symptom of right anterior temporal haemorrhage and hunger is prominent among the symptoms of temporal lobe epilepsy (Gastaut, 1955). An association of AN with temporal lobe epilepsy has also been reported (Signer and Benson, 1990). Bilateral damage to the temporal lobes leads to the Klüver–Bucy syndrome which includes, among other symptoms, hyperphagia and hyperorality (Klüver and Bucy, 1939; Terzian and Ore, 1955). There are several case studies of anorexia associated with tumours affecting the hypothalamus (Heron and Johnston, 1976; Lewin, Mattingly and Millis, 1972; Weller and Weller, 1982) but only one of these tumours was limited to the hypothalamus alone (Lewin, Mattingly and Millis, 1972). An association of AN syndrome with right prefrontal lesions has been reported in several cases (Ward *et al.*, 2000).

In conclusion, lesion studies indicate the hypothalamus and frontal and temporal lobes as physiologically indispensable for eating. Predominance of the right-hemispheric cortical regions is supported by considerable evidence. Especially the right frontal

lesions seem to be causally associated with clear-cut AN syndrome in its whole complexity.

Electrophysiology

Sixty percent of adolescent AN patients have some disturbance of spontaneous electrical activity in their resting electroencephalogram (EEG) which, in most cases, does not improve with weight gain (Rothenberger, Blanz and Lehmkuhl, 1991). Poor modulation of brain responses to auditory stimuli of various intensity and uncoupling of cortical and subcortical systems has been suggested, based on an augmenting/reducing paradigm auditory evoked potential study; this partially normalizes with weight gain (Rothenberger, Blanz and Lehmkuhl, 1991). A study of event-related potentials (ERP) in eating disorders found a prolonged P300 latency (but normal P300 amplitude) in all three ED groups (BN, BPAN, RAN); this may reflect slowness of cognitive processing (Otagaki *et al.*, 1998). Finally, an extensive ERP study by Bradley and coworkers (1997) provides further support for a right hemisphere dysfunction in AN, demonstrating that AN patients fail to show the normal R > L asymmetry for non-verbal tasks seen in control subjects. They also found that the ERP's latency and amplitude abnormalities in AN were most pronounced in the central-parietal region.

Neuroimaging

Neuroimaging research provides direct information on brain dysfunction in eating disorders and Naruo gives a detailed review of both structural and functional neuroimaging studies in Chapter XXIII-8. Only findings most relevant to the neuroanatomy of eating disorders are summarized here.

Whereas most structural imaging findings point to an overall decrease in brain white and grey matter, functional imaging studies, performed either at rest or under a specific challenge, have reported dysfunction of specific brain regions. When AN patients are examined at rest, both global and regional changes in brain function have been reported in terms of increased or decreased brain perfusion or metabolism (Delvenne *et al.*, 1995, 1999; Takano *et al.*, 2001; Naruo *et al.*, 2001). The most frequently reported functional brain abnormalities include global cerebral hypofunction (Delvenne *et al.*, 1995, 1999), anterior cingulate and frontal hypofunction (Delvenne *et al.*, 1995; Nozoe *et al.*, 1995; Takano *et al.*, 2001; Naruo *et al.*, 2001), parietal hypofunction (Delvenne *et al.*, 1995, 1999), and basal ganglia hyperfunction (Delvenne *et al.*, 1999; Herholz *et al.*, 1987). Takano *et al.* (2001) also reported increased perfusion in thalamus and in the hippocampo–amygdalar complex, but these findings have not yet been replicated. Global brain hypometabolism most pronounced in the temporoparietal and frontal regions persists after recovery from AN (Rastam *et al.*, 2001).

In BN patients parietal hypometabolism (Delvenne *et al.*, 1999) and a loss of the normal right > left asymmetry of brain glucose metabolism (Wu *et al.*, 1990) (Andreason *et al.*, 1992) were demonstrated.

To further explore the neural basis of ED symptomatology, specific behavioural challenges (e.g. eating or viewing caloric food) have been used. In AN patients perfusion of the frontal lobes increased in reaction to eating a cake (Nozoe *et al.*, 1993), viewing colour photographs of food and drink activated the right orbitofrontal cortex (Uher *et al.*, 2001) and labelled high-caloric drinks elicited a response in amygdala, insula, anterior cingulate and prefrontal cortex (Ellison *et al.*, 1998). Interestingly, patients with anorexia and bulimia displayed inverse patterns of cerebral perfusion before and after eating a cake: in BN high frontotemporal perfusion at rest abated after eating a cake; in the AN group low frontotemporal perfusion at rest contrasted with an increase while eating (Nozoe *et al.*, 1995). Patients with binge-purging AN (but not restrictive AN) showed increases in glucose metabolism in the right frontal and parietal regions while visualizing a custard cake (Naruo *et al.*, 2000).

In summary, neuroimaging research provides most convincing evidence for a frontal lobe dysfunction in anorexia nervosa; this comprises a decreased resting activity as well as an overreaction of some frontal regions to specific stimuli. Some abnormalities (e.g. parietal hypometabolism) are common to AN and BN, whereas other findings differ between these diagnoses (e.g. frontal lobe reaction to eating).

CONCLUSION

As eating disorders are primarily psychiatric diseases, their genesis and symptomatology are presumed to result from alterations in brain neural networks. In this paper, evidence from physiology, neuropathology, neuropsychology and neuroimaging has been brought together to identify the underlying neural abnormalities. Data obtained with various research methods are summarized in Table XXIII-7.2 according to the brain structures they implicate.

Table XXIII-7.2 Brain structures possibly dysfunctional in ED

Structure	Indirect evidence	Direct evidence
Prefrontal cortex (including orbitofrontal cortex and anterior cingulate)	Eating behaviour Executive cognitive functions deficit (set shifting, problem solving) Personality characteristics	Brain lesions: Ward, 2000; Griffith and Hochberg, 1988; Regard and Landis, 1997 Neuroimaging: Nozoe, 1993, 1995; Delvenne, 1993, 1999; Takano, 2001; Naruo, 2000, 2001; Ellison, 1998; Uher, 2001
Parietal cortex	Visuospatial abilities Number processing Haptic perception Body image Awareness of bodily status Anosognosia Pain perception	Neuroimaging: Delvenne, 1995, 1999 Electrophysiology: Bradley *et al.*, 1997; Grunwald, 2001
Right hemisphere	Cognitive deficit predominantly in non-verbal and spatial skills Right-hemispheric dominance for eating behaviour	Brain lesions: Griffith and Hochberg, 1988; Regard and Landis, 1997; Ward, 2000 Neuroimaging: Nozoe, 1993, 1995; Naruo, 2000; Uher, 2001 Electrophysiology: Bradley *et al.*, 1997
Temporal cortex	Contributes to hunger (Fisher, 1994) and taste recognition (Small, 1997) Klüver–Bucy syndrome	Neuroimaging: Nozoe, 1993, 1995
Insular cortex	Taste, visceral sensing, pain, disgust, body scheme representation	Neuroimaging: Ellison, 1998
Striatum (basal ganglia)	Eating behaviour	Neuroimaging: Herholtz, 1987; Delvenne, 1999
Hypothalamus	Neurohumoral disturbances Eating behaviour	Tumours associated with anorexia: Lewin, 1972

This table reflects an apparent shift in emphasis from hypothalamic and endocrine mechanisms to the neocortical circuits based theories, which is characteristic of much of the current research. The structures in Table XXIII-7.2 are listed roughly in the order of their importance with the reservation that there is functional interdependency within cerebral networks. The available data consistently implicates the association cortices of frontal and parietal lobes as probable loci of dysfunction. Primary involvement of these high-order associative cortices with a multiplicity of functions may reflect the complexity of these diseases. In the face of this complexity and relative lack of consistency in some research results, substantial changes in our concept of ED are still likely to occur and a consensus on the aetiology and neural basis of eating disorders will remain a challenge for future research.

Brain Imaging

Tetsuro Naruo

INTRODUCTION

There is a general consensus that the aetiology of eating disorders is multidetermined, affected by biological, psychological and social factors that interact in a complex fashion (Garfinkel, Kennedy and Kaplan, 1995). And while it is clear that no one cause for eating disorders will be discovered, the role of the central nervous system (CNS) deserves special attention as the CNS must play a central role in mediating and maintaining eating behaviours. A fuller understanding of CNS control of eating may lead to improvements in the medical treatment of various disorders of eating. For these reasons, direct and non-invasive analytic methods of brain imaging are now widely applied in the study of eating disorders (Ellison and Foog, 1998; Krishnan and Gadde, 1998; Grady, 1999; Demaerel, 2000; Hendren, De Backer and Pandina, 2000).

This chapter will review the research findings from brain imaging techniques focusing on anorexia nervosa and bulimia nervosa, and categorizing the studies as either structural or functional. The literature on obesity will also be reviewed, as a substantial proportion of the obese in weight control programs have binge-eating behaviour (De Zwaan *et al.*, 1994) and are reported to have many characteristics in common with patients suffering from eating disorders (Stunkard, 1996).

Tables XXIII-8.1 and XXIII-8.2 present a brief summary of the studies reviewed in this chapter according to the brain imaging techniques used.

STRUCTURAL IMAGING FINDINGS

Computed Tomography

Anorexia Nervosa

Numerous important findings in patients with anorexia nervosa were detected by computed tomography (CT) in studies performed in the 1980s. These structural changes are characterized by an enlargement of the cortical and cerebellar sulci, the interhemispheric fissure and the cisterns, and a widening of internal cerebrospinal fluid (CSF) spaces (Datlof *et al.*, 1986; Lankenau *et al.*, 1985). According to these studies, as body weight increased, these changes, labelled 'pseudoatrophy' returned to normal (Kohkmeyer, Lemkuhl and Poutska, 1983; Artmann *et al.*, 1985).

However, there may be different patterns of recovery for the cortical sulci and ventricles over the course of weight restoration. In one of these studies, 15 anorexic patients out of 25 displayed enlarged ventricles and cortical sulci. After 3 month's treatment, the cortical sulci returned to normal while the ventricles remained enlarged (Dolan, Mitchell and Wakeling, 1988). The authors suggested that ventricular enlargement might require longer than 3 months to recover, or that with sufficient chronicity the observed changes in ventricular size might be irreversible. The observed reversal of sulcal widening following refeeding was interpreted as upholding a hypothesis that the observed changes are secondary to malnourishment.

Table XXIII-8.1 Brain imaging studies of eating disorders: structural brain imaging studies

Instruments	Reference	Subjects	Main findings
CT	Dolan *et al.* (1988)	25 AN	Decreased sulcal widening and persisting ventricular enlargement in recovered AN
CT	Krieg *et al.* (1989)	50 BN vs 50 AN vs 50 C	Enlarged CSF spaces in both AN and BN patients
MRI	Hoffman *et al.* (1989)	8 BN vs 8 C	Greater cortical atrophy in BN patients indicated by SCCR
MRI	Golden *et al.* (1996)	12 AN	Inverse correlation between BMI and total ventricular enlargement
MRI	Kingston *et al.* (1996)	46 AN vs 41 C	Association between lower BW and disturbed flexibility/inhibition and memory
MRI	Lamabe *et al.* (1997)	12 AN vs 18 C	Persisting cerebral grey-matter volume deficits after weight recovery

Table XXIII-8.2 Brain imaging studies of eating disorders: functional brain imaging studies

Instruments	Reference	Subjects	Main findings
SPECT	Gordon *et al.* (1997)	15 AN	Unilateral temporal lobe hypoperfusion
SPECT	Karhunen *et al.* (2000)	19 Obese vs 12 C	Correlation between hunger and the rCBF of the lt. frontal and temporal regions
SPECT	Naruo *et al.* (2000)	7 AN-R vs 7 AN-BPvs 7 C	Activation on the rCBF in rt. frontal cortical regions in AN-BP during imagining food
PET	Andreason *et al.* (1992)	11 BN vs 18 HC	Functional links between depressive symptoms and lt. prefrontal hypometabolism
PET	Delvenne *et al.* (1999)	10 AN vs 10 BN vs 10 C	Global hypometabolism in AN and a common parietal cortex dysfunction in ED
PET	Gautier *et al.* (2000)	11 Obese vs 11 C	Greater increases in rCBF in the prefrontal cortex in obese men to satiation
fMRI	Ellison *et al.* (1998)	6 AN vs 6 C	Activation in a limbic and paralimbic network in AN under food stimuli

In another study, enlarged external CSF spaces were found in 43 (86%) of 50 anorectic patients (Krieg, Lauer and Pirke, 1989a). In a subgroup of 25 subjects examined both at admission and discharge the authors showed that while external CSF was still greater than normal controls, significant decreased had occurred compared to pre-treatment. Among several possible pathogenetic mechanisms thought to be responsible for these morphological brain alterations in patients with anorexia nervosa, hypercortisolemia was suggested as a possible mechanism as reversible changes on CT scan are found not to be unique to anorexia nervosa and have been reported in Cushing's disease, following therapeutic administration of corticosteroids, and in alcohol abuse and dependence.

Bulimia Nervosa

Morphological brain alterations have also been found in patients with bulimia nervosa via CT examinations. A study revealed that patients suffering from bulimia displayed enlarged external CSF spaces. The larger number of patients (13 of 28) than control subjects (2 of 18) displaying signs of cortical atrophy was statistically significant (Krieg, Backmund and Pirke, 1987). It is interesting to note that nine patients who had no history of anorexia nervosa also displayed cortical atrophy. The authors discussed various possible pathogenetic mechanisms, such as changes in the permeability of the blood vessels, diminished blood volume, protein loss with a subsequent movement of intracellular fluid into extracellular spaces or inhibition of brain protein biosynthesis, that have been thought to be responsible for the enlargement of the CSF spaces.

A comparison of 50 bulimia nervosa patients to 50 anorexia nervosa patients and 50 age-matched control subjects, showed increased rates and severity of sulcal widening and ventricular enlargement in both anorexia nervosa and bulimia nervosa subjects compared to controls though the degree and frequency of atrophic changes in bulimics were not so pronounced as in anorexics (Krieg *et al.*, 1989a, 1989b). In this study, the authors assumed that the morphological brain alterations might reflect the endocrine and metabolic reactions to starvation or abnormal eating behaviours as a low concentration of the plasma level of triiodothyronine was inversely correlated with ventricular size in the patients.

Magnetic Resonance Imaging

Anorexia Nervosa

Studies performed using magnetic resonance imaging (MRI) began to appear in the late 1980s, reporting similar findings to those using CT (Palazidou, Robinson and Lishman, 1990; Swayze *et al.*, 1996). MRI studies have expanded on the work done in earlier CT studies. For example, in a study of 12 subjects with anorexia nervosa after 11 months treatment, there was an inverse relationship between body mass index and total ventricular volume (Golden *et al.*, 1996).

Another study compared 12 weight recovered anorexic patients with 13 low-weight anorexic patients and 18 normal controls (Lambe *et al.*, 1997). The weight recovered patient's average BMI was 20.5 and time since weight recovery was more than 1 year. The low-weight patients' average BMI was 15.6. While weight recovered anorexia nervosa patients showed significantly larger grey-matter volume compared to ill subjects, it was still smaller than in the normal controls. The weight recovered group showed no significant difference from the control group on total white-matter volumes though remaining higher than the ill group.

Another study comparing anorexic patients before and after weight gain demonstrated correlations between structural brain abnormalities and neuropsychological function (Kingston *et al.*, 1996). Forty-six patients with anorexia nervosa were compared to 41 normal controls and found to be poor in performance on the attention, visuospatial and memory tasks. On tasks assessing flexibility and learning, no group differences were evident although an examination of deficits in individuals revealed that more anorexics were impaired on both types of tasks. Attention tasks improved, after the patients had gained 10% (BMI = 17.9) of their body weight. The enlarged ventricles and dilatated sulci were both reduced, but showed no correlation with the observed cognitive impairments. The authors also reported that lower weight, but not duration of illness, was associated with poorer performance on tasks assessing flexibility/inhibition and memory, and greater MRI ventricular size. The findings here should be interpreted with caution, but the study is important since it speculates on the relationship between cognitive function and structural findings.

A prospective cohort study using MRI was performed to examine the brains of female adolescents after weight recovery from AN (Katzman *et al.*, 1997). Of 13 patients who underwent an MRI study at low weight, six patients were re-scanned after weight recovery. Quantitative analysis showed that white matter and CSF volumes changed significantly on weight recovery but that there were significant grey-matter volume deficits and enlarged CSF spaces compared to aged-matched female controls. Both of these findings suggest that anorexia nervosa may exert different effects on grey-matter and white-matter volumes, with the former appearing to be more closely related to the degree of weight loss. These results suggest that the abnormalities found in grey matter, white matter, and CSF volumes may resolve to varying degrees and over time with weight restoration.

Since it is well established that glucocorticoids inhibit the proliferation of progenitor cells that occurs in the hippocampal dentate gyrus of adult mammals (Kuhn, Dickinson-Anson and Gage, 1996), hypercortisolemia and other abnormal factors induced by malnutrition may have a specific role in producing the distorted recovery processes of remyelination of grey- and white-matter volumes in patients with anorexia nervosa.

Bulimia Nervosa

Patients with bulimia nervosa have also been investigated with MRI scans. In one study, eight consecutive unmedicated bulimics without a history of anorexia nervosa or alcohol abuse were compared with eight sex and age-matched controls (Hoffman *et al.*, 1989). Using the sagittal cerebral/cranial ratio (SCCR): an easily obtainable and replicable method of quantifying relative cerebral size, the authors found cortical atrophy to be significantly greater in the bulimic group compared to controls. But they failed to find significant differences in ventricle/brain ration (VBR) between bulimics and controls. Methodologic differences in measuring or different metabolic patterns in various brain areas were thought to be responsible for the atrophy found in the two different areas because the correlation between VBR and SCCR was quite low. In discussion the authors described that hypercortisolisms, elevated beta-hydroxy-butyric acid and a loss of brain tissue water due to changes in vascular permeability might be possible causes of brain atrophy.

Anorexia Nervosa and Bulimia Nervosa

Another small study, comparing 18 eating disorder patients (eight anorexia nervosa, 10 bulimia nervosa patients) to 13 normal controls, examined the size and morphology of the pituitary gland using MRI (Doraiswamy *et al.*, 1990). Both anorexics and bulimics showed smaller pituitary gland areas compared with controls. Though the mean values were longer, none of the pituitary measurements in the bulimics differed significantly from those of the anorexics. The authors mentioned that the smaller pituitary sizes

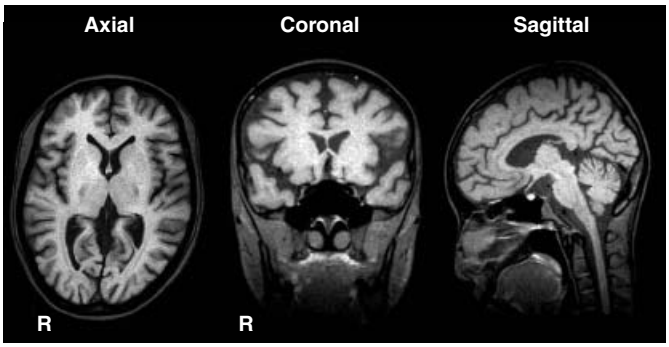

Figure XXIII-8.1 MRI displaying typical brain atrophy of a young female patient with severe anorexia nervosa. Three T1-weighted images show an enlargement of the cortical and cerebellar sulci, cisterns and ventricular dilatation

in the group of patients compared to controls may reflect pituitary atrophy secondary to nutritional or endocrine alterations.

Summary

In summary, early studies using CT and MRI indicated that the morphological alterations in patients with anorexia nervosa were due to weight loss. However, the occurrence of cortical atrophy in normal weight bulimics, as well as relative absence of ventricular enlargement in these patients, suggest more complicated possible mechanisms inducing cerebral atrophy in eating disorders.

Figure XXIII-8.1 shows an example of pseudo cerebral atrophy in anorexia nervosa revealed with MRI. There are obvious structural abnormalities such as an enlargement of the cortical and cerebellar sulci and cisterns, and ventricular dilatation.

FUNCTIONAL IMAGE FINDINGS

Single Photon Emission Computed Tomography

Anorexia Nervosa

Anorexia nervosa has been studied by single photon emission computed tomography (SPECT) since 1989. These studies have used radioactive tracers, allowing the measurement of brain blood flow. In the earlier studies regional cerebral blood flow (rCBF) was measured by the xenon-133 inhalation method.

One early study compared 12 anorexic patients to 12 normal controls at rest using CT and SPECT with xenon-133. This study revealed that the anorexic patients showed no significant reduction in rCBF compared to controls. However, there was a significant inverse relationship between VBR measured by CT and rCBF (Krieg *et al.*, 1989b).

Since the early 1990s ^{99m}Tc-hexamethylpropylene amineoxime (HM-PAO) has become available for the investigation of rCBF. HM-PAO behaves like a chemical microsphere quasipermanently trapped in the brain and allows imagings of regional cerebral perfusion (Inugami, 1988).

SPECT study using HM-PAO observed changes in rCBF before and after weight gain. Subjects were 15 patients with anorexia nervosa, three of whom were re-examined after weight gain. Eight of 15 subjects showed unilateral left-sided temporal lobe hypoperfusion and five of 15 right temporal lobe hypoperfusion. The three subjects re-scanned after weight gain showed a further 10% reduction in perfusion (Gordon *et al.*, 1997). Another study comparing rCBF of anorexic patients before and after 3 months of treatment, reported that the low blood flow in frontal, parietal and frontotemporal areas normalized after weight gain (Kuruoglu *et al.*, 1998).

HM-PAO also allows for activation studies. One preliminary study using a food intake stimulus in five normal controls and seven anorexic patients analysed ratios of the radioactive counts in a region of interest to the cerebellum in various cortical regions before and after eating, and before and after weight gain (Nozoe *et al.*, 1993). Patients showed a significant increase of the percentage of rCBF in the left inferior frontal region but had no significant difference of the ratios before treatment. After weight gain, the patients failed to show significant differences in the percentage of rCBF though they significantly increased the ratios in both sides of the temporal cortex in the rest period.

Another study using a food sight stimulus revealed different response patterns of the percentage of rCBF in anorexic patients with binge/purge behaviour compared to restricting anorexics (Naruo *et al.*, 2000). The results of this study indicate that anorexic patients with habitual binge/purge behaviour display increases in regional cerebral blood flow in the right cerebral hemisphere, especially in the inferior frontal and parietal region with a food-related visual stimulus.

There has recently been progress in converting the techniques of PET imaging into SPECT. Two recent studies using statistical parametric mapping (SPM) 96 analysis reported hypoperfusion in the anterior frontal areas in untreated restricting anorexia nervosa at baseline. The first study using HM-PAO found hypoperfusion in the frontal area, mainly bilaterally in the anterior cingulate cortex (ACC) in restricting anorexia nervosa patients compared to anorexia nervosa patients with binge/purge behaviour and healthy volunteers (Naruo *et al.*, 2001). The other SPECT study using Iodin-123-iodoamphetamine (IMP) and SPM analysis also found hypoperfusion in the ACC and medial prefrontal area. Furthermore, a significant hyperperfusion was found in the thalamus and the amygdala–hippocampus complex when compared to the normal subjects (Takano *et al.*, 2001). Since the frontal regions including the ACC have often been reported to be very important in controlling a wide range of higher brain functions, the identical finding concerning the ACC in these two studies suggested that dysfunction of the ACC may possibly be associated with the causing or maintaining of abnormal eating behaviour in anorexia nervosa patients.

Anorexia Nervosa and Bulimia Nervosa

A study using the same experimental design and radioactive tracer examined eight untreated patients with anorexia nervosa, five patients with bulimia nervosa, and nine normal controls (Nozoe *et al.*, 1995). Comparisons across the three groups using a food intake stimulus showed an increase in ratios of the radioactive counts in a region of interest to the cerebellum in the bilateral inferior frontal and left temporal regions in the bulimic patients at baseline. In the anorexic patients, an overall decrease of the normalized radioactivity before stimulus and a significant decrease in the left temporal region were observed at baseline. After exposure to food the intake stimulus only the anorexic patients showed an increased blood flow in a wide region of the cortex, more specifically bilaterally in the inferior frontal, parietal and occipital regions. The authors hypothesized that the increases in rCBF after a food intake stimulus in both studies could reflect changes necessary for patients with anorexia nervosa to control their eating behaviour. On the other hand, the small or negative changes in rCBF in the superior and inferior frontal regions in the bulimia nervosa patients could be correlated with their eating behaviour.

Bulimia Nervosa

Using iodine-labelled [^{123}I]-2β-carbomethoxy-3β-(4-iodophenyl) tropane ([^{123}I] β-CIT) and SPECT, the first exploratory investigation of brain serotonin and dopamine transporter availability in bulimia nervosa has recently been reported (Tauscher *et al.*, 2001). These authors found that 10 bulimic patients showed a 17% reduction in brain serotonin transporter availability in the hypothalamus and thalamus and a 15% reduction in striatal dopamine transporter availability as compared to controls. In particular, the reduction of [^{123}I] β-CIT binding in the hypothalamus and thalamus was reported to be in line with a previous study demonstrating decreased serotonergic transmission in bulimia nervosa. The authors note that it remains unclear whether the reduced serotonin transporter availability is an aetiologic defect, an adaptive mechanism, or an unrelated epiphenomenona of some other process.

Positron Emission Tomography

Anorexia Nervosa

The first preliminary study on anorexia nervosa using (18-F)-fluordeoxyglucose (FDG) and positron emission tomography (PET) was reported in 1987. It was a comparison study of five female patients with anorexia nervosa, before and after treatment, and 15 young male controls (median 29 years) (Herholz *et al.*, 1987). The results were that the anorexic patients before treatment displayed significant bilateral hypermetabolism in the caudate nuclei and temporal cortex compared to post-treatment. Whole brain metabolism was also reported to be higher in the anorexic patients before treatment compared to post-treatment and controls. The authors mentioned that since cortical pseudoatrophy would be associated with hypometabolism in the atrophic structures the observed hypermetabolism cannot be explained by partial volume effects.

Another study examined cerebral glucose metabolism using FDG in 20 patients with anorexia nervosa and 10 healthy controls. Compared to controls, the anorexic group showed global hypometabolism and an absolute as well as relative hypometabolism of glucose in cortical regions, with the most significant differences found in the frontal and the parietal cortices (Delvenne *et al.*, 1995). Within the anorexic and the normal volunteer groups, no correlations were found between absolute or relative cerebral glucose metabolism (rCMRglu) and BMI, anxiety, or Hamilton Depression Rating Scale scores. Different factors may explain the reduced glucose metabolism in anorexia nervosa. It might be the consequence of neurophysiological or morphological aspects of anorexia nervosa and/or the result of some associated symptoms such as anxiety or depression. Supported by cognitive studies, the authors also hypothesized a primary corticocerebral dysfunctioning in anorexia nervosa.

Bulimia Nervosa

Several studies in bulimia nervosa using PET and FDG or [^{15}O]water have been reported as follows.

A preliminary study of eight female bulimia nervosa patients, eight depressed women and eight normal controls revealed that the normal controls and the depressed patients had high metabolic rates in the right cortical regions, whereas the bulimic group instead had high rCMRglu in the basal ganglia (Hagman *et al.*, 1990). From these findings the authors concluded that although women with bulimia nervosa frequently present with symptoms of depression, the pathophysiologic changes associated with bulima differ from depression.

A study of 11 bulimia nervosa patients and 18 normal controls investigated the relationship between rCMRglu and the symptoms of depression, obsessive–compulsive disorder, and bulimia nervosa (Andreason *et al.*, 1992). It was demonstrated that in the patients with bulimia nervosa a lower left anterolateral prefrontal rCMRglu correlated with a greater amount of depressive symptoms, while left temporal lobe hypermetabolism and asymmetries observed in the bulimic patients appeared to be independent of the mood state. The authors also reported that they failed to observe a pattern characteristic of obsessive–compulsive disorder in the patients with bulimia nervosa.

In a study comparing 10 patients with bulimia nervosa of normal body weight, 10 patients with anorexia nervosa and 10 normal controls, the absolute rCMRglu was reduced only in the anorexic patients (Delvenne *et al.*, 1999). This was hypothesized to be related to the low body weight. On the other hand, both anorexic and bulimic patients displayed a decreased in rCMRglu in the parietal cortex. The authors hypothesized that this region might be particularly sensitive to nutritional factors, leading to characteristic changes in this region.

Recently a PET study using [^{15}O]water investigated rCBF in recovered bulimia nervosa patients (Frank *et al.*, 2000). Comparing nine recovered patients to 13 normal controls, a significant inverse relationship between rCFB in several cortical regions and the thalamus and length of recovery was found. The authors suggest that previously reported alterations in rCBF in bulimia nervosa patients during the ill state is a state-related phenomenon that remits with recovery.

Functional Magnetic Resonance Imaging

Anorexia Nervosa

Functional magnetic resonance imaging (fMRI) is a good tool for investigating regional brain abnormalities associated with specific cognitive processes. Because it can map fine changes in cerebral blood flow without using radioactivity, it is expected to be a useful way to investigate brain function in eating disorders.

Up to now, only one fMRI study has been published. The study compared with six patients with anorexia nervosa and six normal controls using videotaped pictures of drinks labelled high (e.g. chocolate milkshake) and low (e.g. still mineral water) calories, respectively (Ellison *et al.*, 1998). The anorexic group showed a higher level of anxiety along with an increased blood flow in response to the contrasting stimuli, especially in the left insula, anterior, cingulate gyrus and left amygdala-hippocampal region.

The authors suggested that the findings provided evidence that the fear associated with high caloric food in people who have anorexia nervosa is associated with activation in a limbic and paralimbic network. The abnormal activity in this area of the brain was suggested to be a linked with an abnormal preoccupation with food-related items.

Magnetic Resonance Spectroscopy

Anorexia Nervosa

Analysis of the chemical composition of the brain in anorexia nervosa using magnetic resonance spectroscopy (MRS) has been the subject of a few reports.

One study of four anorexic patients suggested that the main cause of the brain structure changes such as brain atrophy, was an abnormality in membrane phospholipid metabolism due to the starving state of anorexia nervosa patients (Kato *et al.*, 1997). Another study, comparing 12 anorexic patients with seven normal controls revealed that the ratio of choline containing compounds relative to total creatine in the grey matter was significantly higher in anorexia nervosa subjects compared to controls, but

that anorexia nervosa subjects showed significantly lower ratios of *N*-acetyl-aspartate relative to choline containing compounds compared to controls (Schlemmer *et al.*, 1998).

Anorexia Nervosa and Bulimia Nervosa

A study comparing a group of anorexia nervosa patients, bulimia nervosa patients, and normal controls using MRI and MRS in three regions of the brain, found that reductions in the myo-inositol and lipid compounds (containing lipids, proteins and lactate) within the frontal white matter correlated with reductions in body weight (Roser *et al.*, 1999). Furthermore, reduced lipid signals were found in the occipital grey matter, but on the other hand, in the cerebellum, the concentration of all metabolites except lipid was increased. The authors suggested that decrease in myo-inositol was related to hyponatoremia or hypercortisolemia in patients with eating disorders. They also suggested that both altered glucose oxidation and fatty acid metabolism in anorexic patients could explain the reduced spectral intensity of these compounds probably caused by a reduced concentration of free lipoproteins in brain parenchyma.

Summary

Progress in functional imaging techniques have made it possible to identify specific areas of abnormal brain functions regardless of structural changes. Interestingly, the recent studies have reported that untreated anorexia nervosa patients showed decreases in regional blood perfusion and metabolism of the anterior frontal areas. However, we should be careful in understanding the localized abnormal areas of brain functions because it is still very difficult to specify the neuronal projections that account for the observed changes in regional activity.

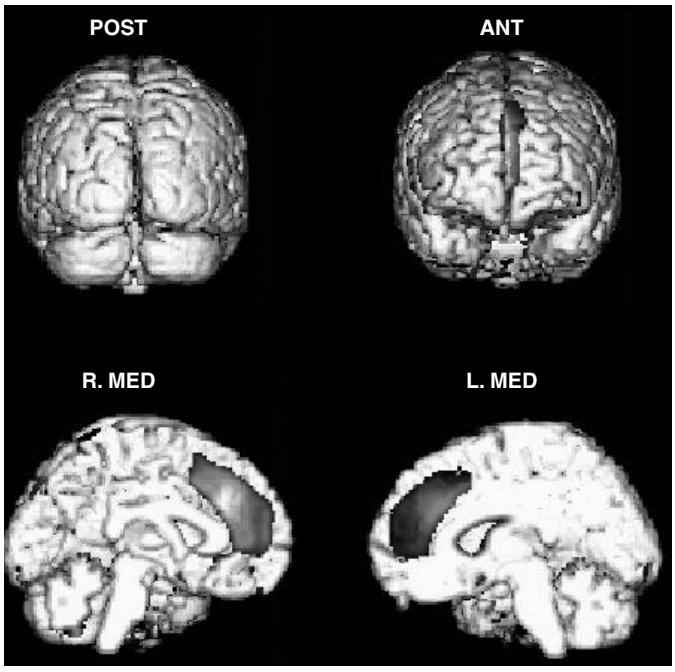

Figure XXIII-8.2 The 3D rendering image displaying area of hypoperfusion. The SPM 96 analysis of SPECT data shows significantly decreased of rCBF in the anorexia nervosa restricters in the bilateral ACC and parts of frontal regions when compared to controls. Height threshold = 3.09, $p = 0.001$, extent threshold = 550

Figure XXIII-8.2 shows the rendering images of an SPM analysis of SPECT data with HM-PAO displaying hypoperfusion both bilaterally in the medial prefrontal regions and in the ACC in restricting anorexia nervosa patients.

RESEARCH ON OBESITY

Although the aetiology of obesity is still unclear, genetic, metabolic, and social factors are all believed to play a role in its development and progression (Stunkard, 1996). Recently, behaviourally distinct subsets of obese persons have been considered to display particular patterns of disordered eating and elevated rates of psychopathology (Devlin, Yanovski and Wilson, 2000). Brain imaging investigations in obese patients may shed light on the mechanisms of the onset and maintenance of obesity. A literature review of this area revealed no studies of structure using CT or MRI, but did locate some functional brain imaging studies.

One study using ^{99m}Tc–ethyl-cysteine-dimer (ECD) and SPECT compared 11 obese women without binge-eating behaviour to 12 normal control females using a food-exposure stimulus. The obese women show higher rCB in right parietal and temporal cortices compared to controls (Karhunen *et al.*, 1997). In addition, higher activity in the right parietal cortex was found to be associated with an enhanced feeling of hunger when looking at food. The authors concluded that the increase in the rCBF of the right cortex after exposure to food could be associated with difficulties in the control of eating since the right hemisphere plays a role in the recognition and control of emotional expressions and related behaviours.

In another study using the same radiotracer in eight obese binge-eating patients and 12 normal controls, regional cerebral blood flow was mapped by SPECT, while the subjects were looking at a picture of a landscape or at a portion of food (Karhunen *et al.*, 2000). When exposed to food the obese patients showed different changes in the cerebral blood flow of the right and left hemisphere, especially in the frontal and prefrontal lobe compared to controls. The increase in blood flow in obese patients was positively correlate with the intensity of hunger. The authors concluded that the left frontal and prefrontal regions could play a role in binge-eating behaviour in humans.

Another study used PET to investigate the functional anatomy of satiation, comparing 11 obese and 11 lean men. It was demonstrated that refeeding after 36 hours of fasting resulted in increases in rCBF in the ventromedial and dorsolateral prefrontal cortex, and decreases in limbic/paralimbic areas and striatum in both groups (Gautier *et al.*, 2000). However, the obese group displayed a significant increase in blood flow in the prefrontal cortex, but a significant decrease in blood flow in the limbic/paralimbic areas, temporal and occipital cortex and cerebellum. The authors suggested that obese individuals have a greater activation of the prefrontal cortex and a greater deactivation of the limbic/paralimbic areas in response to satiation. They also speculated that differences in postprandial amino acid metabolism between lean and obese men might underlie the observed differences in neural activity.

CONCLUSION

The majority of structural studies have examined subjects with anorexia nervosa; few studies have reported on structural changes in bulimia nervosa or obesity. It is now generally agreed upon that alterations in structures such as cerebral atrophy and enlargement of the ventricles are secondary to low body weight (Addolorato *et al.*, 1998). The more recent use of volumetric methods assessing grey- and white-matter volumes has made it possible to assess these changes. While these structural abnormalities typically revert

to normal with weight restoration, the process of this recovery is poorly understood. The precise aetiology of these changes is controversial, hypercortisolemia being an attractive explanation, as associations have been demonstrated between hypercortisolemia and the magnitude of structural brain abnormalities (Katzman *et al.*, 2001).

The use of functional brain imaging techniques has led to significant improvements in our understanding of the characteristic brain functional changes in eating disorders and obesity. However, the limitations of these techniques must be acknowledged because of the following reasons. Changes in regional brain activity are considered to reflect the activity of terminal neuronal fields which include those from local interneurons and afferent projections arising in other sites (Tataranni *et al.*, 1999). Comparisons of studies across countries are complicated by varying diagnostic criteria and differences in establishing appropriate comparison groups. Spatial resolution, contrast resolution of individual subtraction images, and accuracy of the image deformation algorithm make it difficult to specify in greater detail the structures that are responsible for the observed increases in regional brain activity (Woods, 1996).

Furthermore, significant challenges remain for functional imaging. These include the effects of prolonged starvation, the administration of medication, and the effect of comorbidity such as depression and obsessive–compulsive disorders. It is also not clear as to what constitutes optimal experimental designs to compare scans at rest or after specific stimuli or tasks. Technical problems in accounting for individual variations in the shape and volume of the brain have yet to be overcome. It is not yet clear whether the findings to date are only state effects, secondary to starvation, or whether any might be pre-existing trait phenomena. Future studies should try to address these various problems.

Finally, brain imaging techniques are believed to serve as the bridge between the molecular clinical domains of this field (Mazzoitta, 2000). Therefore, using the rapidly developing brain imaging techniques in the study of eating disorders is likely to provide us with important information regarding the understanding of the disease and its possible treatment.

ACKNOWLEDGEMENTS

I would like to thank Dr S. Nozoe and Dr D.B. Woodside for comments and corrections to this manuscript, and Dr Y. Nakabeppu and Ms J. Tsutsui for their assistance in preparing this manuscript.

The Genetics of Eating Disorders

Kelly L. Klump, Cynthia M. Bulik, Walter H. Kaye and Michael Strober

INTRODUCTION

Anorexia nervosa (AN) and bulimia nervosa (BN) are disorders characterized by abnormal patterns of eating behaviour and disturbances in attitudes and perceptions toward weight and shape. In AN, there is an extreme fear of weight gain despite increasing emaciation. BN usually emerges after a period of dieting (Bulik *et al.*, 1997; Mussell *et al.*, 1997) and is characterized by alternating patterns of binge eating and compensatory behaviour. Binge eating, which is the consumption of a large amount of food in an uncontrollable manner, is typically followed by either self-induced vomiting, excessive exercise, fasting, and/or the misuse of laxatives, diuretics or enemas. Although abnormally low body weight excludes a BN diagnosis, 25% to 30% of patients with BN have a prior history of AN (Eckert *et al.*, 1995; Bulik *et al.*, 1997; Strober, Freeman and Morrell, 1997; Garfinkel, Moldofsky and Garner, 1980). Common to individuals with AN and BN are pathological concern with weight and shape, depression, and anxiety (Mitchell *et al.*, 1986; Keck *et al.*, 1990; Fornari *et al.*, 1992; Bulik *et al.*, in press).

The aetiology of these disorders is presumed to be multiply influenced by developmental, social, and biological processes (Garner, 1993; Treasure and Campbell, 1994). However, the exact nature of these interactive processes remains incompletely understood. Cultural attitudes towards thinness have relevance to the psychopathology of eating disorders, but they are unlikely to be sufficient to account for the pathogenesis of these disorders. Notably, dieting behaviour is quite common in industrialized countries throughout the world, yet AN and BN affect only an estimated 0.3% to 0.7%, and 1.7% to 2.5%, respectively, of females in the general population (APA, 1994). Moreover, numerous descriptions of AN date from the middle of the 19th century suggesting that factors other than modern culture play an aetiologic role. In addition, both syndromes have a relatively homogeneous clinical presentation, sex distribution, and age-of-onset, supporting the possibility of some biological susceptibility. This is not to discount the role of culture, as the introduction of Western ideals of thinness may serve to release a biological propensity toward eating disorders (Becker, 1999) possibly by increasing behaviours such as dieting that may trigger the spiral of disordered eating.

Recent findings from behaviour genetic studies suggest that this biological vulnerability might be genetic in nature. In this paper, we will highlight these emerging findings and suggest areas for future research.

HERITABILITY

Family Studies

Family studies provide initial data regarding genetic influence on a disorder by establishing whether it clusters amongst biologically-related individuals. Controlled family studies have generally found increased rates of eating disorders in relatives of women with AN and BN compared to relatives of controls (Biederman *et al.*, 1985; Lilenfeld *et al.*, 1998; Strober *et al.*, 1990, 2000). Findings from the largest and most systematic studies (Lilenfeld *et al.*, 1998; Strober *et al.*, 2000) suggest a 7–12-fold increase in the prevalence of AN and BN in relatives of eating disordered probands. This clustering of eating disorders in families of AN and BN individuals provides strong support for familial transmission of both disorders. However, given that first-degree relatives share both genes and environments, these studies cannot differentiate genetic versus environmental causes for the observed familiality. Systematic studies of twins are the means by which to disentangle the relative aetiological influence of genes and environment.

Twin Studies

Twin studies differentiate genetic from environmental effects by comparing similarity for a trait/disorder between identical (monozygotic (MZ)) and fraternal twins (dizygotic (DZ)). This comparison is based on the fact that MZ twins share all of their genes identical by descent, whereas DZ twins share, on average, half of their genes identical by descent. Consequently, MZ twin correlations that are $\simeq$ two times greater than DZ twin correlations suggest genetic effects. In general, greater MZ relative to DZ twin similarity for AN and BN has generally been found (Holland *et al.*, 1984, 1988; Fichter and Noegel, 1990; Treasure and Holland, 1990). Estimates indicate that roughly 58–76% of the variance in the liability to AN (Klump *et al.*, 2001; Wade *et al.*, 2000), and 54–83% of the variance in the liability to BN (Bulik, Sullivan and Kendler, 1998; Kendler *et al.*, 1991) can be accounted for by genetic factors. Although the confidence intervals on these estimates are wide, consistent findings across studies support moderate heritability of these traits (Bulik *et al.*, 2000). For both AN and BN, the remaining variance in liability appears to be due to unique environmental factors (i.e., factors that are unique to siblings in the same family) rather than shared or common environmental factors (i.e., factors that are shared by siblings in the same family).

Eating disorder symptoms themselves also appear to be moderately heritable. Twin studies of binge eating, self-induced vomiting, and dietary restraint suggest that these behaviours are roughly 46–72% heritable (Sullivan, Bulik and Kendler, 1998; Klump *et al.*, 2000). Likewise, pathological attitudes such as body dissatisfaction, eating and weight concerns, and weight preoccupation show heritabilities of roughly 32–72% (Klump *et al.*, 2000; Rutherford *et al.*, 1993; Wade *et al.*, 1998, 1999). Taken together, findings suggest a significant genetic component to AN and BN as well as the attitudes and behaviours that contribute to, and correlate with, clinical eating pathology.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Developmental Differences

A caveat to the above conclusions is that there appears to be developmental differences in genetic effects across adolescence. Two recent twin studies (Klump *et al.*, 2000, in press) from the Minnesota Twin Family Study (MTFS) have examined this issue by comparing genetic influences on eating attitudes and behaviours in population-based samples of 680 11-year-old twins and 602 17-year-old twins. In the first of these studies, essentially no genetic influence was found for weight preoccupation scores and overall eating pathology in 11 year-old twins, whereas 52–57% of the variance in these attitudes and behaviours could be accounted for by genetic factors in the older cohort (Klump *et al.*, 2000). Increased genetic influence across age was also found for body dissatisfaction scores, although effects were much less dramatic. The authors speculated that these findings may reflect an activation of aetiologic genes during puberty.

In a follow-up study (Klump, McGue and Iacono, in press), the 11-year-old cohort was divided into a pre- and post-pubertal group in order to directly examine the effect of puberty on the heritability of these traits and behaviours. Findings revealed a pattern of results similar to those reported in the initial study (Klump *et al.*, 2000). Genetic factors accounted for 0% of the variance in overall eating pathology scores in pre-pubertal twins, but accounted for 53% of the variance in post-pubertal twins. Although sample sizes were small in the post-pubertal group ($n = 39$ pairs), the similar pattern of twin correlations in the two studies suggested that puberty may account for the dramatic age differences observed earlier. Increased heritability in post-pubertal relative to pre-pubertal twins *who were the same age* provided strong evidence of potential pubertal activation of the heritability of eating pathology that may be mediated by ovarian hormones. These findings are important for highlighting not only developmental differences in genetic effects, but also the potential role of ovarian steroids in the heritability of these disorders.

COMORBIDITY

Individuals with AN and BN commonly present with comorbid psychopathology — most notably affective and anxiety disorders (Bulik *et al.*, 2000). Family and twin studies have been effective in illuminating the causes of comorbidity (Neale and Kendler, 1995) and addressing to what extent comorbidity among these disorders might arise as a function of a shared genetic effect.

Psychopathology

Substance Use Disorders

Family studies investigating substance use disorders suggest relatively low prevalence among relatives of restricting AN probands (Holderness, Brooks-Gunn and Warren, 1994; Lilenfeld *et al.*, 1998). In contrast, rates are elevated in relatives of probands with BN. However, results from three studies (Kaye *et al.*, 1996; Schuckit *et al.*, 1996; Miller *et al.*, 1998) indicate that there is no evidence of a cross-transmission of BN and substance use disorder in families, and twin data (Kendler *et al.*, 1995) have shown that the genes influencing susceptibility to alcoholism were independent of those underlying risk to BN.

Major Depression

Several family and twin studies have examined the covariation between eating disorders and major depression. Studies of AN probands have yielded relative risk estimates for depression in the range of 2.1 to 3.4 (Strober *et al.*, 1990; Lilenfeld *et al.*, 1998). Likewise, studies of BN probands indicate that their first-degree relatives are significantly more likely to develop major depression than relatives of controls (Lilenfeld *et al.*, 1998). However, most studies considering the effects of proband comorbidity on familial risk have shown that affective illness is more likely to be transmitted by probands with this same diagnostic comorbidity (Strober *et al.*, 1990; Lilenfeld *et al.*, 1998). These later studies suggest that although eating disorders and depression may share some aetiologic factors, there are also unique factors specific to each. Two recent twin studies support this conclusion, as both found evidence for shared as well as unique genetic influences on major depression and both AN and BN (Walters *et al.*, 1992; Wade *et al.*, 2000).

Anxiety Disorders

Several different anxiety disorders have been examined for their genetic relationships with eating pathology. In general, evidence supports shared genetic transmission between these disorders and both AN and BN. For example, although obsessive–compulsive disorder (OCD) appears to segregate independently from AN and BN in families (Lilenfeld *et al.*, 1998), shared familial transmission has been found between obsessive-personality disorder (OCPD) and AN and BN (Lilenfeld *et al.*, 1998). In addition, shared familial transmission has been found between broadly defined AN and BN and separation anxiety and overanxious disorder (Keel *et al.*, submitted), and between BN and both simple phobia and panic disorder (Kendler *et al.*, 1995). Taken together, these findings suggest the existence of a broad, genetically influenced obsessive phenotype with core features of rigid perfectionism, anxiety, and a propensity towards behavioural constraint.

Personality and Physical Characteristics

Personality Traits

Individuals with AN and BN exhibit characteristic personality traits including high levels of stress reactivity, negative emotionality, and harm avoidance (Brewerton, Hand and Bishop, 1983; Casper, 1990; Kleifield *et al.*, 1994a, 1994b; Bulik *et al.*, 1995, 2000; O'Dwyer, Lucey and Russell, 1996; Klump *et al.*, 1999, 2000). These characteristics persist after recovery (Casper, 1990; O'Dwyer, Lucey and Russell, 1996; Klump *et al.*, 1999) from the disorder and are independent of body weight (Klump *et al.*, 2000), suggesting that they may be trait disturbances contributing to the disorders' development. The moderately heritable nature of these traits (Tellegen *et al.*, 1988) suggests that relationships may be genetic in nature.

Four studies have examined familial relationships between personality traits and eating disorders, with many suggesting familial co-transmission. Klump *et al.* (1999) found increased levels of negative emotionality and stress reactivity, and decreased levels of well-being, in family members of restricting AN probands compared to control relatives. Likewise, Lilenfeld *et al.* (2000) found increased perfectionism and stress reactivity scores in non-eating disordered relatives of bulimic probands compared to control relatives. Carney, Yates and Cizadlo (1990) failed to find shared transmission between DSM-III-R personality disorder characteristics and BN, although their use of lower prevalence personality disorder symptoms rather than more normative personality characteristics may have prohibited detection of significant effects.

Recent twin study results suggest that familial relationships between personality and eating pathology may be genetic in nature (Klump, McGue and Iacono, in press), as genetic rather than environmental influences have been found to underlie phenotypic

and familial relationships between these characteristics. However, genetic influences that are independent of those operating in personality also appear to contribute to eating pathology (Klump, McGue and Iacono, in press).

Body Mass Index

Vulnerability to obesity has been found to be a risk factor for bulimia nervosa (Fairburn *et al.*, 1997). Body weight is highly heritable (Stunkard *et al.*, 1990) leading to questions of shared genetic transmission between body weight and eating pathology. One study directly examined this question by investigating shared genetic transmission of body mass index (BMI) and disordered eating including body dissatisfaction, weight preoccupation, overall eating pathology, and the use of compensatory behaviours such as self-induced vomiting and laxative abuse (Klump *et al.*, 2000). Findings suggested some shared genetic transmission, although again, the majority of genetic influence on these disordered eating variables was independent of the genes influencing BMI.

Shared Transmission between AN and BN

Cumulating evidence suggests that AN and BN likely share some aetiologic features. Clinically, approximately 50% of women with AN develop BN during the course of their illness and ~30% of women with BN report a history of AN (Bulik *et al.*, 1997; Eckert *et al.*, 1995; Garfinkel, Moldofsky and Garner, 1980; Strober, Freeman and Morrell, 1997).

Family and twin studies indicate an increased risk of both AN and BN in relatives of AN and BN probands (Walters and Kendler, 1995; Lilenfeld *et al.*, 1998; Strober *et al.*, 2000), suggesting a shared familial component between the two disorders. In addition, subthreshold forms of eating disorders appear to lie on a continuum of liability with full eating disorders (Kendler *et al.*, 1991). These findings suggest the existence of a broad eating disorder phenotype with possible shared genetic predispositions.

Summary

Research reviewed above suggests that AN and BN may share genetic transmission with each other and with body weight, personality, anxiety, and possibly major depression. However, findings also suggest that there are genetic influences on eating pathology that are independent of those influencing the traits/disorders mentioned above. This complexity is the norm rather than the exception in psychiatric genetics and highlights the need for additional research to further characterize the genetic variance of these disorders.

MOLECULAR GENETIC STUDIES

A detailed comparison of the molecular genetic designs that can be brought to bear upon complex traits is beyond the scope of this chapter (Lander and Schork, 1994; Risch and Merikangas, 1996; Martin, Boomsma and Machin, 1997). Briefly, there are two general strategies in humans: linkage and association studies (Sham, 1998).

Linkage studies can be used in gene discovery: with a sufficiently large number of multiplex pedigrees or extreme sibling pairs (Allison *et al.*, 1998), anonymous genetic markers scattered across the genome can be used to identify the chromosomal regions that may contain genes that contribute to a disorder such as AN or BN. This appealing strength is tempered by the low power (Risch and Zhang, 1996) and resolution (Roberts *et al.*, 1999) likely for linkage studies of complex traits.

Association studies are conceptually equivalent to the familiar case-control design. This design is particularly useful and powerful when prior knowledge of the pathophysiology of a trait suggests a number of candidate genes. However, the use of this design is controversial because of the risk of false positive findings when studying a sample that contains individuals of evolutionary diverse ancestry (Kidd, 1993). Obtaining genotypes on other family members can reduce this risk but at the cost of reduced statistical power.

Association Studies

Evidence linking AN and BN to monoamine functioning (Gorwood *et al.*, 1998) have led researchers to target serotonin and dopamine-related genes in association studies. Several groups have reported an increase in the −1438/A allele of the 5-HT_{2A} receptor gene in AN women compared to controls (Collier *et al.*, 1997; Enoch *et al.*, 1998; Sorbi *et al.*, 1998; Nacmias *et al.*, 1999). However, additional studies of this and other serotonin-related genes (5-$HT_{1D\beta}$, 5-HTT, 5-HT7, tryptophan hydroxylase receptor (TPH)) have failed to find significant associations in AN (Hinney *et al.*, 1997a, 1997b, 1999a; Campbell *et al.*, 1998, Han *et al.*, 1999; Ziegler *et al.*, 1999) or BN (Burnet *et al.*, 1999; Nacmias *et al.*, 1999) individuals. Studies have also failed to find increased allele frequencies of the dopamine D_3 (Bruins-Slot *et al.*, 1998) and D_4 (Hinney *et al.*, 1999b) receptor genes in AN relative to controls. These genes have not yet been examined in individuals with BN.

The primary role of weight control, feeding, and energy expenditure in the pathology of AN and BN has lead researchers to examine genes related to these processes. Results thus far have been mixed, as tests for association between AN and neuropeptide Y5 and Y1 (Rosenkranz *et al.*, 1998), the β_3 adrenergic receptor gene (Hinney *et al.*, 1997c), the melanocortin-4 receptor gene (Hinney *et al.*, 1999c), and the leptin gene (Hinney *et al.*, 1998) were all negative. However, studies have found an increase in the D11S911 allele located near the UCP-2/UCP-3 gene in AN subjects relative to controls (Campbell *et al.*, 1999), as well as an increase in the oestrogen receptor β 1082/G allele in AN relative to obese and overweight subjects (Rosenkranz *et al.*, 1998). Once again, associations between most of these genes and BN have not been investigated.

Findings suggest possible associations between the 5-HT_{2A} receptor gene, the UCP-2/UCP-3 gene, and the oestrogen receptor β gene with AN. However, additional research is necessary to clarify conflicting findings and replicate initial results. Moreover, association studies of BN are needed, as this disorder has been much less studied than AN and findings thus far have been generally negative.

Linkage Studies

We and a number of collaborators (Kaye *et al.*, 2000) have recently completed the first study to date (Grice *et al.*, submitted) using genome-wide linkage analyses in AN or BN. This multicentre study is funded by the Price Foundation of Switzerland and uses allele-sharing linkage analyses to identify genes contributing to eating disorders in 196 families with two or more family members with AN, BN, or eating disorder not otherwise specified (EDNOS). Initial analyses of this dataset show only modest evidence for linkage, with peaks observed on chromosomes 4, 11, 13, and 15 with NPL scores >1. The highest peak was a NPL score on chromosome 4 (Grice *et al.*, in preparation). These modest results are likely due to decreased power to detect linkage as a result of large number of loci influencing the phenotype as well as considerable sample heterogeneity (i.e., inclusion of AN, BN, and EDNOS). These possibilities suggest that additional studies using more homogeneous phenotypes and larger numbers of subjects would increase power to identify genetic effects.

We have recently completed a larger, genome-wide linkage study of approximately 400 families with two or more family members with AN, BN, or EDNOS. This larger study will provide the necessary power to detect linkage and may prove to be the first to identify susceptibility loci for these disorders. In addition, we are currently in the process of collecting genetic data on approximately 700 AN individuals and their parents. This homogeneous sample will be used to conduct association analyses such as those described above and will provide additional power to detect genes of modest to large effect.

CONCLUSIONS

Data described above are clear in establishing a role for genes in the development of eating pathology. Estimates from the most rigorous studies suggest that >50% of the variance in liability to eating disorders and disordered eating behaviours can be accounted for by additive genetic effects. The remaining variance appears to be due to unique rather than common environmental effects. These high estimates indicate a need for studies identifying the specific genes contributing to this large proportion of variance. Twin and family studies suggest that a number of heritable characteristics that are frequently comorbid with AN and BN may share genetic transmission with these disorders, including anxiety disorders/traits, body weight, and possibly major depression. Developmental twin research is beginning to shed light on why eating disorders tend to develop within a relatively narrow developmental window. Additional work is required to enhance our understanding of how puberty (and which aspects of puberty) influences the apparent activation of genetic effects on disordered eating.

Molecular genetic research of these disorders is in its infancy. However, promising areas for future research have already been identified (e.g., 5-HT2A receptor gene, UCP-2/UCP-3 gene, oestrogen receptor β gene), and several large-scale linkage and association studies are currently underway. These studies are likely to provide invaluable information regarding both the appropriate phenotypes to be included in genetic studies as well as the genes with the most influence on the development of these disorders.

The Therapeutic Armamentarium in Eating Disorders

James E. Mitchell, Scott Crow, Tricia Cook Myers and Steve Wonderlich

INTRODUCTION

In this paper we will briefly summarize the available literature on the empirically tested treatments for patients suffering from eating disorders. We will address the traditional eating disorders of anorexia nervosa and bulimia nervosa, and will also include binge-eating disorder, a condition included as an example of 'eating disorders — not otherwise specified' in the DSM-IV as a disorder for further study. We focus on treatments that have been shown to be effective in randomized trials, but include other clinical information when it appears relevant and necessary to the reader's understanding of that particular area.

In perusing this text, many readers will notice several trends that typify this literature. First and of greatest clinical concern, the reader will notice the relative paucity of literature on the treatment of patients with anorexia nervosa, despite the fact that anorexia nervosa was the first identified eating disorder and clearly is the most severe, with a significant well-documented risk for morbidity and mortality. There are a number of factors that have contributed to the relative lack of research in this area, including the following: (1) anorexia nervosa is a relatively rare condition and it is difficult for individual treatment centres to acquire the necessary number of subjects to complete randomized trials; (2) patients with anorexia nervosa, by virtue of their illness, many times are not particularly motivated to be cooperative with treatment and therefore it is difficult for them to be compliant with research treatment protocols; (3) when initially seen many patients with anorexia nervosa are critically ill, and require a multiplicity of interventions (e.g., medical stabilization, occasionally hospitalization, family involvement, individual counselling, medication management) which markedly complicates the ability of researchers to design clinical trials which adequately control for all of these variables; (4) anorexia nervosa patients are often quite difficult to treat, again given the nature of their illness, and this undoubtedly dissuades many potential investigators from pursuing work in this area. All of these factors have contributed to what currently is an apparent and quite worrisome lack of knowledge regarding the best treatments for patients with this disorder.

Second, readers of this text will probably also notice that although the treatment literature on bulimia nervosa is better developed, this entire literature has been published in the last 20 years. This is attributable to the fact that bulimia nervosa was only first identified as a discrete diagnostic entity in 1979 (Russell, 1979) and randomized clinical trials were first implemented several years after that.

Third, readers may notice that the literature on binge-eating disorder is also quite limited. This again is attributable to the fact that binge-eating disorder was only described in its current form in the DSM-IV, which was published in 1994. At that time there were little data regarding this group of patients, and our current understanding of this disorder has developed since then.

Fourth, an observation that may strike some readers as surprising is the finding that psychotherapy plays a clearly important and, in some cases, central role in the treatment of patients with eating disorders. The reader is therefore reminded that psychological interventions that result in psychological changes often result in corollary changes in the underlying biology, and therefore discussions of such therapies in a text on biological psychiatry is quite appropriate.

We turn now to the treatment literature on these three conditions.

Pharmacotherapy of Bulimia Nervosa

The pharmacotherapy of bulimia nervosa can be conveniently divided into three areas: (1) antidepressant trials, which have employed a variety of types of agents using various experimental designs ranging from acute treatment studies to relapse prevention studies; (2) studies examining the utility of non-antidepressant pharmacological approaches — none of which have been definitive, but several of which are interesting and show promise; and (3) a handful of studies regarding the relative efficacy of pharmacotherapy and psychotherapy for patients with bulimia nervosa.

Antidepressant Therapy of Bulimia Nervosa

Early in the course of our understanding of bulimia nervosa, research groups studying this condition noted that many of the patients were depressed (Russell, 1979). Based on this observation, it was hypothesized that patients might be better able to control their bulimic symptoms if their depression were treated. Some researchers even went so far as to hypothesize that bulimia nervosa might be a variant of affective disorders, although few would endorse such a model currently (Pope *et al.*, 1983).

Given this background, a number of antidepressants were tried. Following the initial observation that tricyclic and MAO inhibitors both seemed beneficial for these patients, a series of randomized treatment trials were undertaken. These studies are summarized in Table XXIII-10.1, and as can be seen the list has grown rather lengthy. In examining these studies, several issues emerge. First, the number of compounds studied and the classes of compounds studied (e.g., MAOIs, tricyclics, SSRIs) is large but not exhaustive. Second, the sample size in most of the studies has been modest, the exceptions being the large multicentre studies involving fluoxetine that were funded by Eli Lilly, who subsequently sought and received FDA approval to market fluoxetine for bulimia nervosa in the US. Third, although not illustrated, there is a great deal of variability in response rates to placebo. This probably speaks to a number of issues, one of which is the lack of standardization of the protocols for administering agents in this population, a problem we have discussed previously in the literature (Mitchell *et al.*, 2000). Fourth, the reductions in the frequencies of target eating behaviours

are generally large and consistently superior to those seen with placebo. Fifth, despite this finding, the majority of subjects treated with these agents are not free of symptoms at the end of treatment, a particularly worrisome finding given the fact that research suggests that subjects who are not abstinent at the end of treatment may subsequently relapse to a more severe syndrome.

A few other studies have addressed relapse prevention (Walsh *et al.*, 1991; Fichter *et al.*, 1996; Romano, 1999), and indeed the data suggest that there is clearly an effect for drug therapy, although findings in these studies are also discouraging in that some patients relapse on medication, and a high dropout rate occurs at long-term follow-up, suggesting that the maintenance of patients on drug therapy, even if their initial response is favourable, may be difficult to accomplish.

Given these limitations, the agent that has been studied in the largest number of clinical trials is fluoxetine hydrochloride, and of particular importance clinically, the first multicentre trial demonstrated superiority for 60 mg over 20 mg in the treatment of bulimia nervosa (FBNC, 1992). The second multicentre treatment study (Goldstein *et al.*, 1995) and the relapse prevention trial (Romano, 1999) both employed 60 mg as an initial dosage. This suggests that subjects can either be started at this dosage or should have the dosage fairly rapidly escalated to this dosage to achieve optimal results.

Although such data cannot be easily summarized, studies using antidepressants have also demonstrated significant improvement on other variables such as mood, anxiety, and measures of core psychopathology as measured by various instruments. Therefore, the drugs do not appear just to suppress the core symptoms of binge eating and vomiting, but appear to have more global effects on the syndrome.

Accompanying this growing literature has been a growing acceptance of pharmacotherapy on the part of non-medical mental health practitioners and on the part of patients. While there was initial resistance on the part of health care professionals in the early 1980s to refer patients for pharmacotherapy, and while many patients were very resistant to the idea of drug treatment, most therapists now appreciate the worth of this approach, and not uncommonly patients seek treatment with pharmacotherapy.

Other Pharmacotherapies for Bulimia Nervosa

A variety of other agents have been tried, some for intriguing theoretical reasons. Phenytoin was tried for bulimia nervosa following the observation that a group of patients with binge-eating behaviour had abnormal electroencephalograms (Green and Rau, 1974), although subsequent studies have failed to find an exaggerated rate of EEG abnormalities in patients with bulimia nervosa (Mitchell, Hosfield and Pyle, 1983). The results of this study were ambiguous, yet surprisingly no attempt has been made to further examine the utility of this agent (Wermuth *et al.*, 1977).

Narcotic antagonists were used following the observation that the endogenous opioid system is involved in the modulation of feeding, particularly stress-induced and hedonically driven feeding in various animal models (de Zwaan and Mitchell, 1992). While some early work using short acting narcotic antagonists suggested positive effects (Jonas and Gold, 1986, 1987), randomized treatment trials at usually applied dosages have failed to find evidence of efficacy (Ingoin-Apfelbaum and Apfelbaum, 1987; Mitchell *et al.*, 1989), while open-label trials employing higher doses, which can only be used if one is willing to accept the risk of possible hepatotoxicity, suggested positive effects (Jonas and Gold, 1988). Given the current state of knowledge, until non-hepatotoxic agents are available, narcotic antagonists cannot be recommended as treatment, although their utility as adjunctive agents in other situations at usual doses could reasonably be explored.

d-Fenfluramine was not found to be particularly useful (Russell *et al.*, 1988; Fahy, Eisler and Russell, 1993). However, this compound has been shown subsequently to cause valvular heart disease (Cannistra and Gaasch, 1999). This is a moot point now, given the removal of both fenfluramine and d-fenfluramine from the market secondary to drug-induced valvular dysfunction.

A report demonstrating the efficacy of ondansetron, marketed as an anti-nauseant, over placebo in a randomized clinical trial recently appeared (Hartman *et al.*, 1997). The results are interesting theoretically but the magnitude of the improvement was not in excess of those achieved in trials finding modest benefits with antidepressants.

Psychotherapy of Bulimia Nervosa

Since the early 1980s numerous studies have investigated the efficacy of psychotherapy for bulimia nervosa. Cognitive-behavioural therapy (CBT) has been shown to be more beneficial than placebo antidepressant medication (Whittal, Agras and Gould, 1999) in the treatment of bulimia nervosa. Randomized trials indicate that CBT is superior to both support groups and wait-list controls (Lacey, 1983; Lee and Rush, 1986; Leitenberg *et al.*, 1988; Agras *et al.*, 1989). CBT has also been shown to be as effective or more effective than non-directive (Kirkley *et al.*, 1985), short-term focal (Fairburn *et al.*, 1986), supportive–expressive (Garner *et al.*, 1993), and supportive non-directive therapies (Walsh *et al.*, 1997). In fact most controlled treatment research to date has supported CBT as the psychotherapy of choice in the treatment of bulimia nervosa.

Recently, however, there has been some evidence that a therapy that does not specifically address the bulimic behaviours may be as effective as CBT in decreasing bulimic symptoms. Specifically,

interpersonal therapy (IPT), originally developed as a treatment for depression (Klerman *et al.*, 1984), may also be efficacious for the treatment of bulimia nervosa. Fairburn and colleagues (1991) compared CBT, behavioural therapy and a therapy that contained many elements of IPT and concluded that although CBT was most helpful in reducing bulimic symptoms at the end of treatment, at one- and six-year follow-up IPT and CBT were found to be equally effective. More recently, a multicentre study replicated this finding using IPT in its originally developed form (Agras *et al.*, 2000).

CBT and IPT differ in some significant ways. CBT addresses eating-related thoughts and behaviours and can be divided into three stages. The first stage focuses on education about the cognitive model of bulimia nervosa, which proposes that bulimic behaviours are maintained by weight and shape-related thoughts and attitudes, and specific behavioural techniques such as self-monitoring, regular eating, alternative behaviours and weekly weighings. The second stage continues to address these behavioural techniques; however, the main emphasis is on restructuring faulty cognitions and increasing problem solving skills. Additionally, this stage of treatment may also address low self-esteem, if applicable. Relapse prevention is the focus of the final stage of treatment.

CBT appears to be effectively delivered in both individual and group formats with a typical treatment length of 20 sessions. There appears to be considerable benefit to asking the patient to attend sessions twice per week during the first month of treatment, after which sessions are held on a weekly basis. CBT can also include, or be augmented with some form of dietary counseling. Lastly, there is evidence that CBT can be effectively delivered in the form of self-help manuals when guided by a non-specialist (Cooper, 1994; Waller *et al.*, 1996).

IPT, on the other hand, concentrates on current interpersonal functioning and tends to eschew issues related to eating problems and weight. During the initial phase of IPT treatment, interpersonal problems associated with the eating disorder are identified with the remainder of the therapy sessions geared toward resolving these interpersonal deficits.

One drawback of all treatments for bulimia nervosa, including antidepressant medication, is the low rate of abstinence from bulimic behaviour at the end of treatment. Another problem is the unavailability of empirically supported psychotherapies for those with bulimia nervosa due to lack of psychotherapist training (Mussell *et al.*, 2000). In addition, there is evidence that if a patient hasn't responded to CBT by the sixth session, she is unlikely to improve with additional sessions of CBT (Agras *et al.*, 2000).

These concerns have prompted researchers to begin to examine alternative approaches, such as stepped care models of treatment. Although controlled trials have supported the use of CBT and, in two studies, IPT, in the treatment of bulimia nervosa, the majority of psychotherapists are not trained to deliver such treatments. Stepped care models have arisen due to this growing disparity between research and practice. Given that supervised CBT self-help manuals and antidepressant medication are more readily available than full CBT, they seem to be appropriate first line interventions. Full CBT could then be offered to those individuals who fail to respond to these initial interventions. A study examining this approach is currently underway.

Pharmacotherapy vs Psychotherapy in the Treatment of Bulimia Nervosa

Given the growing literature on the efficacy of antidepressant treatments for bulimia nervosa, as well as the growing literature on the efficacy of various forms of psychotherapy, one logical step was to compare the relative efficacy of each approach versus the efficacy of the combination of these approaches. Five such studies have been published. In an initial trial comparing imipramine to intensive outpatient cognitive-behavioural group psychotherapy to the combination, clear superiority was found for CBT, with evidence of greater improvement on some variables (e.g., depression and anxiety) when active medication was added (Mitchell *et al.*, 1990). A second trial utilizing desipramine and individual CBT found similar results with added benefit on some variables (e.g., dietary restraint) with the combination (Agras *et al.*, 1992). Two studies are difficult to interpret because of a high dropout rate during treatment and a high dropout rate to follow-up (Leitenberg *et al.*, 1994; Goldbloom, Olmsted and Davis, 1996). The fifth study employed the most sophisticated design. Published by Walsh *et al.* (1997), the study involved randomization of outpatient bulimia nervosa subjects to one of five treatment cells: (a) medication management, which involved treatment with desipramine followed by treatment with fluoxetine if abstinence was not achieved; (b) and (c) treatment with individual cognitive-behavioural therapy with medication management or placebo; and (d) and (e) treatment with a control psychotherapy condition — supportive psychotherapy — with medication management or placebo.

The results showed that CBT was superior to supportive psychotherapy, and medication management was superior to placebo. In a *post-hoc* analysis, the best results overall were achieved using both medication management and CBT.

In summary, the literature on psychotherapy versus drug therapy versus combined treatment suggests that CBT is clearly superior to drug therapy alone, and arguments can be made for using the combination, particularly among patients who are depressed at baseline.

Pharmacotherapy of Binge-Eating Disorder

There are both similarities and differences in the state of our knowledge concerning the pharmacologic treatment of bulimia nervosa and binge-eating disorder. On the one hand, many of the trials conducted using subjects with binge-eating disorder thus far have been informed by previous work in bulimia nervosa. Often the same agents have been employed (for example, SSRIs and desipramine). Similarly, the major focus of treatment has been on the diminishment of binge-eating frequency as the major outcome variable. Much as with bulimia nervosa, the attendant symptoms have received less focus. One point of departure from the treatment of bulimia nervosa involves the issue of weight. The majority of individuals with binge-eating disorder have body mass indices that would currently be classified as overweight or obese, and presumably are at increased risk for the medical morbidity and mortality typically associated with obesity. Previous work suggests that binge eating may or may not be a predictor of poor outcome in weight loss therapy and of weight regain after treatment (Ho *et al.*, 1995; Hsu, Betancourt and Sullivan, 1996; McGuire *et al.*, 1999; Sherwood, Jeffery and Wing, 1999). However, most overweight or obese individuals seeking treatment for binge-eating disorder are very interested in losing weight, so treatments which result in control of binge eating but not weight loss are relatively disappointing to them. Therefore, it appears that successful treatment of those with binge-eating disorder would include the successful treatment of their weight problem as well.

Most of the drug trials completed to date have involved antidepressants, with the SSRIs being used most commonly (Marcus *et al.*, 1990; McCann and Agras, 1990; Alger *et al.*, 1991; de Zwaan, Nutinger and Schonbeck, 1992; Stunkard *et al.*, 1996; Hudson *et al.*, 1998; McElroy *et al.*, 2000). These studies have reported outcomes in terms of both binge-eating frequency and weight loss, but have targeted the issue of weight loss to varying degrees. Trials involving desipramine, fenfluramine, fluvoxamine, and sertraline have all found greater decreases in binge eating and greater rates of abstinence at the end of treatment in drug-treated patients compared to those receiving placebo. On the other hand, trials of

fluoxetine and imipramine have been negative in terms of binge-eating outcome.

Only three studies, Marcus *et al.* (1990), using fluoxetine, Hudson *et al.* (1998), using fluvoxamine, and McElroy *et al.* (2000), using sertraline, have shown active drug to produce more weight loss than placebo. In the Marcus *et al.* fluoxetine trial, which was lengthy (approximately one year), there was substantially more weight loss in the active drug group (13.9 kg vs 0.6 kg). Most of the weight loss occurred early in the trial, and subjects appeared to reach a plateau. Additionally, after the end of treatment, fluoxetine patients experienced fairly prompt regain of lost weight. In the fluvoxamine trial, although there was more weight loss in individuals receiving active drug, the difference between drug and placebo-treated patients was quite small (1.3 kg). In the sertraline trial, a weight loss of 5.6 kg occurred with active drug vs 2.4 kg with placebo.

Of historical note, there is one report of a trial of d-Fenfluramine in the treatment of binge-eating disorder (Stunkard *et al.*, 1996). Interestingly, d-Fenfluramine was superior to placebo in terms of binge-eating outcome, but there was no evidence for difference in weight loss over only eight weeks. However, d-Fenfluramine has been taken off the market in the United States.

Psychotherapy of Binge-Eating Disorder

A number of treatment studies targeting weight loss have examined the outcome for binge eating versus non-binge-eating obese subjects. The available studies are ambiguous as to whether or not obese binge eaters lose comparable amounts of weight as non-binge eaters in obesity treatment (Marcus *et al.*, 1988, 1990; Wadden, Foster and Letizia, 1992; de Zwaan, Mitchell and Mussell, 1992) but do suggest that abstinence from binge eating can be promoted by instituting a regimented diet (Yanovski, Gormally and Lese, 1994). In fact, these studies suggest that behavioural therapy in conjunction with dietary interventions for weight loss may be adequate to treat binge-eating disorder, at least in the short term. Because the presence of binge eating does not seem to increase dropout rates, it seems reasonable to include individuals with binge-eating disorder in weight management programs (Ho *et al.*, 1995).

Comorbid psychopathology is also common in individuals with binge-eating disorder. Therefore, another subset of studies has targeted binge eating as well as comorbid depression and anxiety. Initially, treatment manuals for bulimia nervosa were modified to address binge-eating disorder (e.g., Fairburn, 1995). Similar to treatment for bulimia nervosa, CBT for binge-eating disorder includes self-monitoring, stimulus control, alternative behaviours, and a pattern of regular eating, as well as cognitive restructuring, problem solving, and relapse prevention. These treatments successfully reduce the frequency of binge eating; however, weight reduction, a primary goal for many of these patients, has been modest at best with the cognitive-behavioural interventions (Wilfley *et al.*, 1993). As a result, many BED treatment approaches have been expanded to include a weight loss component. This subset of studies has incorporated sequential or concurrent treatment for obesity, binge eating and comorbid psychopathology.

In a series of studies (Agras *et al.*, 1995, 1997; Eldredge *et al.*, 1997), overweight participants were initially treated with 12 weeks of CBT. Participants who stopped binge eating then received weight loss therapy while those who continued to binge eat received IPT or additional sessions of CBT. The results showed that participants lost weight when treated with subsequent weight loss therapy and were still able to maintain abstinence from binge eating. Although there was no added benefit for treatment with subsequent IPT, a substantial number of participants who initially failed to reduce binge-eating frequency were successful with an extended course of CBT. At one-year follow-up those treated with CBT and weight loss therapy showed a 64% reduction in binge eating and a 33% abstinence rate. Those who were abstinent from binge eating were able to maintain a 4 kg weight loss while participants who were still binge eating gained an average of 3.6 kg.

Another study investigated the addition of CBT to the refeeding phase of a combined treatment of behavioural weight loss and VLCD for binge-eating obese (de Zwaan, Mitchell and Mussell, 1996). These authors found that although the acute treatment package was effective in reducing binge eating and in inducing weight loss, the addition of CBT did not prevent weight regain compared to the rate of regain in those not receiving CBT.

Cognitive-behavioural self-help manuals can also be beneficial for individuals with binge-eating disorder. When guided by a non-specialist, this type of therapy is cost-effective, timely, and may be less stigmatizing than traditional CBT. This method of treatment seems to be effective when guidance is provided via videotape and written instructions (Peterson *et al.*, 1998), or by telephone (Wells *et al.*, 1997), and in a face-to-face format (Carter and Fairburn, 1998).

In conclusion, the available evidence seems to support an integrated treatment of CBT and dietary intervention for optimum treatment of binge-eating disorder. Binge eating, weight loss and comorbid psychopathology should all be addressed. In addition, it may be appropriate to recommend guided self-help prior to implementing more formalized treatments, although this question needs further study.

Pharmacotherapy of Anorexia Nervosa

As noted above, relatively little information exists about effective pharmacologic strategies for the treatment of anorexia nervosa. We will review the limited number of controlled trials that have been conducted. In looking at this literature a few generalizations should be considered. First, a wide variety of different classes of agents have been tried. This undoubtedly reflects the difficult challenge of treating individuals with this illness, and the fact that most trials to date have been negative. Second, the outcome measures used to decide whether treatments are beneficial usually have been either weight gain or the maintenance of a relatively healthy body weight. As described elsewhere in this volume, fear of becoming fat, body image disturbance and perfectionism and obsessionality are critical core features of anorexia nervosa; addressing these problems in pharmacologic treatment seems a desirable and probably a necessary goal. Unfortunately, to date, these symptoms have received little attention in the controlled treatment literature. Third, anorexia nervosa is uniformly viewed as an illness needing long-term treatment, yet most of our knowledge to date is limited to short-term trials.

The placebo-controlled drug trials for anorexia nervosa that have been conducted are listed in Table XXIII-10.2. In contrast to bulimia nervosa, for which antidepressants are the most commonly tried agents, only a minority of trials have employed antidepressants. Typically, these trials have been conducted in individuals in intensive outpatient or inpatient treatment setting, with a goal of increasing body weight. To date, one study has shown support for the use of medication to aid short-term weight gain in subjects at low weight. That study (Halmi *et al.*, 1986) compared cyproheptadine in a dose of 32 mg per day, amitriptyline in a dose of 175 mg per day, and placebo over a short period. In that trial, the rates of weight gain with both active drugs exceeded that seen with placebo. Unfortunately, other trials of cyproheptadine (Vigersky and Loriaux, 1977; Goldberg *et al.*, 1979) and amitriptyline (Biederman *et al.*, 1985) have been negative. Similarly, in a small trial the antidepressant clomipramine was not more effective than placebo (Lacey and Crisp, 1980). Given the high rate of comorbidity between anorexia nervosa and obsessive–compulsive

Table XXIII-10.2 Placebo-controlled drug trials for anorexia nervosa

Reference	*N*	Duration (weeks)	Treatment	Outcome (weight gain vs placebo)
Virgersky and Loriaux, 1977	24	8	Cyproheptadine	No difference
Goldberg *et al.*, 1979	81	Variable	Cyproheptadine	No difference
Halmi *et al.*, 1986	72	4	Cyproheptadine	Cyproheptadine > placebo in rate of weight regain
Lacey and Crisp, 1980	16	Variable	Clomipramine	No difference
Gross *et al.*, 1981	16	4	Lithium	No difference
Biederman *et al.*, 1985	25	5	Amitriptyline	No difference
Halmi *et al.*, 1986	72	4	Amitriptyline	Amitriptyline > placebo in rate of weight regain
Vandereycken and Pierloot, 1982	18	6	Pimozide	No difference
Vandereycken, 1984	18	6	Sulpiride	No difference
Gross *et al.*, 1983	11	4	Tetrahydrocannabinol	No difference
Casper *et al.*, 1987	4	8	Clonidine	No difference
Stacher *et al.*, 1993	12	12	Cisapride	No difference

disorder, clomipramine would seem a logical choice; however, the dose (50 mg) was relatively low and might well have been subtherapeutic.

A wide range of other agents have been tried. These include lithium (Gross *et al.*, 1981), the antipsychotics pimozide (Vandereycken, and Pierloot, 1982) and sulpiride (Vandereycken, 1984), and drugs noted to increase appetite, tetrahydrocannabinol (Gross *et al.*, 1983) and clonidine (Casper, Schlemner and Javaid, 1987). In each case, active drug and placebo did not differ in efficacy. Finally, of historical note, cisapride was used in one trial (Stacher *et al.*, 1993). This agent was theoretically appealing given the symptoms of impaired intestinal motility among anorectic individuals, but this drug, too, was no more effective than placebo, and it has been taken off the market in the United States due to concerns about cardiovascular toxicity.

Another area of interest in the pharmacotherapy of anorexia nervosa involves the use of medications in individuals restored to a normal or near normal body weight, in an attempt to prevent relapse. One controlled trial has been reported thus far (Kaye, 1996). In this relapse prevention trial, subjects receiving active drug were less likely to relapse than those receiving placebo. The results of this trial are interesting in light of other work using fluoxetine in acutely ill, low weight anorectic individuals. In one double-blind, placebo-controlled protocol, fluoxetine in a dose of up to 60 mg per day did not differ from placebo in terms of weight gain or other measures in a series of inpatients (Attia *et al.*, 1998). Similarly, in a separate study, neither the short-term in-hospital course nor the long-term follow-up course of the group of anorectic patients was improved by the use of fluoxetine (Strober *et al.*, 1999). One potential explanation for these seemingly contradictory results could be that the efficacy of fluoxetine in anorexia nervosa may be highly dependent on the phase of the illness in which it is being used. The results of these trials seem to concur with the prevailing clinical opinion that when individuals are at very low weight, pharmacotherapy is unlikely to be effective. On the other hand, pharmacotherapy both for anorexia nervosa and perhaps for comorbid problems as well, appears to be more effective once weight has been restored.

Based on the results of these studies, pharmacotherapy for anorexia nervosa at this time is typically confined to one of two situations. The first is the use of medications, typically fluoxetine, in an attempt to maintain weight in weight-recovered individuals. Second, a variety of psychopharmacologic agents are used to provide the appropriate treatment for comorbid psychopathology.

Psychotherapy of Anorexia Nervosa

Despite the fact that anorexia nervosa has been studied for a long period of time, the number of empirical trials in patients in this population has been quite limited. Part of this reflects the difficulty in conducting trials in this area, as detailed in the introduction to this chapter. However, this situation is beginning to be remedied, in that the number of randomized trials which have recently appeared or which are now underway has increased dramatically, and one can only hope that the result of these studies will better inform our treatment of this group of patients, many of whom remain chronically ill, and some of whom die of the disorder.

One group of investigators that has been quite interested in examining various treatment methodologies for patients with anorexia nervosa includes Arthur Crisp and his colleagues at St. George's Hospital in London. In a series of publications, treatment techniques for anorexia nervosa have been examined (Hall and Crisp, 1987; Deeble *et al.*, 1990; Crisp *et al.*, 1999; Gowers *et al.*, 1994). This series of studies has documented that 'dietary advice' can be useful in inducing weight gain, compared to psychotherapy alone. Perhaps in the most controversial of these studies, 90 subjects with anorexia nervosa were randomly allocated to one of four treatment cells: inpatient treatment, assessment interview only, and one of two outpatient treatment cells. All three of the active treatment regimens resulted in improvement, and there appeared to be no significant advantage for the inpatient treatment program, despite the fact that the outpatient treatment programs offered were of relatively brief duration.

In another series of studies, Russell, Dare, Isler, and colleagues (for summaries please see Russell *et al.*, 1987; Eisler *et al.*, 1997) have sequentially examined different models of outpatient treatment for weight restored anorectic patients. In an initial study, these investigators found that family therapy was more effective for younger patients who had been ill for a briefer period of time, while the older more chronic patients did better with individual therapy. The second study, which included adult patients with anorexia nervosa who had been weight restored, found that family therapy was superior to individual psychoanalytic or individual supportive therapy. A third study found that a conjoint therapy approach, wherein patients were seen with their families, was less effective in inducing weight gain, but more effective in changing various psychological parameters, than family therapy where the patients and the family were each seen alone.

Another group of investigators has examined family therapy versus individual therapy with adolescents, employing either a behavioural family systems therapy approach or an ego-oriented

individual therapy approach (Robin *et al.*, 1994, 1995, 1999). The results of these studies suggest that the behavioural family systems therapy produced greater overall weight gain and was more likely to be associated with resumption of menses; however, both treatments were effective in producing improvement in eating attitudes, depression and eating-related family conflict.

Also of note, a pilot study by Treasure *et al.* (1995) found that a group of adult anorexia nervosa patients reported subjectively greater improvement when treated with cognitive analytical treatment as opposed to educational behavioural treatment, but there were no differences in other outcome parameters. Most recently Geist *et al.* (2000) contrasted family therapy versus family psychoeducational treatment in 25 adolescents requiring hospitalization for eating disorders, and found no significant group differences, suggesting that both interventions appeared to be effective, in a study with a relatively small sample size.

Taken together, these studies indicate quite clearly that structured forms of psychotherapy appear to benefit patients with anorexia nervosa. The findings regarding inpatient versus outpatient treatment in the protocol by Crisp and colleagues are of concern, and seems to be in conflict with the clinical impression of many researchers in the field, and clearly needs to be replicated. Other work suggests that many patients, particularly younger patients, may benefit from family involvement.

DISCUSSION

Both pharmacotherapy and psychotherapy play a role in the treatment of all three eating disorders. Bulimia nervosa appears to respond optimally to treatment with CBT, with the possible addition of fluoxetine in those comorbidly depressed. Pharmacotherapy plays a more limited role in the treatment of anorexia nervosa, but is probably useful in preventing relapse is limited among those also receiving counselling. Our knowledge of the treatment of binge-eating disorder, although results to date suggest that interventions that target both weight loss and binge eating are most useful.

Animal Models of Sleep Disturbances: Intrinsic and Environmental Determinants

Peter Meerlo, Bernard M. Bergmann and Fred W. Turek

INTRODUCTION

Although each mammalian species has its own sleep characteristics in terms of the total amount and distribution of sleep over the day (Campbell and Tobler, 1984; Zepelin, 2000), most of them share the fundamental regulatory principles with human beings (Borbely, 1982, Mistlberger *et al.*, 1983; Tobler, 2000). First, most species display a daily rhythm in sleep and wakefulness that is under the control of an endogenous biological clock in the brain. Second, within sleep, there is a cyclic alternation of two different states, non-rapid-eye-movement sleep (NREM) and rapid-eye-movement sleep (REM). And third, there is a homeostatic drive for each of the two sleep states that accumulates when the sleep state is absent. The longer an organism is awake, the higher its need for sleep. Remarkably, the exact functions of NREM and REM sleep are still unknown, but both states apparently serve vital functions. Studies in rats have shown that prolonged deprivation of either or both sleep states ultimately results in death (Rechtschaffen *et al.*, 1983; 1989). Studies of biological rhythms and sleep states in animals have greatly extended our knowledge of the regulatory mechanisms of sleep and provided clues to its functions. In addition, because of the similarities in sleep between human beings and other mammalian species, laboratory animals also provide a useful tool to gain insight into human sleep disorders.

Sleep disturbances can have a variety of underlying causes and contributing factors, and often are the outcome of a complex interplay between intrinsic factors and environmental influences. This chapter will summarize how sleep in animals can be affected by intrinsic factors (e.g., the physiological profile of an individual as determined by its genes, development, and age) as well as external factors (such as stressors and other environmental influences). Animal research allows detailed studies of each of these possible components and, as such, animal models can be a relevant source of information on the aetiology and mechanisms of sleep disorders.

We have chosen to categorize and present the animal literature on sleep disturbances roughly according to their intrinsic or extrinsic cause since that is what many studies use as a starting point. Although there are a number of animal models that mimic a specific sleep disorder (e.g., narcolepsy), a more common approach is to examine the influence of a certain intrinsic factor or environmental condition on sleep rather than modelling a sleep disorder *per se* (e.g., the influence of ageing or stress). The results of studies using the latter approach do not always allow a symptom-based classification as generally is used for human sleep disorders. For example, since insomnia in humans is often ascribed to stress, studying the influence of stressors on sleep in animals and its possible physiological pathways is highly relevant to the understanding of human sleep disorders. However, studies in mice and rats show that various stressors induce dynamic and complex changes in sleep that cannot simply be listed as insomnia. Therefore, we choose to present these models under the heading of stress, rather than insomnia.

The first sections hereafter describe how sleep disorders may be related to genes and development. The genetic models include successful models of narcolepsy as well as selected lines of rats with changes in particularly REM sleep. The developmental models show how influences during early stages of life can affect adult sleep and potential sensitivity to sleep disorders. These models also are characterized in particular by changes in adult REM sleep regulation. The following section discusses animal models of sleep in ageing, and the paragraphs thereafter deal with alterations in sleep due to disturbances of the circadian clock. Finally, a number of sections summarize the changes and disturbances in sleep that may occur in response to environmental factors, such as light and temperature, and, probably the most commonly cited cause of disturbed sleep, stress.

GENETIC MODELS

A variety of genetic tools and approaches are used to study gene effects on sleep in animals, including comparisons of different strains of rats or mice, knockout mice, or mice strains with other mutations. Whereas many of these studies are undertaken to unravel basic physiological mechanisms underlying sleep regulation, some of the models provide relevant information on genetic factors in sleep disturbances or genetic influences on the sensitivity to sleep disorders.

Narcoleptic Dogs and Mice

Probably the first true animal model of a sleep disorder was the finding of narcoleptic behaviour in dogs (Mitler *et al.*, 1974). Narcolepsy is a seriously disabling neurological disease that is characterized by disturbed night-time sleep and excessive daytime sleepiness, as well as pathological manifestations of REM sleep and cataplexy, often triggered by emotional expressions (Bassetti and Aldrich, 1996; Guilleminault and Anagnos, 2000). Early studies identified a narcoleptic phenotype in several breeds of dogs, including Doberman pinchers, which have played an important role in unravelling the genetic basis of the disease and also contributed to the development of treatment strategies (Baker *et al.*, 1982; Nishino and Mignot, 1997). More recently, mice were discovered with narcoleptic phenomena similar to those seen in dogs

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

(Chemelli *et al.*, 1999). Taken together, the different animal models point to a link between narcolepsy and a dysfunction of the hypocretin/orexin neuropeptide system in the brain (for review, see Siegel, 1999). Hypocretin/orexin neurons are located in the hypothalamus and have widespread projections to various brain areas, including the brainstem, the limbic system, and the cerebral cortex (Peyron *et al.*, 1998). Originally, the hypocretin and orexin peptides were discovered independently by different research groups, and the function of these peptides appeared to be related to the regulation of food intake (De Lecea *et al.*, 1998; Sakurai *et al.*, 1998). In subsequent studies the orexins and hypocretins not only turned out to be identical, but also were found to have a major effect on sleep. The narcoleptic dogs, which are now known to have a mutation in one of the hypocretin receptors, have disturbed sleep and cataplexy attacks much like those in human patients (Lin *et al.*, 1999). Moreover, mice whose gene coding for the hypocretin/orexin peptide has been inactivated exhibit clear, narcolepsy-like symptoms, including an increase in sleep time during their normal activity phase, sleep-onset REM sleep episodes, and sudden behavioural arrests (Chemelli *et al.*, 1999). Pharmacological studies in rats have confirmed a role for hypocretins/orexin in sleep-wake regulation, and administration of the peptide increases wakefulness and suppresses REM sleep (Hagan *et al.*, 1999; Piper *et al.*, 2000).

Taken together, the results suggest that hypocretins/orexins serve as an arousal factor and suppress REM sleep, and a lack of hypocretin/orexin signalling might be the cause for much of the narcoleptic symptomatology (Siegel, 1999). Based on these results from animal research, subsequent studies found that human narcolepsy is indeed associated with a specific loss of hypocretin/orexin neurons and undetectable levels of the peptide in the brain and cerebrospinal fluid, supporting a role for hypocretin peptides in sleep disorders such as narcolepsy, and opening new avenues for drug development and treatment procedures (Nishino *et al.*, 2000; Peyron *et al.*, 2000; Thannickal *et al.*, 2000).

Rat Strains with REM Sleep Disorders

A number of studies on selected lines of rats have explored alterations in REM sleep regulation and its possible relevance to human disorders such as depression. Human depression is characterized by changes in REM sleep regulation, especially an increase in REM sleep early in the night, and it has been suggested that a dysregulation of REM sleep may be linked to the development of the mood disturbance (Berger and Riemann, 1993; Vogel *et al.*, 1980). Two rat lines in particular have been studied in this context, the Flinders Sensitive Line rats (Shiromani *et al.*, 1988) and the Wistar Kyoto rats (Dugovic *et al.*, 2000). The Flinders Sensitive Line was selectively bred for hypersensitivity of the cholinergic system (Overstreet, 1993) whereas the Wistar Kyoto rat was originally bred as a normotensive control for spontaneously hypertensive rats (Louis and Howes, 1990). Both of these rat strains show behavioural abnormalities that have been suggested as a model of human depression (Overstreet, 1993; Pare and Redei, 1993). Subsequent analysis of sleep in the Flinders Sensitive rats indeed revealed an increase in the amount of REM sleep, without major changes in NREM sleep (Shiromani *et al.*, 1988; Benca *et al.*, 1996). The Wistar Kyoto rats were found to have more fragmented sleep and an overall increase in the total amount of REM sleep (Dugovic *et al.*, 2000). These models thus support the hypothesis of a link between alterations of REM sleep regulation and mood disturbances such as depression. Although originally these selection lines of rats were not developed as models of sleep disorders, they hold great potential to study whether altered REM sleep regulation has detrimental effects and perhaps is a causal factor in the development of depression-like behavioural disturbances.

DEVELOPMENTAL FACTORS

In addition to genetic models of sleep disturbances, there is evidence from animal research that adult sleep characteristics and perhaps sensitivity to sleep disorders may depend on developmental factors as well. Manipulations and environmental stimuli around the time of birth can lead to profound changes in physiological function and behaviour later in life. Maternal stress, malnutrition, and alcohol ingestion are among several factors that induce developmental changes in the fetus and cause alterations in the offspring's sleep regulation that last into adulthood.

Maternal Stress

One example of developmental influences on sleep regulation is the effect of so-called maternal or prenatal stress. In this model, pregnant female rats are repeatedly subjected to stress, which often comprises immobilization several times a day during the last 1–2 weeks of gestation (Barbazanges *et al.*, 1996). Some of the effects of prenatal stress on the development of the young appear to be mediated by an increase in maternal corticosterone (Barbazanges *et al.*, 1996). After birth, the young are raised in a standard way until adulthood, when physiological function and behaviour are studied. In adulthood, the offspring of mothers subjected to such stress have increased sleep fragmentation and increased amount of REM sleep (Dugovic *et al.*, 1999). Maternal immobilization stress also induces certain alterations in HPA axis function and behaviour that are reminiscent of human depression (Weinstock, 1997). It has therefore been proposed that prenatal stress, similar to the genetic models with increased REM sleep, may be a valuable model to study the relationship between altered sleep and mood disorders (Dugovic *et al.*, 1999). Important in this context is the finding that experimentally depriving adult rats of REM sleep results in hyperactivity, fearlessness, and aggression (Hicks and Moore, 1979; Hicks *et al.*, 1979). Thus, whereas too much REM sleep may be associated with passive and depression-like behaviour, too little REM sleep may result in hyperemotionality and mania.

Maternal Food and Alcohol Intake

There is considerable evidence from studies in female rodents that the caloric content and composition of food, as well as alcohol and drugs during pregnancy, strongly affect the development of the foetuses. Especially maternal malnutrition and alcohol ingestion can result in serious morphological, physiological, and behavioural abnormalities in the offspring, including alterations in sleep regulation. A study on maternal protein malnutrition in rats showed that during adulthood the offspring had more NREM sleep but their REM sleep was less than half that of control animals (Datta *et al.*, 2000). In rat pups that were exposed to alcohol in utero, quiet sleep was reduced and more frequently interrupted by waking episodes (Hilakivi, 1986). In adulthood, the offspring showed a strong reduction in the amount of REM sleep (Stone *et al.*, 1996), an effect that, for unknown reasons, may be particularly severe in the female offspring (Sylvester *et al.*, 2000). Although the changes in sleep after maternal malnutrition and alcohol intake were not hypothesized to reflect a specific sleep disorder, it has been suggested that such sleep changes, particularly the decrease in REM sleep, may have detrimental effects on cognitive functions. Importantly, in rats that are exposed to alcohol in utero, the deficits in REM sleep during adulthood seem to predict certain cognitive deficits during ageing (Stone *et al.*, 1996).

It is noteworthy that the reduction in REM sleep in offspring after maternal malnutrition and alcohol intake is opposite to the increase in REM sleep seen after maternal stress. Apparently, developmental influences on adult sleep-wake patterns strongly depend on the nature of the stimulus. Moreover, these studies on maternal malnutrition and alcohol intake support the hypothesis that not only too much, but also too little REM sleep may be associated with specific malfunctions and disease-like manifestations. As already mentioned above, REM sleep deprivation appears to result in hyperemotionality. In addition, although the evidence is contradictory, other studies have linked REM sleep loss to a decrease in cognitive performance and disturbances in learning and memory (for review, see Graves *et al.*, 2001; Siegel, 2001; Smith, 1996).

AGEING

Many reports suggest that the prevalence of certain sleep disorders and insomnia increase during human ageing (for review, see Bliwise, 2000). However, the study of sleep and human ageing is severely complicated by factors such as disease and medication, and several reports suggest that poor sleep in the elderly is in many cases secondary to medical illness rather than chronological age (Foley *et al.*, 1995; Gislason and Almqvist, 1987). Controlled studies in animals can shed light on such issues, and measurements in a variety of mammalian species have explored the changes in sleep that occur with ageing. The most commonly used animal model for studies on ageing and sleep is the rat. In old rats of about 20–24 months, ageing-related changes in sleep include a dampening of the sleep-wake rhythm amplitude, more fragmentation of sleep, a decrease in deep NREM sleep, and, sometimes, slight overall decreases in the amount of sleep, especially REM sleep (Mendelson and Bergmann, 1999; Rosenberg *et al.*, 1979; Van Gool and Mirmiran, 1983). However, the changes can be fairly subtle, and not all studies have found clear changes in basal sleep patterns in old rats (see Mendelson and Bergmann, 1999; Zepelin *et al.*, 1972). The age-related changes in sleep may vary considerably between individual animals as well as between strains of rats (Li and Satinoff, 1995; Shiromani *et al.*, 2000), suggesting that the consequences of ageing may strongly depend on genetically determined individual characteristics.

Importantly, although age-related changes in *baseline* sleep may not always be consistent, there seems to be a more robust change in the compensatory sleep *rebound* after a period of sleep deprivation (Mendelson and Bergmann, 2000; Shiromani *et al.*, 2000). Young rats respond to extended wakefulness with an increase in the time spent in NREM sleep and an increase in NREM sleep intensity, as reflected in an increase in EEG slow waves, as well as an increase in REM sleep (Borbely and Neuhaus, 1979; Tobler and Borbely, 1986). In old animals, however, the compensatory NREM sleep rebound is diminished (Mendelson and Bergman, 2000; Shiromani *et al.*, 2000). The REM sleep rebound after sleep deprivation was also found to be attenuated, but only after a very long period of sleep deprivation of 48 h (Mendelson and Bergmann, 2000), and not after milder 12-h sleep deprivation (Shiromani *et al.*, 2000). Moreover, whereas in young animals extended wakefulness is generally followed by an immediate recovery rebound, in aged rats the rebound is not only attenuated but also sometimes delayed (Mendelson and Bergmann, 2000). Taken together, the results seem to point to a decline in the homeostatic response to sleep loss in ageing rats.

Age-related changes in sleep have been reported for several other mammalian species, including mice (Welsh *et al.*, 1986), hamsters (Naylor *et al.*, 1998), and cats (Bowersox *et al.*, 1984). Many of the sleep changes that occur during ageing in these species are comparable with those seen in the rat. A notable difference is that, in both hamsters and cats, ageing is associated with a slight increase in the total daily amount of NREM sleep. The reason for this difference is not fully understood, but it has been explained as an attempt to compensate for lower sleep efficiency as reflected in a decrease in electroencephalographic (EEG) slow waves (Naylor *et al.*, 1998).

Some of the ageing-related changes in sleep in the various animal models, such as a higher fragmentation of sleep and a decrease in sleep-wake rhythm amplitude, are thought to be due to alterations in the biological clock that is driving the sleep-wake rhythm (see next section). In addition, the decline in the compensatory response to sleep deprivation in the rat suggests that also the homeostatic mechanisms underlying NREM sleep regulation are affected by age. Interestingly, part of the age-related sleep changes in rats can be prevented by housing them in an enriched environment (Van Gool and Mirmiran, 1986), an observation which suggests that an increase in behavioural activity and sensory input may alleviate the consequences of ageing. A recent study in humans indeed confirmed that structured physical and social activity can improve night-time sleep in the elderly (Naylor *et al.*, 2000). These latter findings illustrate the potential value of animal models in finding treatment strategies and therapies for sleep disturbances in ageing.

CLOCK DISTURBANCES

In most mammalian species, the alternation of sleep and wakefulness occurs in a rhythmic fashion, and sleep is preferentially consolidated to certain periods of the day. The regulation of such daily rhythmicity, which is not restricted to sleep but is manifest in most biological functions, is under the control of an endogenous oscillator, or 'clock', located in the suprachiasmatic nuclei (SCN) of the hypothalamus (Moore and Eichler, 1972; Stephan and Zucker, 1972; for review, see Klein *et al.*, 1991). Since the periodicity of endogenous circadian rhythms often slightly deviates from 24 h, synchronization to the environment occurs through daily adjustment of the clock by light (Pittendrigh, 1981). For this purpose, the clock in the SCN receives photic information from the environment via a direct neuronal input from the retina (Moore and Lenn, 1972).

Several studies have shown that destruction of the clock by lesioning the SCN results in a fragmented sleep pattern without a clear daily rhythm in mice (Ibuka *et al.*, 1980), rats (Eastman *et al.*, 1984; Mistlberger *et al.*, 1983; Mouret *et al.*, 1978; Tobler *et al.*, 1983), and squirrel monkeys (Edgar *et al.*, 1993). In the mice and rat studies, destruction of the SCN abolished the normal expression of the circadian sleep-wake cycle, but it did not change the total amount of sleep. In the squirrel monkeys, however, lesioning the central oscillator resulted not only in an arrhythmic sleep-wake pattern but also in a pronounced increase in total sleep time. This finding may imply that, at least in some species, alterations in clock function may affect not only the timing and consolidation of sleep but also the homeostatic regulation of sleep duration.

The *Clock* Mutation

An alternative approach to study the effects of changes in clock function on sleep is to examine animals that have a genetically altered clock system. One such model is the *Clock* mouse, which has a mutation in one of the genes that is involved in the regulation of circadian rhythmicity (Vitaterna *et al.*, 1994). Under a normal light-dark cycle, homozygote *Clock* mice still maintain fairly normal activity patterns. However, under conditions of constant darkness, when the endogenous clock is no longer synchronized

to the environment, the *Clock* mice have unstable activity rhythms with an abnormally long, 28-h period. Eventually, the animals even become arrhythmic (Vitaterna *et al.*, 1994). Under both conditions of synchronization to a light-dark cycle and constant darkness, the *Clock* mice have a dampened amplitude of the sleep-wake rhythm and spend less time in NREM sleep than their wild-type counterparts (Naylor *et al.*, 2000). This study confirms that changes in circadian clock function are a potential pathway to disturbance of sleep.

The Ageing Clock

As discussed in a previous section, ageing is often associated with increased sleep fragmentation and reduced sleep-wake rhythm amplitude, part of which may be due to an age-related decline in the functional activity of the endogenous pacemaker in the SCN (for review, see Turek *et al.*, 2001; Weinert, 2000). In line with this, aged rodents sometimes exhibit decreased numbers of SCN cells with vasopressin, one of the primary neurotransmitters in the clock (Van der Zee *et al.*, 1999). Moreover, peak neuronal discharge in the SCN is reduced and more irregular in old animals (Satinoff *et al.*, 1993). In addition, advanced age has been associated with a decrease in responsiveness of the circadian clock to the phase-shifting effects of light and other synchronizers (Penev *et al.*, 1995; Van Reeth *et al.*, 1993; Zee *et al.*, 1992). Taken together, the data from animal studies indicate that in the aged the endogenous oscillator in the SCN is less sensitive to input stimuli that are normally involved in synchronizing the clock to the environment, and that the SCN has an altered output to the rest of the brain and body. However, although a great deal is known about the molecular machinery of the biological clock in the SCN and studies in rodents have revealed several pathways by which the SCN might affect the sleep-wake rhythm (Aston-Jones *et al.*, 2001), it is still unclear which of these pathways might deteriorate during ageing (Shiromani *et al.*, 2000).

Dissociations Between Clock and Environment

In addition to alterations in the central circadian clock itself, disturbed sleep may also arise from a misalignment between the endogenous clock and environmental determinants of the sleep-wake rhythm. In humans, this can occur, for instance, after a long-distance flight when the internal clock is temporarily out of synchrony with the environmental light-dark cycle at the place of arrival, a condition that is referred to as jet lag. In animals, the effects of long-distance flights can easily be mimicked by shifting the light-dark cycle of the housing facility. In one study, rats were subjected to an 8-h advance of the light-dark cycle, comparable to a transatlantic flight from the USA to Europe (Sei *et al.*, 1992). Sleep patterns were studied for 3 days preceding, and 5–7 days following the shift. Especially the rhythm of NREM sleep was severely disturbed and had a strongly dampened amplitude. The daily REM sleep rhythm, however, was less affected. Perhaps the REM sleep rhythm was strongly determined by the clock whereas the dampening of the NREM sleep rhythm may have been the result of interactive effects of the endogenous clock and direct effects of light (see next section). Overall, the amount of both NREM and REM sleep was somewhat increased during the simulated jet lag. Eventually, light input to the clock will lead to resynchronization of the endogenous clock to the new light-dark cycle, but in this particular study recordings did not extend beyond 5–7 days, when alterations in the sleep-wake rhythm were far from normalized. This in itself suggests that long-distance flight may have quite persistent effects. Animal models for jet lag hold great potential for studying concomitant sleep disturbances and treatment strategies.

Taken together, studies on the circadian regulation of sleep and wakefulness imply that alterations in the biological clock or in the light input to the clock can be a major cause of disrupted sleep. The progress that has been made in identifying the molecular and neurobiological substrates of circadian rhythms in animals has broadened our understanding of clock function and the way rhythm disturbances may contribute to disrupted sleep in our society.

ENVIRONMENTAL INFLUENCES

There are a variety of environmental factors, such as light and ambient temperature, that can directly or indirectly affect sleep quality. In human beings, the possibility of self-regulating light exposure and temperature conditions has turned these environmental influences into lifestyle factors that can have positive effects on sleep but may also contribute to the occurrence of disrupted sleep. Although most of the animal studies on light and ambient temperature were undertaken from a fundamental interest and were not presented as models of sleep disorders, some of them provide information that is relevant in the context of disrupted sleep due to inadequate sleep hygiene.

Light Effects

Light is a factor that may have both positive and negative effects on sleep. As mentioned in a previous section, light is important for the regulation of normal circadian rhythmicity, and well-timed exposure to light keeps the sleep-wake rhythm in synchrony with the outside world. However, light at the wrong time of day for prolonged periods of time may shift the clock and lead to disrupted sleep. In addition to direct input to the SCN, there is light input to various other brain regions, including the serotonergic raphe nuclei in the brainstem (Shen and Sembra, 1994), via which route light may modulate sleep and arousal as well (Jouvet, 1999; Portas *et al.*, 2000).

Rodents such as rats are primarily nocturnal animals. Maintained under a 12-h light:12-h dark schedule in the laboratory, both NREM and REM sleep in the rat predominantly occur during the light phase. However, under natural conditions, rats would probably avoid light and spend most of the daytime hours in the darkness of their burrows (Terman *et al.*, 1991). Thus, as in human beings, sleep would most likely occur mainly in darkness. Several studies in rats have shown that light can have potent effects on sleep architecture and sleep intensity. A number of studies that compared sleep under a light-dark cycle with sleep under constant darkness showed that *removal* of the light influence significantly enhances sleep continuity and increases NREM sleep EEG amplitude, a measure of sleep intensity (Tobler *et al.*, 1994; Trachsel *et al.*, 1986). Under these conditions, the overall amount of NREM sleep is not strongly affected by light, but the amount of REM sleep is sometimes suppressed (Trachsel *et al.*, 1986). Another approach that has been used to investigate the effects of light on sleep involves exposing rats to ultra-short light-dark cycles — for instance, cycles with consecutive periods of 1-h light and 1-h darkness (for review, see Borbely, 1978). Also under these conditions, the amount of REM sleep is lower in the light than in the dark. The amount of NREM sleep, however, is higher in the short light phases than in the short dark phases (Alfoldi *et al.*, 1991; Borbely, 1976; Lelkes *et al.*, 1990). Clearly, the effects of light on the amount of NREM sleep are complex, but the data suggest that exposure to light during the normal sleeping phase may disrupt sleep by at least suppressing NREM sleep intensity and REM sleep duration. Animal studies on the effects of light on sleep and the mechanism by which it acts become increasingly important in our rapidly developing 24-h society where we are frequently exposed to artificial light at unusual times, as in shift work.

Ambient Temperature

Another environmental variable that can have both positive and disruptive effects on sleep is the ambient temperature. The effects of ambient temperature on sleep have been studied in various mammalian species, including mice (Roussel *et al.*, 1984), rats (Schmidek *et al.*, 1972), hamsters (Sichieri and Schmidek, 1984), and cats (Parmeggiani and Rabini, 1970). A number of studies suggest that moderate and short-lasting thermal loads may promote NREM sleep (Moriarty *et al.*, 1993; Obal *et al.*, 1995), a finding that is in agreement with increases in NREM sleep in human beings after heating in a warm bath or a sauna (Horne and Reid, 1985; Putkonen *et al.*, 1973). However, exposure to more extreme ambient temperatures for prolonged periods of time may seriously disrupt sleep and reduce NREM sleep time. The amount of REM sleep is generally maximal around thermoneutrality, that is, the ambient temperature at which the metabolic rate is minimal. Both higher and lower ambient temperatures cause a decrease in REM sleep time (Parmeggiani and Rabini, 1970; Rosenthal and Vogel, 1993; Schmidek *et al.*, 1972; Szymusiak and Satinoff, 1981). Studies of rats under very low ambient temperatures around or below 0 °C have shown severe reductions and even complete loss of REM sleep (Amici *et al.*, 1994; 1998). During recovery from cold exposure, REM sleep levels are markedly increased above baseline levels, indicating that during cold exposure the animals are deprived of REM sleep. Clearly, these data indicate that extreme ambient temperatures should be avoided in order to prevent sleep from being disturbed. However, the sleep-stimulating effect of a mild temperature load preceding sleep could perhaps be used as a basis for developing treatments to alleviate sleep complaints.

STRESS

Probably the most frequently cited cause of disrupted sleep and insomnia in humans is 'stress' (Roehrs *et al.*, 2000). Accordingly, there is a great interest in using stress as a starting point for animal models of sleep disturbances. However, animal research shows that the relationship between stress and sleep is rather complex. Stress-induced changes in sleep show a dynamic temporal pattern that depends on the nature and duration of the stressor.

Acute Stress

Stress is usually defined as a non-specific physiological response to any kind of demand that an organism is facing (Selye, 1936). Traditionally, the autonomic sympatho-adrenal axis and the hypothalamic-pituitary-adrenal (HPA) axis are considered to be the main neuroendocrine systems involved in the integrated stress response (Axelrod and Reisine, 1984; Johnson *et al.*, 1992). The increased catecholaminergic activity and HPA axis activity, in a complex interplay with various other neuroendocrine systems, orchestrate an adequate response to the challenge an animal or human being is dealing with. Obviously, coping with environmental challenges requires alertness, and since stress is a state of physiological activation and arousal, by definition, it inhibits sleep. Indeed, exposing animals to stressors is invariably associated with at least a short-lasting increase in wakefulness. Moreover, many of the classical neuropeptides and hormones involved in the stress response are known to promote wakefulness, including catecholamines (Jones *et al.*, 1977; Cespuglio *et al.*, 1982; Lin *et al.*, 1992), corticotropin-releasing factor (CRF) (Ehlers *et al.*, 1986; Opp, 1995), and adrenocorticotropic hormone (ACTH) (Chastrette *et al.*, 1990; Gillin *et al.*, 1974). These data support the notion that acute stress and the concomitant physiological arousal may be an important cause of sleep disruption. The acute stress-induced arousal in animals can be used as a model to study and test the effects of potential hypnotic compounds (James and Piper, 1978).

Interestingly, studies in rats and mice have shown that upon removal of a stressor the arousing effect is rapidly overcome, and that stress may actually promote and increase sleep during the subsequent recovery period (Meerlo *et al.*, 1997; Meerlo and Turek, 2001; Meerlo *et al.*, 2001; Rampin *et al.*, 1991). In addition to this biphasic effect of stress on sleep, the picture is further complicated by the finding that different stressors may have different effects on NREM sleep and REM sleep. For example, whereas *immobilization* of rats and mice in a small tube results in an increase of REM sleep during subsequent recovery (Meerlo *et al.*, 2001; Rampin *et al.*, 1991), a *social conflict* with an aggressive conspecific was found to promote NREM sleep (Meerlo *et al.*, 1997; Meerlo and Turek, 2001). Importantly, although both social conflict and immobilization cause strong sympathetic and HPA axis activation, the respective increases in NREM sleep or REM sleep are apparently due to certain specific aspects of the stimuli. In this respect, one should perhaps not speak in general terms about the effects of stressors on sleep but, rather, refer to the effects of specific stimuli.

What are the specific elements of the different stressors that affect sleep? Clearly, the effects of a stressor may very well consist of multiple, interacting components, some non-specific, and some specific to a particular stimulus. The mechanism underlying an increase in NREM sleep as it is seen after a social conflict is still unknown, but for stressful stimuli that increase REM sleep, various factors have been proposed, including CRF (Gonzalez and Valatx, 1997), corticotropin-like intermediate lobe peptide (CLIP) (Bonnet *et al.*, 1997; Bonnet *et al.*, 2000), and prolactin (Bodosi *et al.*, 2000; Meerlo *et al.*, 2001). In particular, differences in prolactin release may explain some of the differential effects of stress on REM sleep. Prolactin is commonly referred to as a stress hormone, but the change in prolactin levels strongly depends on the nature of the stressor. In line with its effects on sleep, immobilization stress in rodents indeed appears to be characterized by an increase in prolactin that is much larger than what is observed after other stressors such as social conflict or cold stress (Lenox *et al.*, 1980; Meerlo *et al.*, 2001). Moreover, in a comparison between two different strains of mice, immobilization stress induced an increase in REM sleep during recovery only in one strain of mice, which had a large prolactin response (Meerlo *et al.*, 2001). The latter finding also illustrates how modulation of sleep by environmental factors depends not only on the nature of the stimulus but also on the genetic make-up of the individual.

Taken together, studies in rodents show that the final effect of an acute and short-lasting stress on sleep depends not only on the non-specific arousal common to all stressors but also on the specific aspects of a given stimulus. Whereas many of the classical *non-specific* stress response factors initially increase arousal and inhibit sleep, factors *specific* to a particular situation or stimulus may increase either NREM sleep or REM sleep during recovery sleep. Importantly, an increase in NREM sleep or REM sleep after exposure to a particular stressful stimulus is not necessarily a manifestation of dysregulation. Rather, it may be interpreted as a necessary homeostatic recovery process, although the exact nature of this recovery process is still unknown, in the case of both stress-induced sleep and sleep in general (Meerlo *et al.*, 1997).

Although exposure to an acute stressor in animals is generally associated with an increase in wakefulness for as long as the stimulus persists, it seems puzzling that this arousing and sleep-inhibiting effect of the stressor is so rapidly overcome. Moreover, especially the finding of an increase in sleep following certain stressful stimuli may seem to contrast with the general notion that stress is a major cause of sleep disturbances in human beings. However, there is very little information about the effects of acute stressors on human sleep, at least not in response to traumatic

experiences comparable to, for instance, social defeat in rodents. Thus, on the basis of the animal studies, one could hypothesize that, also in our own species, specific stressors may have a stimulatory effect on sleep systems shortly after the initial arousing effects. In fact, anecdotal information suggests that this may indeed be true (Oswald, 1962).

Studying the influence of acute and severe stressors may be a valid approach that mimics what could happen in real life, but, given the minimal and short-lasting wakefulness that occurs afterwards, these acute stress models do not appear to be extremely useful as models for the persistent insomnia so common in our society. For that purpose, one should perhaps use other or chronic stress models.

Repeated or Chronic Stress

In contrast to the acute and severe stress models discussed above, the 'stress' causing sleep disturbances in humans often seems to relate to a subtle cognitive phenomenon, that is, feelings of discomfort, not necessarily associated with an acute challenge (Roehrs *et al.*, 2000). Often, such feelings of discomfort may be based on memories of past events as well as worries and expectations about the future. In that respect, the human brain may be capable of turning a single acute stressor or life event that occurred in the past into a more persistent and chronic stress state. Although certain human cognitive processes may be difficult to model in animals, there are a number of studies that have examined the effects of chronic stress on sleep-wakefulness patterns in the rat.

In one model of chronic stress, sleep was measured in rats that were subjected to a paradigm of around-the-clock intermittent electrical shocks (Kant *et al.*, 1995). In this model of sustained stress, the animals display a wide variety of stress symptoms including elevated plasma levels of stress hormones such as corticosterone, a decrease in food intake and body weight, and disturbed temperature rhythm and activity pattern. The amount of sleep was remarkably reduced the first day of the treatment but normalized in the course of the days thereafter. However, the distribution of sleep over the 24-h cycle remained somewhat disturbed throughout the stress period. The amount of sleep was reduced in the light phase, the normal resting phase of rats, but this was compensated for by an increase in sleep during the dark phase. However, whereas rats under laboratory conditions have the possibility of such compensatory responses, human beings often do not have that possibility. These data show that, although a rat may rapidly overcome the arousal of a single stressful event, repetition of the stressor may add up and culminate in disrupted sleep.

In another study that applied a model of 'chronic mild stress', male rats were subjected to a mixture of noxious stimuli, once or twice a day, for various durations. The stimuli included cage tilt, soiled cage, deprivation of food and water, and housing in a mouse cage, which rats apparently dislike, but also exposure to continuous lighting and stroboscopic lighting (Cheeta *et al.*, 1997). The most significant finding from this study was a reduction in REM sleep latency during the protocol. The day after 3 weeks of a chronic mild stress treatment, the overall amount of sleep as well as the amount of REM sleep was somewhat increased, a finding which may in part reflect a rebound due to sleep that was lost during the actual stress exposure. Unfortunately, stimuli such as the lighting that was applied, although relevant in the context of environmental influences on sleep discussed earlier, may have effects on sleep that have little to do with stress *per se*.

Moreover, both models of chronic stress discussed here partly rely on direct stimulation of the animals, a fact which may explain some of the changes in sleep, whereas stress-related sleep disturbances in humans often appear to be of a more psychological nature. It may very well be that the physiological and neurobiological mechanisms resulting in disrupted sleep due to repeated electrical shocks and stroboscopic light are quite different from those involved in psychological stress in humans. These models are important first steps toward developing relevant models for stress-related sleep disturbances and insomnia, but, perhaps, research on the relationship between stress and sleep would gain by models that are based on, for instance, conditioned fear and arousal in which animals anticipate the occurrence of adverse events. Such an approach may have more resemblance to the psychological stress in humans, and with such a model one may be able to study the central mechanisms by which sleep is disrupted and how such disturbances could best be treated.

CONCLUDING REMARKS

Although the function of sleep is still an unresolved mystery, sleep is clearly necessary for optimal performance and well-being. The results from studies in a wide variety of animal models show that alterations and disruptions of sleep are often associated with changes in cognitive performance, emotionality, and disease. Sleep disturbances are a widespread and serious problem in our society, but animal research continues to push advances in the understanding of the causes and mechanisms of human sleep disorders, and to aid the improvement of treatment procedures and medicines.

ACKNOWLEDGEMENTS

The preparation of this chapter was supported in part by the National Alliance for Research on Schizophrenia and Depression (NASAD), NIH grants R01-AG-18200 and PO1-AG-11412, and a grant from the National Aeronautics and Space Administration through NASA Cooperative Agreement NCC 9–58 with the National Space Biomedical Research Institute.

XXIV-2

Neurotransmitter Systems Regulating Sleep-Wake States

Barbara E. Jones

Three distinct physiological and cognitive states exist in mammals: waking, slow-wave sleep (SWS) and rapid-eye-movement sleep (REMS). Waking is a multifarious state but is generally characterized by fast waves on the electroencephalographic (EEG) record in association with behavioural activity and responsiveness; SWS is characterized by slow waves on the EEG record in association with behavioural quiescence and decreased responsiveness; however, REMS, or 'paradoxical sleep' (PS), is characterized by a unique dissociation of EEG, characterized by fast waves indicative of cortical arousal, and behaviour, characterized by quiescence and diminished responsiveness, indicative of sleep. Viewed in terms of metabolism and energy expenditure, waking requires variable yet relatively high levels of energy expenditure by the brain and body; SWS requires low levels and thus allows conservation and restoration of energy stores in both brain and body; however, REMS requires high levels of energy expenditure by the brain while maintaining minimal energy use by the body. These states occur within a circadian cycle and an ultradian cycle. Depending upon the species, the active, waking phase of the circadian cycle occurs either during the day and light, as in humans, or during the night and darkness, as in cats and rats. Sleep is concentrated to differing degrees in the opposite phase, when it occurs, according to an ultradian rhythm. Across the phylogenetic scale, the period of the ultradian sleep-wake rhythm is correlated with basal metabolic rate and body weight, and thus is apparently determined in part by energy expenditure, storage, conservation and restoration. In addition to their regulation by underlying rhythms, the sleep-wake states are also regulated by homeostatic processes, such that the deprivation of sleep results in an increased drive for sleep and increased occurrence of sleep upon recovery. The rhythmic and homeostatic nature of sleep-wake states indicates the existence of underlying, alternating and accumulating processes that may depend upon changes in chemical transmitters and their receptors in the brain.

Neurotransmitters include small molecules such as glutamate and GABA, acetylcholine and the monoamines, which may act directly upon ion channels or indirectly upon them through second messengers to modify membrane potentials and activity of neurons. They may also include peptides, which function as transmitters, modulators or hormones. Although, to date, no single transmitter/modulator molecule has been found that serves a specific or exclusive function in promoting or generating waking, SWS or REMS, specific neuronal systems containing particular neurotransmitters have been shown to be integral to the promotion of each of these states.

From early physiological studies, it has been known that no specific centres are present in the brain for the generation of any one state, but that redundant neuronal systems are distributed through the brainstem and forebrain, systems which are collectively important for the promotion and maintenance of individual states (Jones, 2000). For **waking** (Figure XXIV-2.1), neurons distributed through the brainstem reticular formation (RF) and concentrated within the oral pontine and mesencephalic fields comprise the ascending reticular activating system, which, by lesions in humans and animals, is known to be critical for the generation and maintenance of the EEG and behavioural components of waking (Moruzzi and Magoun, 1949). This system of neurons gives rise to ascending pathways projecting dorsally into the non-specific thalamo-cortical projection system, which in turn stimulates widespread activation of the cerebral cortex (Dempsey *et al.*, 1941). Other fibres ascend ventrally into and through the hypothalamus up to the level of the basal forebrain (substantia innominata [SI]), from where cortical activation is also relayed in a widespread manner (Starzl *et al.*, 1951). These systems collectively stimulate cortical activation, characterized by high-frequency (beta and gamma) EEG activity. Fibres also terminate in the posterior hypothalamus, where lesions are known in humans and animals to produce a comatose state (Ranson, 1939). As evident as well from electrical stimulation (Hess, 1957), the posterior hypothalamus is an important higher control centre for the sympathetic nervous system, thus coordinating peripheral autonomic responses (increased temperature, respiration, heart rate, blood pressure) with cortical activation. In addition, the descending projections from the brainstem reticular formation, including the caudal pontine and medullary reticular formation, serve to stimulate somatic motor activity, reactivity and postural muscle tonus (as evident in electromyographic [EMG] activity) through facilitatory reticulo-spinal influences (Magoun and Rhines, 1946).

For **SWS** (Figure XXIV-2.2), the medulla appears, to play a role in promoting sleep, particularly neurons in the region of the solitary and vagal, parasympathetic nuclei, which may inhibit the activating neurons located in the ponto-mesencephalic tegmentum (Batini *et al.*, 1959; Favale *et al.*, 1961). Within the forebrain, sleep marked by EEG slow waves may be elicited by low-frequency stimulation of the thalamo-cortical projection neurons (Akert *et al.*, 1952). Most potent there is the influence shown to emanate from the preoptic and anterior hypothalamic (POAH) region, where lesions have produced insomnia and electrical stimulation has promoted sleep, probably in part due to inhibition of the posterior hypothalamus and ponto-mesencephalic reticular formation (von Economo, 1931; Nauta, 1946; Hess, 1954). This region serves in an antagonistic manner to the posterior hypothalamus, inhibiting sympathetic activity and facilitating parasympathetic responses (decreased temperature, respiration, heart rate, blood pressure). SWS appears to emerge from the dampening of cortical activation, somatic motor activity (as evident by decreased EMG) and sympathetic nervous activity along with a shift to a predominance of parasympathetic activity.

For **REMS** (or PS, as it is often also called in animals) (Figure XXIV-2.3), the brainstem appears to contain the essential structures for the generation of the state (Jouvet, 1962). The oral pontine reticular formation (PnO) is necessary for the triggering of ascending and descending parameters of the state, including

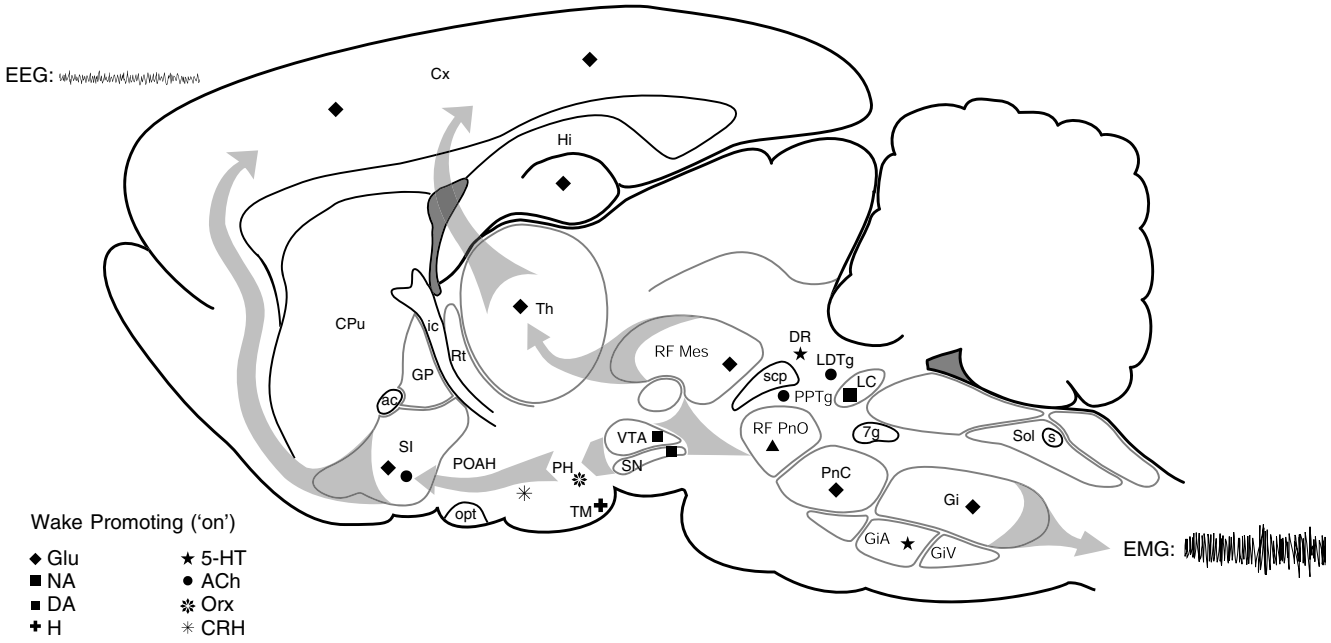

Figure XXIV-2.1 Wake-Promoting Systems. Schematic sagittal view of rat brain showing the major neuronal systems and their major excitatory pathways (arrows) involved in promoting the EEG fast activity (upper left) and EMG high muscle tone and activity (lower right) characteristic of the waking state. The major ascending pathways emerge from the brainstem reticular formation (RF, most densely from the mesencephalic, RF Mes, and oral pontine RF PnO, fields) to ascend along a) a dorsal trajectory into the thalamus (Th) where they terminate upon (midline, medial, and intralaminar) nuclei of the non-specific thalamo-cortical projection system, which projects in turn in a widespread manner to the cerebral cortex (Cx), and b) a ventral trajectory through the lateral hypothalamus up to the basal forebrain where they terminate upon neurons in the substantia innominata (SI) (and septum, not shown), which also project in turn in a widespread manner to the cerebral cortex (and hippocampus, Hi) (Jones, 1995). Descending projections collect from multiple levels of the reticular formation (though most densely from the caudal pontine, PnC, and medullary gigantocellular, Gi, fields) to form the reticulo-spinal pathways. The major transmitter systems that promote waking and discharge maximally ('on') during waking contribute to these ascending and descending systems and are represented by symbols where their cell bodies are located. Glutamatergic (Glu) neurons comprise the vast population of neurons of the reticular formation, the diffuse thalamo-cortical projection system and a contingent of the basalo-cortical projection system. Noradrenergic (NA) neurons of the locus coeruleus (LC) send axons along the major ascending and descending pathways to project in a diffuse manner to the cortex, the subcortical relay stations, brainstem and spinal cord. Dopaminergic (DA) neurons of the substantia nigra (SN) and ventral tegmental area (VTA) project along the ventral pathway in the nigro-striatal system and meso-limbo-cortical system, respectively. Histaminergic (H) neurons of the tuberomammillary nucleus (TM) project in a diffuse manner to the forebrain and cortex. Serotonergic neurons containing 5-hydroxytryptamine (5-HT) of the midbrain (including the dorsal raphe, DR) project to the forebrain, including the cerebral cortex (and hippocampus), as well as the subcortical relay stations, and those of the medulla (in raphe pallidus and obscurus, not shown, as well as pars alpha of the gigantocellular field [GiA]) project to the spinal cord. Cholinergic neurons, containing acetylcholine (ACh), are located in the laterodorsal and pedunculopontine tegmental (LDTg and PPTg) nuclei in the brainstem, from where they project along with other reticular neurons dorsally to the thalamus and ventrally to the posterior hypothalamus and basal forebrain, as well as to the brainstem reticular formation. They are also located in the substantia innominata (SI, and septum, not shown), from where they project to the cortex (and hippocampus). Orexinergic (Orx) neurons in the (perifornical and lateral) mid- and posterior hypothalamus (PH) project diffusely through the forebrain, brainstem and spinal cord to exert an excitatory influence at multiple levels. Corticotropin-releasing hormone (CRH) is contained in neurons within the paraventricular nucleus of the hypothalamus which project to the pituitary, as well as in other scattered neurons (not shown) projecting to other forebrain and brainstem areas that collectively stimulate the hypothalamo-pituitary-adrenal axis and central arousal systems. Some state-specific GABAergic neurons (triangle) may be on during waking to prevent activity of REM-promoting neurons in the oral pontine reticular formation (PnO) (Figure XXIV-2.3) (See Colour Plate XXIV-2.1)

cortical activation, phasic REM along with motor twitches, and tonic postural muscle atonia (Carli and Zanchetti, 1965). The ascending pathways stimulating cortical activation travel along the same routes as those utilized in waking, although the ventral extrathalamic pathway through the basal forebrain and into the limbic cortex appears to be most important (Jouvet, 1962). The descending motor inhibition (as evident from the flat EMG) appears to emerge from the oral pontine reticular formation and to relay through the ventral medullary reticular formation (Magoun and Rhines, 1946). Both visceral and somatic sensory-motor circuits and reflexes are inhibited by this system.

The representation from the classical physiological studies of the distribution of neuronal systems most critically involved in generating waking, SWS and REMS remains valid today. Within those regions and neuronal systems, particular transmitters/modulators have been localized and shown through specific lesions, unit recording, and pharmacological or more recently genetic modulation to play, if not specific, nonetheless differentiated, important roles in promoting waking, SWS or REMS.

WAKE-PROMOTING TRANSMITTER SYSTEMS

Glutamate (Glu) is the most common excitatory neurotransmitter in the brain and is critical for the waking state (Figure XXIV-2.1). It is utilized as the primary transmitter of the neurons within the brainstem reticular formation (RF) and thus is the transmitter of the ascending reticular activating system (Jones, 1995). It is also the transmitter of the non-specific thalamo-cortical projection system (Ottersen *et al.*, 1983) and of a contingent of the basalo-cortical

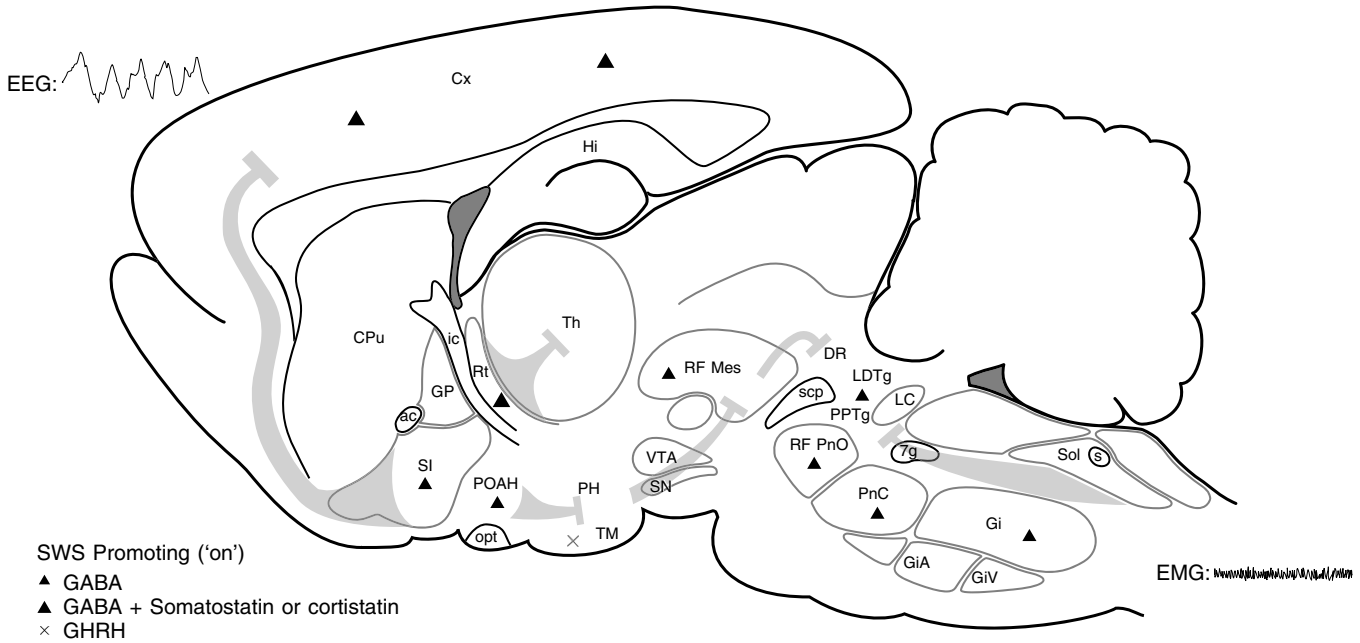

Figure XXIV-2.2 SWS-promoting systems. Schematic sagittal view of rat brain showing the major neuronal systems and their major inhibitory pathways (ending as blocks) involved in promoting the EEG slow-wave activity (upper left) and EMG reduced muscle tone (lower right) characteristic of the slow-wave sleep (SWS) state. Neurons in the region of the solitary tract nucleus (Sol) may exert an inhibitory influence on neurons in the ponto-mesencephalic tegmentum. A dampening influence on the brainstem activating system and the posterior hypothalamus (PH) also emerges from the basal forebrain and preoptic-anterior hypothalamic areas (POAH). From the basal forebrain (substantia innominata [SI]), an inhibitory influence is also exerted upon the cortex (Cx). The major transmitter systems that promote SWS and discharge maximally ('on') during SWS are represented by symbols where their cell bodies are located. These comprise largely GABAergic neurons that, by unit recording and/or c-Fos studies, have been shown to be active during SWS. Particular cortically projecting GABAergic neurons in the SI may have the capacity to dampen cortical activation directly during SWS. Locally projecting GABAergic neurons in the SI may inhibit the cholinergic and glutamatergic cortically projecting neurons. Other GABAergic neurons in the SI and POAH project caudally to the posterior hypothalamus (including the tuberomammillary nucleus [TM]) and brainstem (including RF Mes, DR, LDTg and LC), where they may inhibit multiple wake-active neurons of the activating systems. GABAergic neurons in the reticularis (Rt) nucleus, which surround and innervate the thalamic (Th) nuclei, discharge in bursts to generate spindles while inhibiting the thalamo-cortical projection neurons during SWS. These and local GABAergic neurons in the cortex (Cx) also contain somatostatin or the related peptide corticostatin, which may serve to prolong the inhibition in promoting the slow-wave activity of this state. GABAergic neurons in the brainstem may inhibit local neurons of the ascending reticular activating system as well as those of the descending reticulo-spinal system. Neurons containing growth hormone-releasing hormone (GHRH), primarily located in the arcuate nucleus and projecting to the median eminence, are actively involved in stimulating growth hormone and also promoting slow-wave activity during SWS (See Colour Plate XXIV-2.2)

projection system (Manns *et al.*, 2001). Cortical activation thus depends upon glutamatergic transmission. Glutamate release from the cerebral cortex is highest in association with cortical activation (Jasper *et al.*, 1965). The reticulo-spinal neurons important for increasing muscle tonus, enhancing behavioural responsiveness and stimulating locomotion are also glutamatergic (Grillner *et al.*, 1995).

Drugs that block glutamate transmission by pre- and/or postsynaptic mechanisms (especially the NMDA receptor) comprise some of the anaesthetics, including ketamine (Yamamura *et al.*, 1990) and halothane (MacIver *et al.*, 1996), that produce a loss of consciousness and sensory-motor responsiveness.

Noradrenaline (NA) is a wake- and arousal-promoting transmitter/modulator that is contained in the diffuse projecting locus coeruleus (LC)/subcoeruleus neurons of the pons (Figure XXIV-2.1) and in other hypothalamically projecting and spinally projecting pontine and medullary cell groups. Although lesions of the locus coeruleus nucleus do not result in long-term deficits in cortical activation or waking (Jones *et al.*, 1977), stimulation of the locus coeruleus by electrical or chemical means elicits cortical activation and a vigilant, waking state (Berridge and Foote, 1991). Locus coeruleus neurons discharge at their highest rates during waking, decrease their rate during SWS and cease firing during REMS (Hobson *et al.*, 1975; Aston-Jones and Bloom, 1981b). During waking, they discharge maximally in association with arousal, including attentive and active behaviours, orientation to sensory stimuli, response to painful stimuli and reaction to stressful conditions (Foote *et al.*, 1980; Aston-Jones and Bloom, 1981a; Rasmussen *et al.*, 1986; Abercrombie and Jacobs, 1987a, b). Release of noradrenaline is greatest in association with cortical activation and behavioural arousal, including stress (Nisenbaum *et al.*, 1991; Shouse *et al.*, 2000). In situations of stress, the increased activity of these neurons occurs in parallel with activation of the sympathetic nervous system and the hypothalamo-pituitary-adrenal axis. Through their diffuse projection system that includes the entire forebrain and spinal cord, the locus coeruleus neurons have the capacity to stimulate cortical activation, to activate sympathetic and hypothalamo-pituitary-adrenal systems in the hypothalamus and to excite sympathetic and somatic motor neurons in the spinal cord. Therefore, even though it may not be necessary for maintaining a waking state, the noradrenergic system is important for stimulating a coordinated response to significant sensory stimuli or conditions and thus promoting a maximally attentive and active waking state.

Drugs that diminish noradrenaline, such as alpha-methyl tyrosine (AMT), through inhibition of its synthetic enzyme decrease arousal and enhance both SWS and REMS (King and Jewett, 1971). Drugs that act as agonists at postsynaptic alpha1 receptors

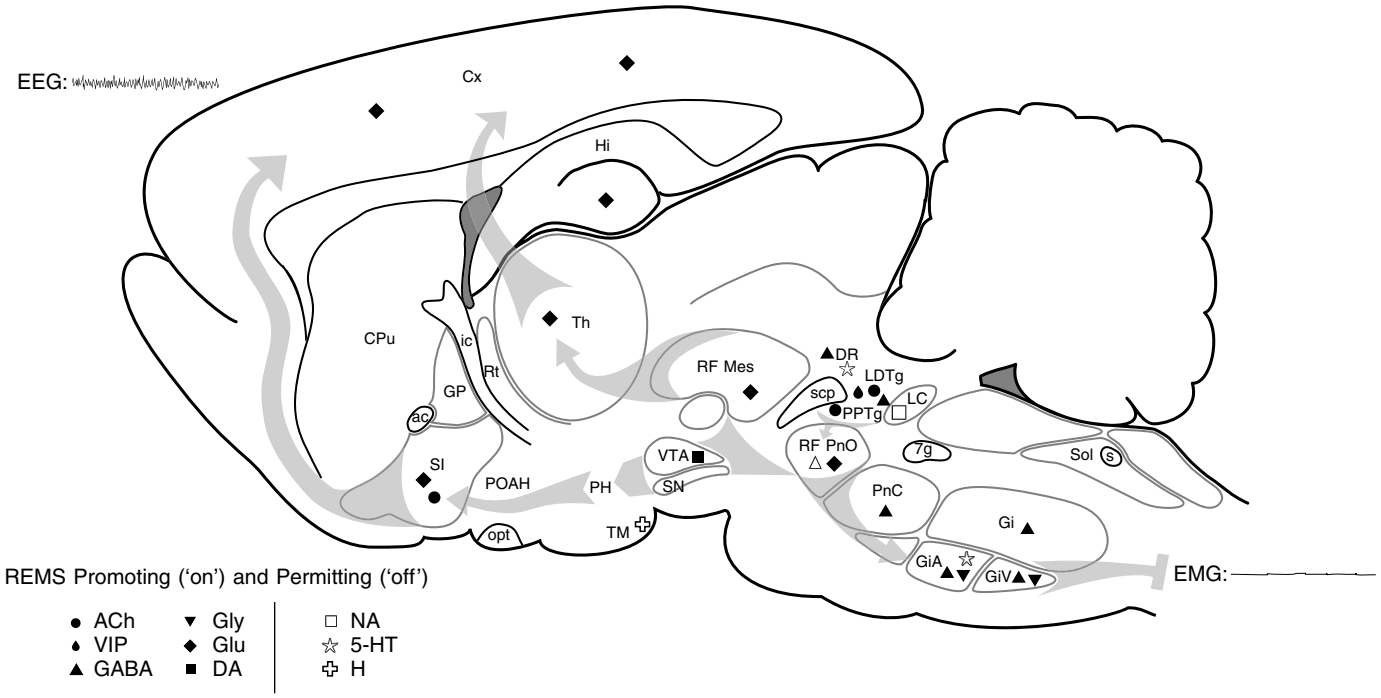

Figure XXIV-2.3 REMS-promoting and REMS-permitting systems. Schematic sagittal view of rat brain showing the major neuronal systems and their (excitatory, ending as arrows, and inhibitory, ending as blocks) pathways involved in promoting the EEG fast activity (upper left) and EMG muscle atonia (lower right) characteristic of rapid eye movement or paradoxical sleep (REMS or PS). Neurons essential for REM sleep are located in the pontine reticular formation, particularly the oral part (RF PnO). The major ascending pathways (indicated by arrows for excitation) promoting cortical activation are similar to those of the waking state; however, the extrathalamic relay into the limbic system may be more important in REMS. The descending motor inhibition (indicated by a block) is triggered by neurons in the oral pontine reticular formation (RF PnO) and partly relayed through neurons in the alpha and ventral gigantocellular fields (GiA and GiV) of the medullary reticular formation en route to the spinal cord. The major transmitter systems that promote REMS and discharge ('on') during REMS are represented by filled symbols, whereas those that are permissive to REMS by stopping their discharge ('off') during the state are represented by empty symbols. Cholinergic neurons that release acetylcholine (ACh) and are located in the laterodorsal and pedunculopontine tegmental nuclei (LDTg and PPTg) are critically involved in promoting REMS through their projections locally into the brainstem reticular formation, and importantly to neurons in the PnO (where they excite glutamatergic neurons and could also inhibit local GABAergic neurons), as well as rostrally into the forebrain. These may be joined in promoting REMS by neurons with similar projections in the region containing vasoactive intestinal peptide (VIP). Noradrenergic (NA) locus coeruleus (LC) and serotonergic (5-HT) dorsal raphe (DR) neurons (as well as histaminergic, H, tuberomammillary neurons, TM) that directly inhibit the cholinergic neurons permit REMS to occur by ceasing their discharge. The arrest of their discharge is effected by local GABAergic neurons, which may be excited by ACh. GABAergic neurons through the caudal pontine (PnC) medullary reticular formation (Gi, GiA, and GiV) may also inhibit local reticulo-spinal and serotonergic raphe-spinal neurons to effect a disfacilitation of motor neurons. In addition, GABAergic and glycinergic neurons in the ventral medullary reticular formation (GiA and GiV) that project to the spinal cord may both directly inhibit motor neurons. One unique group of GABAergic neurons in the PnO ceases discharge during REMS to disinhibit PnO glutamatergic neurons that propagate the ascending and descending correlates of the state. In the ascending pathways, dopaminergic (DA) neurons of the ventral tegmental area (VTA), which are excited by the cholinergic neurons, may be important in activation of the limbic system. The cholinergic basal forebrain neurons (SI and septum) are particularly important in activation of the limbic cortex (hippocampus [Hi]) and neo-cortex (Cx) during REMS (See Colour Plate XXIV-2.3)

stimulate wakefulness. These drugs appear to include modafinil, which stimulates prolonged cortical activation and behavioural arousal, since its effects are blocked by alpha1-receptor antagonists (Duteil *et al.*, 1990; Lin *et al.*, 1992). Through second messengers, alpha1-adrenergic receptors close potassium channels on thalamic and cortical neurons, resulting in their tonic depolarization and the increased excitation that underlies cortical activation (McCormick, 1992). Noradrenaline also acts on alpha2-adrenergic receptors, which commonly open potassium channels through second messengers to hyperpolarize neurons. These receptors are located presynaptically on noradrenergic neurons, as well as postsynaptically on other target neurons. For this reason, drugs that act upon alpha2 receptors are associated with complex, dose-dependent effects upon the sleep-waking cycle. However, the postsynaptic inhibition associated with alpha2 receptors may be important in inhibiting sleep-promoting neurons during waking (see below). Drugs that enhance synaptic levels of noradrenaline through stimulating release and/or blocking reuptake, such as desipramine or amphetamine and possibly also modafinil, enhance arousal, including both cortical activation and muscle tone, and thereby enforce wakefulness, while preventing the onset of both SWS and REMS (Mignot *et al.*, 1993).

Dopamine (DA), like noradrenaline, is principally a wake-promoting transmitter/modulator; however, unlike noradrenaline, it is particularly associated with the pleasurable and rewarding emotional states that may also occur during sleep. Dopaminergic neurons are located in the ventral mesencephalic tegmentum, within the substantia nigra (SN) and ventral tegmental area (VTA) (Figure XXIV-2.1). Dopaminergic neurons of the substantia nigra project predominantly to the striatum, whereas those of the ventral tegmental area project to limbic and medial cortical areas forming the respective nigro-striatal and meso-limbo-cortical projection systems. Lesions of the dopaminergic neurons in the ventral mesencephalic tegmentum result in reduced behavioural arousal; major lesions result in akinesia, along with anorexia and adipsia (Ungerstedt, 1971; Jones *et al.*, 1973). Whereas lesions of the

dopaminergic nigro-striatal neurons decrease locomotion, lesions of the meso-limbo-cortical neurons diminish attentive immobility and simultaneously decrease the high-frequency EEG activity associated with that behavioural state (Galey *et al.*, 1977; Montaron *et al.*, 1982). Lesions have also produced a decrease in REMS (Lai *et al.*, 1999). Surprisingly, however, dopaminergic unit activity has not been found to vary significantly across sleep-wake states when measured as average rate of discharge (Miller *et al.*, 1983; Trulson and Preussler, 1984). Similarly, the average release of dopamine has not been found to vary across the sleep-waking cycle (Trulson, 1985; de Saint Hilaire *et al.*, 2000; Shouse *et al.*, 2000). However, dopaminergic neurons discharge in different patterns such that although continuing at the same average firing rate, they may fire in either a tonic or a bursting pattern. Dopaminergic neurons discharge in bursts during arousing situations and particularly when presented with positively rewarding stimuli or conditions (Mirenowicz and Schultz, 1996). Moreover, dopamine release is greatest during waking when animals are aroused and in positively rewarding situations, including those associated with food and drug reward (Di Chiara and Imperato, 1988; Richardson and Gratton, 1996). Accordingly, dopaminergic neurons would be maximally active by bursting in highly aroused, motivated or rewarding situations during waking. They may also be differentially active during sleep, according to the evidence of a change in pattern of discharge during REMS relative to SWS (Miller *et al.*, 1983). Thus, unlike the other monoamine neurons, they do not cease firing during REMS and may discharge in a manner to contribute to the cognitive correlate of that state, as they do in waking (see below).

Drugs that diminish dopamine through inhibition of its synthesis also diminish noradrenaline, and their soporific effects must accordingly be attributed to the simultaneous depletion of both transmitters. Interpreting the effects of drugs acting upon different dopamine receptors is also difficult because of the presynaptic (D2) and multiple postsynaptic (D1/D2) sites of the receptors. More than EEG activity, dopamine-receptor antagonists most markedly alter behaviour and cognitive state. Neuroleptic drugs that block postsynaptic dopamine receptors, such as pimozide, induce a state of anhedonia (Wise *et al.*, 1978). Drugs that act to enhance synaptic levels of dopamine by blocking reuptake or stimulating release, particularly amphetamine and cocaine, have positively rewarding, pleasurable effects associated with their addictive properties (Di Chiara and Imperato, 1988). These drugs also enhance cortical activation and behavioural arousal (Wisor *et al.*, 2001). Drugs that are used in the treatment of hypersomnolence and narcolepsy, and that accordingly prevent both SWS and REMS, include the amphetamines and modafinil. Although to differing degrees, both these drugs most likely act simultaneously upon dopaminergic and noradrenergic transmission to enforce wakefulness (see above) (Wisor *et al.*, 2001).

Histamine (H) is a wake-promoting transmitter/modulator. The neurons containing histamine are located in the tuberomammillary nucleus (TM) of the posterior hypothalamus (Figure XXIV-2.1) and give rise to diffuse projections through the forebrain. Lesions or pharmacological inactivation of these neurons leads to an acute decrease in waking (Lin *et al.*, 1989; Sakai *et al.*, 1990) and increase in REMS as well as SWS (Sallanon *et al.*, 1988). Like noradrenergic neurons, presumed histaminergic neurons discharge at their maximal rate during waking, decrease their rate during SWS and cease firing during REMS (Sakai *et al.*, 1990).

Drugs that antagonize postsynaptic histamine receptors (particularly H1), the common antihistaminergic drugs used for antiallergy medication, as well as those that occupy the presynaptic autoreceptor (H3), which decrease histamine release, produce somnolence and a decrease in waking and vigilance (Monti *et al.*, 1986; Lin *et al.*, 1988, 1990). Conversely, drugs that act as agonists upon the postsynaptic receptors have the capacity to enforce attentive waking and prevent the onset of SWS (Lin *et al.*, 1988). Through these receptors, histamine blocks potassium channels on target thalamic and cortical neurons and thus stimulates a depolarization of those cells underlying cortical activation (McCormick, 1992; Reiner and Kamondi, 1994).

Serotonin (5-hydroxytryptamine [5-HT]) may promote waking, yet it appears to promote a quiet, satiated waking state that can also facilitate the passage into sleep. It is contained in neurons located in the raphe nuclei within the mesencephalon and pons (including the dorsal raphe [DR]), from which diffuse ascending projections into the forebrain arise, and the medulla, from which descending projections to the spinal cord arise (Figure XXIV-2.1). Lesions of the raphe nuclei have produced complete insomnia in association with a behaviourally agitated state (Jouvet, 1972), leading to the postulate that serotonergic neurons generate SWS. However, electrical stimulation of the midbrain raphe arrested waking behaviours, including eating, although it did not produce sleep (Jacobs, 1973). Moreover, most presumed serotonergic raphe neurons discharge during waking and decrease their discharge during SWS, becoming virtually silent during REMS (McGinty and Harper, 1976; Trulson and Jacobs, 1979). During waking, some presumed serotonergic neurons discharge in association with rhythmic motor activities, such as grooming in cats (Jacobs and Fornal, 1991). Accordingly, they may not generate SWS, although they can promote a quiet waking state that is more conducive to sleep onset. Release of serotonin is also, on average, lower during SWS than during waking (Wilkinson *et al.*, 1991; Portas *et al.*, 1998), but appears to increase during prolonged waking and prior to SWS onset (Python *et al.*, 2001).

Drugs that diminish serotonin levels through inhibition of its synthesis (by *p*-chlorophenylalanine [PCPA]) produce complete insomnia with acute administration (Jouvet, 1972) and a recovery of sleep with chronic administration (Dement *et al.*, 1973). Under both conditions, certain behaviours are increased, including eating, and sexual and aggressive activities, and appear along with a release of the phasic activity (ponto-geniculo-occipital [PGO] spikes) of REMS. The insomnia elicited by PCPA can be reversed with very low quantities of the 5-HT precursor, 5-hydroxytryptophan (5-HTP) (Jouvet, 1972). This effect is also present with local injections of the precursor into the preoptic region (Denoyer *et al.*, 1989). The effects of drugs that act upon individual serotonin receptors are difficult to interpret since they act at multiple presynaptic (5-HT1) and postsynaptic (5-HT1/2/3) sites. Increased synaptic levels of serotonin elicited by the serotonin reuptake inhibitors generally produce relatively quiet waking states, characterized by satiety and thus reduced appetite for food and sex, as well as the psychologically reported reduction in anxiety common in humans (Ursin, 1976, 1980; Sommerfelt and Ursin, 1991; Foreman *et al.*, 1992; Leibowitz and Alexander, 1998; Halford and Blundell, 2000; Kennedy *et al.*, 2000). Like the effects of the precursor, tryptophan, those of the reuptake blockers are best characterized as dampening cortical activation (Ursin, 1980). This effect may be mediated in part by serotonin's inhibitory effect upon cholinergic basal forebrain neurons (see below) through 5-HT1 receptors, which indirectly open potassium channels to hyperpolarize these cells (Khateb *et al.*, 1993). Local microinjections of serotonin into the region of the cholinergic neurons results in the decrease of high-frequency (gamma) cortical activity and the appearance of slow-wave activity with SWS (Cape and Jones, 1998). Through input to the septum, serotonin also dampens theta activity in the limbic system (Vertes *et al.*, 1994). It similarly inhibits cholinergic ponto-mesencephalic neurons that also serve to stimulate cortical activation through their thalamic and other subcortical relay stations (Luebke *et al.*, 1992). In the hypothalamus, serotonin appears to act as a satiety factor in the feeding system (Leibowitz and Alexander, 1998). In the brainstem and spinal cord, serotonin has the capacity to stimulate muscle tone in skeletal muscles (Kubin *et al.*, 1992). Accordingly, serotonin may promote a waking state

during which cortical activation is minimal, and feeding, sexual and aggressive behaviours are dampened, yet rhythmic motor activities and postural muscle tonus are maintained. Serotonergic systems may thus produce a sated, quiet waking state that precedes and facilitates SWS, but prevents REMS (see below).

Acetylcholine (ACh) promotes cortical activation that can be associated with either the state of waking or REMS (see below), as it also stimulates, through brainstem mechanisms, motor inhibition and muscle atonia. Cholinergic neurons are located in the ponto-mesencephalic tegmentum (laterodorsal and pedunculopontine tegmental nuclei [LDTg and PPTg]), as well as the medullary reticular formation, and, like neurons of the ascending reticular activating system, give rise to ascending projections to the thalamus, posterior hypothalamus and basal forebrain (Figure XXIV-2.1). Lesions of the cholinergic ponto-mesencephalic neurons have minimal effects upon waking but eliminate the state of REMS (Webster and Jones, 1988). Another major cholinergic cell group is located in the basal forebrain (substantia innominata [SI] corresponding to the nucleus basalis of Meynert, as well as the septum and diagonal band nuclei) and gives rise to widespread projections to the cerebral cortex (and hippocampus). Lesions of the cholinergic basal forebrain neurons lead to deficits in cortical activation and attention during waking (Stewart *et al.*, 1984; Dunnett *et al.*, 1991). Unit recording of presumed cholinergic neurons in the ponto-mesencephalic tegmentum has indicated that these cells discharge at higher rates during waking than during SWS; most also discharge during REMS and some at higher rates than during waking (El Mansari *et al.*, 1989; Kayama *et al.*, 1992). In the basal forebrain, unidentified but possibly cholinergic neurons discharge at higher rates during waking and REMS than during SWS (Detari *et al.*, 1984; Szymusiak and McGinty, 1986). Release of acetylcholine from both the thalamus and cortex is highest in association with cortical activation and high in both waking and REMS relative to slow-wave sleep (Celesia and Jasper, 1966; Jasper and Tessier, 1971; Williams *et al.*, 1994; Marrosu *et al.*, 1995). During waking, acetylcholine release is high in association with appetitive behaviours, such as eating (Inglis *et al.*, 1994). Acetylcholine release in the hippocampus is highest during REMS (Marrosu *et al.*, 1995); in the brainstem, it is also highest during REMS and the muscle atonia that accompanies that state (see below) (Kodama *et al.*, 1990; 1992).

Drugs that block the muscarinic postsynaptic action of acetylcholine, such as atropine, lead to the loss of fast cortical activity and its replacement by slow waves, despite the persistence of waking behaviours (Longo, 1966; Stewart *et al.*, 1984). This effect is marked behaviourally, nonetheless, by deficits in attention and memory. In addition to affecting glutamate receptors (see above), some anaesthetics, such as ketamine and halothane, appear to block nicotinic receptors (Flood and Krasowski, 2000; Mori *et al.*, 2001). Drugs such as eserine that enhance acetylcholine by blocking its catabolism through the acetylcholinesterase enzyme enhance and prolong cortical activation and diminish cortical slow waves and SWS (Jouvet, 1975; Vanderwolf, 1975). Direct administration of muscarinic agonists into the brain (done of necessity, since most do not cross the blood–brain barrier) also enhances cortical activation. Through second messengers, multiple muscarinic receptors (M1/M3) block potassium channels and lead to prolonged depolarization and increased excitation of their target neurons in the thalamus and cortex (McCormick, 1992). Nicotine also stimulates cortical activation and enhances vigilance (Domino, 1967; Koelega, 1993). Directly linked to sodium ion channels, the nicotinic receptor is associated with rapid depolarization and excitation of target neurons. The muscarinic-nicotinic mixed agonist, carbachol, when injected directly into subcortical sites, stimulates cortical, including limbic, activation accompanied by theta activation, and reduces locomotor activity (Brudzynski and Mogenson, 1986). Such injections can also induce REMS with muscle atonia, particularly when administered into the ponto-mesencephalic tegmentum (see below) (Hernandez-Peon and Chavez Ibarra, 1963; Baxter, 1969; Mitler and Dement, 1974; Amatruda *et al.*, 1975). Acetylcholine thus plays an important role in cortical and limbic activation associated with aroused, attentive, yet also immobile behavioural states, including REMS (see below).

Orexin (Orx), also known as hypocretin, is a wake-promoting neuromodulator that also stimulates eating, for which it was named. It is contained within neurons of the mid- and posterior hypothalamus (PH) that give rise to very diffuse projections through the brain, including the forebrain, brainstem and spinal cord (Figure XXIV-2.1). It appears to have the capacity to enforce waking with muscle tonus since in its absence or that of its postsynaptic receptor, as produced by genetic knockout, narcolepsy results in mice and dogs (Chemelli *et al.*, 1999; Lin *et al.*, 1999). As recently established in human cases, the Orx-containing cells in the hypothalamus are reduced in number with narcolepsy (Thannickal *et al.*, 2000). Orexin acts upon other activating systems including, importantly, the noradrenergic locus coeruleus (Bourgin *et al.*, 2000), histaminergic tuberomammillary (Huang *et al.*, 2001; Bayer *et al.*, 2002) and cholinergic basal forebrain neurons (Eggermann *et al.*, 2001), all of which it excites.

The drug which stimulates waking and vigilance and is used in the treatment of narcolepsy, modafinil, was recently shown by c-Fos immunostaining to activate Orx-containing cells (in addition to other neurons of the activating system) (Estabrooke *et al.*, 2001).

Corticotrophin-releasing hormone (CRH) is a wake-promoting neuromodulator and hormone. It is contained within neurons of the paraventricular nucleus of the hypothalamus (Figure XXIV-2.1) that stimulate release of adrenocorticotrophic hormone (ACTH) from the pituitary. A circadian rhythm of the activity of these neurons is presumably responsible for the circadian rise in human cortisol secretion that occurs in the morning, reaching a maximum upon waking, and more so in the presence of bright light (Leproult *et al.*, 2001). Also contained within other neurons in the hypothalamus and brainstem (not shown) with more widespread projections, corticotropin-releasing hormone may act upon many systems in the brain. Injected into the ventricles of animals, it promotes cortical activation and waking while diminishing slow-wave activity and SWS (Ehlers *et al.*, 1986). It also acts through other transmitter systems, including the locus coeruleus, to promote waking, cortical activation and arousal (Valentino *et al.*, 1993). Such circuits would be highly active during conditions of stress when an attentive waking state is maintained. In addition, however, CRH and ACTH may stimulate REM sleep in association with stress, as evident during REM sleep rebound following deprivation (Marrosu *et al.*, 1990; Gonzalez and Valatx, 1998).

In summary, multiple transmitter/modulator systems play partially redundant yet differentiated roles in promoting and maintaining the cortical activation and behavioural arousal of waking. Glutamatergic neurons, through the reticular activating system, diffuse thalamo-cortical projection system and basalo-cortical system, as well as the cortex, maintain fast excitatory activity through the brain during waking. In the most attentive and aroused conditions, including stress, noradrenergic locus coeruleus neurons, through diffuse projections, promote, maintain and enhance cortical activation and sympathetic and hypothalamo-pituitary-adrenal activation, as well as sensory-motor readiness. Histaminergic hypothalamic neurons, also through diffuse projections, maintain cortical activation and vigilance. These systems work mutually with corticotropin-releasing hormone and orexinergic hypothalamic neurons that serve to enforce a state of waking and prevent the onset of sleep. Serotonergic raphe neurons through diffuse projections also prevent the onset of REMS and loss of muscle tonus associated with that state, but they promote a quiet waking state that precedes and can expedite the onset of SWS. Cholinergic brainstem and basal forebrain neurons that project to the thalamus and cortex stimulate activation

of the limbic cortex and the neo-cortex during waking, but do not oppose and may actually stimulate the loss of muscle tonus that occurs during REMS, when they also promote cortical activation. Dopaminergic mesencephalic neurons may join cholinergic neurons during waking and REMS to stimulate limbic and cortical activation associated particularly with pleasurable states.

SLOW-WAVE SLEEP-PROMOTING TRANSMITTER SYSTEMS

GABA (gamma-hydroxy-butyric acid) is the most common inhibitory amino-acid transmitter in the central nervous system and, as such, is involved in almost all inhibitory processes that occur during different states. It is contained in interneurons through the cortex, hippocampus, thalamus, brainstem and spinal cord. It is also contained in certain long-projection neurons. In addition to suppressing discharge of neurons, GABAergic neurons can pace the activity of neurons in fast or slow rhythms. It should thus be mentioned that GABAergic interneurons and projection neurons are important in contributing to activating gamma and theta activities in the limbic cortex and the neo-cortex (Soltesz and Deschenes, 1993; Whittington *et al.*, 2000). The activity of particular GABAergic neurons is similarly important for pacing slower sleep rhythms while inhibiting activating systems (Figure XXIV-2.2). Through a bursting discharge, GABAergic neurons of the thalamic reticular nuclei play a critical role in the generation of thalamo-cortical spindle activity, by both inhibiting and pacing the thalamic relay neurons in association with the spindles and then slower delta activity through SWS (Steriade and Llinas, 1988). These GABAergic neurons appear to be responsible for closing the afferent gateway through the thalamus to the cerebral cortex during SWS (Hofle *et al.*, 1997). GABA is also contained within long-projection neurons, including those ascending to the cortex from the basal forebrain (Gritti *et al.*, 1997). Such long-projecting GABAergic neurons may be involved in dampening cortical activity in association with cortical slow-wave activity and SWS (Szymusiak and McGinty, 1989; Manns *et al.*, 2000). In addition, GABA is contained in locally projecting neurons within the basal forebrain that may inhibit the cholinergic neurons during SWS (Manns *et al.*, 2000; Szymusiak *et al.*, 2000). It is also contained in neurons projecting to the posterior hypothalamus and brainstem from the basal forebrain and the preoptic-anterior hypothalamic regions (Gritti *et al.*, 1994). It appears from c-Fos expression, in addition to neural firing profiles, that such GABAergic cells are most active with EEG slow-wave activity and SWS (Sherin *et al.*, 1996; Szymusiak *et al.*, 1998; Gong *et al.*, 2000; Manns *et al.*, 2000). Such cells have been identified in the substantia innominata and preoptic region, concentrated particularly in the ventro-lateral preoptic area (VLPO), as well as in the more medial and median preoptic nuclei. These GABAergic neuronal systems serve as gating mechanisms for state changes, since when they are on (closing the gate), neurons in the posterior hypothalamus and brainstem are inhibited, thus allowing sleep; when they are off (opening the gate), neurons in the posterior hypothalamus and brainstem are disinhibited, preventing sleep and promoting waking. Consistent with this view, GABA release is greatest in the posterior hypothalamus during SWS (Nitz and Siegel, 1996), and it is higher in brainstem dorsal raphe and locus coeruleus regions during SWS than waking (Nitz and Siegel, 1997a, b). Collectively, the preoptic GABAergic neurons form an integral part of the regulatory system for autonomic and hypothalamo-pituitary function, inhibiting sympathetic and hypothalamo-pituitary adrenal activity, while dampening the cortical activating system.

GABAergic neurons in the VLPO have been shown to be inhibited by noradrenaline (presumably through an alpha2-adrenergic receptor that opens potassium channels) (Gallopin *et al.*, 2000). Thus, in the absence of noradrenergic input, GABAergic preoptic area neurons may serve to decrease temperature, lower metabolism and decrease blood pressure while dampening activating systems and bringing on sleep. GABAergic neurons are also distributed within the reticular formation among the more numerous glutamatergic neurons (Jones, 1995) and among or around the cholinergic and noradrenergic neurons of the brainstem, from where they may exert a local inhibitory action to dampen the activity of these neurons at sleep onset and during SWS, as well as more markedly during REMS (see below). Local GABAergic neurons may inhibit neurons in the lower brainstem reticular formation to dampen the excitatory reticulo-spinal influence, resulting in the decrease in muscle tonus evident in the EMG during that state. Whereas many GABAergic neurons in the brainstem may be active during both SWS and REMS, others (such as those in the pontine reticular formation) may become inactive during REMS (see below).

Drugs that enhance GABAergic transmission include the major anaesthetic agents, such as pentobarbital (Schulz and Macdonald, 1981), and hypnotic drugs, including the benzodiazepines and benzodiazepine-like drugs (Mendelson, 1985; Smith, 2001). Most of these drugs act via $GABA_A$ receptors, which hyperpolarize and inhibit neurons through opening chloride channels. Whereas barbiturates and other anaesthetic agents directly stimulate this receptor, the benzodiazepines amplify the action of GABA upon the receptor, thus enhancing and prolonging its natural effect in the circuits within which it is released. Accordingly, benzodiazepines may serve to facilitate SWS by facilitating GABA's action within particular circuits that dampen cortical activation. Although the hypnotic drugs in this class increase SWS, they do not increase delta activity but instead increase spindling (Feinberg *et al.*, 2000).

Interestingly, in a case of idiopathic recurring stupor, the blocking of $GABA_A$ receptors could reverse the stupor and normalize the EEG, which was characterized by 14-Hz activity (Tinuper *et al.*, 1992). Gamma hydroxybutyrate (GHB) is another drug that facilitates delta SWS along with REMS within the natural sleep cycle (Broughton and Mamelak, 1980; Lapierre *et al.*, 1990). It restored sleep in a case of fatal familial insomnia (Reder *et al.*, 1995). It appears to act upon $GABA_B$ receptors that hyperpolarize neurons through second messengers that open potassium channels (Williams *et al.*, 1995). Transmitters or their agonists that open potassium channels allow a deeper hyperpolarization (to $\sim -90\,mV$) than those that open chloride channels (to $\sim -70\,mV$), perhaps explaining the enhancement of slow, delta activity with GHB. GHB, as well as other drugs acting upon $GABA_A$ receptors, such as clonazepam, also serve to diminish muscle tone during sleep (see below).

Somatostatin and cortistatin are related peptides that are colocalized with GABA in many neurons within the brain, including those of the reticular thalamic nucleus and the cerebral cortex (Figure XXIV-2.2) (Schmechel *et al.*, 1984; de Lecea *et al.*, 1997), and may be important in inhibiting through those neurons other thalamo-cortical systems, and promoting slow-wave activity during SWS (de Lecea *et al.*, 1996). Since somatostatin inhibits release of most hormones/transmitters, it could act to dampen the release of other transmitters with activating influences in multiple areas. Nonetheless, it should be kept in mind that somatostatin release in the hypothalamo-pituitary-somatic axis is specifically turned off during sleep to allow the SWS-dependent release of growth hormone.

Growth hormone-releasing hormone (GHRH) facilitates SWS (Ehlers *et al.*, 1986; Obal *et al.*, 1996; Zhang *et al.*, 1999). The neurons containing growth hormone-releasing hormone are located principally in the arcuate nucleus, from where they project to the median eminence (Figure XXIV-2.2). Together with the decrease in somatostatin release, growth hormone-releasing hormone is responsible for the increase in human growth hormone release from the pituitary that occurs in association with cortical slow-wave activity

at night during SWS (Van Cauter *et al.*, 1998). Growth hormone-releasing hormone is also contained in other neurons within the hypothalamus (not shown) to provide an innervation to other hypothalamic and preoptic nuclei. Intraventricular administration of the releasing hormone enhances slow-wave activity and SWS in animals (Ehlers *et al.*, 1986). Peripheral administration of a long-lasting analogue of somatostatin, which centrally blocks growth hormone release, decreases SWS, indicating that the releasing factor and the hormone itself may normally promote slow-wave activity and SWS through central mechanisms (Beranek *et al.*, 1997).

Adenosine may facilitate SWS (Benington *et al.*, 1995). It is the by-product of ATP catabolism as well as formation, and it is not associated with any particular group of neurons. Released with most synaptic vesicles, it is potentially released from most active nerve terminals. Acting through second messengers upon receptors (A1) that open potassium channels, adenosine has the capacity to hyperpolarize and inhibit neurons and nerve terminals. Like GABA, it could accordingly function within specific circuits to promote sleep. Its release is increased with prolonged waking episodes (Porkka-Heiskanen *et al.*, 1997).

The drug that is very well known to promote wakefulness and enhance vigilance (Koelega, 1993), caffeine, acts as an antagonist upon adenosine receptors, supporting the notion that adenosine normally acts to promote somnolence and sleep (Yanik *et al.*, 1987).

Insulin, cholecystokinin (CCK) and bombesin can facilitate SWS. These modulators/hormones are released peripherally in association with food intake and digestion. They may act upon the brain to promote SWS through transmission of impulses by the vagal nerve to the solitary tract nucleus or through access to the brain by circulation within regions of the brainstem and hypothalamus that are outside the blood–brain barrier (Danguir and Nicolaidis, 1984; DeMesquita and Hershel Haney, 1986; de Saint Hilaire-Kafi *et al.*, 1989). Cholecystokinin and bombesin are also contained in multiple central neurons in the brain (not shown), where they may also act in association with feeding. Their intraventricular administration facilitates sleep. Collectively, they mediate the postprandial satiety that facilitates sleep onset.

In summary, multiple transmitter/modulator/hormonal systems play differential roles in facilitating the onset of SWS or in generating and maintaining it. Whereas sleep onset is prevented by those systems stimulating the sympathetic and hypothalamo-pituitary-adrenal axis, as during conditions of strong motivational states or stress (see above), it is facilitated by those systems activating the parasympathetic and hypothalamo-pituitary-somatic axis, as during conditions of satiety. Insulin, cholecystokinin and bombesin released with food intake and digestion all facilitate sleep onset. In this manner, serotonin associated with low motivational states, satiety and quiescence may also facilitate sleep onset (see above). Adenosine, which may accumulate in the region of the most active neurons during waking, may selectively inhibit those neurons after prolonged waking to induce sleep. Ultimately, specific GABAergic neurons through the brainstem reticular formation, thalamus and hypothalamus/preoptic area, and basal forebrain are responsible for inhibiting activating and sympathetic systems, as well as enabling the slow rhythms within thalamo-cortical systems that characterize mammalian SWS. Colocalized with GABA in certain thalamic and cortical neurons, somatostatin/corticostatin may enhance this process.

REMS-PROMOTING AND REMS-PERMITTING TRANSMITTER SYSTEMS

Acetylcholine (ACh) is a REMS-promoting transmitter. The neurons containing acetylcholine within the ponto-mesencephalic tegmentum (Figure XXIV-2.3) are critically involved in the generation of REMS, as is evident by its loss following their destruction (Webster and Jones, 1988). In addition to projecting to the forebrain, they provide a dense innervation to the brainstem reticular formation, and particularly to the adjacent oral pontine reticular formation (RF PnO) (Jones, 1991). Electrophysiological studies have established that putative cholinergic neurons in this region discharge in both waking and REMS, and many discharge at their highest rates during REMS (El Mansari *et al.*, 1989). By the use of c-Fos expression as an indicator of neuronal activity, immunohistochemically identified cholinergic neurons were revealed to be maximally active as a population during REMS (Maloney *et al.*, 1999). Acetylcholine release is also maximal during REMS within the brainstem reticular formation (Kodama *et al.*, 1990; Kodama *et al.*, 1992). The cholinergic neurons of the basal forebrain can also promote REMS (Reid *et al.*, 1998; Cape *et al.*, 2000). Moreover, acetylcholine release from the hippocampus is maximal during REMS (Marrosu *et al.*, 1995).

Drugs that enhance acetylcholine levels by blocking its catabolism, such as eserine, promote waking under normal circumstances (see above). However, following depletion of the monoamines by reserpine (see below), eserine stimulates the appearance of REMS (Karczmar *et al.*, 1970). It can also stimulate REMS in depressed patients, who are believed to have increased pressure for REMS, perhaps due to enhanced cholinergic and/or deficient monoaminergic transmission (Sitaram *et al.*, 1976; Gillin and Sitaram, 1984). Carbachol, the muscarinic-nicotinic agonist, when injected into the oral pontine reticular formation (RF PnO), can trigger the state of REMS, including limbic theta activity, phasic oculomotor activity and tonic muscle atonia (Baghdoyan *et al.*, 1987; Vanni-Mercier *et al.*, 1989; Vertes *et al.*, 1993). It presumably mimics acetylcholine there, which is normally released by a rich fibre plexus therein emanating from the ponto-mesencephalic cholinergic neurons. Carbachol's effect, presumably like acetylcholine's, appears to depend upon nicotinic receptors and probably multiple muscarinic receptors, of which the M1/M3, which commonly indirectly close potassium channels, are thought to be important in REMS induction through direct excitation of particular reticular neurons (Velazquez-Moctezuma *et al.*, 1990; Sakai and Onoe, 1997). However, M2 receptors, which may indirectly open potassium channels to hyperpolarize neurons, could be important in selectively inhibiting certain neurons that would otherwise prevent the occurrence of the state and associated muscle atonia (see below).

Noradrenaline, serotonin and histamine (NA, 5-HT and H) play permissive roles in the occurrence of REMS (Figure XXIV-2.3). The importance of this role was first documented in the pharmacological studies (see above) showing that eserine could stimulate REMS, but only under conditions when the monoamines were depleted by reserpine (Karczmar *et al.*, 1970). It was subsequently discovered that the serotonergic neurons (McGinty and Harper, 1976), then found that the noradrenergic neurons (McCarley and Hobson, 1975), and more recently also found that the histaminergic (Vanni-Mercier *et al.*, 1984) neurons cease firing prior to and during REMS. It was proposed that the monoaminergic and cholinergic neurons discharge in a reciprocal manner across the sleep-waking cycle (McCarley and Hobson, 1975). Such a reciprocal relationship is apparent in c-Fos patterns of activation occurring in identified serotonergic and noradrenergic as opposed to cholinergic neurons in association with REMS deprivation as opposed to recovery (Maloney *et al.*, 1999). Since the cessation of firing by the noradrenergic, serotonergic and histaminergic neurons appears to be important for the occurrence of REMS, it is considered that they serve a permissive role in this state. The more recent evidence that serotonin and noradrenaline both hyperpolarize and inhibit the cholinergic ponto-mesencephalic neurons (through 5-HT1 and alpha2 receptors) lends further support to this thesis, indicating that these systems would normally exert an inhibitory influence

upon REMS-promoting cholinergic neurons (Luebke *et al.*, 1992; Williams and Reiner, 1993; Thanker *et al.*, 1998). Both noradrenaline and serotonin are also important for the maintenance of muscle tone characteristic of waking and thus prevention of the loss of muscle tone that occurs with REMS.

Drugs that enhance synaptic noradrenaline or 5-HT, such as amphetamines and tricycles, prevent the occurrence of REMS and associated loss of muscle tonus, as applied in their use in the treatment of narcolepsy (Noising and Mignot, 1997).

Dopamine (DA) is neither clearly REMS-permissive nor REMS-promoting as a transmitter. That dopaminergic neurons continue to discharge (Miller *et al.*, 1983) and dopamine to be released during REMS (see above) suggests that dopamine, in contrast to noradrenaline, does not prevent the occurrence of REMS. Since the dopaminergic neurons in the ventral mesencephalic tegmentum receive an excitatory input from the cholinergic ponto-mesencephalic neurons, which are active during REMS, it is not surprising that dopaminergic neurons are also active during REMS. Recent results from c-Fos studies indicate that immunohistochemically identified dopaminergic neurons of the ventral tegmental area are indeed highly active during REMS, such that they could be discharging in a manner during this state similar to that during highly motivated or rewarding waking states (see above) (Maloney *et al.*, 2002). Accordingly, the dopaminergic neurons could be responsible for some of the ascending components of REMS, including limbic and cognitive changes that could accompany dreaming (Maloney *et al.*, 2002) (Figure XXIV-2.3). The role of dopamine in hallucinations, to which dreams have often been likened, might reflect similar processes underlying these cognitive states (Yeoman, 1995).

Most drugs, like the amphetamines, that enhance dopamine release, as well as noradrenaline and serotonin release, stimulate waking and arousal (see above), and not REMS. However, reports of increased vivid dreams and nightmares, along with increased incidences of hallucinations and psychosis, have been reported with amphetamine and also in the treatment of Parkinsonism with l-DOPA (Moskovitz *et al.*, 1978; Thompson and Pierce, 1999).

GABA serves as a critical transmitter in gating the state of REMS in the brainstem and probably contributing to the muscle atonia of REMS there and in the spinal cord (Figure XXIV-2.3) (Maloney *et al.*, 2000). Many GABAergic neurons appear from c-Fos to be active during REMS, including those surrounding the monoaminergic cells, which they probably are responsible for inhibiting during REMS (Gervasoni *et al.*, 1998; Maloney *et al.*, 1999). Consonant with this action, GABA release is maximal during REMS in the locus coeruleus and dorsal raphe (Nitz and Siegel, 1997a, b). Active GABAergic neurons through the brainstem reticular formation may contribute to muscle atonia indirectly by inhibiting excitatory inputs from pontine and medullary reticulo-spinal and serotonergic raphe-spinal neurons to motor neurons, and thus effecting a disfacilitation of the motor neurons (Maloney *et al.*, 2000). Furthermore, spinally projecting GABAergic neurons in the ventral medullary reticular formation (alpha and ventral gigantocellular fields [GiA and GiV]) may contribute directly to the inhibition of spinal motor neurons. A unique group of GABAergic neurons located in the oral pontine reticular formation (PnO) appear to be less active (or 'off') during REMS relative to SWS (Maloney *et al.*, 2000). Injections of bicuculline into this region were shown to trigger a state of REMS (Xi *et al.*, 1999). In this area, GABAergic neurons may thus act as a gate that, when open (GABA neurons off), allows REMS to occur, but, when closed (GABA neurons on), prevents the occurrence of REMS by inhibiting local reticular neurons that drive REMS. These GABAergic cells could in turn be inhibited by cholinergic neurons or other ponto-mesencephalic GABAergic neurons during REMS.

Drugs that enhance GABA transmission through $GABA_A$ receptors (see above), such as clonazepam, are used in the treatment of REMS behaviour disorder to improve the deficient motor inhibition underlying that condition (Mahowald and Schenck, 1989). Gamma hydroxybutyrate (GHB), which serves as an agonist on the $GABA_B$ receptor (see above), has been used to enhance REMS with muscle atonia, in addition to SWS, during the night in narcoleptic patients in order to diminish narcoleptic attacks during the following day (Broughton and Mamelak, 1980).

Glycine (Gly) is responsible (probably together with GABA) for the postsynaptic inhibition of cranial and spinal motor neurons during REM sleep (Figure XXIV-2.3) (Chase *et al.*, 1989). Together with GABA, it is the other major inhibitory neurotransmitter within the spinal cord. It is also contained in neurons within the medullary reticular formation (alpha and ventral gigantocellular fields [GiA and GiV]) that project to the spinal cord. The drug that blocks glycine, strychnine, can reverse the motor inhibition during REM sleep when applied locally in the region of the motor neurons (Chase *et al.*, 1989).

Glutamate (Glu) plays an important role in the excitation and excitatory action of neuronal systems involved in REMS (Figure XXIV-2.3). It is contained in the majority of neurons within the brainstem reticular formation (above) and in those neurons within the oral pontine reticular formation (PnO) that appear to be critically involved in the generation of REMS and muscle atonia. Glutamate agonists can stimulate REMS when injected into the ponto-mesencephalic tegmentum (Onoe and Sakai, 1995).

Vasoactive intestinal peptide (VIP) is a peptide with REMS-promoting activity, as, when injected into the pontine reticular formation in regions where carbachol stimulates REMS, it can also do so (Riou *et al.*, 1982; Bourgin *et al.*, 1997). Often a cotransmitter with acetylcholine, and located in the region of the cholinergic neurons in the ponto-mesencephalic tegmentum (Figure XXIV-2.3), VIP may act upon similar systems in a more prolonged manner.

In summary, multiple transmitter/modulator systems participate by a particular progression and constellation of events in the generation of REMS. First, the activity of multiple wake-promoting systems is progressively dampened during the SWS that normally precedes REMS. This dampening is effected by particular inhibitory GABAergic neurons that must increase their activity to effect a complete inhibition of noradrenergic, serotonergic and histaminergic cell groups in order to permit the onset of REMS. Lifted from the inhibitory influence of noradrenergic and serotonergic neurons, cholinergic ponto-mesencephalic neurons (and vasoactive intestinal peptide neurons) increase their discharge. Perhaps by a direct inhibitory influence of acetylcholine or by an indirect one through an excitatory influence of acetylcholine on other inhibitory interneurons, specific GABAergic neurons in the oral pontine reticular formation are turned off, opening a gate for the occurrence of REMS through the activity of the oral pontine reticular neurons that release glutamate. These neurons are also directly excited by acetylcholine. Through selective inhibition and excitation of particular reticular neurons, ascending pathways for cortical activation and descending pathways, including glycinergic as well as GABAergic neurons, for motor inhibition are activated. One important ascending pathway may involve dopaminergic neurons that would contribute to the limbic activation and special cognitive components underlying dreaming.

In conclusion, multiple neurotransmitter systems are involved in redundant and interactive ways in promoting waking, SWS and REMS. Glutamate, as the basic excitatory transmitter of the activating system, as well as its forebrain and spinal targets, is critical to the waking state, while noradrenaline, dopamine, histamine, serotonin, acetylcholine and orexin modulate the activating system and

its targets in ways that enhance and prolong but also shape particular waking behaviours and motivational states. GABA, as the basic inhibitory transmitter through the forebrain and brainstem, is critical for SWS and acts through particular neurons in the pacing as well as inhibiting of projection neurons of the activating system and its targets. GABA is also critically involved in REMS, effecting the inhibition of noradrenergic, serotonergic, and histaminergic neurons, which by their cessation permit the occurrence of the state. Released from monoaminergic inhibition, cholinergic neurons by their activity promote REMS, and in this process they excite glutamatergic oral pontine reticular neurons, which are also released from GABAergic inhibition, to propagate the unique ascending forebrain activation and descending motor inhibition of that state.

XXIV-3

Neuroendocrinology of Sleep Disorders

Axel Steiger

INTRODUCTION

The two major methods for the investigation of human sleep are the sleep electroencephalogram (EEG) and the collection of nocturnal hormone profiles. The combination of these electrophysiological and neuroendocrinological methods in young and elderly, female and male normal control subjects; in patients with psychiatric, endocrine and sleep disorders, under baseline conditions and after administration of synthetic and endogenous central nervous system (CNS) active compounds, particularly neuropeptides and neuroactive steroids; and in related animals models has shown that, firstly, during sleep a considerable activity of various endocrine systems occurs, and, secondly, a bidirectional interaction exists between the electrophysiological and neuroendocrine components of sleep. The aim of this chapter is to summarize the current knowledge in this field, which is thought to be the prerequisite for major achievements in the therapy of sleep disorders and of psychiatric disorders as well.

SLEEP EEG AND SLEEP-ASSOCIATED HORMONE SECRETION IN YOUNG NORMAL HUMAN ADULTS

When subjects spend a night in the sleep laboratory, their sleep EEG is analysed either visually by coding each 30-s interval of the night as a sleep stage according to standard guidelines (Rechtschaffen and Kales, 1968), resulting in a hypnogram (Figure XXIV-3.1), or by EEG spectral analysis (Steiger *et al.*, 1993a; Trachsel *et al.*, 1992). The hypnogram shows the cyclic occurrence of periods of non-REM sleep (NREMS) and rapid-eye-movement sleep (REMS). In young normal subjects during the first period of NREMS, the major portion of slow-wave sleep (SWS) occurs. Correspondingly, in EEG spectral analysis, the major portion of slow-wave activity (SWA) is detected. The amounts of SWS and SWA are relatively low during the second half of the night. During this interval, stage 2 sleep preponderates during NREMS. The mean value for the occurrence of the first period of REMS is about 90 min. This first REMS period is relatively short. During 8 h of night sleep, 3–6 sleep cycles are found. The duration of the REMS periods increases throughout the night. Correspondingly, the amount of REMS is higher in the second half of the night than in the first half.

Near to sleep onset in a rather strict, although not absolute, association with the first period of SWS, the major peak of growth hormone (GH) secretion in 24 h is found (Quabbe *et al.*, 1966; Steiger *et al.*, 1987; Takahashi *et al.*, 1968). This GH surge appears to be widely sleep dependent and is suppressed during sleep deprivation (Beck *et al.*, 1975; Sassin *et al.*, 1969). However, in sleep-deprived, but relaxed young men in a supine position, an unchanged nocturnal GH peak was observed (Mullington *et al.*, 1996). During the second half of the night, GH concentrations are low. The pattern of cortisol secretion is inverse to that of GH. After sleep onset, cortisol reaches its nadir. Between 0200 and 0300, the first pulse of cortisol release occurs, and it is followed by further pulses until awakening (Weitzman, 1976). Adrenocorticotrophic hormone (ACTH) is the prime stimulus of nocturnal cortisol secretion in man. Nevertheless, the secretion of ACTH and cortisol may dissociate (Fehm *et al.*, 1984). In summary, during the first half of the night, SWS, SWA and GH preponderate while ACTH and cortisol levels are low. In contrast, during the second half of the night, the amounts of REMS, ACTH and cortisol are high while SWS and GH secretion are low. This pattern suggests

(1) a reciprocal interaction of the hypothalamo-pituitary-somatotrophic (HPS) and the hypothalamo-pituitary-adrenocortical (HPA) systems (the corresponding peripheral end points are GH and cortisol, respectively)
(2) the existence of common regulators of sleep EEG and sleep-associated hormone secretion.

Indeed, there is now a good evidence that a reciprocal interaction of the key hormones of the HPS and HPA systems, GH-releasing hormone (GHRH) and corticotrophin-releasing hormone (CRH), plays a major role in sleep regulation, as indicated in more detail below.

Prolactin rises after sleep onset and reaches its peak during the second or the last third of the night. In males, testosterone rises constantly throughout the night (Weitzman, 1976). Melatonin secretion is related to the light-dark cycle and has its peak during the early morning (Zhdanova *et al.*, 1997).

The secretion of thyroidea-stimulating hormone (TSH) and of the thyroid hormone thyroxin is related to circadian rhythm (Brabant *et al.*, 1987; Chan *et al.*, 1978). The minimum TSH level is found during daytime. TSH rises during the night and reaches its maximum by midnight. Then the levels decline during the early morning hours. The course of thyroxin release is inverse to that of TSH. Thyroxin levels are low during the night and increase during daytime. One study reported declining TSH levels during REMS periods (Follenius *et al.*, 1988).

The hormone most clearly linked to the NREMS-REMS cycle is renin. Plasma renin activity oscillates throughout the night and reaches its peak during NREMS and its acrophase during REMS (Brandenberger *et al.*, 1988) (Figure XXIV-3.6).

Most sleep-endocrine studies have been done on males. A sexual dimorphism is reported in young normal humans. Cortisol secretion is higher in females than in males. A lower amount of SWS during the second half of the night and a greater decrease in SWS and SWA from the first to the second half of the night were found in young normal women (Antonijevic *et al.*, 1999).

Leptin, the protein product of the obese *(ob)* gene, is released from adipocytes in the periphery. It acts within in the hypothalamus (Elmquist *et al.*, 1997) and reduces food intake, probably by

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

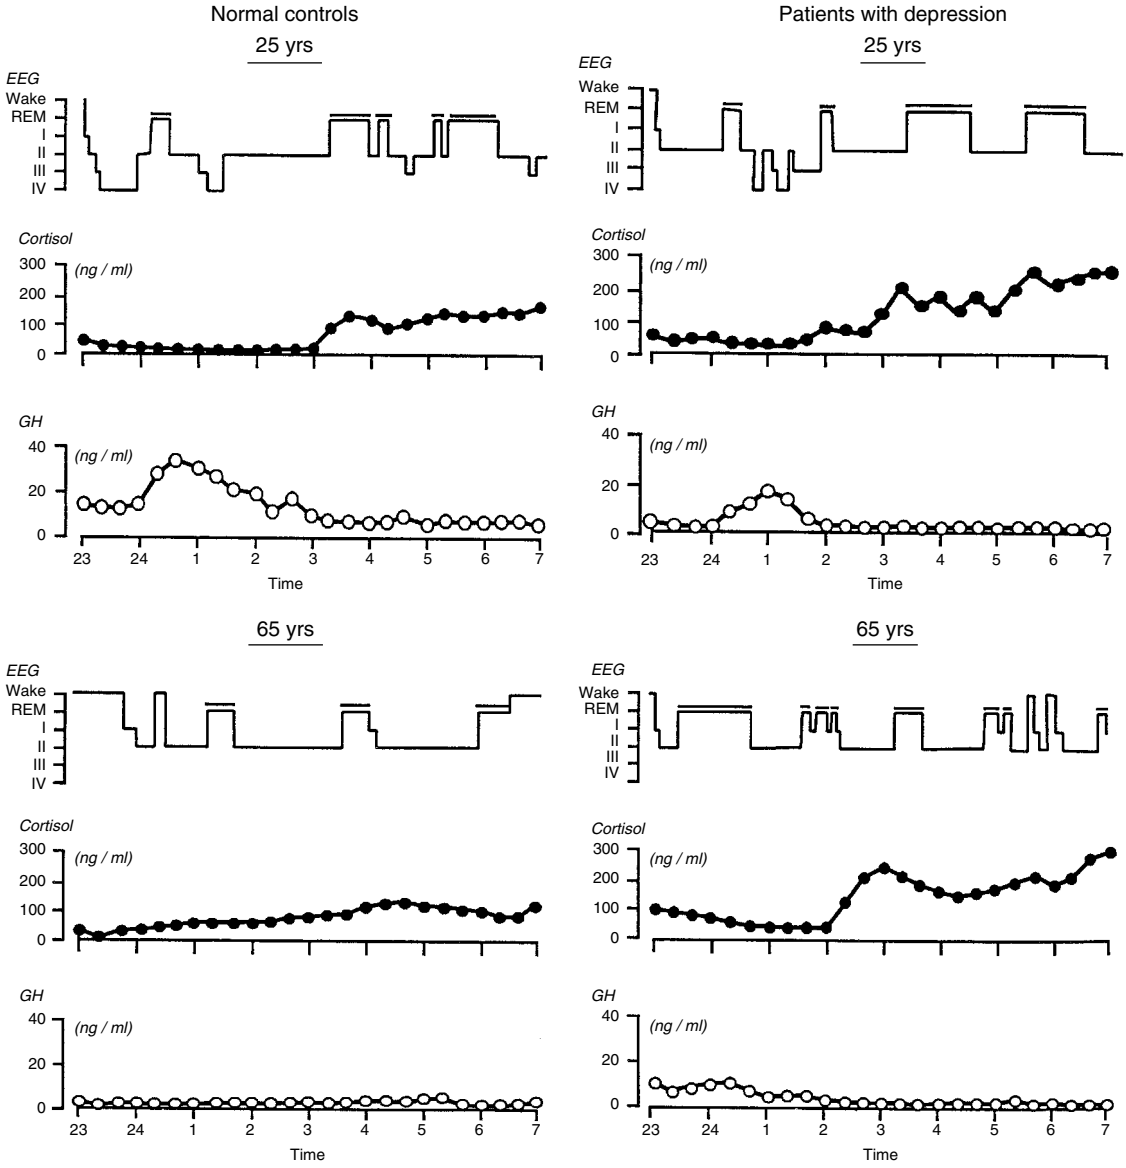

Figure XXIV-3.1 Individual hypnograms and patterns of cortisol and growth hormone (GH) secretion in four male subjects (young and old patients with depression and normal controls)

inhibition of neuropeptide Y (NPY) release (Hanson *et al.*, 1997; Tomaszuk *et al.*, 1996). A circadian rhythm of serum leptin with a maximum between 0000 and 0400, an inverse relationship between leptin and cortisol (Licinio *et al.*, 1997), and a sexual dimorphism with higher leptin levels in women than in men were reported (Deuschle *et al.*, 1996; Saad *et al.*, 1997). Higher nocturnal leptin levels in normal female control subjects than in males were confirmed in a recent study, whereas an inverse correlation between leptin and cortisol was observed in women rather than men (see Figure XXIV-3.2) (Antonijevic *et al.*, 1998).

CHANGES OF SLEEP DURING AGEING

Sleep EEG and nocturnal hormone secretion change throughout the lifespan. There is a controversy whether deterioration of sleep due to ageing starts during puberty or during early adolescence (Bliwise, 1993). It is well established, however, that as early as the third decade of the lifespan, distinct parallel decreases of SWS, SWA and GH secretion start. Near to the onset of the fifth decade, the GH pause occurs. In women, the menopause is a major turning point towards impaired sleep in older age (Ehlers *et al.*, 1993), whereas in men the sleep quality declines continuously during ageing. Correspondingly, in the elderly the amounts of SWS and SWA are low, or SWS may even be totally absent (Figure XXIV-3.1). Furthermore, sleep continuity is disturbed, as is evident from, prolonged sleep-onset latency, increases in the number and duration of nocturnal awakenings, and decreases in sleep efficiency and sleep period time. Finally, REMS time and REMS latency decrease in older age. Controversial reports exist on the effects of age on HPA hormones. Elevated and unchanged cortisol levels have been reported in the elderly. Most studies agree that the amplitude of the cortisol rhythm is blunted. Accordingly, cortisol concentrations during the first half of the night and at the

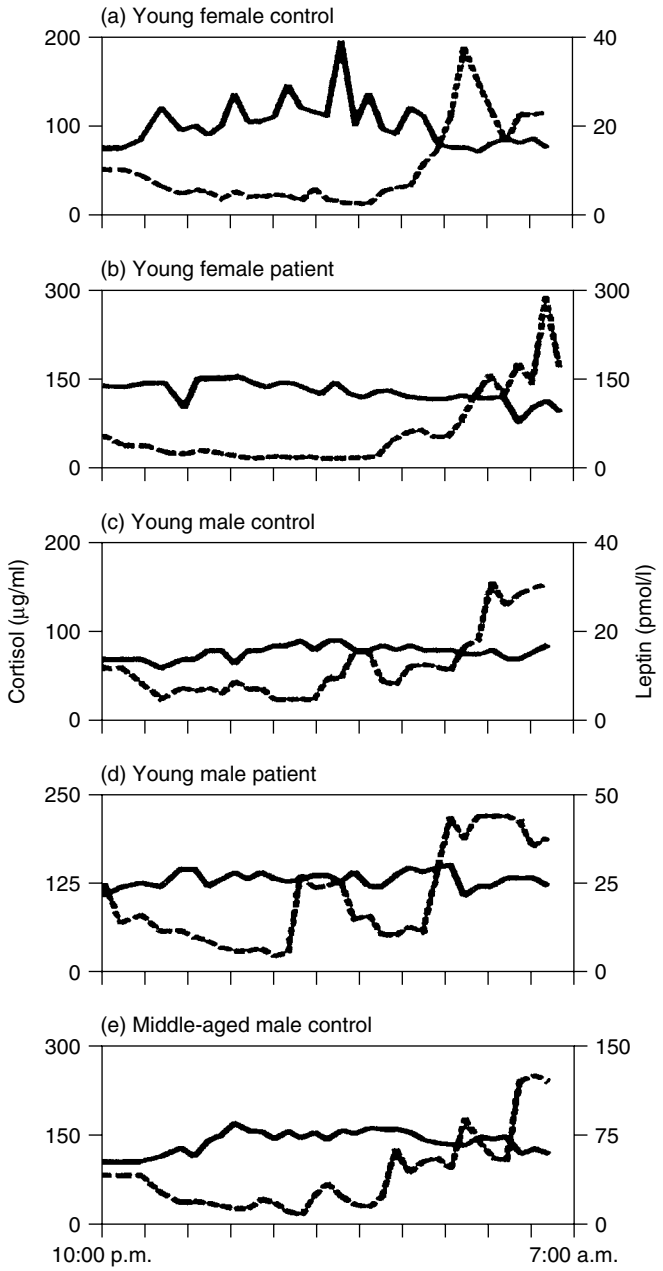

Figure XXIV-3.2 (A–E) Nocturnal profiles of leptin and cortisol. Representative profiles of nocturnal serum levels of leptin and cortisol are shown and correlation analysis between the two hormones was performed: A) young female control ($r = -0.61$, $P < 0.001$); B) young female patient ($r = -0.64$, $P < 0.001$); C) young male control ($r = -0.08$, n.s.); D) young male patient ($r = -0.22$, n.s.); E) middle-aged (42 years old) male control (-0.44, $P < 0.01$). Left y-axis represents plasma cortisol concentrations (dotted line); right y-axis represents serum leptin concentrations (black line) (Reproduced from Antonijevic *et al.*, 1998 with permission of Elsevier Science)

nadir are elevated. Similar results derive from the analysis of the largest sample ($n = 149$) of normal male control subjects (aged 16–83 years) investigated so far (Van Cauter *et al.*, 2000). These authors reported a modest effect of ageing on the 24-h mean cortisol level. Ageing was associated with an elevation of the evening cortisol nadir, but morning maximum cortisol values remained stable across all age ranges. Increases in evening cortisol levels became apparent after the age of 50 years, when sleep became more fragmented and REMS declined. Furthermore, a trend to an association between lower amounts of REMS and higher evening cortisol levels independent of age was found.

Melatonin and, in males, testosterone levels also decrease during ageing. The melatonin levels of older people who reported sleep maintenance problems in a questionnaire did not differ from those of older people reporting normal sleep (Baskett *et al.*, 2001). In contrast to most other hormones, prolactin levels remain widely unaffected by ageing (Van Coevorden *et al.*, 1991).

This complex pattern of age-related changes of sleep-endocrine activity mirrors a central process of ageing with major consequences to mental and physical health. The changes of sleep EEG correspond to a high incidence of insomnia and a high prescription rate of hypnotics in the elderly. A lack of GH is linked to risk of frailty. Elevated HPA activity impairs the capacity to cope with stress and elevates the risk of depression and cardiovascular diseases in higher age.

CHANGES OF SLEEP-ENDOCRINE ACTIVITY RELATED TO DISEASES

Psychiatric Disorders

Depression in Adult Patients

Disturbed sleep is a frequent symptom in most psychiatric disorders. Interestingly, sleep-endocrine changes in patients with depression are similar to those during normal ageing. Characteristically, sleep-EEG findings in depressed patients include disturbed sleep continuity, a decrease of SWS (in younger patients, a shift of the major portion of SWS from the first to the second sleep cycle) and REMS disinhibition (shortened REMS latency, prolonged first REMS period and elevated REMS density, a measure of the amount of rapid-eye movements during REMS) (reviewed by Benca *et al.*, 1992; Reynolds and Kupfer, 1987). Several endocrine aberrations are well documented in affective disorders, particularly HPA overactivity (reviewed in Holsboer, 1999) and HPS dysfunction (reviewed in Steiger *et al.*, 1989). Elevated cortisol and ACTH levels were reported in most sleep-endocrine studies in patients with depression throughout the night or during 24 h, respectively, in comparison to normal control subjects (Antonijevic *et al.*, 2000c; Linkowski *et al.*, 1987) (Figure XXIV-3.1). The circadian pattern of cortisol secretion is preserved during depression. Particularly in females, a positive correlation between age and cortisol levels was found (Antonijevic *et al.*, 2000c). Recently, enhanced cortisol plasma and norepinephrine levels but normal ACTH plasma and CRH cerebrospinal fluid (CSF) levels throughout 30 h were reported (Wong *et al.*, 2000). GH secretion was blunted in most (Jarrett *et al.*, 1990; Sakkas *et al.*, 1998; Steiger *et al.*, 1989; Voderholzer *et al.*, 1993), but not in all (Linkowski *et al.*, 1987) studies. These findings suggest a crucial relationship between shallow sleep, blunted GH and HPA overdrive in depression. In adult patients, ageing and depression exert synergistic effects on sleep-endocrine activity (Antonijevic *et al.*, 2000c). As a result of this synergism, sleep-endocrine changes are most distinct in elderly patients with depression (Figure XXIV-3.1).

As depression is frequently associated with loss of appetite, reduced food intake and weight loss, the secretion of leptin in patients with depression is of interest since leptin is involved in the regulation of food intake. In drug-free patients with major depression, nocturnal serum leptin was significantly higher than in age- and sex-matched controls (Antonijevic *et al.*, 1998). The sexual dimorphism with higher leptin levels in females than in males as described before was confirmed in patients and in controls.

Serum leptin was correlated with body mass index in controls, but not in patients, supporting an altered regulation of leptin secretion in depression. Neither in patients with depression nor male controls was a clear increase in leptin between 0000 and 0400 (as reported by Licinio *et al.*, 1997) or at any other time during the night observed. However, in the group of young female controls (younger than 35 years), an increase in leptin levels between 0000 and 0400 was found, showing the trend to be greater than in young female patients (see Figure XXIV-3.2). This finding suggests that in young female patients with depression the nocturnal leptin surge is blunted. As expected, cortisol levels were enhanced in the patients. As glucocorticoids can prevent the fasting-induced decline of serum leptin, we suggest that hypercortisolism in depression might counteract the reduction in leptin release due to decreased food intake and weight loss. Elevated leptin levels in depression might, in turn, further promote the release of CRH, as shown in animals (Raber *et al.*, 1997; Schwartz *et al.*, 1996), and contribute to HPA system overactivity in depression.

Simultaneous investigation of nocturnal TSH and ACTH levels in drug-free male patients with depression and matched controls showed a blunted TSH and elevated ACTH secretion in the patients. ACTH was negatively correlated to TSH in the first half of the night. These data support the hypothesis that both hypophyseal hormones reflect a common dysregulation of the HPA and the hypothalamo-pituitary thyroid systems in depression, probably as a result of impaired action of the corticotropin-release inhibiting factor (Peteranderl *et al.*, in press).

During antidepressant therapy with tricyclics (amitriptyline, imipramine), a decrease of nocturnal cortisol levels and of REMS and an increase of SWS were found in comparison to baseline values. At this examination, the Hamilton Depression Rating Scale (HAMD) score was improved by about 50% in comparison to the examination before treatment (Steiger *et al.*, 1993b). The effect of subchronic treatment with several antidepressants on sleep EEG and sleep-related hormone secretion was examined in normal male control subjects. The volunteers received first placebo for 3 days, then increasing dosages of antidepressants (the tricyclics amitriptyline, clomipramine and trimipramine, and the selective, reversible, short-acting inhibitors of monoamine oxidase type A, moclobemide and brofaromine for 7–10 days), and finally again placebo after drug withdrawal for 4–8 days (Steiger *et al.*, 1993b). Furthermore, the effects of acute oral administration of the selective serotonin-uptake inhibitor, fluoxetine, and placebo were compared (von Bardeleben *et al.*, 1989). As shown in Table XXIV-3.1, active antidepressant treatment decreased REMS after all substances except trimipramine. Whereas cortisol levels increased after some of the drugs, a distinct blunting of cortisol was observed after trimipramine. After cessation of trimipramine, cortisol levels distinctly exceeded baseline values. It was suggested previously that REMS suppression is the way of action of antidepressants (Vogel *et al.*, 1975). But this hypothesis is challenged by the fact that some antidepressants, including trimipramine, do not suppress REMS. However, normalization of HPA activity appears to be a common mechanism in the action of all antidepressants (Holsboer, 2000; Holsboer and Barden, 1996). This view is supported by the blunting of cortisol after trimipramine, which is known to be an effective antidepressant, although the substance does not share the classical neurobiological effects of most other antidepressants such as REMS suppression, beta-downregulation and inhibition of synaptic uptake of monoamines. In a similar vein, corticosteroid receptor density increased in the rat brain when the animals were treated during several weeks with various antidepressants from several classes, including trimipramine (Reul *et al.*, 1993).

Finally, in a double-blind protocol, the effect of treatment by trimipramine or imipramine on sleep EEG, hormone secretion and psychopathology was compared in patients with depression (Sonntag *et al.*, 1996). Both treatments produced rapid and significant clinical improvement. Imipramine and trimipramine differed, however, in their effects on neurobiological variables. REMS was suppressed and sleep continuity impaired after imipramine, whereas REMS and SWS increased and the sleep quality improved under trimipramine (see Figure XXIV-3.3). Cortisol levels were blunted throughout the night and prolactin was increased after trimipramine, whereas imipramine showed no effect on hormone secretion (see Figure XXIV-3.4).

Sleep-endocrine activity was studied longitudinally between acute depression and recovery in two studies in adult patients. A decrease of ACTH and cortisol throughout 24 h and a normalization of REMS were reported after remission (Linkowski *et al.*, 1987). Since not all of the patients in this study were drug-free at the retest, it is difficult to distinguish between the effects of remission and of antidepressants. Intraindividual comparison of drug-free patients (Steiger *et al.*, 1989) confirmed a decrease of cortisol after remission. In the same study, the prolactin levels of the patients did not differ from those of younger normal controls and remained unchanged after recovery (Steiger and Holsboer, 1997a). Similarly, nocturnal prolactin levels were not distinguishable between patients with depression and matched controls (Jarrett *et al.*, 1987). Furthermore, testosterone levels increased after remission (Steiger *et al.*, 1991). The pathological sleep EEG and blunted GH levels, however, remained unchanged. Sleep EEG showed even a further deterioration, as stage 4 sleep decreased and the number of awakenings increased (Steiger *et al.*, 1989) (see Figure XXIV-3.5). Both studies (Linkowski *et al.*, 1987; Steiger *et al.*, 1989) corroborate that hypersecretion of HPA hormones is a symptom of acute depression in adults.

The decline of cortisol levels after remission (Linkowski *et al.*, 1987; Steiger *et al.*, 1989) is similar to the normalization of results of challenge tests of the HPA system and of CRH CSF levels after recovery (reviewed by Holsboer, 1999). The persistence of most sleep-EEG changes (Kupfer *et al.*, 1993) and of blunted GH levels (Jarrett *et al.*, 1990) in remitted depressed patients has been confirmed over a period of 3 years. Obviously, HPA activity

Table XXIV-3.1 Changes of sleep EEG and nocturnal hormone secretion in normal control subjects after subchronic treatment with antidepressants

				Hormone secretion			
	REMS	NRREMS stages 1 and 2	SWS	Under medication		After withdrawal	
Brofaromine	↓	↑	↓	GH ↓		GH↓	
Moclobemide	↓	ø	ø	Cortisol ↑		Cortisol ↑	
Clomipramine	↓	↑	↓	Cortisol ↑		Cortisol ø	
Amitriptyline	↓	ø	↑	Cortisol ↑	GH ↓	Cortisol ø	GH ↓
Trimipramine	ø	ø	ø	Cortisol ↓	PRL ↑	Cortisol ↑	PRL ↓
Fluoxetine	↓	ø	ø	Cortisol ↑

normalizes independently of sleep architecture. This observation clarifies that hypercortisolism in depression is not a consequence of shallow sleep. Blunted testosterone levels in males during acute depression, however, appear to be secondary to HPA overdrive. Finally, prolactin is not affected by either depression or ageing. The persistence of aberrations of sleep EEG and GH secretion in remitted patients may be explained as a biological scar due to the metabolic aberrations during acute depression. An alternative explanation is that these changes represent a trait in depressed patients. This issue will remain unclear as long as no data are available for comparing intraindividually the premorbid and depressed state in patients. Interestingly, in healthy relatives of patients with depression, some depression-like neurobiological changes were observed. In the Munich Vulnerability Study, healthy subjects with high familial risk of affective disorders were investigated by assessing the neuroendocrine, polysomnographic and psychometric status. Like patients with an acute episode of major depression, the healthy relatives exhibited signs of HPA system overactivity, as shown by the dexamethasone-CRH test, as well as reduced SWS in the first sleep cycle and increased REMS density. On a single case level, 32% of these high-risk probands exhibited depression-like features in at least two of the three areas assessed (Krieg *et al.*, 2001).

Depression in Children and Adolescents

Most but not all sleep-EEG studies in depressed children and adolescents did not find differences between patients and age-matched controls (reviewed by Lauer *et al.*, 1991). Similarly, changes of sleep-related hormone secretion are more subtle in depressed children and adolescents than in adults. In one study in prepubertal children with depression, sleep EEG and cortisol profiles throughout 24 h did not differ from those of children with other psychiatric disorders and controls. Only four of the 45 depressed children showed hypercortisolism. In a retest after recovery, cortisol hypersecretion persisted in only one of the four young patients (Puig-Antich *et al.*, 1989). In another study, prepubertal depressed children had lower cortisol levels during the first 4 h after sleep onset than controls. ACTH, prolactin and GH concentrations did not differ between patients and controls. Examination of clinical characteristics in patient groups revealed lower nocturnal ACTH in depressed inpatients than depressed outpatients and in depressed, sexually abused than depressed, non-abused children (De Bellis *et al.*, 1996). Depressed children who had experienced at least one clearly adverse, stressful life event during the prior year hypersecreted GH at night compared to depressed children without the experience of such an event and normal controls with and without stressful life events (Williamson *et al.*, 1996). This finding is in line with an elevated responsiveness of GH to CRH in adult patients with depression during daytime (Lesch *et al.*, 1988).

In a set of studies, the relationship between the longitudinal clinical course and sleep-endocrine findings in adolescent patients with depression was studied. In one study on sleep and cortisol, the patients and matched controls were retested about 7 years after the initial study. Although initial group comparisons failed to detect significant differences in sleep-endocrine variables, analyses incorporating clinical follow-up showed that changes in sleep EEG and cortisol are associated with differential longitudinal course. Normal controls who would develop depression had shown initially higher REM density and, by trend, shortened REM latency compared to controls without psychiatric disorder. Depressed patients with a recurrent unipolar course showed elevated cortisol levels around sleep onset compared to depressed patients with no further episodes during the follow-up interval (Rao *et al.*, 1996). Nocturnal GH secretion was studied in a large sample of adolescent depressed patients and matched controls. Clinical follow-up was performed approximately one decade later. The original adolescent nocturnal GH data were analysed in the light of the information obtained regarding clinical course into adulthood. Normal controls who developed at least one episode of major depression or dysthymia during the follow-up period differed from depression-free controls by a more rapid increase of nocturnal GH secretion after sleep onset. Of the subjects who had at least one major depressive episode during the follow-up, those who would go on to make suicide attempts released greater amounts of GH during the first 4 h of sleep. Adults with lifetime depression showed blunted GH in the 100 min preceding sleep onset (Coplan *et al.*, 2000).

Mania and Schizophrenia

Only two studies deal with sleep-endocrine activity in psychiatric disorders other than depression. Elevated cortisol levels were also found in acute mania (Linkowski *et al.*, 1994). Cortisol levels were enhanced in the first 3 h of the night, and prolactin was elevated distinctly around sleep onset in patients with schizophrenia. The sleep latency was prolonged, and the sleep efficiency and the time spent in REMS were reduced (Van Cauter *et al.*, 1991).

Sexual Dysfunction

Blunted sleep-related testosterone levels were reported in males with reduced sexual interest in comparison to normal controls (Schiavi *et al.*, 1986).

Dyssomnias

Experts have generated a host of diagnoses of sleep disorders. So far sleep-endocrine data are available only on some of these disorders. 'Dyssomnia' is defined as a disturbance of initiating or maintaining sleep or as excessive sleepiness (American Sleep Disorders Association, 1997). It should be kept in mind that hypersomnia during the daytime in the same patient can be the consequence of disturbed sleep during the night.

Insomnia

In patients with primary insomnia, elevated nocturnal cortisol levels and a shorter quiescent period of cortisol secretion were found in comparison to controls (Rodenbeck *et al.*, 1999). In a sample of younger adult patients with insomnia, a positive correlation between total wake time and 24-h urinary free cortisol was found (Vgontzas *et al.*, 1998). Furthermore, in a group of 10 patients with insomnia, wakefulness was increased and ACTH and cortisol levels were enhanced throughout 24 h in comparison to controls. The most distinct elevations were observed between 1400 and 1730 and between 2100 and 0300 (Vgontzas *et al.*, 2000). These observations point to an elevated activity of the HPA system in primary insomnia. There appear to be similarities in the pathophysiology of primary insomnia and of depression. This is of particular interest, since several epidemiological studies reported a highly increased risk of the development of a depressive episode in patients with persistent insomnia (Vollrath *et al.*, 1989). Unfortunately, so far, the literature offers no studies that integrate sleep-endocrine data in patients with primary insomnia and with depression.

Sleep Apnoea

Sleep apnoea is a disorder characterized by repetitive upper airway occlusion resulting in progressive hypoxaemia that induces arousals and termination of the obstruction. Consequently, marked sleep fragmentation and decrease of SWS are associated with this disease (Bradley and Phillipson, 1985). Nasal continuous positive airway pressure (CPAP) therapy has been shown to eliminate sleep apnoea and related hypoxaemia (Sullivan *et al.*, 1981). In one study, the effect of nasal CPAP therapy on sleep EEG and hormone secretion was investigated in obese patients with obstructive sleep apnoea syndrome. Under baseline conditions, the time spent in SWS and REMS was low, the number of apnoeas was elevated and the arterial oxygen saturation was reduced. With nasal CPAP therapy, all these variables turned significantly to normalization over one night. Furthermore, GH secretion, which was blunted at baseline, significantly increased on the CPAP night. Cortisol secretion did not differ significantly between both conditions (Cooper *et al.*, 1995). Similarly, cessation of nasal CPAP in eight patients regularly using this device led to an immediate recurrence of sleep apnoea, whereas ACTH and cortisol levels remained unchanged (Grunstein *et al.*, 1996). Krieger *et al.* (1991) compared sleep EEG, plasma renin activity and aldosterone levels in male patients with obstructive sleep apnoea at baseline and during one night with CPAP therapy. In untreated patients, frequent awakenings, absence of SWS, and few and short REMS periods were reported. CPAP therapy led to improvements in sleep depth and REMS. In some treated patients, regular NREMS-REMS cycles occurred; in others, the sleep structure remained irregular. Plasma renin activity profiles reflected the pattern of NREMS-REMS distribution as known from normal controls. Increasing plasma renin activity levels coincided with NREMS phases, and declining levels with REMS. When sleep cycles were regular in some of the treated patients, the oscillating plasma renin activity levels also became regular. Irregularities in sleep EEG, such as short sleep cycles and varying length of sleep-phase duration, led to fluctuations of smaller amplitude and to a general non-oscillatory pattern of plasma renin activity. The mean levels of plasma renin activity and aldosterone were significantly enhanced by nasal CPAP treatment.

Narcolepsy

Narcolepsy is thought to be a disorder of REMS regulation. Accordingly, patients with narcolepsy show several abnormalities of their sleep-wake organization throughout 24 h and of the internal sleep structure. Prominent symptoms are cataplexy and excessive daytime sleepiness, which often results in sleep attacks. The sleep EEG of these patients frequently shows sleep-onset REMS episodes, e.g., the occurrence of REMS directly at or during the first 10 min after sleep onset, frequent awakenings and REMS fragmentation. Normal cortisol and melatonin secretion was reported in narcoleptic patients. Blunted prolactin levels were found, and studies on GH release are contradictory, reporting either high or blunted secretion (reviewed by Schulz *et al.*, 1992). Schulz *et al.* (1992) investigated 24-h plasma renin activity and sleep EEG in patients with narcolepsy and in normal control subjects. The mean concentrations of plasma renin activity was similar in patients and controls. The individual hormone profiles reveal that the already mentioned association between renin oscillations and the NREMS-REMS cycle was preserved. Plasma renin activity profiles exactly reflected the irregularities and disturbances in the sleep structure of the patients with narcolepsy (see Figure XXIV-3.6). In contrast to controls, in these patients no upward trend of plasma renin activity was found. The authors argued that this phenomenon is probably induced in the control subjects by the repetitive occurrence of longer episodes of NREMS. Due to marked sleep fragmentations in the narcoleptic patients, the duration of NREMS was often insufficient to stimulate plasma renin activity. This hypothesis is supported by the more recent finding that SWA stimulates plasma renin activity (Luthringer *et al.*, 1995). In accordance with this observation, sleep-onset REMS episodes that are not preceded by NREMS are not accompanied by relative decline of plasma renin activity.

In patients with narcolepsy, leptin levels were examined in CSF and serum from a blood sample collected in the morning. When these were compared to two control groups of patients with depression and patients with a non-inflammatory neurological disorder, respectively, leptin serum levels were blunted, whereas CSF levels did not differ significantly between groups (Schuld *et al.*, 2000). The authors suggested that reduced leptin production in narcolepsy may be caused by deficiency of hypocretin. It is thought that hypocretins are involved in the pathophysiology of narcolepsy, because mice whose hypocretin gene has been inactivated exhibit a narcolepsy-like phenotype. Furthermore, CSF levels of hypocretins are blunted in patients with narcolepsy (Sutcliffe and de Lecea, 2000).

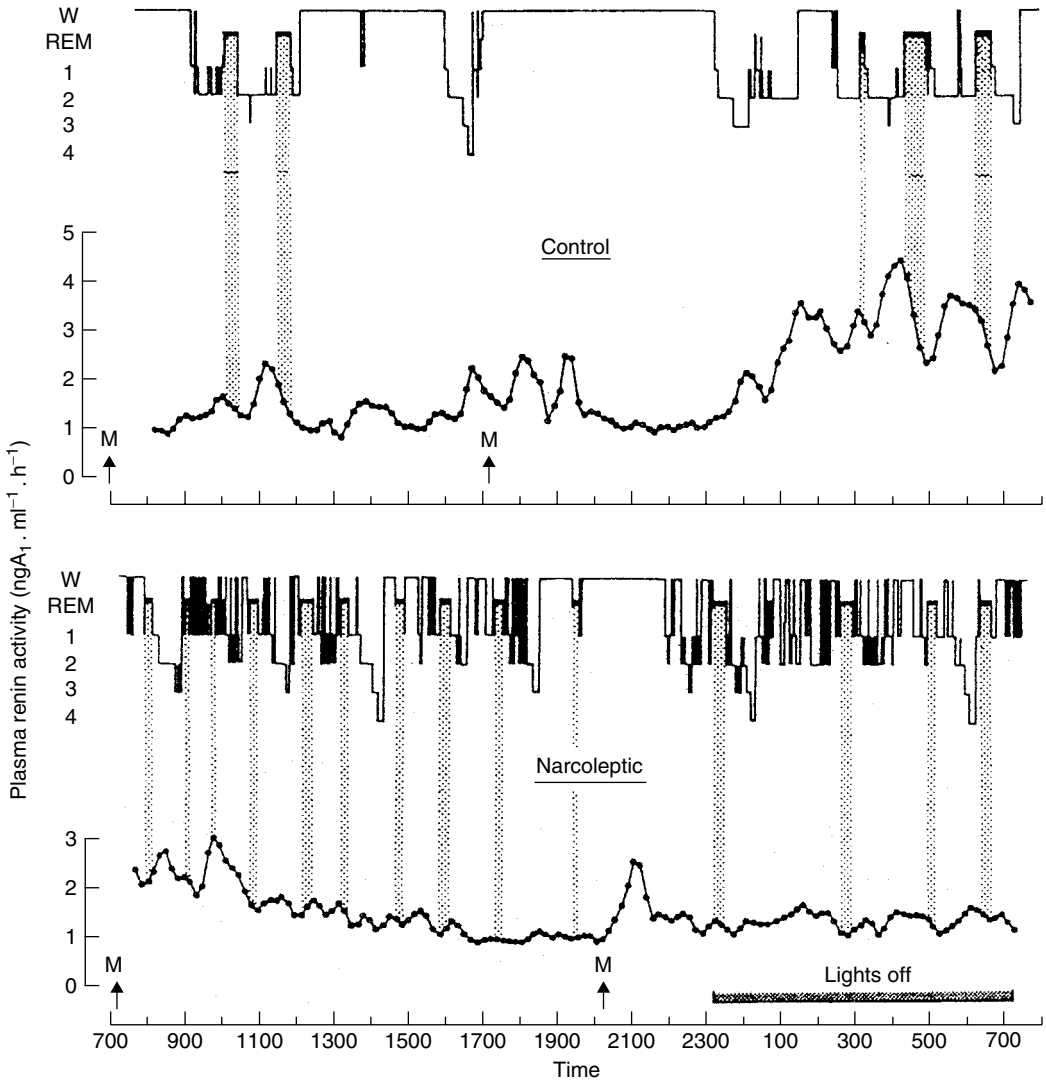

Figure XXIV-3.6 Individual 24-h profiles of plasma renin activity and the corresponding sleep-stage pattern for one control subjects and one patient with narcolepsy (Reproduced from Schulz *et al.*, 1992 by permission of SLEEP)

Restless Legs Syndrome

Restless legs syndrome is a clinical entity characterized by uncomfortable dysaesthesia or paraesthesia in the legs and less frequently in the arms, occurring primarily at rest in the evening hours. Ten male, never-medicated patients with chronically mild to moderate symptoms of this disorder did not show aberration of sleep EEG and of 24-h hormone profiles of cortisol, GH and prolactin, in comparison to age-matched male controls (Wetter *et al.*, in press).

Sleep-Wake Rhythm Disorders

The circadian rhythm of circulating melatonin and the sleep-wake rhythm were investigated in five patients with chronic sleep-wake rhythm disorder and matched controls (Rodenbeck *et al.*, 1998). All the patients showed altered circadian melatonin rhythm variables. The melatonin onset to sleep onset interval varied between the patients, and the melatonin acrophase of sleep- onset interval was prolonged in four patients. The authors concluded that individual phase relations exist between the circadian melatonin rhythm and the sleep-wake cycle in patients with chronic sleep-wake rhythm disorders. Since a prolonged melatonin acrophase to sleep-onset interval was the most consistent finding regardless of aetiology, this abnormality is thought to be a maintaining factor in this disorder as a result of the reduced phase-resetting properties of the circadian pacemarker. Furthermore, rather low circadian melatonin amplitudes and a subsensitivity to daylight are thought to maintain the disorder, at least in some patients.

Familial Advanced Sleep-Phase Syndrome

Familial sleep-phase syndrome is a rare disorder with disabling early evening sleepiness and early morning awakening. Three kindreds with a profound phase advance were identified. In the patients, polysomnographic measures of sleep phase were advanced by almost 4 h compared with those of control subjects. The melatonin and temperature rhythms were also both phase advanced by 3–5 h. The patients tended to fall asleep during solar clock times

corresponding to the 'maintenance of wakefulness zone' in healthy subjects. They also tended to wake up during solar clock times corresponding to the circadian peak of sleepiness in controls. These findings define a hereditary circadian rhythm variant associated with a short endogenous period (Jones *et al.*, 1999).

Disturbed Sleep Associated to Medical Disorders

Fatal Familial Insomnia

Fatal familial insomnia is a rare disease with selective thalamic degeneration that results in chronic sleep loss (Lugaresi *et al.*, 1986). Cortisol levels have been reported to be elevated from the early stages of the disease, further increasing with disease progression. ACTH concentrations, however, remained normal even in later stages (Montagna *et al.*, 1995). In two patients, 24-h profiles of GH and prolactin were studied longitudinally (Portaluppi *et al.*, 1995). The nocturnal GH peak disappeared simultaneously with sleep loss whereas the physiological rhythm of prolactin secretion with normally placed nocturnal acrophases was still present for months after total disruption of the sleep-wake cycle. Complete obliteration of the prolactin rhythm was found only in the advanced stages of the disease as the result of a progressive decrease in the circadian amplitude of variation.

Blindness

A high prevalence of sleep disorders is known in blind people. Subjects with no conscious light perception (NPL) have a higher occurrence and more severe sleep disorders than those with some degree of light perception. It was shown that patients with NPL are likely to have free running circadian rhythms of melatonin, cortisol and sleep (Skene *et al.*, 1999).

Brain Injury

As mentioned before, the persistent changes of sleep EEG and GH in depressed patients after recovery (Steiger *et al.*, 1989) may represent a biological scar due to the metabolic aberrations during acute depression. A recent study on young male patients who survived severe brain injury supports this view (Frieboes *et al.*, 1999). Several months after the injury, the cortisol concentrations of these patients did not differ from normal controls. The GH levels and sleep-stage 2 time of the patients, however, were lower than in the controls. These findings point to similarities between the sleep-endocrine activity of patients who survived brain injury and of those who recovered from depression. In the survivors of brain injury, it appears likely that either HPA overactivity due to stress under the intensive care situation or treatment with glucocorticoids in a subgroup contributed to the changes of NREMS and GH.

Obesity

Several studies report blunted nocturnal GH secretion in obese patients (Ferini-Strambi *et al.*, 1991). Ferini-Strambi *et al.* (1991) examined sleep EEG and sleep-related GH secretion in obese patients without obstructive sleep apnoea before and after weight loss due to a hypocaloric diet. They were compared with lean control subjects. Sleep-EEG parameters did not differ significantly between groups. Before weight loss, there was nearly a total lack of GH secretion in the obese subjects. After weight loss, the mean body mass index in these patients decreased from 37.1 to 31.4 (controls 22.3). Although the sleep architecture in obese patients was unchanged after weight loss, GH concentrations increased, suggesting a partial restoration of GH secretion.

Whipple's Disease

In a patient with long-lasting nearly complete sleep loss due to cerebral Whipple's disease (Lieb *et al.*, 1999), GH secretion was nearly flattened over 24 h. The methodological limitation of this case report is the fact that GH concentrations were determined every 30 min. Therefore, it appears possible that some minor peaks were not detected. Nevertheless, these data suggest that severe chronic sleep loss is accompanied by marked blunting of GH release (Lieb *et al.*, 2000).

Sleeping Sickness

The sleep-wake cycle is distinctly changed in human African trypanosomiasis (sleeping sickness). Sleep EEG and 24-h hormone profiles were compared in patients with sleeping sickness and controls (Brandenberger *et al.*, 1994). A marked sleep fragmentation was found in the patients. The circadian rhythm of cortisol was attenuated in all but one of the six patients. In patients and normal subjects, SWS was associated with the declining phases of cortisol secretion. In the patients, profiles of prolactin and plasma renin activity did not show the increase normally associated with long sleep periods but reflected the disturbances of sleep and wakefulness throughout 24 h. In both patients and controls, REMS began during the descending phases of prolactin pulses. In both groups, plasma renin activity reflected the sleep-stage distribution, with NREMS occurring during the ascending phases and REMS during the descending phases of the oscillations. However, in the patients, sleep fragmentation often did not allow sufficient time for plasma renin activity to increase, as known in regular sleep cycles.

Disturbed Rhythms due to Environmental Influences

Modern civilization influences the physiological sleep-wake schedule of millions of people throughout the world. Intercontinental air travel, shift work and prolonged awake time due to artificial light exert distinct effects on sleep-endocrine activity.

Jet Lag

In an experiment, sleep, EEG and hormone secretion were studied in normal subjects before and after a flight from Europe to the USA. The GH secretion adapted quickly to the new sleep schedule, but it took 2 weeks for the cortisol pattern to be totally adjusted (Desir *et al.*, 1981). Dissociation of sleep and cortisol rhythm during the first few days after long-distance travel may contribute to the symptoms of jet lag.

Light

The major environmental factor influencing the timing of neuroendocrine rhythms via the suprachiasmatic nucleus is light. This view is further supported by studies in which 24-h hormone profiles were sampled in normal control subjects on two separate occasions, once after they were chronically exposed to simulated short (8-h) 'summer nights' and once after they were chronically exposed to simulated long (14-h) 'winter nights'. The duration of the period of rising cortisol levels, active melatonin secretion and high prolactin secretion was longer during the 'winter nights' than during the 'summer nights' (Wehr, 1998).

Shift Work

In shift workers, a long-lasting resistance of the cortisol rhythm to total adaptation to an inverted sleep schedule was detected. Young male night workers who had been permanently on night shift for at least 2 years were compared to day-active control subjects. Sleep EEG and hormone secretion were examined in each group during the usual sleep time (0700–1500 in the night workers, and 2300–0700 in the control subjects, respectively). Furthermore, hormone secretion was investigated during the usual work time. Sleep-EEG variables did not show major differences between the groups. In contrast, cortisol levels were enhanced and TSH levels were blunted in the night workers during the usual sleep time. However, cortisol levels were blunted in the night workers during their work hours. During this interval, a transient increase of prolactin occurred (Weibel and Brandenberger, 1998). Another study from the same laboratory (Weibel *et al.*, 1997) found a more random distribution of GH pulses during sleep in the daytime sleep of night workers than controls.

Sleep in Endocrine Disorders

Hypo- and hypersecretion of various hormones is regularly linked to disturbed sleep. Insomnia is the most frequent sleep-related symptom in these disorders. Only in patients with prolactinoma has enhanced sleep depth been reported so far.

Disorders of HPS System

Given the strong association between SWS and GH secretion, it was interesting to investigate patients with inborn or acquired lack of GH secretion and those with excessive GH levels in acromegaly.

In eight patients, isolated GH deficiency was initially diagnosed by slow growth velocity, an abnormal insulin hypoglycaemia test and retarded bone age. In comparison to normal controls, SWS in these patients was reduced, whereas total sleep time and time spent in stages 1 and 2 were increased (Åström and Lindholm, 1990). The same laboratory reported a decrease in SWA in these patients (Åström and Jochumsen, 1989). Guilhaume *et al.* (1982) examined a small sample of children with psychosocial dwarfism. At the initial examination, the amount of SWS was low. After several weeks in a new environment, an improvement of sleep quality was observed during recovery of growth, particularly an increase of SWS.

In patients with acromegaly, obstructive sleep apnoea syndrome is frequent due to hyperplasia of the upper airway soft tissue (Hart *et al.*, 1985). But also patients with acromegaly but without sleep apnoea have daytime sleepiness and an abnormal sleep structure. One year after adenectomy, REMS time and SWS time increased in patients with acromegaly (Åström and Trojaborg, 1992).

HPA System Aberrations

The capacity of the adrenal glands to produce corticosteroids is severely reduced in Addison's disease (Gillin *et al.*, 1974). There exist only a few case reports on these patients, and these reports do not suggest major changes of their sleep EEG. Garcia-Borreguero *et al.* (2000) compared patients with Addison's disease under two conditions, either continuous hydrocortisone replacement therapy or shorter hydrocortisone withdrawal. Under hydrocortisone replacement, REMS latency was shortened, and REMS time and intermittent wakefulness were increased in comparison to hydrocortisone withdrawal. The authors suggest that cortisol may be needed to facilitate the initiation and maintenance of REMS.

Excessive cortisol levels are produced in patients with Cushing's disease, of either central or peripheral origin. SWS is decreased in these patients (Krieger and Glick, 1974; Shipley *et al.*, 1992). In one study, increases of sleep latency and intermittent wake time and disinhibition of REMS (shortened REM latency, elevated REMS density) were also reported (Shipley *et al.*, 1992). Particularly the latter report suggests that sleep-EEG changes in Cushing's disease and in depression are similar.

Hypothyroidism and Hyperthyroidism

Changes of sleep-wake behaviour are characteristic symptoms of diseases of the thyroid gland. From clinical practice, it is well known that hyperthyroidism is linked with insomnia, whereas fatigue is frequently observed in patients with hypothyroidism. Astonishingly, there are only a few data on sleep EEG in these diseases. One study reported that SWS was reduced in patients with hypothyroidism in comparison to normal controls. The sleep EEG normalized after therapy (Kales *et al.*, 1967).

Prolactinoma

Comparison of patients with hyperprolactinoma and normal controls showed a separate increase of SWS in the patients (Frieboes *et al.*, 1998).

EXPERIMENTAL MODELS OF CHANGES OF SLEEP-ENDOCRINE ACTIVITY

A host of preclinical, human and clinical studies have investigated the interaction of sleep EEG and endocrine activity. The applied methods include transgenic animals; manipulation of endocrine activity in animals by surgery; manipulation of sleep-wake behaviour in normal human control subjects, as by partial or total sleep deprivation; and exogenous administration of hormones, particularly peptides and steroids, to animals and humans. The knowledge accumulated from these studies helps us to understand the pathophysiology of the aberrations reported before in this chapter. Ehlers and Kupfer (1987) were the first to advance the hypothesis that the key peptides of the HPS and the HPA systems, GHRH and CRH, play a major role in sleep regulation. Today this view is corroborated by many data. Besides stimulating GH release, GHRH has been shown to promote NREMS, particularly SWS, in various species including the human (male subjects) (reviewed in Krueger and Obál, 1993), and to blunt HPA hormones in human males (Steiger *et al.*, 1992; Antonijevic *et al.*, 2000b; Antonijevic *et al.*, 2000c). In contrast to GHRH, CRH stimulates the HPA hormones ACTH and cortisol, blunts GH release, impairs sleep and enhances vigilance. Furthermore, a REMS-promoting effect of CRH has been discussed (Steiger, in press). It is thought that changes of the GHRH/CRH ratio result in changes in sleep-endocrine activity. Besides GHRH and CRH, there are other endocrine factors which appear to participate in sleep regulation (see Figure XXIV-3.7).

HPA Hormones

The synthesis and release of CRH is reduced by a hypothalamic gene defect in the Lewis rat. Lewis rats spend less time awake and show more SWS than intact control rats. After intracerebroventricular (ICV) administration of CRH, waking increased

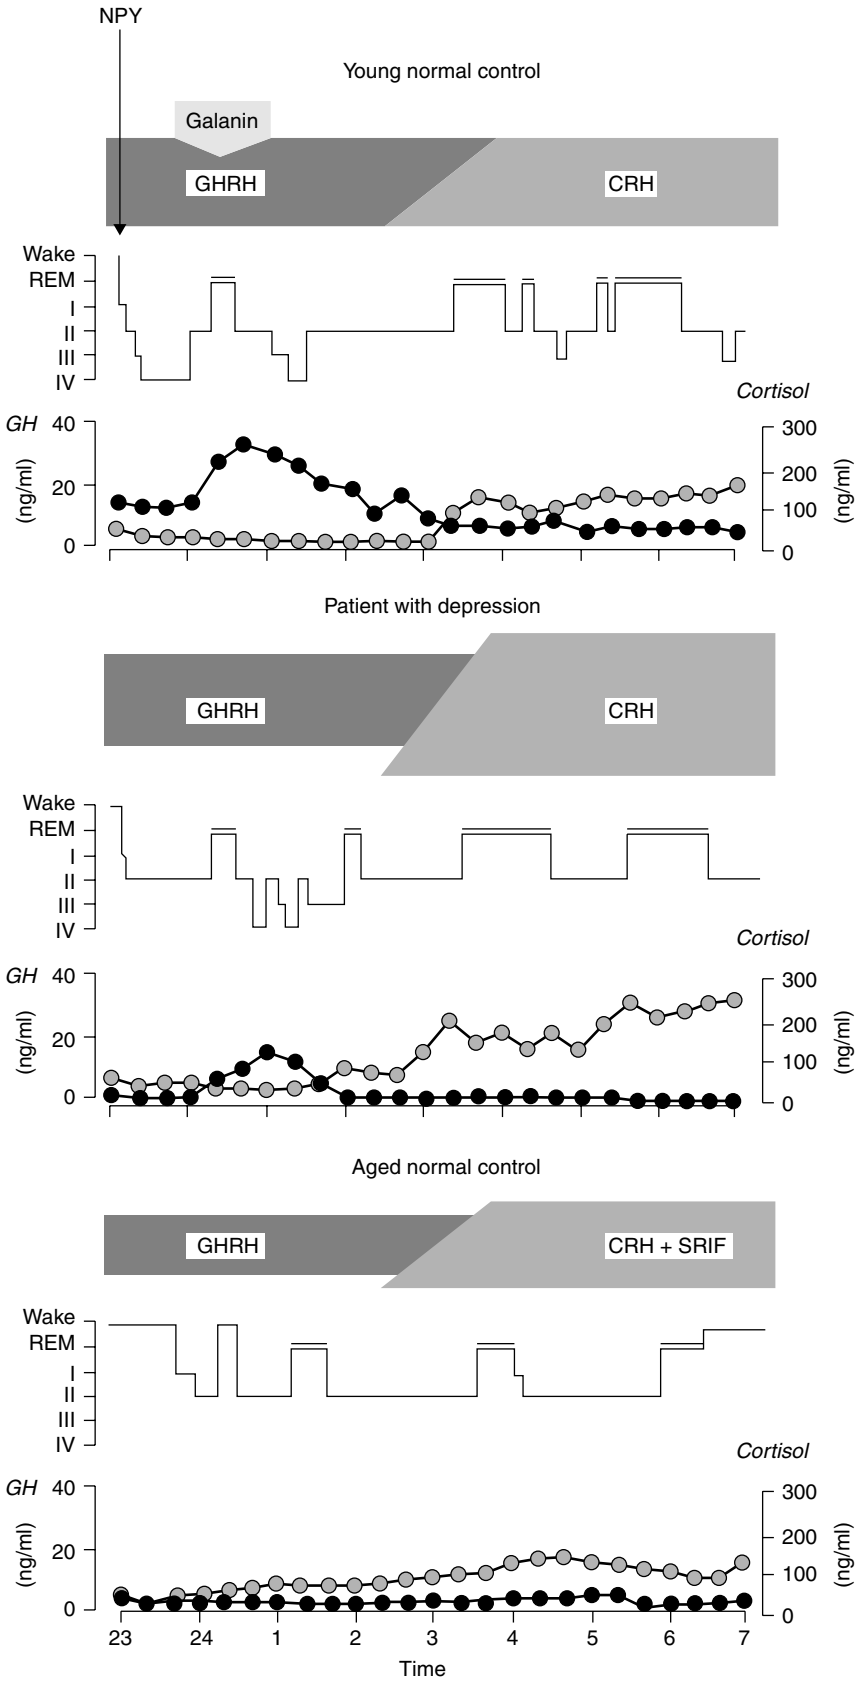

Figure XXIV-3.7 Model of peptidergic sleep regulation

similarly in Lewis and control rats. The sleep-disturbing effects of CRH are suggested by this study (Opp, 1997). In rats, after adrenalectomy and corticosterone replacement, the concentration of this hormone remained about $100\,ng\,ml^{-1}$ throughout 24 h. In the sham-operated control group, however, corticosterone levels ranged between peak levels of about $240\,ng\,ml^{-1}$ in the evening and the minimum of about $20\,ng\,ml^{-1}$ in the morning. Sleep EEG differed only slightly between groups. Slightly more, but shorter, REMS episodes were observed in the adrenalectomized group than the control rats. Obviously, the tonic levels of corticosterone exerted only minor effects on spontaneous sleep-wake behaviour (Langebartels and Lancel, 2000).

ICV administration of CRH diminished SWS in rats (Ehlers *et al.*, 1986) and rabbits (Opp *et al.*, 1989). Moreover, after 72 h of sleep deprivation, SWS was reduced in rats. Furthermore, sleep latency and REMS time increased (Marrosu *et al.*, 1990). Similarly, in young, normal, male control subjects after pulsatile intravenous (IV) administration of $4 \times 50\,\mu g$ human CRH between 2200 and 0100, SWS decreased during the second half of the night, whereas REMS decreased. Furthermore, the GH peak was blunted and during the first hours of the night, cortisol concentration was elevated (Holsboer *et al.*, 1988). In human sleep-endocrine studies, the time, the dosage and the protocol of the administration of peptides are crucial methodological issues. Repetitive administration around sleep onset (Holsboer *et al.*, 1988) mimics the physiological partial release of CRH. In contrast, after continuous nocturnal infusion of CRH, no effect on the sleep EEG was found (Fehm *et al.*, 1993). Moreover, after hourly IV injections of $10\,\mu g$ CRH between 0800 and 1800, sleep EEG remained unchanged during the following night (Kellner *et al.*, 1997). In this study, melatonin levels were blunted after CRH. This finding suggests that the low melatonin syndrome in patients with depression is secondary to CRH overdrive. The responsiveness of sleep to CRH appears to increase during ageing. This theory is suggested by a study comparing the influence of a single dose of ovine CRH given 10 min after sleep onset between young and middle-aged normal control subjects (Vgontzas *et al.*, 2001). In young men, sleep EEG remained unchanged, whereas wakefulness increased and SWS decreased in the middle-aged subjects.

Two studies reported conflicting results after administration of CRH antagonists to rats. In one study, two different antagonists, alpha-helical CRH and astressin, were given before the dark period. These substances reduced wakefulness in a dose-dependent manner, whereas the time courses of these effects differed between drugs (Chang and Opp, 1998). Administration of the substances before the light period had no effect on sleep. The authors concluded that CRH contributes to the regulation of physiological waking. In contrast, in another study (Gonzalez and Valatx, 1997), alpha-helical CRH was effective only in stressed animals. In these rats, REMS was elevated and declined to values of the nonstressed condition after the drug. In sleep-deprived rats, REMS rebound, but not SWS rebound, was diminished by alpha-helical CRH during recovery sleep. The authors suggested that stress acting via CRH may be the major factor inducing the REMS rebound after sleep deprivation (Gonzalez and Valatx, 1998). Some of the cited preclinical work (Gonzalez and Valatx, 1997; Gonzalez and Valatx, 1998; Marrosu *et al.*, 1990) suggests that CRH promotes REMS. From the study in young human controls, the role of endogenous CRH in REMS regulation is uncertain, however, since CRH diminished REMS (Holsboer *et al.*, 1988).

Studies on the effects of ACTH and cortisol on sleep may help to differentiate the central and peripherally mediated sleep-EEG changes after CRH in human subjects. As reviewed elsewhere (Steiger, in press), suppression of REMS is a common effect of the acute administration of CRH, ACTH and cortisol in humans, whereas a synthetic ACTH (4-9) analogue affected neither cortisol release nor REMS (Steiger and Holsboer, 1997b). Furthermore, inhibition of cortisol synthesis by metyrapone in young normal men reduced SWS and cortisol while REMS remained unchanged (Steiger *et al.*, 1998). It is likely that endogenous CRH was enhanced in this study since ACTH was elevated. Interestingly, the effects of subchronic treatment with steroids differ from acute administration in normal controls. Sleep EEG was investigated in female patients with multiple sclerosis at baseline and after 2 and 9 days of administration of the glucocorticoid receptor agonist methylprednisolone. After 2 days, no major effects were found. After 9 days, REMS latency was shortened, REMS density increased and a major portion of SWS shifted from the first to the second NREMS period. These effects are similar to sleep-EEG aberrations in patients with depression (Steiger and Antonijevic, 2001).

Furthermore, the administration of the mixed glucocorticoid and progesterone receptor antagonist, mifepriston, is a method to modulate the HPA system. In a single case study in a normal control after oral mifepriston, ACTH and cortisol were enhanced. Sleep quality was disturbed markedly as sleep latency and intermittent wakefulness increased and SWS and REMS decreased (Wiedemann *et al.*, 1992). The sleep-disturbing effects of mifepriston were further corroborated by a set of studies from the same group (Wiedemann *et al.*, 1994; Wiedemann *et al.*, 1998). Whereas HPA hormones are widely dependent on a circadian rhythm, most studies report increases of ACTH and cortisol after awakenings and during sleep deprivation (reviewed by Steiger, in press).

HPS System

Hormones of the HPA system can modulate sleep. GHRH is the endogenous substance with the best-documented sleep-promoting activity. ICV administration of GHRH to rats and rabbits increases SWS (Ehlers *et al.*, 1986; Obál *et al.*, 1988). The same effect is seen when GHRH is injected into the medial preoptic area in rats (Zhang *et al.*, 1999) or IV in rats (Obál *et al.*, 1996). NREMS increases when GHRH is inhibited by receptor antagonists (Obál *et al.*, 1991) or by negative feedback inhibition of GHRH after administration of GH (Mendelson *et al.*, 1980; Stern *et al.*, 1975) or insulin-like growth factor-1 (Obál *et al.*, 1999). Hypothalamic GHRH mRNA is dependent on a circadian rhythm. In the rat, the highest concentration is found at the beginning of the light period when sleep propensity reaches its maximum in these nocturnal animals (Bredow *et al.*, 1996). Furthermore, hypothalamic GHRH contents display sleep-related variations (Gardi *et al.*, 1999). A major role of GHRH in sleep promotion by sleep deprivation is indicated since GHRH antibodies antagonize this effect in the rat (Obál *et al.*, 1992). Furthermore, hypothalamic GHRH mRNA has been found to be increased after sleep deprivation in rats (Toppila *et al.*, 1997; Zhang *et al.*, 1999). The sleep rebound following sleep deprivation was inhibited by microinjections of a GHRH antagonist into the area preoptica of the rat (Zhang *et al.*, 1999). Very big 'supermice' slept more than normal mice (Lachmansingh and Rollo, 1994). However, dwarf rats with deficits in the central GHRHergic transmission and reduced hypothalamic GHRH content had less NREMS than control rats (Obál *et al.*, 2001). Taken together, these data suggest that GHRH is a common stimulus for NREMS, particularly SWS and GH secretion.

We showed that GHRH promotes sleep also in humans. After repetitive IV administration of GHRH during the first few hours of the night, SWS and GH secretion increased in young normal male controls and cortisol secretion decreased (Steiger *et al.*, 1992). Sleep promotion in young men by GHRH was confirmed after IV(Kerkhofs *et al.*, 1993; Marshall *et al.*, 1999) and intranasal

(Perras *et al.*, 1999a) administration. We investigated the effects of GHRH on sleep-endocrine activity in three states with a change of the GHRH/CRH ratio in favour of CRH: first, the second half of the night in young normal men; second, in elderly normal men and women; and, third, in patients with depression.

In the first case, in young normal men, administration of GHRH during the early morning hours (0400–0700) prompted no major effects on sleep EEG, particularly no change of SWS. GH increased whereas HPA hormones remained unchanged (Schier *et al.*, 1997). In the second case, in the normal elderly, during the daytime, the response of GH to GHRH was blunted (Iovino *et al.*, 1989). Similarly, we found only a weak sleep-promoting effect of GHRH in the elderly. The first NREMS period was prolonged and the time of awakenings decreased, whereas SWS remained unchanged (Guldner *et al.*, 1997). In the third case, the influence of pulsatile IV administration of GHRH during the first few hours of the night was tested in 42 drug-free patients of both sexes with major depression (age range 19–76 years) and matched controls. Interestingly, a sexual dimorphism in the response to GHRH was found. In male patients and controls, GHRH inhibited ACTH levels during the first half of the night and cortisol levels during the second half of the night. In contrast, these hormones were enhanced in females, regardless whether they were healthy or depressed. Similarly, NREMS and stage 2 sleep increased in male patients and controls, whereas opposite sleep-impairing effects occurred in women. These data confirm a reciprocal antagonism of GHRH and CRH in males, whereas a synergism of GHRH and CRH is suggested in females. The latter issue may be an explanation for the increased prevalence of mood disorders in women (Antonijevic *et al.*, 2000b; Antonijevic *et al.*, 2000c).

The major antagonist of GHRH in the regulation of GH is somatostatin. In rats, systemic administration of the somatostatin analogue octreotide decreased NREMS (Beranek *et al.*, 1999). Similarly, SWS was reduced in young normal men after subcutaneous administration of octreotide (Ziegenbein *et al.*, 2000). Octreotide is known to be more potent than exogenous somatostatin. This is shown by the fact that repetitive IV administration of somatostatin impaired sleep in normal elderly controls (Frieboes *et al.*, 1997), whereas it had no effect in young normal men (Steiger *et al.*, 1992).

Galanin

Under repetitive IV administration of galanin to young normal men, SWS and the duration of REMS periods increased, whereas the secretion of GH and cortisol remained unchanged (Murck *et al.*, 1999).

Neuropeptide Y (NPY)

Besides GHRH, NPY appears to be a physiological antagonist of CRH. Originally, this theory was based on the opposite effects of CRH and NPY in animal models of anxiety (reviewed in Steiger and Holsboer, 1997b). This view is supported by recent studies on the sleep-EEG effects of NPY. After ICV administration of NPY to rats, EEG spectral activity changed in a way similar to the effects of benzodiazepines (Ehlers *et al.*, 1997a). Furthermore, the prolongation of sleep-onset latency by CRH was antagonized dose-dependently by NPY in rats (Ehlers *et al.*, 1997b). Similar effects were observed in young normal men. Repetitive IV administration of NPY prompted decreases of sleep latency and the first REMS period, and increases of stage 2 sleep and sleep period time, and blunted cortisol and ACTH secretion (Antonijevic *et al.*, 2000a). Moreover, in patients with depression of both sexes with a wide age range and age-matched controls, the sleep latency was shortened after NPY, whereas cortisol and ACTH levels and the first REM period remained unchanged (Held *et al.*, 1999). These data suggest that NPY participates in sleep regulation, particularly in the timing of sleep onset as an antagonist of CRH acting via the $GABA_A$ receptor.

Vasoactive Intestinal Polypeptide (VIP)

Pulsatile IV administration of vasoactive intestinal polypeptide (VIP) in young normal male control subjects decelerated the NREMS-REMS cycles. Each cycle was prolonged, the cortisol nadir appeared to be advanced and the GH surge was blunted (Murck *et al.*, 1996). These findings suggest that VIP exerts a specific effect on the temporal organization of sleep-endocrine activity, including the timing of the cortisol nadir. It appears likely that VIP affects the circadian clock, resulting in prolonged sleep cycles and earlier occurrence of the cortisol nadir. Blunted GH surge may be explained as a result of the advanced elevated HPA activity.

HORMONES AS THERAPY IN SLEEP DISORDERS

Several approaches were applied to use hormones or synthetic analogues in the treatment of sleep disorders. In most cases, the rational was the substitution of declining hormone levels.

Oestrogen Replacement Therapy

In postmenopausal women oestrogen replacement therapy by skin patch (50 μg of estradiol per day) enhanced REMS and reduced intermittent wakefulness during the first two sleep cycles. The normal decrease in SWS and SWA from the first to the second sleep cycle was restored by oestrogen (Figure XXIV-3.8) (Antonijevic *et al.*, 2000d). These data suggest that oestrogen treatment after the menopause can help to restore the normal sleep-EEG pattern in women.

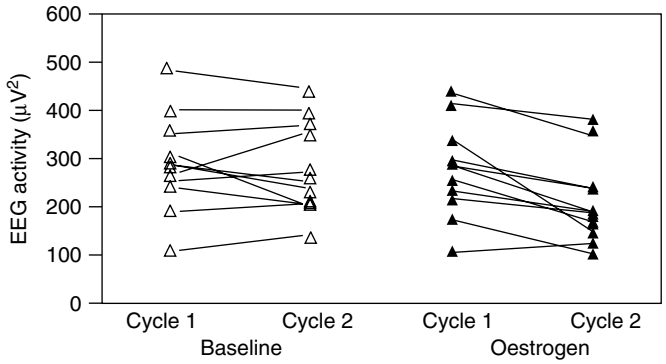

Figure XXIV-3.8 Changes in delta electroencephalographic activity from first to second cycle during baseline and oestrogen replacement therapy (ERT). A change in delta electroencephalographic (EEG) activity from first to second non-rapid-eye movement during baseline (open circles) was not consistently observed, whereas during ERT (filled circles) a normal decrease in delta activity from first to second non-rapid-eye movement period was observed in most subjects (expressed as percentage change of the respective value from first to second non-rapid-eye movement period: $-2.4\% \pm 5.4\%$ during baseline versus $-20.4\% \pm 5.7\%$ during ERT; univariate F test after one-factorial (treatment) analysis of variance, including covariate short-term versus long-term ERT; $n = 11$; F1, $9 = 8.8$; $P < 0.05$)

GHRH and GH Secretagogues

Acute repetitive IV (Guldner *et al.*, 1997) and intranasal (Perras *et al.*, 1999b) administration of GHRH in elderly subjects had only a relatively weak sleep-promoting effect compared to the increase of SWS in young men after this peptide. A pilot study tested the hypothesis that after priming (e.g., daily IV administration of GHRH every 2 days for 12 days) the sleep-promoting effect of GHRH would be restored in the elderly. The study results in two subjects do not support this hypothesis (Murck *et al.*, 1997). GH secretagogues are synthetic peptides. These substances share the capacity of GHRH to stimulate GH release, although they act via a specific GH secretagogue receptor, and not at the GHRH receptor. As in the observations after GHRH, oral administration of one GH secretagogue, MK-677, for 1 week, had a distinct sleep-promoting effect in young men and only a weak effect in elderly controls (Copinschi *et al.*, 1997). Obviously, the capacity of GHRH and GH secretagogues to promote sleep in the elderly is reduced. It might be necessary to start with the substitution of GHRH or related analogues earlier during the lifespan in order to counteract the sequelae of their declining endogenous activity.

Vasopressin

After 3 months' daily intranasal administration of vasopressin to elderly subjects, SWS was enhanced markedly, whereas intermittent wakefulness and self-rated sleep quality remained unchanged (Perras *et al.*, 1999b).

Melatonin

Study results on a beneficial effect of melatonin in young and elderly subjects are ambiguous (Baskett *et al.*, 2001). A possible side effect of long-term treatment with melatonin is a blunting of sexual steroids in men and women. So far, there is a lack of sufficient data from clinical studies to recommend melatonin as an effective alternative sleeping pill. Some studies suggest that, as a result of its phase-shifting properties, melatonin may be helpful in the treatment of rhythm disturbances, such as jet lag and disturbed rhythms in blind patients (Sack *et al.*, 2000; Zhdanova *et al.*, 1997).

CONCLUSIONS

The data reported in this chapter corroborate the bidirectional action of sleep EEG and endocrine activity. Shallow sleep and sleep loss due to various causes are frequently linked to elevated secretion of cortisol and ACTH and blunted GH levels. Another clear link has been shown between changes of the sleep-wake rhythm and the pattern of melatonin activity. The link between the NREMS-REMS cycle and the oscillations of plasma renin activity known from normal controls appears to be preserved in disrupted sleep patterns. Although it is so far unknown what factors are the common regulators of sleep and plasma renin activity, the role of GHRH and CRH as links between sleep EEG and peripheral hormone secretion is well established. At least in male subjects, GHRH appears to stimulate GH and SWS and to inhibit HPA hormones. CRH exerts opposite effects. Changes of the GHRH/CRH ratio occur during normal ageing (reduced GHRH activity) and in depression (CRH overactivity). Common features of these states are shallow sleep, blunted GH and elevated cortisol levels. Sleep-EEG changes in dwarfs (low GHRH) and subjects with acromegaly (feedback inhibition of GHRH due to excessive GH levels) can be similarly explained. Gender differences in sleep regulation are suggested by the opposite effects of GHRH in normal and depressed women in comparison to men. This issue needs further clarification.

Besides GHRH and CRH, other peptides and steroids are thought to participate in sleep regulation. Like CRH, somatostatin is sleep-impairing factor, and, like GHRH, NPY and galanin promote sleep. VIP appears to be involved in the temporal organization of sleep. The similarities between sleep-EEG in patients with depression and with Cushing's disease and in patients with multiple sclerosis after subchronic administration of a glucocorticoid agonist suggest, that besides CRH, elevated glucocorticoid levels also contribute to the sleep-EEG changes in depression. So far, the use of hormones in the therapy of sleep disorders is rare. Since the hypnotics of today do not induce physiological sleep (Steiger and Lancel, 2000), novel substances are needed that correspond better to human physiology. The progress in sleep-endocrine research should help to develop such therapeutic strategies. In the related field of antidepressants, the recent development of CRH antagonists (Holsboer, 1999; Zobel *et al.*, 2000) is an encouraging example.

Neuroimmunology of Sleep

Jeannine A. Majde and James M. Krueger

INTRODUCTION

Sleep consumes a third of our lives, but its functions are unknown. Excess, inhibited, or fragmented sleep often accompanies psychiatric disorders or their treatments. The fatigue and confusion associated with the abnormal sleep may constitute a major complaint of the patient. Before we can begin to understand the pathological sleep associated with psychiatric disorders, it is essential that we have a better understanding of normal sleep and its functions. Ironically, the major insights we have gained into the regulation of normal sleep come from another class of pathologies, acute infectious diseases. This chapter will summarize what we have learned about sleep regulation through analysis of the molecular changes associated with infections.

Acute infections are generally detected clinically by the manifestations of fever and malaise. Included in the concept of malaise is the subjective feeling of profound fatigue and the overwhelming need to sleep. Sleep is detected and measured primarily through analysis of electroencephalographic (EEG) patterns, as has been described elsewhere in this text. Over the last 20 years we have characterized the EEG changes that occur in response to several acute infections. These changes will be described in more detail later in this chapter, but consistent features are the manifestation of increased slow-wave or non-rapid-eye-movement sleep (NREMS), increased slow-wave amplitudes, and often the reduction of total REM sleep (Krueger and Majde, 1994). These sleep characteristics are seen regardless of whether the stimulus is a purely microbial component or an actual infection. A major breakthrough in our conceptualization of sleep regulation is the realization that the peripheral cytokines produced in response to an infectious or other inflammatory stimulus are responsible for triggering the subjective need to sleep as well as the characteristic sleep changes. Furthermore, these same cytokines are actively involved in regulating physiological sleep.

Cytokines are a large class of protein hormones produced primarily by cells of the immune system or by damaged epithelial cells. Over 100 cytokines have been identified to date. One subclass of cytokines, the chemokines, appears to act primarily in a paracrine fashion to regulate inflammation at the site of tissue damage. However, a large and loosely defined subclass of cytokines, the proinflammatory cytokines, act not only locally but also systemically to trigger all of the characteristic responses to inflammatory challenge, including fever, anorexia, and somnolence. Thus, at least one function of proinflammatory cytokines appears to be signalling the brain that the host is threatened by invading micro-organisms and that adaptive responses are required (Hart, 1988). The best-characterized proinflammatory cytokines are the interleukin-1s (IL1α and IL1β), IL6, and tumour necrosis factor-α (TNF-α). The array of physiological, behavioural, haematological, and biochemical responses initiated by these cytokines is termed the acute-phase response (APR). In addition to proinflammatory cytokines, growing evidence points to an important systemic role of anti-inflammatory cytokines such as IL10, IL4, IL13, and transforming growth factor-β (TGF-β) in the inhibition of the APR, including the excess sleep component. In the sections to follow, we will outline the evidence that proinflammatory and anti-inflammatory cytokines regulate both pathological and physiological sleep.

In addition to cytokines, several classical hormones, such as growth hormone-releasing hormone (GHRH), corticotrophin-releasing hormone (CRH), and prolactin, have been implicated in sleep regulation. Growth factors such as nerve growth factor (NGF), neurotropins, epidermal growth factor, and fibroblast growth factor are involved as well (reviewed by Krueger and Obál, 1997). The gaseous neurotransmitter nitric oxide (NO) has also been implicated (Kapás *et al.*, 1994; Kapás and Krueger, 1996). The regulation of these hormones and NO synthesis by cytokines may form the basis for the association of cytokines and sleep.

INDIGENOUS MICROBIAL FLORA AND CYTOKINE STIMULATION IN THE HEALTHY INDIVIDUAL

It is widely recognized from such conditions as rheumatic heart disease that bacteraemia can occur in response to dental work. Profound immunodeficiency disorders such as AIDS have also demonstrated that the massive microbial flora that lines our mucosal surfaces, particularly the intestine, can escape protective mucosal barriers when normal immune defences are impaired. Much less is known about our day-to-day exposure to these micro-organisms because this exposure is not perceptible. However, studies of the intraintestinal lymphoid tissue, the Peyer's patches, reveal specialized epithelial cells that can transport bacteria to adjacent macrophages for degradation (Owen *et al.*, 1986). Bacteria and their breakdown products accumulating in the Peyer's patches then can enter the portal circulation or the mesenteric lymph (Sartor *et al.*, 1988). Though not quantified, it is thought that millions of bacteria may be cleared by this mechanism daily.

The first insights into the relationship of microbial products to sleep were gained from structural studies on a sleep factor isolated from human urine (Krueger *et al.*, 1982a). This factor proved to share the unique chemical properties of the peptidoglycans found in the cell walls of bacteria (Krueger *et al.*, 1982a). Peptidoglycans comprise 90% of the cell wall of Gram-positive bacteria and 5–20% of the cell wall of Gram-negative bacteria (Krueger and Majde, 1990). Subsequent sleep studies with various natural and synthetic peptidoglycans revealed that the minimally active unit is a glycopeptide consisting of the sugar *N*-acetylmuramic acid (found only in bacteria) and the dipeptide L-alanine-D-alanine, termed muramyl dipeptide (MDP) (Krueger *et al.*, 1982b). MDP and certain derivatives have immunological

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

adjuvant properties. Peptidoglycans also contain the bacterially unique amino acids D-glutamic acid (eukaryotes employ primarily L-amino acids) and diaminopimelic acid, as well as L-lysine. Many peptidoglycan derivatives are pyrogenic as well as somnogenic.

In addition to the peptidoglycans found in all bacterial cell walls, the lipopolysaccharide (LPS) moiety of the endotoxin component of Gram-negative bacterial cell walls also potently alters sleep through induction of proinflammatory cytokines (Krueger and Majde, 1994). A majority of studies on cytokine induction by microbial products have employed LPS as the stimulus. Other bacterial components such as lipoteichoic acid and lipoproteins also stimulate proinflammatory cytokine induction, although their effects on sleep have not been analysed. Recently, it has been recognized that structural differences in bacterial DNA are recognized by the immune system with the production of cytokines (Sweet *et al.*, 1998). It is not yet known whether bacterial DNA plays a role in bacterial illness or in sleep responses to bacteria.

It has recently been determined that bacterial and fungal cell-wall components, although structurally distinct, are detected by phagocytes through activation of Toll-like receptors (TLRs), a receptor type first demonstrated as a host-defence mechanism in fruit flies (Aderem and Ulevitch, 2000). Activated TLRs then signal the phagocyte to release proinflammatory cytokines.

A common feature of all microbial components (with the possible exception of bacterial DNA) capable of inducing cytokines is their chemical resistance to biodegradation (Krueger and Majde, 1994). While mature macrophages and neutrophils carry enzymes capable of degrading peptidoglycans (lysozyme, *N*-acetylmuramyl-L-alanine amidase, Hoijer *et al.*, 1997), these enzymes do not always achieve complete degradation and fragments may be secreted extracellularly (Pabst *et al.*, 1999). These secreted partial degradation products can then serve as steady stimulators of cytokine release by neighbouring phagocytes. Little direct evidence exists for this cytokine source from the intestine, however, because the portal blood and mesenteric lymph of healthy individuals are rarely accessed. Furthermore, it is clear that soluble receptors and other binding factors exist in body fluids that are capable of neutralizing and facilitating the clearance of cytokines (Dinarello, 2000). Low levels of cytokines, especially IL1s, routinely circulate in association with intrinsic binding factors. These binding factors are likely to play a significant role in determining the levels of cytokines free to bind to cell receptors and activate neighbouring or distant cells.

While there are substantial gaps in our knowledge of physiological cytokine regulation, indirect evidence supports a role for indigenous flora in the regulation of both body temperature and sleep, in that animals with reduced indigenous flora have lower body temperatures and sleep less (Krueger and Majde, 1994). Rats treated with antibiotics that reduce intestinal flora have reduced NREMS but normal REMS (Brown *et al.*, 1990). Furthermore, neutralization of the proinflammatory cytokines IL1β and TNFα with antibodies or endogenous binding factors also reduces spontaneous sleep (see section below on *IL1β and TNFα*).

Whereas much remains to be elucidated regarding the exact source of the cytokines regulating physiological sleep, the means by which cytokines produced in the periphery can affect the brain have been extensively investigated. Three possible routes to the brain for peripheral cytokines have been implicated: brain circumventricular organs (Blatteis and Sehic, 1997), specific transporters in the blood–brain barrier (Banks *et al.*, 1991), and sub-diaphragmatic vagal afferents (Kapás *et al.*, 1998; Hansen and Krueger, 1997). Of these three routes, stimulation of the vagal nerve has been most closely linked with sleep regulation. The liver paraganglia contain IL1 receptors (Goehler *et al.*, 1997). Systemic bacterial LPS and IL1 both induce increased IL1β mRNA production in the brain, and this effect is blocked by vagotomy (Hansen *et al.*, 1998a; Layé *et al.*, 1995). Excess NREMS in response to systemic IL1β is also blocked by vagotomy (Hansen and Krueger, 1997). Other events that promote NREMS such as excessive food intake are also dependent on vagal innervation (Hansen *et al.*, 1998b). The relative importance of these three brain access routes in regulating both physiological and pathological sleep under different conditions is unknown, although direct action on the brain via circumventricular organs and/or blood–brain barrier transporters would require elevation of unbound cytokines in the circulation.

CHANGES IN SLEEP DURING ACUTE INFECTIONS OR CHALLENGE WITH MICROBIAL COMPONENTS

Acute infections such as influenza are associated with an overwhelming need to sleep and an increase in total sleep time. Our knowledge of polysomnographic sleep changes in acute infections is derived from animal studies, as only subjective sleep reports have been acquired during acute infections in man (Smith, 1992). As mentioned previously, acutely infected animals demonstrate increased NREMS and diminished REMS as well as increased amplitudes of EEG slow waves, which are considered an index of the intensity of sleep (Krueger and Majde, 1994). These gross changes occur in bacterial, fungal, and viral infections, but with different kinetics depending on the infective organism, dose, and route (Toth, 1999).

The sleep alterations in acute bacterial, fungal, and viral infections have been recently reviewed in detail (Toth, 1999) and in summary form (Krueger *et al.*, 2001). Studies with bacteria in rabbits include both human pathogens (*Staphylococcus aureus*, *Streptococcus pyogenes*, and *Escherichia coli*) and the rabbit pathogen *Pasturella multocida* (Toth, 1999). Challenge of rats with baker's yeast or rabbits with *Candida albicans* induces sleep alterations similar to those seen in animals challenged with Gram-positive bacteria (Toth, 1999). Viral sleep alterations have been analysed in an abortive rabbit model of influenza virus and an abortive mouse model of Newcastle disease virus. NREMS and delta-wave amplitudes are increased and REMS decreased during the febrile period in all of these infections (Toth, 1999). A similar but more prolonged sleep alteration is seen in an active influenza infection in mice when virus is administered in such a manner as to cause pneumonitis, whether or not a lethal infection ensues (Fang *et al.*, 1995a; Toth, 1999). When the same amount of virus is delivered only to the upper respiratory tract, no changes in sleep or other symptoms are seen (Fang *et al.*, 1996).

The same fundamental sleep changes occur in response to challenge with bacterial cell-wall peptidoglycans or LPS, with biodegradation-resistant fungal cell-wall polysaccharides, or with synthetic or virus-associated double-stranded RNA derived from viral replication intermediates (Krueger and Majde, 1994). These fungal and viral components stimulate proinflammatory cytokine induction similarly to that induced by bacterial cell-wall components, though by different mechanisms.

It is the central thesis of this chapter that microbially upregulated cytokines initiate the sleep changes associated with acute infections, presumably because the amounts of cytokines produced exceed the levels that can be bound and cleared by the body. Unbound cytokines produced in the periphery then act upon the brain, probably via vagal afferents (Hansen *et al.*, 1998a), to induce IL1β in relevant brain regions. This thesis is supported by the observation that excess NREMS, fever, and other behavioural responses induced by systemic LPS, muramyl peptides, or IL1β are attenuated by central inhibition of IL1β (Kent *et al.*, 1992; Klir *et al.*, 1994; Takahashi *et al.*, 1996). The extensive evidence

that IL1 and TNF play a role in physiological and pathological sleep regulation is discussed in the section below on humoral regulation.

It should be noted that, whereas we have focused on cytokines as triggers of the APR, other inflammatory mediators such as the eicosenoids may also play a role in the CNS response to infection. It is widely recognized that prostaglandin E_2 (PGE_2) is an important mediator of the fever response to infection (Kluger, 1991). PGD_2 and PGE_2 have also been implicated in sleep regulation (Hayaishi, 1988; Terao *et al.*, 1998). IL1 induces brain astrocytes to produce both prostaglandins (Hayaishi, 1988), and IL1 promotes sleep when injected into a PGD_2-sensitive brain region (Terao *et al.*, 1998). Thus, IL1 within the brain may regulate sleep in part through eicosenoid induction.

The proinflammatory cytokine response to microbes or their stimulatory components is grossly indistinguishable from the proinflammatory cytokine response to other inflammatory stimuli such as tissue damage, although infections are more commonly associated with sleep alterations than are other acute inflammatory states. Whether the relative potency of infections is qualitative or quantitative is unknown.

SLEEP ALTERATIONS IN CHRONIC INFECTIONS AND CHRONIC INFLAMMATORY STATES

Chronic infections with such agents as human immunodeficiency virus (HIV) or hepatitis virus are much more difficult to dissect than are acute infections because they are inevitably associated with diffuse chronic inflammation. In addition to the proinflammatory cytokine cascade characteristic of acute inflammation, chronic inflammation has the added complexity of manifesting a simultaneous anti-inflammatory cytokine cascade. Sleep responses have been examined following administration of single anti-inflammatory cytokines (Krueger and Majde, 1994), and IL10, IL4, and TGFβ all have been found to reduce sleep (Kushikata *et al.*, 1998). However, no studies have attempted to characterize the sleep effects of the complex mixture of pro- and anti-inflammatory cytokines that occurs in chronic inflammation. Studies of sleep in chronic infections suggest, however, that the proinflammatory cytokines dominate sleep regulation in clinical disease.

The chronic infections that have been most extensively investigated with respect to sleep changes are the immunodeficiency virus infections of humans and cats; trypanosome infections of rabbits, rats and humans; and prion infections of mice, rats, cats, and humans (reviewed by Toth, 1999). All of these infections directly affect the brain, and their associated sleep alterations may reflect inflammatory changes within the brain. Because patients infected with the human immunodeficiency virus HIV-1 or the prion causing Creutzfeldt-Jakob disease often manifest psychiatric disorders, what is known about their sleep changes is summarized here.

Sleep changes in HIV-1 infections have been studied during asymptomatic and symptomatic phases. Asymptomatic HIV-1-infected men express increased NREMS during the second half of the night, sleep fragmentation, and abnormal REMS architecture (reviewed by Toth, 1999). These altered sleep patterns precede neurological involvement or onset of secondary infections (Darko *et al.*, 1995). Progression to overt AIDS is marked by reduced NREMS, marked sleep fragmentation, and profound disruption of sleep architecture.

Prions, infectious agents associated with profound dementia, also cause alterations in sleep. Rats inoculated with the scrapie prion demonstrate unusual spiking patterns in the EEG during wakefulness 4 months after inoculation (Toth, 1999). Later NREMS and active wakefulness are reduced and drowsiness is increased (Toth, 1999). Cats challenged with Creutzfeldt-Jakob brain homogenate demonstrate increased NREMS, reduced wakefulness, and abnormal REMS 20 months after inoculation (Toth, 1999). The condition known as fatal familial insomnia is associated with prion-related thalamic neurodegeneration (Toth, 1999). Deletion of the prion protein gene results in altered sleep and circadian rhythms in mice (Toth, 1999).

Less is known about the specific sleep alterations associated with chronic inflammatory diseases, although sleep disorders are prominent components of such diseases as rheumatoid arthritis, fibromyalgia, and chronic fatigue syndrome. Sleep alterations in these three diseases will be briefly described here, as they may affect the psychiatric patient or cause the patient to seek psychiatric help.

Fatigue is a common symptom of all chronic inflammatory diseases. In autoimmune disorders such as rheumatoid arthritis, the fatigue is probably due to the associated sleep fragmentation with frequent movement of the extremities and frequent arousal (Mahowald *et al.*, 1989). Alpha-delta sleep patterns where EEG NREMS intrudes on delta sleep are characteristic. Increasing sleep though treatment with the hypnotic drug triazolam reduces morning stiffness and daytime sleepiness without improving sleep fragmentation (Walsh *et al.*, 1996). Rats experiencing chronic adjuvant arthritis display fragmented sleep, sleep less during the normal sleeping period, and thus lose their normal diurnal sleep rhythms (Landis *et al.*, 1988). Non-steroidal anti-inflammatory analgesics have complex effects on the sleep in these animals (Landis *et al.*, 1989). The pain associated with rheumatic diseases does not appear to cause the fragmented sleep (Hirsch *et al.*, 1994), but the disrupted sleep may contribute to the pain (Moldofsky *et al.*, 1993).

Syndromes associated with chronic fatigue, subjective cognitive impairment, and diffuse myalgia rather than focal inflammation (joint swelling) of the type seen in rheumatic diseases include fibromyalgia and chronic fatigue syndrome. Fibromyalgia is distinguished from chronic fatigue syndrome clinically by its associated marked fibrositis. Depression is also commonly associated with both these disorders. Recently, the depression in chronic fatigue syndrome was shown to be associated with a characteristic REM latency that has been associated with other depressive disorders (Morehouse *et al.*, 1998). Most patients with these syndromes complain of non-restorative sleep, and sleep fragmentation similar to that in rheumatoid arthritis is characteristic of fibromyalgia (Branco *et al.*, 1994). One study has indicated that the association of these two syndromes with sleep disorders is no greater than in patients with psychiatric disorders not associated with pain (Buchwald *et al.*, 1994). Both syndromes are frequently preceded by a febrile illness, but fibromyalgia is also commonly associated with both psychological distress and primary sleep disorders such as sleep apnoea and periodic limb movement (Moldofsky, 1993).

The sleep disorder in chronic fatigue syndrome is essentially the same as that in fibromyalgia (Moldofsky, 1993), although the association with primary sleep disorders such as sleep apnoea is not seen. Circadian rhythm disruption of melatonin secretion and core temperature is seen in chronic fatigue syndrome, which may or may not be a consequence of the sleep disorder (Williams *et al.*, 1996). It has been proposed that fibromyalgia and chronic fatigue are both clinical manifestations of the reciprocal relationship between the immune and sleep-wake systems. Interference with either the immune system (by an infection generating large amounts of cytokines) or the sleep-wake system (by sleep deprivation) affects the other system and will be accompanied by symptoms of chronic fatigue (Moldofsky, 1993). Interestingly, a study of the chronic fatigue and arthralgia syndrome that commonly follows infection with the tick-borne spirochete causing Lyme disease reveals sleep

features similar to those of other chronic inflammatory diseases (Bujak *et al.*, 1996).

HUMORAL REGULATION OF SLEEP — THE INVOLVEMENT OF IMMUNE SYSTEM PRODUCTS

While our discussion above has focused on microbial products and inflammatory mediators in sleep regulation, we would be remiss if we failed to emphasize that sleep is ultimately regulated by both neural and humoral mechanisms that interact and are inseparable. Neural mechanisms of sleep regulation have been extensively reviewed elsewhere (Steriade and McCarley, 1990); here we will focus on humoral mechanisms.

The involvement of specific neurotransmitters in sleep regulation is often included within the concept of humoral regulation of sleep. Almost all well-characterized neurotransmitters have been implicated in one or more aspects of sleep-wake regulation. In this section we will focus on neuromodulator involvement in sleep regulation, specifically IL1β, TNFα, and GHRH in physiological NREMS regulation, and prolactin (PRL) and vasoactive intestinal peptide (VIP) in REMS regulation, because for these substances there is extensive evidence for their involvement in physiological sleep regulation. In the section below on central targets in the brain, we will present evidence for the concept that IL1, TNF, and other somnogenic growth factors such as NGF induce sleep via nuclear factor kappa B (NFκB)-dependent mechanisms; several events downstream from NFκB activation, such as cyclooxygenase-2 (COX-2) and inducible-nitric oxide synthase (iNOS) induction, also seem to be involved in sleep regulation.

IL1β and TNFα

IL1β or TNFα given centrally or systemically induce prolonged large increases in the amount of time spent in NREMS in every species thus far tested (rats, rabbits, mice, monkeys, sheep, and cats). For example, 3 μg of TNF given intraperitoneally to mice induces about 90 extra min of NREMS during the first 9 h after injection (Fang *et al.*, 1997). The excess NREMS induced by IL1β or TNFα is associated with high-amplitude EEG slow waves (Krueger *et al.*, 1984). Similar supranormal EEG slow waves occur during NREMS after sleep deprivation (Pappenheimer *et al.*, 1975) or during the initial sleep responses to infectious challenge (Toth and Krueger, 1988). These supranormal EEG slow waves are posited to reflect a higher intensity of NREMS (Borbély and Tobler, 1989). Low somnogenic doses of IL1β and TNFα have little effect on REMS, whereas doses that induce large increases in NREMS often reduce duration of REMS. In rats (Lancel *et al.*, 1996; Opp *et al.*, 1991) and cats (Susic and Totic, 1989), higher doses of IL1β inhibit sleep.

The excess NREMS induced by either IL1β or TNFα appears to be physiological in the sense that after low somnogenic doses, sleep architecture remains normal; animals continue to cycle through stages of sleep and wakefulness, although within each cycle there may be more NREMS. After IL1β or TNFα treatment, sleep remains readily reversible; for example, the entry of the experimenter into the room quickly awakens the cytokine-treated

Table XXIV-4.1 Putative sleep-regulatory substances

Sleep-promoting substances	Sleep-inhibitory substances
Interleukin-1β[1,4] (ILβ)	Hypocretin
Interleukin-1α[4] (IL1α)	Corticotropin-releasing hormone[4] (CRH)
Interleukin-2[4] (IL2)	Adrenocorticotropin hormone[4] (ACTH)
Interleukin-6[4] (IL6)	Alpha melanocyte-stimulating hormone[4] (αMSH)
Interleukin-15[4] (IL15)	Interleukin-4[4] (IL4)
Interleukin-18[4] (IL18)	Interleukin-10[4] (IL10)
Epidermal growth factor[4] (EGF)	Interleukin-13[4] (IL13)
Acidic fibroblast growth factor[4] (aFGF)	Transforming growth factor β[4] (TGFβ)
Nerve growth factor[3,4] (NGF)	Somatostatin (SRIH)
Brain-derived neurotropic factor[3] (BDNF)	Insulin-like growth factor-1[4] (IGF-1)
Neurotropin-3 (NT3)	Soluble TNF receptor[4] (STNFR)
Neurotropin-4 (NT4)	Soluble IL1 receptor[4] (sIL1R)
Interferon-α[4] (IFNα)	Interleukin-1-receptor antagonist[4] (IL1RA)
Interferon-γ[4] (IFNγ)	Glucocorticoid[4]
Tumour necrosis factor α[1,4] (TNFα)	Prostaglandin E_2[4] (PGE_2)
Tumour necrosis factor β[4] (TNFβ)	
Oleamide	
Growth hormone-releasing hormone[1,3,4] (GHRH)	
Adenosine[1,3,4]	
Prostaglandin D_2[1,3,4] (PGD_2)	
Nitric oxide[1,3,4] (NO)	
Nuclear factor kappa B[4] (NFκB)	
Uridine	
Vasoactive intestinal peptide[1,2] (VIP)	
Growth hormone[2,4] (GH)	
Prolactin[1,2,4] (PRL)	
Insulin[4]	

[1] Substances for which there is extensive evidence for their involvement in physiological sleep regulation.
[2] Promotes REMS only.
[3] Promotes both NREMS and REMS.
[4] Also involved in host defence.

animals. After such a disturbance, the return to NREMS is generally more rapid after IL1β- or TNFα-treatment than in control animals. After somnogenic doses of either IL1β or TNFα, there are no gross behavioural abnormalities; sleep postures remain normal and no motor dysfunction is evident. Changes in sleep-coupled autonomic functions also remain intact; for example, changes in brain temperature associated with sleep state persist in IL1β- or TNFα-treated animals.

As mentioned earlier, inhibition of either IL1 or TNF reduces spontaneous NREMS, thereby strongly implicating these substances in physiological sleep regulation. Thus, anti-TNF or IL1 antibodies, soluble IL1 or TNF receptors, and the IL1 receptor-antagonist cytokine inhibit spontaneous NREMS and the expected NREMS rebound induced by sleep deprivation (Krueger and Majde, 1994). The latter data suggest that IL1 and TNF are also involved in sleep-deprivation-induced excess NREMS. In contrast, inhibition of IL18 (related to IL1) does not affect spontaneous NREMS, although it does attenuate bacterial cell-wall product-induced sleep (Kubota *et al.*, 2001). Other physiological inhibitors of IL1 or TNF also inhibit spontaneous sleep; the list includes IL4 (Kushikata *et al.*, 1998), IL10 (Opp *et al.*, 1995), IL13, TGFβ, PGE_2, α-melanocyte-stimulating hormone, glucocorticoids, and CRH (reviewed by Krueger & Obál, 1997) (Table XXIV-4.1) (Figure XXIV-4.1). Many of these substances form part of a feedback mechanism dampening the proinflammatory cytokine cascade (Figure XXIV-4.1).

There are diurnal variations within the brain of IL1β mRNA (Taishi *et al.*, 1997) and TNF mRNA levels (Bredow *et al.*, 1997), as well as IL1β (Nguyen *et al.*, 1998) and TNFα (Floyd & Krueger, 1997) protein levels. These diurnal variations occur in the hypothalamus (an area involved in sleep regulation) and several other brain areas including the hippocampus and the cerebral cortex. After sleep deprivation, hypothalamic IL1β mRNA levels (Taishi *et al.*, 1998; Mackiewicz *et al.*, 1996) and TNF mRNA levels (Veasey *et al.*, 1997) increase. In contrast, related molecules such as the IL1 receptor accessory protein are not affected by sleep deprivation (Taishi *et al.*, 1998). IL1β also seems to be involved in the excess NREMS associated with excess food intake; rats on a cafeteria diet express increased IL1β mRNA in the hypothalamus during peak food-induced sleep responses (Hansen *et al.*, 1998c). In humans, there is a diurnal rhythm in plasma levels of TNFα, and plasma levels of TNFα correlate with EEG-slow-wave activity (Darko *et al.*, 1995). Furthermore, in humans, plasma levels of TNFα increase after sleep deprivation (Yamusa *et al.*, 1992), and the ability of circulating white blood cells to produce TNFα increases after sleep deprivation (Uthgenannt *et al.*, 1995; Hohogen *et al.*, 1993).

Mutant mice lacking the TNF 55-kDa receptor do not exhibit sleep responses if given TNFα, although they are responsive to IL1β (Fang *et al.*, 1997). In contrast, mutant mice lacking the IL1 type I receptor are unresponsive if given IL1β, but do exhibit robust NREMS responses if given TNFα (Fang *et al.*, 1998). Both strains of mice sleep less than strain controls, although the sleep deficit in the TNF-receptor knockout mice occurs mostly during daylight hours while that in the IL1 type I receptor knockout mice occurs during the night-time. In humans, sleep deprivation induces enhanced levels of the 55-kDa soluble TNF receptor, but not the 75-kDa soluble TNF receptor (Shearer *et al.*, 2001).

Certain clinical conditions associated with excessive sleepiness also seem to involve cytokines; that is, sleep apnoea patients have elevated TNF plasma levels (Entzian *et al.*, 1996; Vgontzas *et al.*, 1997). HIV-AIDS patients have disrupted TNF rhythms (Darko *et al.*, 1995). Treatment of rheumatoid arthritis patients with the TNF 75-kDa soluble receptor alleviates the fatigue associated with the disease (Franklin, 1999). TNFα is elevated in chronic fatigue patients (Moss *et al.*, 1999). Elevated TNF also occurs in pre-eclampsia patients accompanied by excess sleep (Edwards *et al.*, 2000). Postdialysis fatigue is also associated with elevated TNF levels (Dreisbach *et al.*, 1998; Sklar *et al.*, 1998), and cancer patients receiving either TNFα or IL1β report fatigue (e.g., Eskander *et al.*, 1997). Infectious challenge induces a plethora of proinflammatory cytokines and many other substances implicated

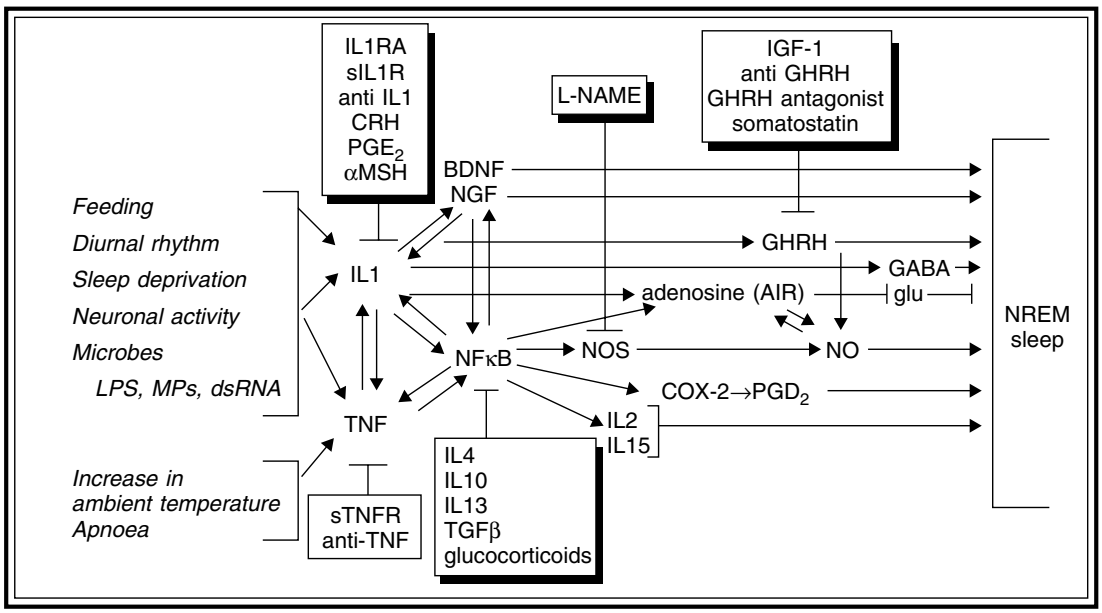

Figure XXIV-4.1 Biochemical cascades are involved in sleep regulation. Substances in boxes inhibit sleep and inhibit the production or actions of the sleep-promoting substances illustrated via feedback mechanisms. Inhibition of one step does not completely block sleep, since parallel sleep-promoting pathways exist. These redundant pathways provide stability to sleep regulation. Our knowledge of the biochemical events involved in sleep regulation is more extensive than that illustrated. For abbreviations, see Table XXIV-4.1

in sleep regulation. These same substances also play a role in host defence (Table XXIV-4.1).

The Somatotrophic Axis

In humans, a major peak in growth hormone (GH) release occurs during the first period of deep, slow-wave sleep (Takahashi *et al.*, 1968). Furthermore, abnormal GH secretory patterns are associated with sleep disorders (e.g., Aström and Linhölm, 1990). In addition, during extended wakefulness, GH release is suppressed, and when subjects are allowed to sleep, excess GH secretion occurs (e.g., Moldofsky *et al.*, 1988). Nevertheless, dissociation between GH release and sleep can occur (Carlson *et al.*, 1972), and it is thus posited that GHRH provides the link between GH release and sleep (Obál *et al.*, 1988; reviewed by Krueger *et al.*, 1999).

GHRH administration induces increases in the amount of time spent in NREMS in several species including rats, rabbits, and humans (reviewed by Krueger and Obál, 1997). For instance, in humans, systemic injection of GHRH (e.g., Steiger *et al.*, 1992) and a GHRH-containing nasal spray (Perras *et al.*, 1989) enhance NREMS. The GHRH-induced NREMS is characterized by supranormal EEG slow waves and, thus, is thought to be of greater intensity. GHRH can also induce increases in REMS (Obál *et al.*, 1988). However, in hypophysectomized animals, GHRH induces only NREMS (Obál *et al.*, 1996), and the REMS-promoting actions of GHRH are thought to be the result of pituitary GH release. The sleep induced by GHRH appears normal in the sense that it is easily reversible if animals are disturbed, and no abnormal behaviours are evident.

Inhibition of GHRH — for example, by using an anti-GHRH antibody or a GHRH peptide antagonist — inhibits spontaneous NREMS and sleep rebound after sleep loss (e.g., Zhang *et al.*, 1999). Transgenic mice that overexpress GH in the brain have less NREMS, but not REMS; these mice have less GHRH and more somatostatin (SRIH) in the brain (Zhang *et al.*, 1996). Furthermore, dwarf rats and lit/lit mice, which underexpress GHRH receptors in the hypothalamus, also have reduced NREMS and REMS (Obál *et al.*, 2001; Alt *et al.*, 2001). Inhibition of GHRH by antibodies also attenuates IL1β-induced excess NREMS, thus suggesting that IL1β elicits its effects on sleep, in part, via GHRH (reviewed by Krueger *et al.*, 1999).

Within the hypothalamus, GHRH-containing neurons are found in the arcuate nucleus and around the ventral medial nucleus. The former project to the median eminence and are probably involved in GH release. The ventromedial GHRHergic neurons, including those in the paraventricular nucleus, project to both the median eminence and to the basal forebrain. The preoptic area — basal forebrain — is involved in NREMS regulation; for example, damage of this area is associated with insomnia (von Economo, 1930), and rapid electrical stimulation of this area induces NREMS. This area also contains GHRH receptors. Microinjection of GHRH into the anterior hypothalamus induces excess NREMS, whereas injection of the GHRH peptide antagonist into the same area inhibits NREMS and attenuates sleep rebound after sleep loss (Zhang *et al.*, 1999). There is a diurnal rhythm of GHRH mRNA within the hypothalamus, but not other areas of brain; the highest levels occur during the onset of daylight hours, which is the peak sleep period in rats (Bredow *et al.*, 1996). After sleep deprivation, there also is an increase in GHRH mRNA levels in the hypothalamus (Zhang *et al.*, 1998). These changes in GHRH mRNA are found only in the extra-arcuate GHRHergic neurons (Toppila *et al.*, 1997). The GHRH content of the hypothalamus also has a diurnal rhythm, with the highest values at the beginning of the dark period, and decreased amounts associated with sleep loss (Gardi *et al.*, 1998), suggesting that GHRH release is associated with higher sleep propensity.

Other members of the somatotropic axis also influence sleep and GHRH secretion. SRIH inhibits GHRH and GH release, and it inhibits NREMS, presumably via its effects of GHRH. In contrast, SRIH stimulates REMS despite the fact that it inhibits GH release (Beranek *et al.*, 1997). GH by itself stimulates REMS (reviewed by Krueger and Obál, 1997), and the promotion of REMS by GHRH in thought to be mediated via release of pituitary GH. Furthermore, microinjection of GHRH into the basal forebrain induces NREMS, but not REMS. GH may, via its metabolic actions, have a NREMS-promoting activity; sleep is reduced in rats treated with anti-GH antibodies (Obál *et al.*, 1997a). In contrast, GH stimulates insulin-like growth factor-1 (IGF-1); IGF-1 has a brief inhibitory action on both REMS and NREMS (Obál *et al.*, 1998).

The role of the somatotrophic axis in sleep responses elicited by infectious agents remains relatively uninvestigated. However, GH release is increased during infection, and is induced by cytokines such as IL1 and TNF. GH also has many direct actions on immunocytes, and the effects of IL1 on sleep involve, in part, GHRH. Finally, preliminary data from our laboratory indicate that lit/lit mice that lack functional GHRH receptors sleep less after being challenged with influenza virus; normal mice sleep much more (Alt *et al.*, 2001). Collectively, such data suggest a role for the somatotropic axis hormones in sleep regulation in health as well as in disease.

Prolactin

REMS is enhanced in response to systemic administration of PRL in hypophysectomized pontine cats (Jouvet *et al.*, 1986). Since this initial anecdotal report, several additional lines of evidence have implicated PRL in the regulation of REMS (reviewed by Roky *et al.*, 1995). The major findings are as follows:

1. Administration of exogenous PRL stimulates REMS in cats, rabbits, and rats.
2. PRL-induced increases in REMS develop slowly, over 2–3 h, and are then maintained for several hours.
3. PRL-induced changes in sleep are restricted to REMS; that is, NREMS is not altered after bolus injection of PRL.
4. In rats, PRL enhances REMS only during the light period.
5. In contrast, REMS is suppressed during the light period and is enhanced at night in PRL-deficient rats (Valatx *et al.*, 1990).
6. Rats made chronically hyperprolactinaemic, by grafting pituitaries under the kidney capsule, have increases in REMS during the light period of the day (Obál *et al.*, 1997b).

Interestingly, small enhancements in NREMS were also observed in these animals. REMS and NREMS are also enhanced in hyperprolactinaemic pseudopregnant rats (Zhang, 1995). Slight increases in NREMS might be attributed to a GH-like effect of chronically increased PRL.

The modulation of REMS is a central action of PRL. Thus, intracerebral injection of PRL or anti-PRL antibodies stimulates or inhibits REMS, respectively (Roky *et al.*, 1995). Brain PRL may originate from two sources: it is produced by hypothalamic neurons, and PRL is also released by the anterior pituitary, and circulating PRL is transported into the brain via a specific receptor-mediated transport mechanism residing in the choroid plexus (Walsh *et al.*, 1987). The REMS-promoting activity of blood-borne PRL is suggested by several observations. REMS is enhanced after systemically injected PRL (Jouvet *et al.*, 1986; Obál *et al.*, 1989), excess PRL released from pituitary grafts (Obál *et al.*, 1989), or stimulation of endogenous PRL secretion from the pituitary (Obál *et al.*, 1994). Furthermore, ether stress induces increases in plasma levels of PRL and REMS; the latter increases do not occur if rats are hypophysectomized or if they are treated with anti-PRL antibodies before being exposed to the ether stressor (Bodosi *et al.*,

2000). Nevertheless, only small decreases in REMS occur when basal, non-stimulated blood PRL is immunoneutralized (Obál *et al.*, 1992). Increases in plasma PRL stimulate REMS, but, at normal concentrations, circulating PRL has only a slight effect on REMS regulation. The impact of increased blood PRL on REMS is, in part, attributed to a stimulation of the expression of PRL receptors in the choroid plexus because PRL enhances its own transport into the brain. It is likely that intracerebral PRL modulates REMS under physiological conditions whereas pituitary PRL provides additional stimulating influence when PRL secretion is high, as in stress. Furthermore, intracerebroventricular injections of VIP and PACAP promote REMS (Obál *et al.*, 1989; Fang *et al.*, 1995b) and elicit expression of PRL mRNA in the hypothalamus (Bredow *et al.*, 1994). Anti-PRL antibodies block VIP-induced REMS response. In conclusion, the observation that PRL is probably involved in modulating REMS and is also involved in host-defence provides another link between sleep and host-defence mechanisms.

CENTRAL TARGETS IN THE BRAIN: NFκB AND NO SYNTHASES

The biochemical regulation of NREMS is undoubtedly complex, involving many biochemical cascades operating in several cell types within the brain. Several of the sleep-regulatory substances (Figure XXIV-4.1) are either upregulated in response to NFκB activation or themselves induce NFκB activation. For instance, several sleep-promoting substances activate NFκB; the list includes IL1, TNF, NGF, interferon-α, epidermal growth factor, acidic fibroblast growth factor, insulin, and insulin-like growth factor (reviewed by Krueger and Majde, 1994; Krueger *et al.*, 1999). Furthermore, NFκB is involved in the expression of IL2, cyclooxygenase-2, inducible NOS (reviewed by Eizirik *et al.*, 1996), IL1, TNF (reviewed by Ballou *et al.*, 1996), NGF, and the adenosine A_1 receptor (Nie *et al.*, 1998), all of which are part of the biochemical network involved in sleep regulation (Figure XXIV-4.1). Other substances, such as IL4, IL10 (e.g., Clarke *et al.*, 1998), and glucocorticoids (see Barnes, 1997), directly or indirectly inhibit NFκB activation, and they inhibit sleep (Krueger *et al.*, 1999). Furthermore, sleep deprivation promotes NFκB activation in murine cerebral cortex, and cortical NFκB activation has a diurnal rhythm, with higher levels of activation occurring during daylight hours (the sleep period in mice) than during the dark period (Chen *et al.*, 1999). Thus, the activation of NFκB correlates with high sleep propensity. Furthermore, a NFκB cell-permeable inhibitor peptide, given centrally, inhibits spontaneous NREMS and REMS, and attenuates IL1β-enhanced NREMS (Kubota *et al.*, 2000). Finally, NFκB is involved in the production of several other transcription factors that could also be involved in sleep regulation, such as c-fos (Shiromani *et al.*, 1998).

NO also seems to function as an endogenous sleep-promoting substance. NO is produced by three distinct NO synthases (NOSs), all of which are found in the brain. NOS inhibitors injected systemically or intracerebroventricularly (i.c.v.) suppress REMS and NREMS in rats and rabbits (reviewed by Kápas *et al.*, 1993). Conversely, systemically or i.c.v. administered, the NO donors *S*-nitrosyl-*N*-acetylpenicillamine (SNAP) and 3-morpholinosydnonimine (SIN-1) mimic the effects of sleep deprivation, in that each induced prolonged increases in the duration and intensity of NREMS in rats after a 7–9-h delay (Kapás *et al.*, 1996). Furthermore, NREMS responses after sleep deprivation are diminished in rats given a NOS inhibitor prior to deprivation (Riberio *et al.*, 2000). Inducible NOS (iNOS or NOS-2) is stimulated by proinflammatory cytokines and is dependent on NFκB activation, making this isoform an attractive candidate for sleep regulation.

While the specific signalling mechanisms involved in sleep responses to NO stimulation remain incompletely understood, one effect probably involves modulation of cholinergic signalling within pontine nuclei linked to sleep-wake regulation. Thus, decreased acetylcholine release occurs in the pontine reticular formation (PRF) of cats injected into the PRF with NOS inhibitors (Leonard and Lydic, 1995; 1997), and is accompanied by decreased REMS. Injection of the pedunculopontine tegmental nucleus (PPT) with NOS inhibitors likewise affects sleep, with reduced REMS and NREMS observed in cats (Datta *et al.*, 1997) and rabbits (Williams *et al.*, 1997). Conversely, increases in REMS and NREMS occur after PPT injection of the NO precursor L-arginine in rats (Hars, 1999), or the NO donor SNAP (*S*-nitroso-*N*-acetylpenicillamine) in cats (Leonard and Lydic, 1997). Thus, manipulation of NO levels in this neuronal circuit appears to influence sleep and waking states through modulation of the cholinergic neurotransmission involved in ascending reticular activation.

NO may also affect sleep through interaction with other sleep-regulatory pathways. For instance, NO production is induced by a number of other sleep-regulatory substances, including IL1, GHRH, adenosine (Rosenberg *et al.*, 2000), and TNFα (reviewed by Krueger and Majde, 1994). The somnogenic effects of IL1 signalling may be exerted, in part, by its induction of NO, as enhanced sleep in rabbits after i.c.v. IL1 injection is abolished if the rabbits are given a NOS inhibitor (Kapás *et al.*, 1994).

It is hypothesized (L. Kapás, personal communication) that opposing influences of NO on circadian and homeostatic sleep-regulatory mechanisms are responsible for sleep-wake regulation. In the suprachiasmatic nucleus (SCN) of rats, NO sensitivity is highest during the dark, behaviourally active period. NO production in the SCN is enhanced by retinohypothalamic glutamate release, and functions to promote arousal, possibly via a cGMP-dependent enhancement of neurotransmission. Conversely, NO promotes sleep within the brain structures involved in homeostatic sleep regulation. Within these sites, NO sensitivity does not exhibit circadian variation. Rather, NO production progressively increases in a neuronal use-dependent manner, such that its tonic release may influence multiple potential effectors, which collectively may increase sleep propensity. NO is elevated in mouse influenza-infected lungs (Akaike *et al.*, 1996), but NOS activity in the brain has not been examined in influenza. However, mice lacking inducible NOS do not have as large a NREMS response after influenza viral challenge (Chen *et al.*, unpublished).

SLEEP DEPRIVATION AND IMMUNE CONSEQUENCES

Rats deprived of sleep for 2–3 weeks die (Rechtschaffen *et al.*, 1983). The probable cause of death is septicaemia; the bacteria cultured from the blood are primarily facultative anaerobes indigenous to the host (Everson, 1993). Whether death or septicaemia occurs in other species after sleep deprivation has not been determined. In any case, the results with rats suggest that loss of sleep leads to host-defence breakdown. Consistent with this notion are the more recent findings that after just a few days of sleep deprivation viable bacteria can be cultured from organs of filtration such as mesenteric lymph nodes (Everson & Toth, 1997; Landis *et al.*, 1997), and the number of bacteria in the intestine increases (Everson, 1993; Bergmann *et al.*, 1996b). The mechanisms responsible for these effects remain unknown, although, as described below, several immune system measures are altered by sleep deprivation. Furthermore, these sleep-linked changes in bacteria could be related to a normal endosymbiotic relationship between bacteria and the host. Rats treated with antibiotics (neomycin and metronidazole) have reduced NREMS but normal REMS (Brown *et al.*, 1990), thereby suggesting that bacterial products could affect everyday sleep (reviewed by Krueger and Majde, 1994), as discussed above in the section on indigenous microbial flora.

In contrast to long-term sleep deprivation, short-term sleep deprivation does not result in death and, under some circumstances, may even enhance host-defence mechanisms. For example, in one study, rats deprived of sleep had smaller tumours than corresponding control animals (Bergmann *et al.*, 1996a). Other studies suggest that short-term sleep deprivation has little effect on infection. In human studies of sleep deprivation, there has been a failure to demonstrate an increased incidence of infection. However, most of these studies involve healthy young volunteers in unchallenging environmental conditions. In fact, if studies were designed to increase the probability of infection, they probably would not be approved. Consistent with these human studies is a report that sleep deprivation of rabbits failed to exacerbate *E. coli*-induced clinical illness (Toth *et al.*, 1995). Nevertheless, there is a wealth of data indicating that short-term sleep deprivation is associated with changes in immune system parameters.

Several laboratories have measured natural killer cell (NK) activity in conjunction with sleep and sleep loss. In several of these studies, circulating NK activity decreased after sleep deprivation (Moldofsky *et al.*, 1989; Irwin *et al.*, 1994, 1996). In other studies, circulating NK activity increased after sleep deprivation (Born *et al.*, 1997; Dinges *et al.*, 1994). Although there is a reduction of NK activity in depressed insomniac patients (Irwin *et al.*, 1992), in normal individuals NK activity may decrease during sleep (Moldofsky *et al.*, 1989). In summary, it seems likely that sleep or sleep loss may affect NK activity, but the magnitude and direction of such effects is sensitive to specific experimental conditions and the subject population.

Sleep deprivation affects several other facets of the immune system, including antigen uptake (Casey *et al.*, 1974), lymphocyte DNA synthesis (Palmblad *et al.*, 1979), phagocytosis (Palmbald *et al.*, 1976), mitogen responses (Moldofsky *et al.*, 1989), circulating immune complexes (Isenberg *et al.*, 1981), circulating IgG levels (Renegar *et al.*, 1998), secondary antibody responses (Brown *et al.*, 1989), and a variety of lymphocyte subsets (Dinges *et al.*, 1994). Sleep deprivation is also associated with changes in cytokines. Sleep loss is associated with an enhanced ability of lymphocytes to produce interferon (Palmblad *et al.*, 1976), increased white blood cell and monocyte TNF production (Yamasu *et al.*, 1992; Uthgenannt *et al.*, 1995), increased production of IL1β and IFNα by cultures of whole blood (Hohagen *et al.*, 1993), and increased plasma IL1 activity in humans and rats (Moldofsky *et al.*, 1989; Opp & Krueger, 1994). In normal people, and in people with sleep disorders, plasma levels of cytokines are related to the sleep-wake cycle or sleep disturbance. For example, IL1 plasma levels peak at the onset of NREMS (Moldofsky *et al.*, 1986), and TNF levels vary with EEG-slow-wave amplitude (Darko *et al.*, 1995). Patients with obstructive sleep apnoea syndrome have altered plasma TNF (Entzian *et al.*, 1996; Vgontzus *et al.*, 1997). Patients with psychoses who have reduced sleep have enhanced IL1β plasma levels (Appelberg *et al.*, 1997).

Collectively, the data cited above strongly suggest that sleep and sleep loss affect immune function. Nevertheless, few studies have directly measured the effect of sleep on host outcome. Study results often leave one uninformed as to whether the effects of sleep or sleep loss is adverse or beneficial to the host. Despite such limitations, it does appear that sleep influences immune function. Furthermore, currently, it appears that short-term sleep loss may enhance host defences, whereas long-term sleep loss is devastating.

RECUPERATIVE PROPERTIES OF SLEEP

There is no direct evidence that sleep per se aids in recuperation from infectious diseases or inflammation, primarily because of the difficulty of isolating sleep as an independent variable. Thus, during manipulations of sleep, such as sleep deprivation many physiological parameters vary. For example, sleep deprivation, is associated with changes in hormonal and cytokine production, body temperature, food intake, metabolic rate, etc. However, there are some data consistent with the notion that sleep is beneficial during infectious disease. After microbial challenge, rabbits that had robust NREMS responses within the first 12 h had a higher probability of survival than animals that failed to exhibit NREMS responses (Toth *et al.*, 1993). Although this evidence is correlative in nature, it suggests that perhaps our grandmothers' folk wisdom of the curative and preventative properties of sleep may, in fact, be correct. In any event, it is likely that physicians will continue to prescribe bed rest and sleep because this is often just what the patient wants to do.

Psychophysiology of Sleep Disorders

R.T. Pivik

INTRODUCTION

Understanding the disordered presupposes a fundamental knowledge of the normal reference state or behaviour. It should come as no surprise, therefore, that our understanding of the psychophysiology of sleep disorders is limited, given that our knowledge of the characteristics and processes associated with normal sleep physiology and related variations in cognition can, in many respects, be considered elementary. Until relatively recent times, the development of knowledge about sleep was restricted by conceptual limitations and behavioural barriers. The emphasis on wakefulness as the state during which the most important behavioural and cognitive accomplishments occurred diminished the importance of sleep as a behaviour worthy of or even requiring investigation. This attitude was reflected in the view of the waking state as 'the sole portion of ... existence that "counts" in any way, sleep appearing as "time out" from the game of living' (Kleitman, 1963: p. 3) — an attitude reinforced by the behavioural inertness characteristic of the sleeping organism. Still, the influence of sleep on waking behaviour is undeniable and evident both in its timing and duration. The occurrence of sleep can be considered to be subject to limited volitional control since it is possible to remain awake for long periods of time or to select convenient times and environments for sleeping. However, at times the pressure for sleep is irresistible and sleep will occur despite the known likelihood of potentially deadly consequences, as while driving an automobile. The amount of sleep obtained has also been shown to be important for normal waking activities. The adverse effects of reduced sleep on alertness and performance are well documented (Monk, 1991; Gillberg and Äkerstedt, 1994), and, in the extreme, the long-term absence of sleep may lead to death (Horne, 1988; Everson, 1995; Bentivoglio and Grassi-Zucconi, 1997). From these observations, two important inferences can be drawn: 1) sleep is not simply a passive state during which physical activities are suspended; and 2) sleep processes interact with those occurring during waking in complementary and synergistic ways to maintain and extend life. Until the mid-20th century, insight into the nature of this codependence was prevented by the inability to obtain information regarding ongoing processes from the sleeping organism. Technologic developments during the past half-century have largely removed obstacles to these efforts. Notable among these developments has been the ability to conduct recordings of central nervous system and related autonomic and peripheral nervous system activities over the extended time periods that sleep typically occurs. More recently, these measures have been supplemented with assessments of state-related variations in brain metabolism using imaging procedures.

The interest in applying these technologic tools to chart variations in sleep physiology across the night was accompanied by an equally intense curiosity regarding what these measures might reveal about the occurrence of mental activity during sleep. The long-standing belief that experiences of mental activity continue during sleep in the form of dreams suggested that sleep was not a mental void. Furthermore, since these mental experiences occur during times of sustained disengagement from the environment, the nature of psychophysiological relationships under these circumstances could be different than those present during wakefulness. The advent of the new methods brought the study of these relationships within the range of effective experimental control. Investigations using these new procedures revolutionized the study of sleep, and the findings from this research have forced a redefinition of concepts regarding physiological and psychological activities and events that can be considered normal.

Although it is apparently the natural order that the states of sleep and wakefulness remain separate, their codependence renders them inseparable and interactive. Some aspects of these state interactions are fixed, and others more variable. Since the existence of higher mammals can be considered a closed system generally dichotomized into states of sleep and wakefulness (although conditions exist which do not clearly fall into either of these categories, such as coma and anaesthetic states), interactions based on state duration are constrained and essentially hydraulic in nature — that is, increases in time spent in one state are at the expense of time spent in the other.

It can be assumed that an important determinant of state duration is the time needed to satisfy functional requirements. Consequently, an important source of sleep-wakefulness interactions derives from the manner in which within-state behaviours (or processes) affect, or are reflective of, the realization of these requirements. Broad examples of such variations would include the nature of waking activity (e.g., resting vs. vigorous physical activity) or sleep quality (e.g., quiescent vs. disturbed). Such variations have both immediate within-state effects as well as longer-term, between-state consequences.

The relative inaccessibility of sleep processes to systematic study delayed the recognition of these interactions and consequences as significant determinants of behaviour. This delayed acknowledgement was evident in the absence of sleep-related variables among factors considered contributory to mental disorders in the initial publications of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) in 1917 and 1952 (DSM-I). The publication of DSM-I occurred near the time that rapid-eye-movement (REM) sleep was discovered (Aserinsky and Kleitman, 1953) — a revelation that effectively launched the new era of sleep research. Fifteen years later (1968), DSM-II appeared, and for the first time sleep disorders were included (referenced under 'Special Symptoms'). By 1979, an understanding of sleep had developed to the point that a 'Diagnostic Classification of Sleep and Arousal Disorders' could be published. Beginning with the publication of DSM-III one year later, the involvement of sleep disorders in the determination of mental status has been consistently and more fully represented.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

As background for a consideration of the associations between disordered sleep and mental processes, a brief overview of fundamental observations that have been made regarding normative sleep physiology and sleep-associated cognition will be provided.

SLEEP PHYSIOLOGY: DESCRIPTIVE ASPECTS

As previously mentioned, the technology that provided the window through which investigators could view sleep processes in progress was the ability to conduct long-term recordings of electrophysiological activities. Although this technology was available and being used to describe sleep-related variations in electroencephalographic (EEG) activities in the 1930s (Loomis *et al.*, 1937, 1938), it would be another 15 years before the discoveries that brought renewed attention to the study of sleep would begin to be made. These discoveries consisted of reports of recurring episodes of physiological activation during sleep that were related to the occurrence of dreaming (Aserinsky and Kleitman, 1953, 1955; Dement, 1955; Dement and Kleitman, 1957a, 1957b; Dement and Wolpert, 1958a, 1958b). Subsequent research has provided a detailed map of the physiological and psychological dimensions of sleep.

The work begun by Loomis *et al.* (1937, 1938) in describing sequential brain potential patterns during sleep has been expanded to include the additional physiological descriptors (measures of autonomic and muscle activities), and stages of sleep have been defined and their variations charted across the night (Dement and Kleitman, 1957a; Rechtschaffen and Kales, 1968). Examples of physiological variations characteristic of sleep-wakefulness and within sleep-stage differentiations are presented in Figures XXIV-5.1 and XXIV-5.2. Sleep-stage determinations in these figures are based on the standardized criteria for the

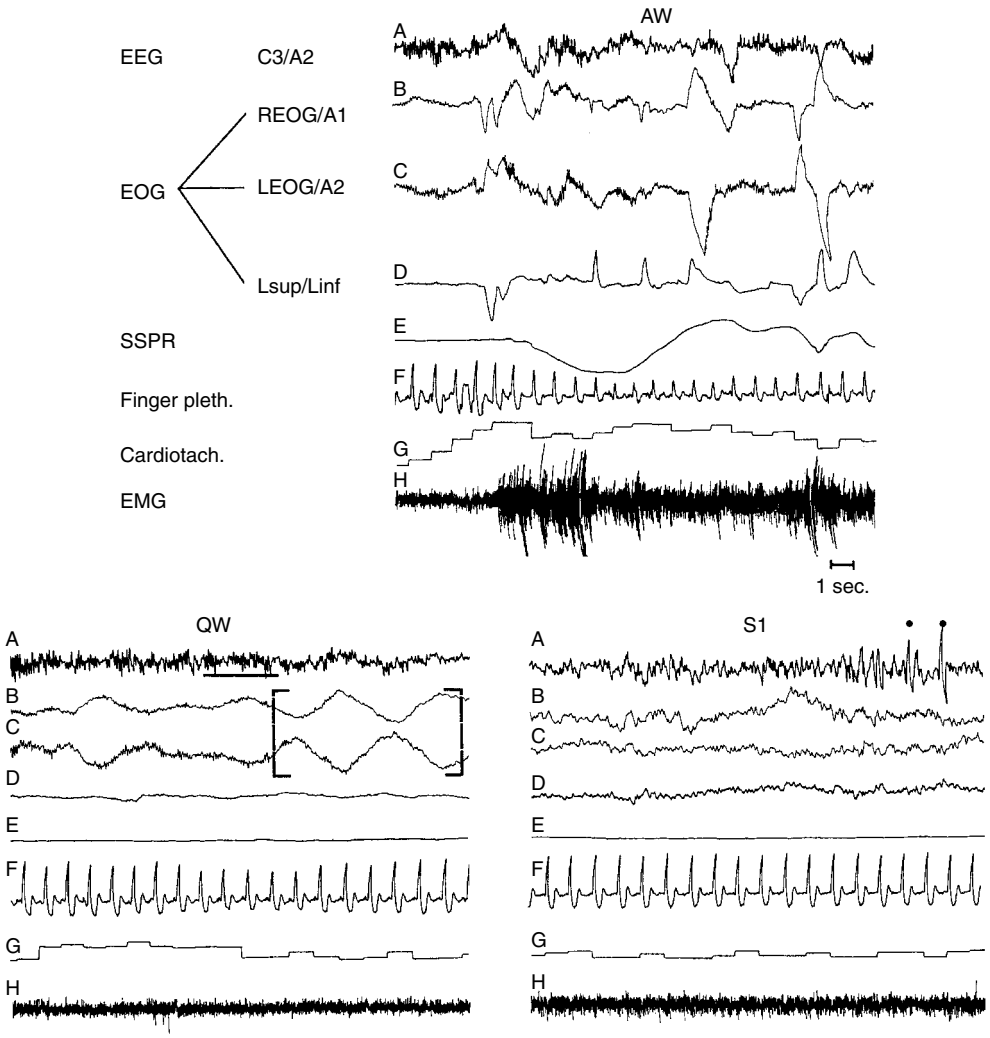

Figure XXIV-5.1 Polygraphic tracings of physiological measures associated with sleep-wakefulness state variations. Eight channels of activity (A–H) are depicted during active and quiet wakefulness (AW and QW, respectively) and the first stage of sleep (NREM stage 1, or S1). The recorded variables include the electroencephalogram (EEG; C3/A2, channel A), the electro-oculogram (EOG; horizontal [right and left outer canthi] and vertical [placements superior and inferior to right eye orbit], channels B, C, and D, respectively), autonomic activity (spontaneous skin potential response [SSPR], channel E), finger plethysmogram (channel F), cardiotachometer recordings (channel G), and the facial (orbicularis oris) electromyogram (EMG; channel H). In these examples, the passive decrease in EMG activity which commonly occurs at sleep onset (S1) does not become evident until slow-wave sleep (Figure XXIV-5.2, S3 and S4). Electrophysiological features of note are alpha activity (underscored, channel A) and slow, rolling eye movements (channels B and C) preceding sleep onset in QW, and vertex sharp waves in stage 1 (see dots, channel A). See text for discussion of sleep-stage definitions and electrophysiologic composition (Reproduced from Pivik, 2000, by permission of Cambridge University Press)

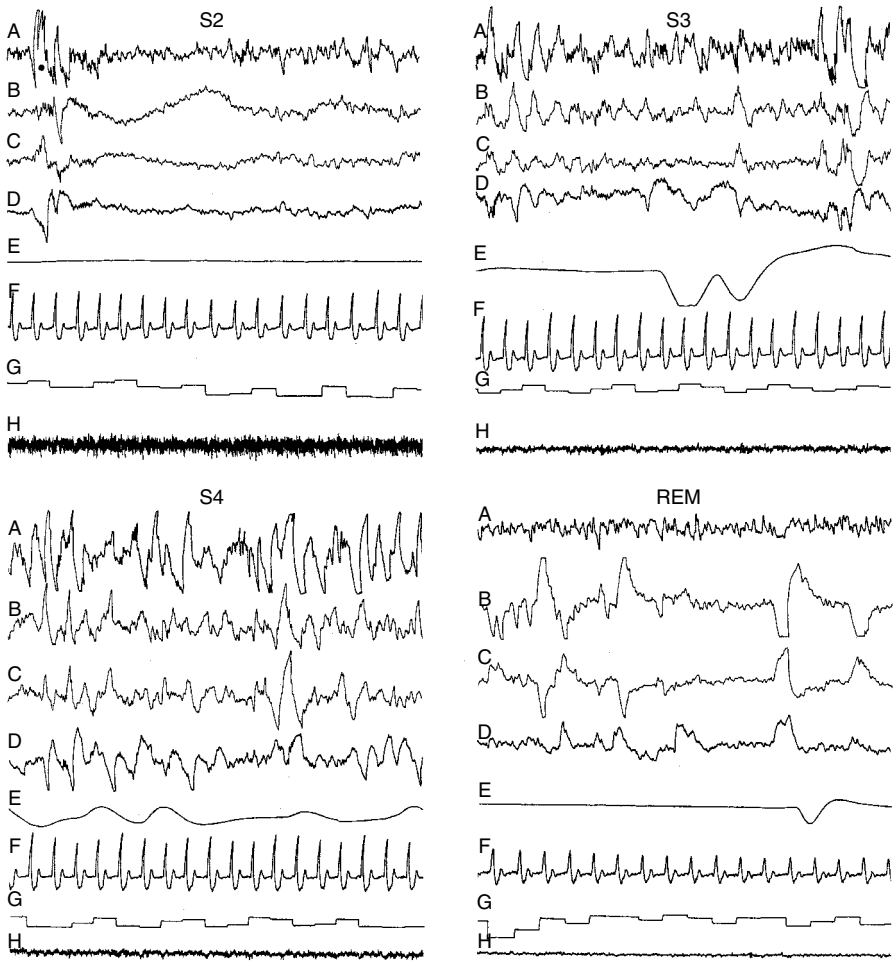

Figure XXIV-5.2 Polygraphic tracings of physiological measures associated with variations in sleep stages (NREM stages 2–4 [S2–S4] and REM). For explanation of channels A–H, see Figure XXIV-5.1. Of note is the occurrence of stage 2 K-complexes (see dot, channel A). See text for discussion of sleep stage definitions and electrophysiological composition (Reproduced from Pivik, 2000, by permission of Cambridge University Press)

sleep-stage analysis of adult human sleep published by Rechtschaffen and Kales (1968). These figures include the basic measures required for sleep evaluation (EEG, EOG, and EMG; channels A, B, C, and H), as well as optional measures, such as recordings of vertical eye movements (channel D) and autonomic activity (channels E, F, and G). In these illustrations, wakefulness (AW and W) is associated with a low-voltage, mixed-frequency EEG, blinking, rapid eye movements, and variations in the levels of tonic facial EMG activity.

As accurately described by Davis *et al.* (1938), 8–12 Hz alpha activity is diminished during the transition from wakefulness to sleep. This is accompanied by a slowing of EEG activity, an increase in 4–7 Hz theta activity, the sporadic occurrence of vertex sharp waves, and the appearance of slow horizontal eye movements, while facial muscle tonus may decrease relative to levels present during relaxed wakefulness (see Figure XXIV-5.1, S1). Stage 2 is defined by the intermittent occurrence of K-complexes and 12–14 Hz spindle activity against a background of relatively low amplitude, mixed-frequency EEG activity (Figure XXIV-5.2). Relative to stage 2, during stages 3 and 4 (slow-wave sleep) there are increasing amounts of delta activity (0.5–4 Hz) present in each scoring epoch. Stage 3 epochs must contain 20–50%, and stage 4 epochs more than 50%, of this activity (Figure XXIV-5.2). Collectively, stages 1–4 are referred to as non-REM (NREM) sleep. REM sleep is defined by a relatively low-voltage, mixed-frequency EEG, the absence of K-complexes or spindles, the sporadic occurrence of eye movements, and reduced levels of submental and facial EEG activity (Figure XXIV-5.2). Other distinctive EEG features which may be present during REM sleep are bursts of theta activity (sawtooth waves) preceding clusters of eye movements (Berger *et al.*, 1962), and alpha activity which is 1–2 Hz slower than subjects' waking alpha frequency (Johnson *et al.*, 1967).

Associated with these sleep stages are other variations in physiologic measures which, although not integral to stage determination, serve to reinforce and validate stage differentiation. Prominent among these are the presence of generalized physiologic activation during REM sleep, including increases in the rate and irregularity of respiratory (Snyder *et al.*, 1964; Aserinsky, 1965) and cardiovascular (Snyder *et al.*, 1963, 1964; Pivik *et al.*, 1996) activities, and increased density of eye movements as a function of time both within individual REM periods and within REM periods across the night (Aserinsky, 1969, 1971). Electrodermal activity in REM sleep is reduced and more similar in form to responses of this system during wakefulness (Broughton *et al.*, 1965; Hauri and Van de Castle, 1973b). These REM-associated variations occur against a background of centrally mediated inhibition of facial and submental musculature and spinal monosynaptic reflexes (Jouvet and Michel, 1959; Berger, 1961; Hodes and Dement, 1964; Jacobson *et al.*,

1964; Pompeiano, 1966, 1967). Other notable physiologic variations that occur in association with REM sleep include increases in body movements and K-complexes just prior to REM periods (Dement and Kleitman, 1957a; Pivik and Dement, 1968, Halasz *et al.*, 1977) and reduced numbers of K-complexes and increased spindle activity in the few minutes following REM periods (Pivik and Dement, 1968; Azumi *et al.*, 1975).

With the exception of unusual levels of autonomic, hormonal, and motor activation present during slow-wave sleep, physiological activation during most NREM sleep is unremarkable. During stage 4, for example, dramatic increases in electrodermal activity are common (Broughton *et al.*, 1965; Johnson and Lubin, 1966) (Figure XXIV-5.2). Electrodermal activation of this intensity would normally indicate enhanced arousal, yet the arousal threshold during stage 4 is higher than that of all other sleep stages (Goodenough *et al.*, 1965; Bonnet and Moore, 1982; Lammers and Badia, 1991; Busby *et al.*, 1994). An explanation consistent with these data attributes this overactivity to the release of subcortical control areas involved in the production of these responses from inhibition by higher centres, and not to a condition of enhanced physiological arousal (Johnson and Lubin, 1966; Johnson, 1973). During slow-wave sleep, approximately 80% of the total daily secretion of growth hormone is released (Takahashi *et al.*, 1968; Sassin *et al.*, 1969; Born *et al.*, 1988). It is also during this time that a variety of arousal disorders (termed parasomnias), characterized by varying degrees of motor and autonomic activity, occurs (Roffwarg, 1979). More detailed considerations of the nosology, description, and treatment of these and other sleep-related disorders are available (*International Classification of Sleep Disorders Diagnostic and Coding Manual* [*ICSD*, 1990] or *Principles and Practice of Sleep Medicine* [Kryger *et al.*, 2000]).

The nature and organization of the physiologic variations described above differ distinctly from those present during wakefulness, and these differences can be summarized as follows:

1. The presence of waveforms unique to sleep — for example, endogenously determined K-complexes, 12 to 14 Hz spindle activity, vertex sharp waves, and frontal sawtooth waves.
2. The prevalence and concentration of activities — for example, the enhancement of slower EEG frequencies (delta and theta), and the concentration of these and other activities, such as eye movements or galvanic skin responses (GSRs), at specific times of the night. With respect to EEG activity, computerized analyses have shown that in only rare instances is the EEG composed of a single frequency; even in the desynchronized low-voltage EEG of wakefulness in normal individuals, there is a small but nonetheless real component of delta activity present (Lubin *et al.*, 1969; Hoffman *et al.*, 1979). The shift away from the higher frequencies associated with arousal during wakefulness and the concentration on slower activities are what make sleep unique.
3. The predictable constellations of physiological patterns that occur — for example, concentrations of delta activity are associated with high GSR activation during slow-wave sleep, and indices of cortical, ocular-motor, and autonomic arousal are associated with sustained muscular inhibition during REM sleep (Pivik, 1986: p. 384).

In the course of studying the global patterns of state change during sleep another fundamental observation was made, that is, that sleep-stage pattern variations across the night were largely predictable from night to night, indicating the existence of the sleep cycle (Dement and Kleitman, 1957a) (Figure XXIV-5.3). Sleep profiles such as those illustrated in Figure XXIV-5.3 are useful for representing general sleep characteristics, such as latencies, cyclicity, stage distribution, and relative amounts of sleep disturbance. These graphs underscore the concentration of stage 4 in the first third of the night and REM sleep in the last third (Williams

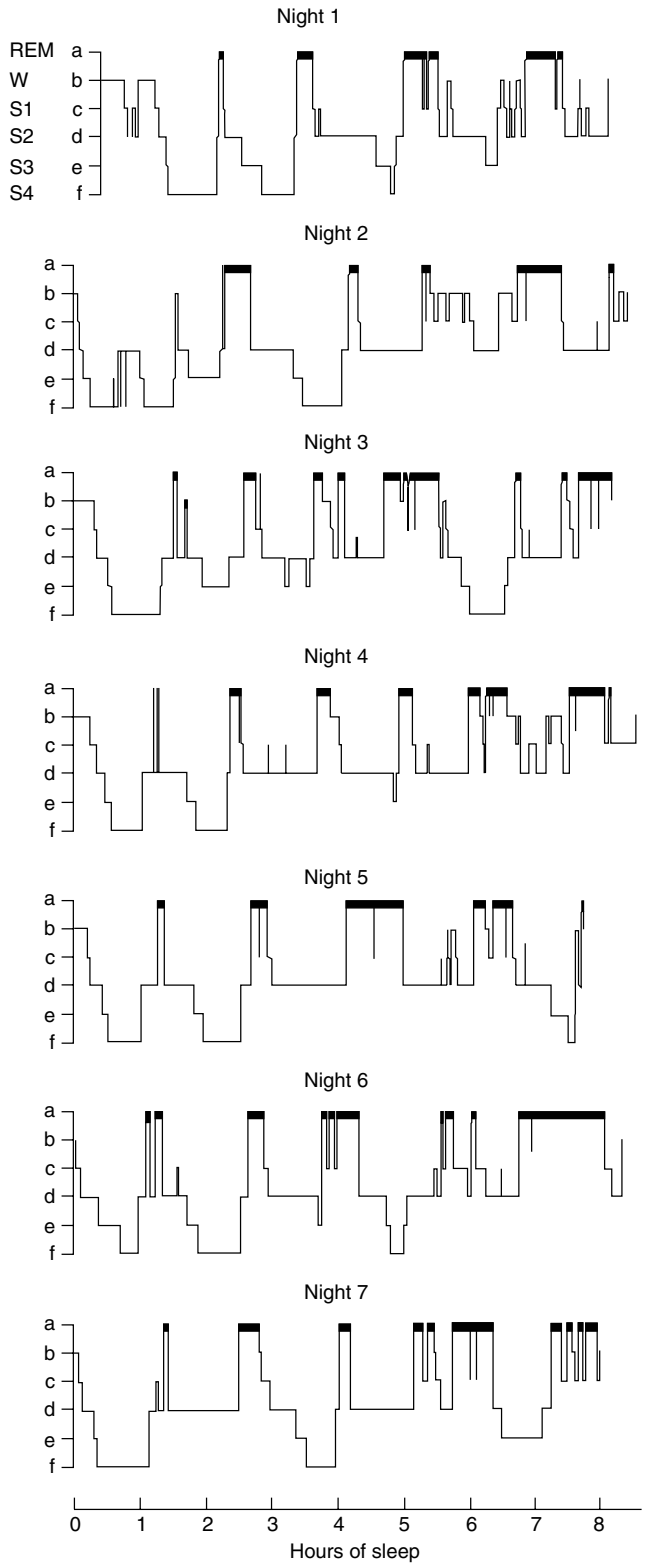

Figure XXIV-5.3 Sleep profiles depicting variations in sleep stages (ordinate) as a function of time asleep (abscissa). These profiles, based on seven consecutive nights of baseline sleep in a young adult, illustrate the stability of sleep patterns across nights, the presence of patterned oscillations between REM (darkened rectangles) and NREM sleep (i.e., sleep cycle), and the decrease in stage 4 and increase in REM sleep as a function of sleep time within a given night (Reproduced from Pivik, 2000, by permission of Cambridge University Press)

et al., 1964, 1966) — observations consistent with the exponential decrease in delta activity across the night as determined from computerized analyses of EEG sleep data (Feinberg *et al.*, 1978; 1980). Figure XXIV-5.3 also illustrates the relative difficulty in initiating REM mechanisms early in the night, as indicated by the latency to REM sleep (normally about 90 min) and the general brevity of REM periods that may occur during the first 2 h of sleep (Dement and Kleitman, 1957a; Berger and Oswald, 1962; Roffwarg *et al.*, 1966).

SLEEP COGNITION: DESCRIPTIVE ASPECTS

The discovery that dreaming is associated with a physiological state that recurs predictably across each night and which normally accounts for one quarter of each night of sleep in the adult, forced a reconsideration of beliefs that dreams occur only sporadically and under special conditions. It is not surprising, therefore, that the initial wave of psychophysiological studies of sleep following the discovery of REM sleep was significantly influenced by the belief that REM sleep provides an objective measure of dreaming, and that dreaming occurs only during these periods. These studies commonly reported high recall following arousals from REM sleep (approximately 80%) and a relative mental void in NREM sleep (less than 10% recall). There were also reports of subjects who typically failed to recall dreams even from REM sleep (Goodenough *et al.*, 1959; Goodenough, 1978). However, reports of mental activity following arousals from NREM sleep (Goodenough *et al.*, 1959) persisted. By 1967, there were nine such studies reporting NREM recall values of 23–74% (reviewed in Foulkes, 1967). The apparent discrepancy between the early and later studies regarding the presence of mental activity during NREM sleep can be attributed in part to differences in what investigators accepted as a dream report. The early studies did not provide a definition of what was required for an acceptable dream report, but relied rather on an intuitive and implicit understanding of the nature of the dream. Nevertheless, these studies provided an important insight into the nature of the dreaming process by indicating that in most individuals this process was most evident during REM sleep.

However, a systematic and effective evaluation of mental activity during sleep requires an operational definition of what would be accepted as a dream, and the suggested definitions have been wide-ranging. For example, Berger (1967: p. 16) defined the dream as a 'verbal report describing an occurrence involving multisensory images and sensations, frequently of a bizarre and unreal nature and involving the narrator himself', whereas Foulkes (1978: p. 3) extended this definition to include simply 'thinking'. The acceptance of more fragmentary and less perceptual reports as valid data revealed the presence of a much more extensive mental life during sleep; thus, reports of greater than 50% recall from NREM sleep arousals were not uncommon (Goodenough *et al.*, 1959; Foulkes, 1962; Pivik and Foulkes, 1968; Molinari and Foulkes, 1969; Zimmerman, 1970; Herman *et al.*, 1978). There were, however, qualitative distinctions between REM and NREM reports (Rechtschaffen *et al.*, 1963; Foulkes and Rechtschaffen, 1964; Pivik, 1971; Antrobus, 1983), and these may be characterized as follows:

> Reports obtained in periods of REM activity showed more organismic involvement in affective, visual and muscular dimensions and were more highly elaborated than non-REMP reports. REMP reports showed less correspondence to the waking life of the subjects than did reports from spindle and delta sleep. The relatively frequent occurrence of thinking and memory processes in spindle and delta sleep was an especially striking result (Foulkes, 1962: pp. 24–25).

Although REM reports were generally more complex, vivid, and bizarre, and NREM reports more mundane and less 'dream-like', NREM reports characterized as dreaming can be as common (Goodenough *et al.*, 1965) or more common (Foulkes, 1960, 1962; Rechtschaffen *et al.*, 1963; Bosinelli *et al.*, 1968; Pivik and Foulkes, 1968; Zimmerman, 1968; Pivik, 1971) than NREM thinking reports. However, with one exception, REM and NREM rep ts can be reliably distinguished (Monroe *et al.*, 1965; Bosinelli *et al.*, 1968). The exception relates to mentation elicited following arousals during sleep onset. Sleep onset mentation is similar to REM sleep on variables such as incidence, hallucinatory dramatic quality, and report length (Foulkes and Vogel, 1965; Foulkes *et al.*, 1966; Vogel *et al.*, 1966; Vogel, 1978), as well as perceptual and emotional qualities (Vogel *et al.*, 1972). The finding that dream-like mental activity is not restricted to REM sleep forced a rethinking of concepts such as those equating REM sleep deprivation with dream deprivation (Dement, 1960) or those suggesting that REM sleep dreams are vital to psychological normality during wakefulness (Sampson, 1965, 1966; Vogel *et al.*, 1975).

Recent research has suggested even more drastic revisions of traditional concepts regarding the occurrence and process of dreaming. For example, the presence of large amounts (40–70% of total sleep time) of REM sleep in infants presented an obvious problem for a strict identification of dreaming with this sleep stage (Roffwarg *et al.*, 1966; Pivik, 1983; Louis *et al.*, 1997). The implausibility of infants experiencing such an extensive dream life was recognized, and it forced the question of when in the course of early development the REM sleep dreaming association did become evident. When systematic studies of dreaming in early childhood were conducted (Foulkes, 1982; Foulkes *et al.*, 1990), they revealed that dreams with the formal properties present in adult dreams did not begin to appear until the age of 8 or 9 years, and required the processes used for imagery during waking. The conclusion was drawn that dreaming 'is a symbolic process with strong cognitive prerequisites and with a developmental history much like that of waking symbolic thought [and waking consciousness]' (Foulkes, 1996: p. 619). This parallelism between cognitive processes during waking and sleep is apparent in reports indicating the absence of visual imagery in the dreams of the congenitally blind or those blinded before the time when dreaming with properties similar to those in adults appears, but the presence of such imagery in the dreams of those blinded after this time (Foulkes, 1993; Kerr, 1993).

One implication of the developmental findings reviewed above is that the association between dreaming and REM sleep is not automatic and inevitable. There is a growing literature suggesting not only that dreaming is not confined to a particular sleep stage, but that it may even occur independently of sleep (Foulkes, 1985; Ellman and Antrobus, 1991; Antrobus and Bertini, 1992; Cavallero and Foulkes, 1993; Cicogna *et al.*, 2000). This more pervasive view of the occurrence of dreaming follows if the conditions and properties associated with this experience are distinguished from the larger state contexts in which they may occur. Accordingly, dreaming may be understood as 'the form assumed by consciousness whenever there is residual but somewhat dissociated cognitive/cerebral activation in the relative absence of direction either from the person's environment or from voluntary self-control' (Foulkes, 1997: p. 3). However, a better understanding of the processes defining or contributing to these experiences will require a more specific knowledge of the various brain areas and systems differentially active during dream and non-dream experiences. The use of functional imaging technology in the study of physiological and cognitive processes during sleep (Hong *et al.*, 1995; Maquet *et al.*, 1996; Braun *et al.*, 1997, 1998) promises to provide the kind of psychophysiological specificity necessary for these determinations. Of course, other processes integral to the study of dream experiences are also subject to state-determined influences and variations; for example, learning and memory are

being examined in this regard (Maquet, 2001; Stickgold *et al.*, 2001; Siegel, 2001).

PSYCHOPHYSIOLOGICAL VARIATIONS ASSOCIATED WITH SLEEP DISORDERS

The preceding overview has shown that the marked behavioural and physiological differences between wakefulness and sleep are generally associated with equally marked differences in associated cognitive activity, with waking cognition being generally more organized, rational, and self-directed and sleep cognition more disorganized, irrational, and under little volitional control. Recognizing these state and condition influences on cognitive activity, and appreciating the nature and extent of differences between normal wakefulness and sleep along these dimensions, we may expect the physiological and behavioural correlates defining disorders of sleep to present with unusual and informative psychophysiological relationships. The full range of such relationships remains to be determined since the identification of sleep disorders is an ongoing process. Some appreciation of the breadth and complexity of these disorders can be gained from the number of listings presented in *The International Classification of Sleep Disorders* (1990) — the only systematic updating of sleep disorders since the first diagnostic classification appeared in 1979. This volume identifies 66 disorders, and includes a section describing another 11 disorders which are under consideration for inclusion pending further investigation. The organizational principles used to classify sleep disorders in this publication were generally adopted in the sleep disorders section of the most recent DSM edition (American Psychiatric Association, 1994). Basically, these disorders are differentiated according to whether they are considered primary sleep disorders, that is, those that are 'presumed to arise from endogenous abnormalities in sleep-wake generating or timing mechanisms' (American Psychiatric Association, 1994: p. 551), or whether they result from other conditions — specifically, mental disorders, medical conditions, or substance abuse. The following review will focus on disorders for which the nature of the psychophysiological relationships has been most thoroughly described, namely, those classified among the primary sleep disorders and those associated with mental disorders.

PRIMARY SLEEP DISORDERS

The primary sleep disorders present a wide array of behavioural conditions reflecting the consequences of disturbed sleep-wake control processes. These conditions have been divided into two general categories, namely, those associated with difficulties involving the amount, quality, or timing of sleep (the dyssomnias), and those characterized by disorders of arousal and state transition (the parasomnias).

Dyssomnias

One of the most prevalent of sleep disturbances — primary insomnia — is classified among the dyssomnias. The incidence of this problem in the general population has not been accurately determined. However, of those referred to sleep disorders clinics with complaints of chronic insomnia, 15–25% receive a diagnosis of primary insomnia, placing this second in prevalence only to diagnoses of insomnia related to mental disorders (46%) (American Psychiatric Association, 1994; Hajak, 2000). Although the term 'insomnia' implies an absence of sleep, the nature of the sleep disturbances associated with this disorder commonly involves difficulties in initiating (increased sleep latency) and maintaining sleep (frequent awakenings, and increases in stage 1 and decreases in stages 3 and 4 sleep). One type of primary insomnia, psychophysiological insomnia, is characterized by a combination of somatized tension, resulting in increased physiological arousal, and learned sleep-preventing associations, that is, a conditioning of bad sleep habits. It is therefore commonly referred to as 'learned' or 'behavioural' insomnia (Hauri, 2000). Studies have indicated a high level of dream recall in these subjects, attributed in part to the high frequency of awakenings (Schredl *et al.*, 1998). The dreams of these individuals have been reported to reflect waking life stressors (Schredl *et al.*, 1998), and reports following arousals from fragmented REM sleep have been characterized as vivid and frightening (Lee *et al.*, 1993), suggesting a complementarity of waking and sleep cognition in terms of concerns and affect.

The abutment of wakefulness and sleep states occurs nowhere as unexpectedly and suddenly as it does in patients with 'narcolepsy'. This term was first used in 1880 to describe the pathological occurrence of repetitive, brief episodes of irresistible sleep (Gélineau, 1880). Since that time, the association of these sleep attacks with a distinct set of clinical features has been recognized, and the latter now comprise the diagnostic criteria for this disorder. These features include: excessive daytime sleepiness; cataplexy — the sudden loss of muscle tone, most frequently precipitated by emotional behaviour such as laughter, surprise, or intense excitement; sleep paralysis — a condition of motor inhibition occurring while falling asleep or on awakening during which the individual is fully conscious and aware but unable to initiate any volitional motor activity; and hallucinations — either hypnogogic (occurring while falling asleep) or hypnopompic (occurring while awakening). This syndrome clearly involves a dysfunction of REM sleep mechanisms, as evidenced by the initiation of sleep by full-blown REM periods, or the presence of elements of REM sleep, that is, motor inhibitory processes and hallucinations, during waking-sleep state transitions (reviewed by Guilleminault and Anagnos, 2000). The abrupt and irresistible imposition of elements of REM sleep on the waking subject not only creates potentially hazardous physical situations for the many individuals afflicted with this disorder (prevalence estimated at ~0.05% [Dement *et al.*, 1972, 1973]), but may also introduce psychological disturbances. The latter have been related to the unusual psychophysiological circumstances brought about by the rapid transition from waking consciousness to that associated with REM sleep physiology — a state transition that is associated with striking changes in state-related brain functional relationships (Hong *et al.*, 1995; Braun *et al.*, 1998).

Normally, the transition from wakefulness to sleep is characterized by a gradual relinquishing of waking conscious control that occurs across a succession of introspective stages. Kleitman (1963) considered Vihvelin's (1948) three-stage description as representative of this process and summarized these stages as follows: '(a) a progressive narrowing of the field of consciousness, as a quantitative change in psychological processes; (b) a stage of "pure" hypnagogic hallucinations, as a qualitative change in psychological processes; and (c) a vacillation between wakefulness and sleep, when hypnagogic hallucinations are confused with dreams' (pp. 79–80). Later studies (Foulkes and Vogel, 1965; Vogel *et al.*, 1966) tied the sleep onset-associated psychological changes to EEG and EOG patterns present during this time. Vogel *et al.* (1966), in summarizing the corresponding psychophysiological changes occurring during this state transition, noted that the progression from relaxed wakefulness (characterized by alpha activity and occasional rapid eye movements), through stage 1 sleep and into stage 2 sleep was associated with a progressive loss of control over the course of mental activity, then a loss of awareness of the environment, and finally a loss of reality orientation and the onset of hallucinations. These progressive variations characteristic of normal wakefulness-sleep transitions are bypassed during narcoleptic sleep attacks. During these episodes, the sudden interruption of waking physiological processes by those of REM sleep can create an unusual and disturbing

mental state in which the hallucinatory processes characteristic of REM sleep cognition are joined with the incorporation of elements from the patient's waking environment. The result is a confusing mental experience in which the boundaries between dreaming and reality are blurred to the extent that patients question their sanity (Broughton, 1982; Zarcone and Fuchs, 1976) or may sincerely believe that a hallucinatory experience, such as sexual abuse, was real (Hays, 1992). Many of the dreams of narcoleptics, whether occurring at sleep onset or during nocturnal sleep, are particularly intense, bizarre, and frightening (Ribstein, 1976; Broughton, 1982; Lee *et al.*, 1993; American Psychiatric Association, 1994; Schredl, 1998). In part, these characteristics may reflect the influence of the fragmentation of REM sleep (Montplaisir *et al.*, 1978) or the effects associated with motor inhibitory processes (that is, sleep paralysis) (Ribstein, 1976; Honda, 1988).

Parasomnias

The disorders represented among the parasomnias include behaviours disruptive of sleep that develop during sleep-wake transitions or during sleep. Many of these are behaviours that are normally confined to wakefulness (walking, talking, or urinating) and others, such as sleep terrors and nightmares, reflect intense physiological or behavioural disturbances peculiar to sleep. These disorders may be sleep-stage specific in their expression (sleepwalking and sleep terrors during slow-wave sleep and nightmares during REM sleep) or may occur throughout sleep (sleep talking and enuresis). Several develop early in life and resolve before adulthood (night terrors, sleepwalking, and enuresis), whereas others typically emerge in adults (REM sleep behaviour disorder).

The study of mental activity associated with various parasomnias has provided informative, and at times surprising, insights into brain–behaviour relationships. For example, consistent with findings indicating reduced recall of sleep mentation after awakenings from slow-wave sleep (Pivik and Foulkes, 1968; Pivik, 1971; Armitage, 1980), the recall of mental experiences associated with parasomnias occurring during slow-wave sleep (sleepwalking and sleep terrors) is limited and fragmentary (see Pivik, 2000a and Nielsen and Zadra, 2000 for reviews). This relative absence of recall seems particularly remarkable when associated with the marked physiological arousal and expressiveness that occurs during sleep terrors. During these episodes, subjects appear to be responding to frightful and horrific thoughts and images. Although an identification of these experiences with nightmares may seem warranted, sleep terrors and nightmares have been shown to be clearly differentiated along several dimensions — including time of occurrence — as well as in terms of behavioural and physiological correlates (Nielsen and Zadra, 2000).

The inability to access mental experiences more directly during sleep behaviours such as sleep terrors and nightmares while these experiences are ongoing frustrates our attempts at better understanding of these behaviours. Verbal communication with the sleeping subject could circumvent this barrier, and the spontaneous occurrence of talking during sleep would appear to provide unique access to the sleeping mind. Furthermore, this access would span both REM and NREM sleep since sleep talking — although most prevalent during slow-wave sleep — may occur in all sleep stages (Arkin, 1991). Unfortunately, it has not been possible to initiate and maintain intelligent dialogue with subjects while they are asleep, and attempts to induce subjects to relate ongoing mentation while remaining asleep via posthypnotic suggestions have not been successful (Arkin *et al.*, 1970; Arkin, 1978). Moreover, when reports have been available to assess the relationship between what was said and what was reported, the degree of concordance is quite variable, and often no discernible association is evident (Arkin, 1991).

The unique physiological and psychological attributes that set REM sleep apart from other waking and sleep states provide the basis for an unusual group of parasomnias associated with this state. These can be quite dramatic and exceptionally intense in their expression, and their consequences may include immediate and extended effects that are both mental and physical in nature. Perhaps the most readily recognized among these disorders is the nightmare. The essential characteristics and ramifications of these frightening dream experiences have been succinctly summarized as follows:

> Nightmares typically occur in a lengthy, elaborate dream sequence that is highly anxiety provoking or terrifying. Dream content most often focuses on imminent physical danger to the individual (e.g., pursuit, attack, injury). In other cases, the perceived danger may be more subtle, involving personal failure or embarrassment. Nightmares that occur after traumatic experiences may replicate the original dangerous or threatening situation, but most nightmares do not recount actual events. On awakening, individuals with this disorder can describe the dream sequence and content in detail. Nightmares usually terminate with an awakening that is associated with a rapid return to full alertness and a lingering sense of fear or anxiety. These factors often lead to difficulty returning to sleep. Nightmare Disorder causes significant subjective distress more often than it causes demonstrable social or occupational impairment. However, if nocturnal awakenings are frequent, or if the individual avoids sleeping because of fear of nightmares, the individual may experience excessive sleepiness, poor concentration, depression, anxiety, or irritability that can disrupt daytime functioning. (American Psychiatric Association, 1994: p. 580).

Nightmares are experienced by individuals of all ages, but because of a variety of factors — such as diverse study populations, varying frequency criteria, and different methods of assessment (retrospective self-report vs. daily logs) — reliable estimates of prevalence have been difficult to determine. It is agreed, however, that although this disorder is most common in children (rates of 10–90%), its presence in the adult population remains substantial (8–25%) (Neilsen and Zadra, 2000; Partinen and Hublin, 2000). Despite the prevalence of this form of dream disturbance, the causal factors for these experiences have not been extensively studied and are not well understood. Psychopathology has been implicated, but the findings have not been consistent (reviewed by Nielsen and Zadra, 2000). Possible insights into the mechanisms underlying the nightmare that might come from physiological studies of sleep have been limited because of the paucity of such investigations. Although the general nature of the findings has not been particularly surprising, that is, increased autonomic activation (Fisher *et al.*, 1970, 1973; Nielsen and Zadra, 1997) and signs of increased EEG arousal (Nielsen *et al.*, in press), the degree of autonomic activation was unexpectedly low given the intensity of the associated psychological experiences. As a possible explanation for these findings, it has been suggested that a dissociative process similar to that thought to be effected by behavioural therapies, such as systematic desensitization and flooding, may be invoked. This process is postulated to reduce the level of sympathetic activation that normally occurs in association with the processing of stressful imagery, effectively desomatizing the imagery (Fisher *et al.*, 1970; Perlis and Nielsen, 1993; Nielsen and Zadra, 2000). Although the persistence of such complex functional relationships across sleep-waking states is uncommon, the uncoupling of physiological activation and cognitive activity during sleep is not. For example, the intense levels of electrodermal activity that regularly occur during stages 3 and 4 sleep (Burch, 1965) apparently have little effect on the recall or qualitative aspects of sleep mentation (Hauri and Rechtschaffen, 1963; Pivik, 1971; Tracy and Tracy, 1974). Similarly, it might be expected that because of the common occurrence during REM sleep of penile erections (Fisher *et al.*, 1965; Karacan *et al.*, 1966) and clitoral engorgement

(Cohen and Shapiro, 1970), many REM reports would contain overt sexual content. However, with the exception of lucid dream reports (LaBerge *et al.*, 1983; Laberge, 1985), REM reports with such features are uncommon (Fisher, 1966; Hall and Van de Castle, 1966). Furthermore, even during lucid dreams containing sexual activity, there is some dissociation between content and associated autonomic activity; that is, expected variations have been observed for respiration and skin conductance measures, but not for heart rate (LaBerge, 1985; 1992).

A final example of psychophysiological relationships present during wakefulness that do not persist unchanged during sleep comes from studies examining the correspondence between the visual aspects of dream imagery and the rapid eye movements of REM sleep. The discovery that dreams are associated with a physiological sleep state during which eye movements are prominent suggested the possibility that these eye movements serve the same function during sleep as they do during wakefulness, that is, to track positional changes in visual targets. Attempts to demonstrate this relationship, which came to be known as the scanning hypothesis (Roffwarg *et al.*, 1962), have been largely unsuccessful (reviewed by Rechtschaffen, 1973; Pivik, 1991). However, more positive relationships between eye movement and dream imagery may exist in lucid dreams (LaBerge, 1992), and imaging procedures have indicated that the same cortical areas are involved in the control of eye movements during waking and REM sleep (Hong *et al.*, 1995).

Two other types of REM-associated parasomnias — sleep paralysis and REM sleep behaviour disorder — can be viewed as cases of dissociative behaviours. This perspective is understandable when it is recognized that the REM state consists of the integration of activities from different sensory and motor systems — as evidenced in the disparate physiological activities that define and characterize this state, that is, EEG activation, motor inhibition, eye movements, and autonomic variability — and that these various systems are selectively susceptible to malfunctions that compromise normal sleep-wake state boundaries and result in abnormal amalgamations of sleep and waking behaviours. Sleep paralysis — the experience of motor inhibition during the process of falling asleep or waking up — is an example of such a malfunction. In this case, inhibitory processes involved in the suppression of motor activity during REM sleep occur independently of REM sleep and in conjunction with conscious awareness (Hishikawa and Shimuzu, 1995; Hishikawa, 1976). Sleep paralysis is a cardinal symptom of narcolepsy, but occurs independently of this disorder at least once in the lifetimes of 25–50% of the general population (Spanos *et al.*, 1995; Fukuda *et al.*, 1998; Cheyne *et al.*, 1999; ICSD, 1990). As a chronic complaint, isolated sleep paralysis is reported to have only a 3–6% prevalence rate (ICSD, 1990).

The psychological experiences accompanying these sleep paralysis episodes are distinguished by elements of fear, terror, and panic, often occurring together with sensory hallucinations (Hishikawa, 1976; Hufford, 1982; Buzzi and Cirignotta, 2000). Although these episodes occur at times of state transition during which hallucinatory experiences are common, it is clear that the latter experiences can, and generally do, occur independently of this motor inhibition (Buzzi and Cirignotta, 2000; Nielsen and Zadra, 2000). Even during sleep, arousals made during times of tonic EMG suppression occurring just prior to, but still independently of, REM sleep onset are not associated with either greater recall frequency or reports that are more dream-like (Larson and Foulkes, 1969; Pivik, 1971). Clearly, however, the awareness of motor inhibitory effects during these transitory states can contribute directly to the concurrent cognitive experiences. This is apparent in the reports of the threatening and terrifying feelings that develop in association with the restrictions in movement and respiration that characterize this condition (Hishikawa, 1976; Hufford, 1982). It has been suggested, however, that mental experiences occurring in association with sleep paralysis may be intensified relative to hypnagogic and hypnopompic experiences not accompanied by this motor inhibition (Hufford, 1982; Takeuchi *et al.*, 1994), but the processes involved have not been specified.

Whereas sleep paralysis represents the displacement of REM-associated motor inhibitory processes from REM sleep to sleep-wake transitional states, REM sleep behaviour disorder (RBD) results from the failure of these inhibitory processes to be maintained during REM sleep. This disorder typically develops later in life (after the age of 50 years) and occurs predominantly in men (Mahowald and Schenck, 2000; Olson *et al.*, 2000). The overall prevalence rate for this disorder has been reported to be 0.5% (Ohayon *et al.*, 1997). Recognized as a distinct clinical disorder in 1986 (Schenck *et al.*, 1986), this disorder was included for the first time in the latest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994).

It is not uncommon for motor inhibition to vary in intensity during REM sleep. Depending on the duration of such reduced inhibition and covariations in other physiological measures, these intervals would normally be interpreted as interruptions in the continuity of REM sleep periods and would be scored as stage 1 sleep or relaxed wakefulness. Certainly, these episodes would go behaviourally unnoticed. What sets these transient reductions in inhibition apart from the loss of inhibition in RBD is the remarkable behaviours that occur at these times in RBD. These outbursts are characterized by excessive motor activity that often results in injuries to individuals or their sleeping partner (Mahowald and Schenck, 2000; Olson *et al.*, 2000). These behaviours are usually related to the associated dream content which commonly deals with themes involving acts of aggression and defence, and may be considered to represent instances where dreams are being acted out. The notion that the motor inhibition during REM sleep may function to prevent the expression of hallucinatory activities finds support in animal studies in which selective subcortical lesions are followed by hallucinatory-like behaviours at times when REM sleep periods are expected to occur (Jouvet and Delorme, 1965; Henley and Morrison, 1974; Morrison *et al.*, 1979). However, the general restriction of these outbursts in RBD to dream behaviour of a violent nature (Nielsen and Zarda, 2000; Mahowald and Schenck, 2000; Olson *et al.*, 2000) and evidence that RBD behaviours can occur despite the presence of full muscle atonia (Schenck *et al.*, 1988; Lapierre and Montplaisir, 1992) precludes the general conclusion that muscle atonia during REM sleep normally functions to prevent the acting out of dreams.

MENTAL DISORDERS

The association between disordered minds and disordered sleep has been recognized for centuries. In the fifth century AD, Caelius Aurelianus noted that 'those who are on the verge of phrenitis or are slipping into the disease show the following signs: continual sleeplessness or troubled sleep with confused dreams' (p. 21). He later advised, 'Then in all cases let the patients sleep — for timely sleep refreshes no less than food' (p. 49) (Drabkin, 1950). Hundreds of years later, in 1892, Hammond, a psychiatrist, stated: 'In my opinion no one cause is so productive of cerebral afflictions as persistent wakefulness' (Hammond, 1892: p. 174). It was to be expected, therefore, that when methods allowing a more extensive and thorough evaluation of sleep became available, they would be applied to the study of sleep in patients with psychiatric disorders. It is of historical interest that the new sleep research became focused almost immediately upon studies of psychiatric patients. To a great extent, this was determined by one of the more remarkable revelations made regarding sleep — namely, the finding

that dreaming was associated with a physiological sleep state that occurred predictably each night. The opening up of this new cognitive territory to systematic study and the influence of earlier speculations linking dreams and psychoses (Wundt, 1897; Jackson, 1958) served to attract many psychiatrists and psychologists to this new discipline, thereby ensuring a cognitive emphasis for these early studies. Among mental disorders, those receiving the greatest attention from sleep researchers have been schizophrenia, and mood and anxiety disorders.

Schizophrenia

The earliest investigations applying the new technology to the study of sleep were conducted in individuals diagnosed with schizophrenia (Dement, 1955; Koresko *et al.*, 1963; Rechtschaffen *et al.*, 1964). Schizophrenia is a very debilitating illness, characterized by a wide range of cognitive and motor symptoms — including the presence of delusions and hallucinations, disorganized speech, and disturbed affect — that occurs in 0.4–2.7% of the population (Benson and Zarcone, 2000). Beliefs of an identity between the processes underlying hallucinations and dreams (Jackson, 1958; Jung, 1960) raised exciting possibilities that studies of sleep in these patients might provide significant insights into the pathophysiology of their disorder. The initial wave of studies failed to find evidence of REM sleep abnormalities (Dement, 1955; Koresko *et al.*, 1963) or indications of REM sleep physiology during waking hallucinations in these patients (Rechtschaffen *et al.*, 1964).

Although subsequent research has identified parameters which distinguish sleep in schizophrenia from that in age-matched comparison groups, such as poor sleep efficiency, shorter latency to the onset of the first REM period (REM latency), and reduced amounts of slow-wave sleep (see Benson and Zarcone, 2000), the research emphasis in this population has been on relationships between REM sleep mechanisms and hallucinations. A significant role in this research has been played by a procedure designed to determine the consequences of the elimination of dreaming upon behaviour. This procedure, originally termed 'dream deprivation', involved awakening subjects at the onset of each REM period and was based on the premise that if REM periods were prevented from occurring, dreaming could not take place. The initial studies applied this technique to non-schizophrenic subjects, and the results were interpreted as indicating that dreaming or REM sleep was essential to waking psychological normality (Dement, 1960; Dement and Fisher, 1963; Sampson, 1965, 1966). Not only has subsequent research failed to support this interpretation of those data (Vogel, 1975), but there are indications that for some clinical groups REM deprivation may have beneficial effects on waking symptomatology (Vogel, 1968; Vogel *et al.*, 1975).

Although the psychological sequelae of REM deprivation did not indicate the existence of a simple transfer function between hallucinatory activity during sleep and wakefulness in schizophrenia, there were other consequences of REM deprivation that offered possible explanations of how such interactions might take place. The most prominent of these were increases in the amount of time spent in REM sleep following deprivation (the REM rebound) and an apparent intensification of physiological activity within REM periods, such as increases in phasic events such as brief muscle twitches and eye movements (Dement, 1960; Dement *et al.*, 1966; Dement *et al.*, 1969). Reports indicating reductions in the amount of REM rebound in actively ill schizophrenics compared to those in remission or to normal subjects raised the possibility that REM-associated behaviours were being expressed during, or 'leaking out' into, wakefulness (Azumi *et al.*, 1967; Zarcone *et al.*, 1968; Gillin *et al.*, 1974; Jus *et al.*, 1977). However, these findings were not consistently observed (see Vogel, 1975), and adverse psychological effects of REM deprivation in such subjects have not been observed (Vogel, 1975; Vogel *et al.*, 1975; Hoyt and Singer, 1978; Benson and Zarcone, 2000). Similarly, extensive examination of variations in indices of REM sleep phasic activity during sleep in these patients, as well as investigations into the relationship of these events to sleep cognition in normal subjects, has not demonstrated the hoped-for identity between these events and hallucinatory activity (Pivik, 1986, 2000b; Benson and Zarcone, 2000).

Relative to the research effort that has been expended in investigating the physiology of sleep in schizophrenia, the research devoted to the study of dream content in these patients has been minimal. It would be quite amazing if the mental experiences of these patients during sleep did not reflect their waking psychopathology, and observations made by Dement (1955) in the first study of these patients after the discovery of REM sleep appeared to confirm this expectation. In that study, he noted the unusual presence of inanimate, stationary objects in over half the reports he obtained. A review of reports limited to the characteristics of dream content in schizophrenia that have been verified, that is, have been replicated at least once (Kramer and Roth, 1979), was limited to 22 studies — only 11 of which were conducted in sleep laboratories. From the entire series of studies, the authors characterized the dreams of schizophrenics as 'more hostile, more affective, and containing more evidence of the schizophrenic thought disorder, i.e., unrealistic, bizarre, and so on, than those of non-schizophrenics' (p. 381). A subsequent review more than two decades later could add only six more papers to this list, and concluded that these 'few additional articles on dreaming in schizophrenia contributed little to our knowledge of the dreams of these patients. The inattention to dreams in schizophrenia may be part of the shift from the psychological to the biological study of psychiatric disorders, and more particularly to the greater interest in mood disorders than in schizophrenia' (Kramer, 2000: p. 513).

Mood Disorders

It is true that mood disorders have been the subject of intense study. This interest appears to be proportional to the prevalence rate of these disorders in the general population and to the prevalence of sleep disturbance among those with this diagnosis. Major depression, the most common of the mood disorders, is present in 5–12% of men and 10–25% of women (Boyd and Weissman, 1981). Furthermore, as indicated in a recent review, this disorder 'has been studied polysomnographically more than any other psychiatric disorder, and the majority of patients have shown objective sleep disturbances' (Benca, 2000, pp. 1142–1143). Common subjective complaints regarding sleep problems in these patients emphasize difficulties in initiating and maintaining sleep and include reports of disturbing dreams (Benca 2000). The sleep disturbances are generally pervasive throughout sleep and are not limited to a specific time of night, sleep stage, or process. They are reflected in measures indicating compromised sleep continuity (increased sleep latency, sleep fragmentation by awakenings, and early morning awakening [Oswald *et al.*, 1963; Zung *et al.*, 1964; Gresham *et al.*, 1965]), decreased slow-wave sleep (Hawkins and Mendels, 1966; Gillin *et al.*, 1979; Kupfer *et al.*, 1985), and REM sleep abnormalities (reduced latency to the first REM period [Kupfer and Foster, 1972; Akiskal *et al.*, 1982; Emslie *et al.*, 1990], prolonged duration of the first REM period [Feinberg *et al.*, 1982; Borbély *et al.*, 1984], and increased eye movement density during REM sleep [Kupfer *et al.*, 1985; Waller *et al.*, 1989]).

The general reliability of these findings, together with insights provided by various treatment procedures that have proven to have antidepressant effects — such as pharmacologic and behavioural

(sleep deprivation) interventions — have led to the development of several hypotheses to account for the observed interactions among depression, sleep, and treatment variables. Prominent among these have been explanations attributing various features of these interactions to the adverse effects of excessive REM sleep in these patients (the REM pressure hypothesis [Vogel, 1975; Vogel *et al.*, 1975]), irregularities in the neurochemical control of REM sleep (the cholinergic-aminergic imbalance hypothesis [Jankowski *et al.*, 1972; McCarley, 1982; Sitaram *et al.*, 1984]), variations in the circadian control of REM sleep, and autonomic and hormonal variables (the phase-advance hypothesis [Wehr and Wirz-Justice, 1981; Wehr *et al.*, 1983]), and a deficiency in homeostatic sleep-inducing processes (the process S deficiency hypothesis [Borbély and Wirz-Justice, 1982]). A recent review that summarized the rationale, strengths, and weaknesses of these hypotheses concluded that, although each offered plausible explanations for some of the recognized sleep and depression relationships, none provided a full accounting for these findings (Benca, 2000).

From his review of 31 studies examining dream characteristics in depressed individuals, Kramer (2000) concluded that 'in depression there is a decrease in the frequency and length of dream reports. The dreams are commonplace, but have content characteristics of interest. There is an increase in death themes in depressed suicidal patients and in bipolar patients before becoming manic.... It is evident that a past focus is not universal in depression, nor indeed was it unique to the depressed state. Affects such as anxiety and hostility are not prominent in their dreams' (p. 514).

Some observations that have been made in these studies are especially relevant to issues of the interactions between cognitive activity during sleep and wakefulness. For example, poorer treatment outcome or greater difficulty in problem resolution has been associated with distinct qualitative dream features, as in disorganized dreams without human characters (Greenberg *et al.*, 1990), masochism (Cartwright and, Wood, 1993), or the extent to which problems are incorporated into the dream (Cartwright, 1991). Such findings not only have prognostic implications, but are consistent with suggestions that dreams in these patients may facilitate waking coping functions (Kramer, 1993).

Anxiety Disorders

That an experience may have profound extended effects on both waking and sleep behaviour is nowhere better exemplified than in subjects with post-traumatic stress disorder. Following the traumatic experience, these subjects typically exhibit a range of anxiety and fear-related symptoms and repeatedly relive or re-experience the event in the form of intrusive images and thoughts during wakefulness, and arousal disturbances and nightmares during sleep (American Psychiatric Association, 1994). In a general population survey, Helzer *et al.* (1987) reported a 1% general prevalence among those surveyed, with an increase to 3.5% if they had been physically attacked or had served in Vietnam.

Sleep-related disturbances are a common, and often the principal, complaint among patients with this disorder (Kramer, 1979; Kramer *et al.*, 1984; Mellman and Davis, 1985). These disturbances are reflected as problems with initiating or maintaining sleep, and sleep disturbance as a result of nightmares occurs in over half of these patients (Horowitz *et al.*, 1980; van der Kolk *et al.*, 1980; Mellman and Davis, 1985). In addition to the obvious REM-related nature of many of these disturbances (Ross *et al.*, 1989), arousals may also develop from NREM sleep (Schlosberg and Benjamin, 1978; van der Kolk *et al.*, 1984; Hefez *et al.*, 1987). However, Uhde (2000) has noted that, despite the absence of a specific REM sleep parameter that was consistently deviant in this disorder, 'it is nevertheless impressive how often *some* type of REM-related abnormality is reported in patients with post-traumatic stress disorder' (p. 1135).

The nature of dreams in patients with this disorder has been a focus of extensive research. Kramer (1979) has argued that disturbing dreams are more defining as characteristics of this disorder than are the other observed sleep disturbances. In summarizing his review of 61 articles that have been published on this topic during the past 34 years, Kramer concluded: 'An adequate characterization of the phenomenology of the disturbing dream remains to be done. It can be confirmed that the dream is disturbing and that the dream events may be outside the realm of current waking experience. The literature does not support the position that the dream is affect-laden or that the dream is easy to recall. It is not known if the dream is any more or less vivid than other dreams' (p. 516).

CONCLUSIONS

This review began with a statement about how understanding what is normal is a prerequisite for understanding what is not. Often, what comes to be recognized as normal borders on the unbelievable. For example, 50 years ago it was inconceivable that hallucinations accompanied by paralysis would occur predictably 4–6 times each night (that is, REM sleep). The nature of some abnormalities also strains the imagination. For example, how could it be that individuals would not only stop breathing while asleep, but also remain unaware this had happened even though it occurred hundreds of time during the night (that is, sleep apnoea)? The cataloguing of normal and abnormal sleep behaviours in this paper, while not exhaustive, does give an indication of the wide range of forms these behaviours may assume, and does provide a glimpse of the complexity of the physiological and psychological processes that accompany these variations.

The generally negative impact of disordered processes on both sleep and waking behaviours — whether emanating primarily from sleep or wakefulness — would seem to force the conclusion that whatever individual or symbiotic functions are served by these states, they are best satisfied with as little between-state interference as possible. However, the dependence of these states on the same biological substrates — although functionally reorganized for some behaviours — makes it inevitable that the barrier separating sleep and wakefulness would be vulnerable to cross-state influences. Usually, these border violations result in minor disturbances in state continuity (sleep fragmentation or decreases in waking attention), but they may also be expressed as dramatic and debilitating full-scale invasions when inappropriate waking behaviours erupt during sleep (as in REM behaviour disorder) or wakefulness is abruptly terminated by the imposition of sleep (as in narcolepsy).

Presumably, if a condition of functional balance were to be achieved between states, it would be reflected in the absence of adverse cross-state influences. However, since achieving such a condition of détente is obviously difficult (but perhaps not impossible; see Carskadon, 1979; Dement and Carskadon, 1982), the biological permission for between-state interactions that exists — even though it may at times work to great behavioural disadvantage — must be considered normal and perhaps functional. It is the task of future research — guided rather than constrained by prevailing theories — to re-examine and revise current concepts and definitions of state and normality, and to provide a more informed understanding of the bases for ordered and disordered behaviours and their relationships to one another.

The Neuropsychology of Sleep Disorders

Raymond Cluydts and Edwin Verstraeten

INTRODUCTION

Within the vast area of the life sciences, sleep and sleep disorders have received increasing attention and interest during recent decades from governmental and health authorities, the news media, and the public in general. A big step forward in the recognition of sleep as an important aspect of our health was based on findings revealing the numerous effects of poor or inadequate sleep on daytime functioning and quality of life in general.

Epidemiological studies show (Partinen and Hublin, 2000) that a vast majority of children, adolescents, adults, and the elderly can expect to suffer for either a short or longer period in their lives, from some kind of sleep problem. In addition to primary insomnia, sleep disturbances associated with breathing problems, muscular contractions, or irritability during the night, as well as narcolepsy and circadian rhythm disorders, have been identified. These conditions have selective effects on either sleep stages, such as REM or non-REM sleep, or sleep onset, the continuity of sleep, or sleep architecture. This disturbance or lack of sleep has been associated with serious safety consequences not only for the patient, but also for the public. Daytime sleepiness has been recognized as a major intervening factor. A sleepy brain cannot function normally and attend to ongoing activities. Many disasters witnessed in recent years, such as train, coach, and car crashes, may be related to ignorance of the limits of human performance after sleep loss.

On the individual level, extensive clinical and neuropsychological investigation of the sleep-disordered patient seems necessary to understand fully the impact of sleep disorders on the patient's daily activities. But, next to the process of diagnosis, the results obtained from this neuropsychological examination can provide the clinician with clues for a comprehensive treatment plan and outcome measures of the therapy.

Neuropsychological Findings in Sleep-Wake Disorders

The fact that sleep loss and poor sleep result in daytime impairment of cognitive functioning is inferred not only from real disasters but also mainly from two types of research and clinical findings. First there are research data on the effects of total and partial sleep deprivation and sleep fragmentation; secondly, we can rely on clinical data gathered from patients suffering from sleep disorders.

Decades of research on sleep deprivation show the consistently detrimental effects of sleep shortage on next-day performance. Good reviews on this topic are numerous (Walsh and Lindblom, 1997; Bonnet, 2000; Pilcher and Hufcutt, 1996; Dinges and Kribbs, 1991). Most of these studies were performed to reveal the function(s) of sleep, providing us with key information about areas in the neurocognitive field that are susceptible to these experimental manipulations. These areas include attentional performance (impact of daytime sleepiness), mood changes, and memory function. But can these experimentally induced sleep disturbance be compared to the sleep disturbance experienced by insomniacs? Probably not. At best, this experimentally induced sleep fragmentation and partial sleep deprivation can be compared to the effects of an acute shift-work or jet-lag situation. We do not consider induced sleep deprivation a condition of 'insomnia' but one of 'sleeplessness'. Furthermore, these experiments are conducted in laboratory situations and are very much affected by selection bias (students as volunteers), experimental set-effects (motivation), and testing and instrumentation effects (learning), so that a generalization of these findings to a sleep disorder population is absolutely unwarranted. Our patients are mostly confronted with non-stimulating situations and lack of motivation in everyday life. Nevertheless, the findings in the three areas described above can give us some clues on promising areas to explore in insomniacs. However, we should certainly not restrict our studies to these areas only. Moreover, the finding that, in many studies on partial sleep deprivation in volunteers, few neurocognitive effects were evidenced cannot be simply generalized to the patient population.

From clinical practice, we know that patients suffering from sleep disorders complain not only of poor sleep, but also of significant impairment of their daytime activities. This includes cognitive impairment such as memory deficits (both encoding and retrieval) and limited attention span; some patients even report specific disorders such as visuoperceptual and spatial orientation difficulties. These clinical observations became the focus of some population-based studies in recent years. These studies confirm that patients with insomnia experience more problems with memory, concentration, thinking, and ability to accomplish tasks (Roth and Ancoli-Israel, 1999). These problems not only affect quality of life scales (Zammit *et al.*, 1999) but are also associated with poor occupational performance and increased absenteeism. Leger (1999) estimated the annual economic impact of insomnia in France to be around US$ 2 billion.

A crucial question is whether these neurocognitive phenomena are just one part of a larger 'neurotic' complex that is 'complaint'-driven, or whether a causal relationship between the sleep complaint and the reported daytime neurocognitive impairment can be demonstrated. In the next sections, we will discuss the data available on neurocognitive functioning in patients suffering from following sleep disorders: primary insomnia, sleep apnoea syndrome, and narcolepsy.

PRIMARY INSOMNIA

Insomnia is usually defined according to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition) (DSM-IV) (American Psychiatric Association, 1994) or the *International Classification of Sleep Disorders* (ICSD) (Revised) (American

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Sleep Disorders Association, 1997). The DSM-IV criteria for 'primary insomnia' are not exactly the same, but overlap largely with the ICSD categories psychophysiological insomnia, sleep stage misperception and idiopathic insomnia. We can assume that in many studies very heterogeneous groups of patients were tested in the morning so that results obtained need to be interpreted with care. Earlier studies performed in the 1970s and 1980s used 'poor sleepers' as research subjects without screening for sleep-related breathing disturbances, movement disorders, or other medical conditions. Therefore, we will discuss only recent studies that used appropriate screening methods. Extensive reviews on the topic can be found in Riedel and Lichstein (2000) and Fulda and Schulz (2001) [see also References]. We will focus on recent studies by Hauri (1997), Edinger *et al.* (1997), and Rosa and Bonnet (2000). Three areas of interest already identified in sleep deprivation studies will be considered: sleepiness, mood, and cognition.

Sleepiness

Three methods for assessing daytime sleepiness are well accepted: the Stanford Sleepiness Scale (SSS) (Hoddes *et al.*, 1973), a 7-point sleepiness rating scale and the Epworth Sleepiness Scale (ESS) (Johns, 1991), which asks patients about the likelihood of falling asleep in eight situations, are subjective measures. The former is a measure of 'state' sleepiness, whereas the latter measures 'trait' aspects of sleepiness.

As an objective test to be performed in a laboratory under strictly standardized conditions, the Multiple Sleep Latency Test (MSLT) (Carkadon *et al.*, 1986) is accepted worldwide as a routine procedure in all sleep disorders centres: it measures sleep onset latency in five 20-min naps with 2-h intervals during the day.

The study of Edinger *et al.*, (1997) is typical: in sharp contrast to the effects of sleep deprivation on daytime napping, insomniacs do not show shortened sleep latencies on the MSLT recorded either in the sleep laboratory or at home. The study of Bonnet and Arand (1995) even found an increased mean sleep onset latency in insomniacs. This finding suggests that insomniacs have difficulty in falling asleep, either at night or during the day; in them, a neurobiological substrate that introduces sleep (sleep drive) seems to be defective and/or the wake drive is too elevated.

Hauri (1997) found higher scores on the SSS in insomniacs, and this finding has been confirmed in other studies that also administered this state measure of sleepiness during the day after a polysomnographic (PSG) recording. Data with the ESS are conflicting and less available, as this scale is much more often used in patient groups presenting with high daytime sleepiness. A floor effect may be the reason for this negative finding in primary insomniacs.

Mood

The Profile of Mood States (POMS) (McNair *et al.*, 1981) is a self-administered rating scale comprising six well-defined dimensions of affect: tension-anxiety, depression, anger, fatigue-inertia, vigour-activity, and confusion-bewilderment. It assesses intensity of a mood state and can cover any time period, but the scale is usually administered in reference to how someone feels at the moment of completion. It is an interesting procedure to be used in insomnia for at least two reasons. Firstly, it allows one to detect an underlying anxiety and/or depressive component. Although primary insomniacs do not fit the criteria for generalized anxiety or major depressive disorder, we see in our consultation primary insomniacs who present with elevated anxiety and depression at non-clinical levels. This was also observed in the study by Bonnet and Arand (1995).

Secondly, as primary insomniacs may confuse feelings of fatigue and sleepiness, the fatigue scale of the POMS can depict this particular state in the absence of sleepiness. Indeed, primary insomniacs complain more about fatigue than sleepiness, as was found by Fichten *et al.* (1995). Maybe we should reconsider more the impact of feelings of fatigue in these patients. In contrast to sleepiness and cognition, there is a clear bidirectionality between mood and sleep. Rosa and Bonnet (2000) found that patients complaining about their sleep had higher tension, depression, anger, and confusion scores on the POMS in comparison to controls, but when the same group of subjects in the study were grouped by poor EEG sleep instead of the complaint itself, the same results were found, indicating dysphoric mood in both situations. Interestingly, the POMS fatigue scale was related only to the poor EEG criterion, and not to the complaint factor.

Cognition

The studies by Hauri (1997) and Edinger *et al.* (1997) will be discussed, as both are methodologically sound and original. Hauri compared not only insomniacs with normal controls, but also the performance of the insomniacs after their best night with that after their poorest of three nights. Edinger compared performance after a PSG recording in the sleep laboratory with performance after an ambulatory recording at the patient's home.

Hauri's study included 26 insomniacs, starting from a screening total of 75. They filled out a sleep diary and the SSS for 1 week, slept in the laboratory on 3–4 occasions, and were tested by a well-validated test battery (Roehrs *et al.*, 1995), tapping many neurocognitive functions. The insomniacs performed worse than matched controls, and, in particular, were more variable on a simple visual reaction time test (initiation time). A complex reaction time test showed less variability but again a slower initiation and total reaction time. Insomniacs also remembered fewer digits in the Wechsler Digit Span Test, but the Digit-Symbol Substitution, Auditory Verbal Learning, and Auditory Vigilance Task were performed at the same level as the healthy controls. Of most importance, no significant differences on the cognitive tasks could be found in comparing performances after the worst and the best nights in the insomniacs.

The Edinger *et al.* (1997) study found no differences in the Simple Reaction Time Test performance between insomniacs and controls, but made an interesting observation in the Continuous Performance Test. This test is a signal detection task in which target letters have to be identified from background letters. Insomniacs recorded in the sleep laboratory performed better at this task than those who were recorded at home; the reverse was found for healthy controls. Moreover, among those who slept at home, the normal sleepers performed better during daytime testing than the insomniacs, whereas after a night in the sleep laboratory the reverse was found. This indicates that after a night in the sleep laboratory, normal sleepers might have been somewhat sleep deprived and perform worse, whereas the worst performance in insomniacs was observed the day after a sleep recording in their usual sleep environment. The sleep laboratory environment may have produced some extra arousal, or there may be a 'reversed first night' effect (Hauri, 1989) in the insomniacs.

In a further study, Rosa and Bonnet (2000) reported that when patients were grouped on the basis of poor EEG nights, a poorer performance on the memory test (number of words recalled) was associated with two nights of poor EEG sleep, but the same phenomenon was observed when the subjects were grouped on the basis of their complaint: subjects with sleep complaints remembered fewer words. All other performance tests (vigilance, motor steadiness, etc.) were not significantly different whatever comparison was made.

Conclusion

It seems that neurocognitive deficits in primary insomniacs are very difficult to demonstrate at this time. Some of problems we encounter in these studies are as follows:

- types of insomnia patients included and characteristics of the insomnia (type, severity, and duration of the sleep problem)
- home versus sleep laboratory PSG recordings
- types of tests/tasks used (real world?)
- effects of age, gender, and education on test performance
- control of confounding variables such as motivation, mood
- robustness of the effect (test-retest).

These issues will be considered in turn.

A selection bias is one possible source of unreliability. The selection criteria in earlier studies were most probably not adequately defined, resulting in very heterogeneous groups of insomnia patients. We can rule out possible medical/psychiatric origins during a screening night, but then we still have different subtypes of primary insomniacs: psychophysiological, idiopathic, and possibly sleep-stage misperception as well. Another possible selection bias is the type of referral. In most studies, patients are solicited by newspaper advertisement, but sometimes they are referred from a sleep disorders centre. In some studies (Rosa and Bonnet, 2000), patients were recruited from both sources. There might have been a tendency towards morbidity in those patients seeking help via a sleep laboratory or their physician. Edinger *et al.* (1997) have posed an interesting question: when studying patients with insomnia, should we study their sleep in the sleep laboratory or at home? Regarding their daytime performance testing, Edinger *et al.* suggest that a sleep laboratory PSG put insomniacs at an advantage and healthy controls at a disadvantage, and that when insomniacs are recorded at home they show the attentional/concentration deficits of which they typically complain. Maybe the daytime performance testing should be administered at home as well to find even more of these daytime complaints, as the trip to the laboratory might induce a certain arousal in these patients.

This brings us to the next point of interest, which is the type of tests used. Some studies use a broad range of clinical psychological tests, mostly multifactorial in nature, whereas other authors prefer tasks developed by cognitive psychologists. Unfortunately, we lack a rationale for the selection of tests or tasks used or a theoretical framework of the neurocognitive functions that are assessed. Given the recent findings on the important role of sleep on memory consolidation (Maquet *et al.*, 2000; Poe *et al.*, 2000), we probably should look in more detail at this phenomenon and at test encoding at night and recall in the morning in these patients. Given the effects of age and gender on sleep, and given the skewed distribution of sleep complaints with respect to these factors (more females and more elderly with complaints), we must not forget that these same factors can also have a tremendous effect on performance testing.

Controlling for confounding factors in these highly complex matters is difficult. Factors such as motivation and mood, which are probably highly influenced by sleep quality, can interfere with daytime performance testing. Therefore, a good definition of the dependent variables and the possible confounders that can be controlled for by analysis of covariance is a necessity. Certainly, simple, univariate analyses lead to simplistic conclusions, given these highly interrelated variables. More studies investigating the robustness of the daytime neurocognitive effects in insomniacs are needed. One good example is the Pilcher *et al.* (1996) study, which shows — albeit in young adults, and not in insomniacs — that there is a stable relationship over time between sleep quality ratings and health, well-being, and daytime sleepiness. Longitudinal studies with insomniacs are rarely found, but therapeutic intervention studies might offer an opportunity here. They obviously include more assessments over time, and if daytime performance outcome measures are included, in addition to mood and other relevant measures, it would be a big step forward if the reversibility of the morbidity at baseline in these patients could be demonstrated.

Patients with primary insomnia do complain about daytime complications comprising the domains of cognition and affect. However, several studies show that it is difficult to demonstrate a clear-cut daytime neurocognitive deficit that is causally related to the sleep problem. Some factors contributing to this have been explained. A subjective sleep complaint itself does not mean a PSG-objectified sleep disturbance *per se*. Only a complaint of 'non-restorative' sleep might be related to an increased number of arousals during sleep.

Thus, there certainly exists a gap in our understanding of primary insomnia, and promising hypotheses have been formulated. Sleep-stage misperception, a disorder in which a complaint of insomnia or excessive sleepiness occurs without objective evidence of sleep disturbance, and psychophysiological insomnia have been related to fast EEG during sleep onset (Perlis *et al.*, 2001). Hyperarousal certainly explains why insomniacs who cannot fall asleep at night have the same difficulty during the daytime multiple sleep latency tests, but hyperarousal itself does not predict poor EEG sleep (Bonnet and Rosa, 2001). In addition to sleep drive, the wake-drive system needs careful consideration in our patients (Bonnet, 1997; Cluydts *et al.*, 2002).

Tension, anxiety, and mild psychopathology in primary insomniacs have repeatedly been demonstrated (Nowell *et al.*, 1997; Buysse *et al.*, 1994; Cluydts *et al.*, 1996), but these phenomena can be the result of years of non-successful searching for help in these patients. Saletu-Zyhlarz *et al.* (1997) showed that generalized anxiety disorder (GAD) patients who complain about poor sleep quality do well in some attention, concentration, and memory tasks, whereas their motor performance decreases, and they related these findings to a state of hypervigilance and hyperarousal. This agrees well with the proposed neurocognitive model of insomnia (Perlis *et al.*, 1999; 2001), which suggests that beta and gamma activity is enhanced during sleep onset in primary insomniacs.

Incorrect beliefs, expectations, and attributes concerning sleep have been identified in insomniacs, and these can be corrected successfully by cognitive-behavioural therapy (Edinger *et al.*, 2001; Morin *et al.*, 1993). Again, are these cognitions the cause or the result of years of suffering? The model of Spielman (1987) might offer some help here, as it describes predisposing, precipitating, and perpetuating factors in the development of insomnia. Within a biopsychosocial perspective, one might consider a 'fragile sleep system' or a hyperaroused nervous system as a predisposing factor that could develop into a sleep complaint in acute stress but could also develop more insidiously. The well-known conditioning processes may then contribute to the perpetuation or exacerbation of the complaint. All these hypotheses need to be further developed and evaluated.

Future research might also redirect our attention to the concept of 'sleep quality' which is so strongly related to daytime well-being and health. A better understanding of the biopsychosocial factors that contribute to the perception of the quality of our sleep might eventually result in the full recognition of the 'non-restorative sleep' syndrome.

SLEEP APNOEA

Obstructive sleep apnoea syndrome (OSAS) is a sleep-related breathing disorder characterized by repetitive episodes of complete cessation of airflow (apnoea) or decreases in airflow (hypopnoea) due to upper airway obstruction. Nocturnal apnoea and hypopnoea result in brief arousals from sleep and are frequently associated with intermittent hypoxaemia. The apnoea-hypopnoea index (AHI)

is defined by the average number of episodes of apnoea plus hypopnoea per hour of sleep. 'Mild', 'moderate', and 'severe' cases of OSAS are defined as AHI of 5–15, 16–30, and >30, respectively (American Academy of Sleep Medicine, 1999). These respiratory disturbances are associated with daytime symptoms, the most important being sleepiness and neuropsychological dysfunctioning. Obstructive sleep apnoea is the most common cause of excessive daytime sleepiness among patients evaluated at sleep disorder centres. The prevalence of this syndrome is about 4% in middle-aged men meeting minimal diagnostic criteria (AHI > 5) (Young *et al.*, 1993), is higher among males than females (Partinen and Telakivi, 1992), and increases in the elderly (Ancoli-Israel *et al.*, 1987).

We begin by discussing excessive daytime sleepiness. Furthermore, the literature on neurocognitive dysfunction is reviewed. This is followed by a discussion of some relevant methodological considerations that are particularly important in hypersomnia research. We also point out pathophysiological mechanisms of the neuropsychological impairments. Next, an overview of sleep apnoea patients' driving performance is provided. Finally, we summarize reported psychosocial symptoms and the effects of treatment in sleep apnoea.

Sleepiness

Excessive daytime sleepiness is the most common complaint in apnoea patients, as evidenced by subjective ratings such as the Stanford Sleepiness Scale (Kribbs *et al.*, 1993; Sforza and Lugaresi, 1995), the POMS (Kribbs *et al.*, 1993), and the ESS (Engleman *et al.*, 1996; Hardinge *et al.*, 1995). Objective measures of sleepiness/alertness also demonstrate clinically significant impairments. The MSLT demonstrates sleep onset latencies in apnoea patients consistently below the normal threshold of 10 min, suggesting mild to moderate sleepiness (Cheshire *et al.*, 1992; Engleman *et al.*, 1994; Kribbs *et al.*, 1993; Lamphere *et al.*, 1989). In severe apnoea patients, the mean sleep onset latency is usually in the pathological range of 5 min or less (Bédard *et al.*, 1991b; Sforza and Lugaresi, 1995). In mild sleep apnoea patients, however, average ESS ratings and average sleep onset latencies on the MSLT are at the high end of the normal range (Engleman *et al.*, 1997; Redline *et al.*, 1997). The Maintenance of Wakefulness Test requires the subject to remain awake while sitting up in bed during four 40-min trials at 2-h intervals throughout the day (Mitler *et al.*, 1982). This procedure provides evidence of significant decreases in sleep onset latency in OSAS patients (Poceta *et al.*, 1992; Sforza and Krieger, 1997). The ability to stay awake may be a more important parameter of daytime performance than the propensity to fall asleep (Roth *et al.*, 1980; Johnson, 1992). The same protocol as in the Maintenance of Wakefulness Test is used in the Oxford Sleep Resistance Test, which is a procedure to evaluate sleepiness from a behavioural perspective by measuring lapses in reaction time responses to a light-emitting diode regularly illuminated for one in every three seconds. This test distinguishes healthy subjects (mean latency to lapsing 39.8 min) from sleep apnoea patients (10.5 min) (Bennett *et al.*, 1997).

In most studies, weak to moderate positive correlations ($r = 0.3–0.5$) are found between severity of sleep apnoea and severity of daytime sleepiness measured by self-report (Johns, 1993; Rosenthal *et al.*, 1997) or by objective assessment (Poceta *et al.*, 1992; Roehrs *et al.*, 1989; Roth *et al.*, 1980). Some studies, though, report no significant correlations between sleep parameters and MSLT scores, thus suggesting hypoxaemia as a major determinant of daytime sleepiness (Bédard *et al.*, 1991a; Cheshire *et al.*, 1992). Notwithstanding this, most findings indicate sleep fragmentation as the primary cause of excessive daytime sleepiness (Day *et al.*, 1999). For example, Colt *et al.* (1991) found that OSAS patients showed similar improvements in daytime sleepiness after two nights of treatment with nasal continuous positive airway pressure, whether or not the researchers induced repetitive nocturnal hypoxaemia. Therefore, they concluded that sleep disruption, rather than hypoxaemia, leads to daytime sleepiness. It should be noted, however, that, in this study, a small sample size was used (seven patients) and that hypoxaemia could be induced for only two nights. Conversely, in a study in which nocturnal oxygen was administered to improve oxygenation without having an effect on sleep fragmentation, no improvement in daytime sleepiness was found (Gold *et al.*, 1986). Moreover, multiple regression research has identified sleep fragmentation as the best predictor of daytime sleepiness in apnoea patients (Roehrs *et al.*, 1989; Verstraeten *et al.*, 1996).

Cognition

Neurocognitive performance reported in the moderate to severe sleep apnoea literature can be subdivided into the areas of attention, executive function, memory and learning, and psychomotor function.

Attention

Sleep apnoea patients typically show vigilance decrements. The so-called Steer Clear, a simulated driving programme, has been used to assess vigilance. It measures simple reaction time performance on a 30-min task that requires the subject to avoid about 780 obstacles presented at varying intervals. Significantly higher obstacle hit rates in severe or older OSAS patients have been demonstrated (Findley *et al.*, 1991; 1995), as well as time-on-task decrements (Findley *et al.*, 1999). However, Ingram *et al.* (1994) found no significant correlation between mild apnoea in community-dwelling older adults and Steer Clear performance. On another laboratory-based Divided Attention Driving Test, 21 severe apnoea patients performed worse than 21 normal controls on all measures, with the largest decrement in tracking error. The performance of half of the patients was worse than any control subject, some even performing worse than alcohol-intoxicated control subjects (George *et al.*, 1996). In addition, community-acquired subjects with mild to moderate sleep-disordered breathing (AHI 10–30) performed worse during the last 2 min on a 10-min visual vigilance test (perceptual sensitivity) than healthy controls (Redline *et al.*, 1997), while severe OSAS patients (mean AHI 65) performed worse on the Continuous Performance Test than chronic obstructive pulmonary disease patients that experience both daytime and nighttime hypoxaemia (Roehrs *et al.*, 1995).

In view of the relationship of working memory to attention (see, e.g., Baddeley, 1992), we discuss working-memory function in this section as far as the 'slave systems' are concerned. The 'visuospatial sketch pad' is assumed to be a slave system capable of holding visuospatial information, while the 'phonological loop' performs a similar function for speech-based information. These systems are coordinated and linked to long-term memory by the 'central executive', being concerned with attentional control rather than storage (see *Executive function* section). It has been shown that moderate to severe apnoea patients exhibit decreased working-memory spans for both verbal (digit span) and visual (Corsi block-tapping) information (Kales *et al.*, 1985; Naëgelé *et al.*, 1995). Severe OSAS patients also performed poorly on the Wechsler Digit-Symbol Substitution (Bédard *et al.*, 1991b), which is a measure of information processing speed, or their AHI was significantly correlated with performance on this test (Cheshire *et al.*, 1992). However, information processing speed in subjects with mild to moderate sleep-disordered breathing did

not differ from controls (AHI < 5) (Kim *et al.*, 1997; Redline *et al.*, 1997).

Executive Function

The concept of 'executive function' refers to a multidimensional construct of (loosely) related higher-order cognitive processes such as planning, cognitive flexibility, response initiation and inhibition, problem solving, goal-directed behaviour, and self-regulation, of which the central executive of working memory is an important subordinate operation. Relatively few controlled studies exist on executive functioning in sleep apnoea. A frequently used neuropsychological task of executive function is the Trail Making Test. In this test, the subject has to connect in proper order 25 circled numbers randomly arranged on a page (part A), and 25 circled numbers and letters by alternating between these numbers and letters (part B). Some authors have found that patients performed worse on the Trail Making Test, part B, assessing cognitive flexibility (Bédard *et al.*, 1991b; Findley *et al.*, 1986), whereas others have not found such deficits (Naëgelé *et al.*, 1995; Greenberg *et al.*, 1987; Kim *et al.*, 1997). As performance on Trail Making, part A, was not included in the former studies, appropriate interpretation may be problematic (see methodological considerations below). Moreover, hypoxaemic patients in the study of Findley *et al.* (1986) showed oxygen desaturation even during the day, thus hampering the evaluation of the specific impact of sleep apnoea. Both moderate to severe (Naëgelé *et al.*, 1995) and mild to moderate (Redline *et al.*, 1997) apnoea patients remembered fewer Wechsler digits backwards, a test which is a measure of the 'central executive' of the working memory. However, Naëgelé *et al.*'s (1995) findings showed that patients also remembered fewer forward digits, while Redline *et al.* (1997) presented no data on forward digits (see methodological considerations below). The latter authors also found no deficits in their mild to moderate OSAS sample in performance on the Trail Making Test, the Wisconsin Card Sorting Test (number of perseverative errors), and a serial digit-subtraction task (Redline *et al.*, 1997). No significant decreases in verbal fluency were found in moderate to severe (Naëgelé *et al.*, 1995) or in mild to moderate OSAS (Kim *et al.*, 1997). In contrast, Bédard *et al.* (1991b) did demonstrate such an impairment. Interestingly, no deficit and no significant association were found between verbal fluency and severity of hypoxaemia in chronic obstructive pulmonary disease patients (Stuss *et al.*, 1997). Regarding planning abilities, apnoeics made more errors on the Wechsler Mazes Test (Bédard *et al.*, 1991b). They also needed a higher number of moves in a three-disc Tower of Toronto (a simplified version of the Tower of Hanoi) experiment, whereas, surprisingly, there was no significant difference between patients and controls on the more difficult four-disc Tower of Toronto (Naëgelé *et al.*, 1995). Furthermore, Naëgelé *et al.* (1995) found that patients needed more time to complete the so-called interference condition of the Stroop Color-Word Test measuring focused attention and inhibition of interfering habitual responses. Unfortunately, no data were provided on the 'easy' test conditions (see methodological considerations below). Scores on a modified Wisconsin Card Sorting Test, another frequently used test of executive function, in 17 moderate to severe OSAS patients, were not impaired as far as the number of categories achieved and total number of errors are concerned. However, these patients made more perseverative errors than the control group matched for age, verbal IQ, and educational level (Naëgelé *et al.*, 1995). When moderate patients (either AHI 10–40 or oxygen saturation level of <85% below 10 min) were compared to severe patients (either AHI > 40 or oxygen saturation level of <85% over 10 min), no significant differences in perseverative errors emerged, a finding which is in agreement with the lack of relationship between severity of hypoxaemia and Wisconsin Card Sorting performance in chronic obstructive pulmonary disease patients (Stuss *et al.* 1997).

Memory and Learning

It has been repeatedly found that moderate to severe apnoea patients show reduced short-term memory of both verbal and visual material (Bédard *et al.*, 1991b; Borak *et al.*, 1996; Kales *et al.*, 1985; Klonoff *et al.*, 1987; Naëgelé *et al.*, 1995) (see also *Attention* section above). In addition, these patients exhibited delayed recall deficits for both verbal and visual information (Bédard *et al.*, 1991b; Naëgelé *et al.*, 1995). In mild to moderate sleep-disordered breathing, however, neither immediate nor delayed verbal recall memory deficits was found (Kim *et al.*, 1997; Redline *et al.*, 1997). Moreover, these patients showed no procedural memory dysfunction, as measured with a 'pursuit rotor' task (Redline *et al.*, 1997).

Psychomotor Function

Manual dexterity was found to be impaired in moderate to severe OSAS patients (Bédard *et al.*, 1991b; Greenberg *et al.*, 1987), but not in mild to moderate patients (Kim *et al.*, 1997). Block *et al.* (1986) also found lowered psychomotor speed in mildly sleep-disordered breathing. Interestingly, a relationship between hypoxaemia and reduced complex perceptual motor and simple motor performance has been repeatedly demonstrated in chronic obstructive pulmonary disease patients (Krop *et al.*, 1973; Grant *et al.*, 1982; Grant *et al.*, 1987). Moreover, these lung patients exhibit a lower finger-tapping speed than OSAS patients (Roehrs *et al.*, 1995).

Before concluding this overview of neurocognitive function, we now return to the available executive function data. In general, it has been claimed that OSAS patients exhibit executive control deficits (see Day *et al.*, 1999; Décary *et al.*, 2000; Engleman and Joffe, 1999, for reviews). It should be noted, however, that research on higher attentional (executive) dysfunction should be guided by sound theoretical neuropsychological models of attention. This is especially important in sleep disorders characterized by excessive daytime sleepiness, since it is well known that sleepiness, as a result of sleep deprivation and/or sleep fragmentation, has significant effects on cognitive function (Bonnet, 2000; Dinges and Kribbs, 1991; Tilley and Brown, 1992), not the least of which is general cognitive slowing. As cognitive slowing underlies the higher executive functions, the effect of this basal slowing in information processing should be controlled for. This can be illustrated using the already mentioned Trail Making Test. Part A of this test is a measure of visual search, psychomotor speed, and visuomotor tracking. Part B, in addition to the same visuomotor activity and visual search processes as in part A, also requires task switching. Because of this additional demand, part B is considered to be a measure of cognitive flexibility. This test is scored in terms of the time in seconds required for part A and part B, respectively. However, it should be kept in mind that performance on part B can never be evaluated without taking into account the performance on task A. In other words, an underlying impaired basic process, such as in part A, can be responsible for a deficit in part B. Overall, this is true for all complex attention tests. Data from other tasks or other task conditions within the same test should always be considered to interpret neuropsychological data appropriately (van Zomeren and Brouwer, 1994). Other typical examples of such tests are the Digit Span Forwards and Backwards (Lehto, 1996) and the Stroop Color-Word Task (Henik, 1996). As the pervasive effects of sleepiness on cognitive function are not fully taken into account in the sleep apnoea literature, the findings of executive deficits should be regarded as tentative.

Aetiological Factors of Cognitive Dysfunction

The pathophysiological mechanisms that cause neurocognitive deficits in sleep apnoea have been argued to be sleep fragmentation and nocturnal hypoxaemia. The relative contribution of these aetiological factors is still a contentious issue (e.g., Verstraeten *et al.*, 1996). The investigation of the specific impact of these causal factors is complicated by the fact that sleep fragmentation is highly correlated with nocturnal respiratory disturbances. In any case, most studies suggest that both sleep fragmentation and nocturnal hypoxaemia contribute to the neurocognitive impairments (see Engleman and Joffe, 1999, for a detailed review). Some researchers have suggested differential effects of alertness impairment and nocturnal hypoxaemia (Bédard *et al.*, 1991b). According to their interpretations, reductions in psychomotor and executive function seem to be related to the extent of hypoxaemia, whereas attention and memory dysfunction appear to be associated with daytime sleepiness. As there is no agreement on this, further research is needed. One strategy to assess the impact of the two hypothesized pathophysiological mechanisms is to examine to what extent treatment leads to improvement in neuropsychological function (see below).

Driving Performance

For an excellent review on the relationship between sleepiness and motor and working accidents, the reader is referred to the December 1995 Supplement of the *Journal of Sleep Research* (Åkerstedt, 1995). It has been repeatedly shown that sleepiness may account for a considerable portion of automobile accidents (e.g., Horne and Reyner, 1995). To investigate the relationship of motor vehicle accidents to sleep-disordered breathing, Young *et al.* (1997) performed a population-based study in which 913 employed adults were involved and objective governmental records of accidents were used. Men with AHI of >5, compared to those without sleep-disordered breathing, were significantly more likely to have at least one accident in 5 years (odds ratios = 3.4 for habitual snorers, 4.2 for AHI 5–15, and 3.4 for AHI of >15). Men and women combined with AHI of >15 were more likely to have multiple motor vehicle accidents in 5 years (odds ratio = 7.3). Laboratory-based driving simulators were employed to assess driving ability in OSAS. For instance, the 20-min Divided Attention Driving Test requires division of attention between tracking and visual search. Severe apnoea patients performed worse than age-matched normal controls in mean tracking error (George *et al.*, 1996). The MSLT and AHI explained less than 25% of the variance in tracking error. Self-reported accident frequency does not appear to be significantly related to the severity of sleep-disordered breathing (Stoohs *et al.*, 1994). These findings indicate the difficulty of identifying individual OSAS patients at increased risk of accidents by PSG or behavioural testing.

Psychosocial Impact

The most frequently, though not always reported, psychological problem in the sleep apnoea literature is depression, as assessed with personality inventories or psychiatric screening questionnaires. It should be noted, however, that depressive symptoms on, for instance, the Zung self-rating depression scale and symptoms of sleep apnoea may overlap (e.g., fatigue, sleep disruption, impaired task performance, indecisiveness, decreased libido, and constipation from inactivity), indicating that such scales have not been adequately validated for use in sleep-disordered patients (Lee, 1990). Therefore, it is recommended in medical disorders to use assessment instruments that exclude many somatic items. For instance, the Freiburger Personality Inventory, a questionnaire measuring 12 personality traits, has only two out of 138 items confounded with daytime sleepiness. Using this inventory, it was found that even severe OSAS patients' average values were within the normal range of all scales (Cassel, 1993). In another interesting study, severe OSAS patients waiting for surgical treatment were compared to patients awaiting coronary artery bypass surgery (Klonoff *et al.*, 1987). Both patient groups showed similar subclinical elevations on the Minnesota Multiphasic Personality Inventory scales of depression, hysteria, and hypochondriasis. Moreover, these elevated levels of emotional distress before surgery in both groups were significantly ameliorated 3 months after successful surgical intervention for the respective diseases. Overall, these findings are in line with the consensus nowadays that the psychological problems of OSAS patients are not unique to sleep apnoea, but are rather a characteristic response to any chronic medical disorder (Roth *et al.*, 1995), and that psychological well-being is normalized after treatment (Engleman *et al.*, 1994; Platon and Sierra, 1992).

Treatment Effects

Nasal continuous positive airway pressure (CPAP) has become the non-surgical treatment of choice for obstructive sleep apnoea. Overall, CPAP treatment has shown, either by self-report (Engleman *et al.*, 1996) or by randomized placebo-controlled crossover design (Engleman *et al.*, 1994), that daytime function improves significantly. CPAP therapy reduces effectively both subjective (Hardinge *et al.*, 1995; Kribbs *et al.*, 1993) and objective daytime sleepiness (Sforza and Lugaresi, 1995; Kribbs *et al.*, 1993; Poceta *et al.*, 1992). Driving performance on a realistic simulator (Haraldsson *et al.*, 1995), on Steer Clear (Engleman *et al.*, 1994), or on the Divided Attention Driving Test (George *et al.*, 1997) recovers significantly after therapy. In addition, research shows that CPAP therapy reverses most neurocognitive deficits (Bédard *et al.*, 1993; Engleman *et al.*, 1994; Naëgelé *et al.*, 1998). However, Naëgelé *et al.* (1998) found no improvements in verbal and visual short-term memory. Furthermore, Bédard *et al.* (1993) demonstrated persistent deficits in planning abilities and manual dexterity after CPAP treatment. As these functions were related to hypoxaemia in their study, these researchers have suggested irreversible anoxic frontal brain damage. However, poor treatment compliance (Berthon-Jones *et al.*, 1996; Hoy *et al.*, 1999; Reeves-Hoche *et al.*, 1994: average duration of use ranging from 3.2 to 4.7 h/night) may explain the residual deficits, all the more so because some daytime somnolence, although greatly improved, persisted compared to healthy controls. Finally, as already noted, enhancements in psychological well-being were consistently found after nasal CPAP therapy (Engleman *et al.*, 1994; Platon and Sierra, 1992).

NARCOLEPSY

The narcoleptic tetrad was well described by Gélineau (1880) in a classic paper: excessive daytime sleepiness with sleep attacks, cataplexy, sleep paralysis, and hypnagogic hallucinations. The onset of adolescence is often the beginning of this neurological condition, which is more prevalent in males than females. Regarding cognitive dysfunction, these patients often complain of memory disturbances (especially encoding). Lhermitte (1930) gave a neuropsychological description of the amnesic phenomena, and Broughton *et al.* (1981), in a series of studies, repeatedly encountered subjective memory complaints in narcoleptics.

More recent studies, such as that of Beusterien *et al.* (1999), with large patient groups ($n = 558$) also found that, in addition to other psychosocial and intrapersonal problems, narcoleptics have difficulty in maintaining concentration and attention, a problem which

can be reversed by appropriate treatment. Brain-imaging studies (Bassetti *et al.*, 1997; Heyde *et al.*, 2001) did not provide evidence of structural anatomical anomalies. As the emphasis in narcolepsy research moved towards the hypocretin/orexin deficiency (Siegel, 1999; Nishino *et al.*, 2000) (hypocretinergic neurons are located in the lateral hypothalamus and are believed to control monoaminergic and cholinergic activity during sleep), interest has rekindled in possible neurocognitive deficits associated with this disorder. Initially, these deficits were thought to be related to a suspected monoaminergic and cholinergic involvement. Can the subjective attention and memory complaints of these patients be objectified by formal neuropsychological testing?

Aguirre *et al.* (1985) compared 10 untreated narcoleptics with matched controls on a battery of verbal and non-verbal memory tests and could not detect a memory deficit. They concluded that it is these patients' drowsiness that induces a subjective memory problem, as the short duration of the tests and the test session itself made it possible for the patients to counteract sleepiness. Henry *et al.* (1988) found a reduced vigilance and diminished memory encoding with longer response latencies in a classic Sternberg task in four of their eight patients when they were not treated. (The Sternberg task is a recognition memory-scanning task in which subjects need to make a reaction time response to indicate whether or not a test digit is a member of a previously memorized list of digits. The reaction time increases with the size of the set to be memorized.) Under treatment, these deficits almost fully recovered. Rogers and Rosenberg (1990) recorded on-task EEG in 30 narcoleptics and 30 healthy controls during the Wechsler Memory Scale and Digit Substitution tests, Rey's Auditory Verbal Learning and Complex Figure test, and the Profile of Mood States. No significant differences on the different measures of attention/concentration or memory tests could be detected. The continuous EEG recordings did show changes in alertness that were not accompanied by poor test performance. In a 'temporal isolation' study in which six untreated narcoleptics were allowed to follow their free-running circadian rhythm for a part of the study (Pollak *et al.*, 1992), only very minor differences in neuropsychological test performance were found. Again, the impairment of an accuracy measure in a serial search task was related to occasional lapses in attention, according to the authors. The only evidence of a very specific perceptual encoding deficit that underlies poor memory and complex reaction time performance comes from Henry *et al.* (1993), who compared 10 unmedicated narcoleptic patients with controls.

It is a common observation that most studies on cognitive processes in narcolepsy include a very small number of patients and use short duration tests that are often too engaging and stimulating. Often a theoretical rationale for the tests selected is missing and, finally, no comparison group comprising other hypersomnia, but non-narcoleptic, patients is introduced in the study design, so that it is difficult to detect narcolepsy-specific cognitive deficits.

Schulz and Wilde-Frenz (1995) used a monotonous task, the Critical Flicker Fusion Test, during a period of 10 h and found that the 10 narcoleptic patients were unable to maintain a steady performance level throughout the experiment. Finally, Hood and Bruck (1996) used an experimental protocol in which narcoleptic patients were tested in a low- and in a high-arousal condition. During the high-arousal condition, narcoleptics performed at the same level as healthy controls in the task under automatic control. On the contrary, complex tasks such as word fluency, semantic reasoning, and the paced auditory serial addition task were highly dependent on fluctuations in arousal.

From the evidence available, it seems correct to conclude that cognitive impairment in narcoleptic patients is a function of the daytime sleepiness they suffer from. These episodes of sleepiness have a temporal character, making it difficult to demonstrate cognitive deficits without an appropriate experimental protocol.

GENERAL CONCLUSION

Summarizing the currently available evidence on the existence of neuropsychological impairment as a consequence of disturbed sleep, we find few hard data on significant daytime cognitive deficits in chronic primary insomnia. Memory and attention problems often occur, but they can also be interpreted as symptoms of a more general malaise in these patients. They worry excessively about their sleep, and the possible consequences of poor sleep, and behavioural treatment seems to be their first choice. Studies on both pharmacological and behavioural interventions should include these cognitive outcome measures to find out whether the above described morbidity can be reversed.

Regarding sleep apnoea syndrome, the size and range of cognitive deficits increase with the severity of sleep-disordered breathing. Most of the community-based studies with only mild sleep-disordered breathing have documented no or only weak relationships between sleep apnoea and neuropsychological function. In contrast, studies using clinic patients have found neuropsychological impairments. These impairments may exist only in patients with more severe sleep-disordered breathing and/or in conjunction with significant daytime sleepiness. Narcoleptic patients do present with specific memory and attention problems, but these seem to be related to the attacks of daytime sleepiness they suffer from.

We have chosen to discuss possible daytime dysfunctions following some selective sleep disorders, thereby inevitably making a selection. Other sleep disorders such as idiopathic hypersomnia, and shift-work and jet-lag-related sleep disturbances are also suspected to result in cognitive deficits, as has been shown by Cho (2001). The mechanisms involved, including prolonged higher cortisol levels affecting sensible brain structures such as the hippocampus, should also be investigated and explored in chronic primary insomnia.

Further research is certainly needed to address the many methodological considerations we discussed in the previous paragraphs. Fine-grained analyses to divide cognitive abilities into their subcomponents in well-defined groups of insomnia, sleep apnoea, idiopathic hypersomnia, and narcoleptic patients are urgently needed.

Sleep Disorders — Functional Neuroanatomy

Pierre Maquet

INTRODUCTION

Sleep is probably the last complex and integrated behaviour of which the functions remain poorly understood. Nevertheless, since the last half of the 20th century, an impressive body of knowledge has been accumulated on sleep in mammals, especially cats and rodents. Much is now known on the mechanisms that maintain wakefulness, non-rapid eye movement (non-REM) sleep and rapid eye movement (REM) sleep, down to cellular and molecular levels.

In parallel, studies on patients and normal human subjects suggest that similar mechanisms generate sleep and sustain wakefulness in humans. However, we are still far from a comprehensive understanding of human sleep and its disorders at the fine-grained level of description reached in animal studies. Therefore, at present, it remains difficult to interpret the human pathology of sleep in terms of the underlying neuronal disturbances. Some exceptions, however, are mentioned in this chapter. For instance, recent breakthrough in molecular biology shed some light on the pathophysiology of narcolepsy in animals and, hopefully, in humans.

Sleep regulation does not involve only the generation of wakefulness and sleep periods. It also includes the interaction of sleep processes with the internal circadian rhythms and the external synchronizers, especially light. These aspects of sleep regulation are also important to consider because of the related human pathology.

This chapter provides an overview on the generation of sleep and wakefulness. It is not meant to review these mechanisms in the greatest detail but to put emphasis on the mechanisms that might be disturbed in sleep disorders. It is divided into two parts: (a) the regulation of circadian cycles and (b) the generation of wakefulness, non-REM sleep and REM sleep.

GENERALITIES ABOUT SLEEP

Sleep is not a homogeneous process. It is composed of two main sleep states: non-REM sleep and REM sleep. These two types of sleep differ in many aspects, such as their circadian distribution, their pattern of cellular activity and their physiological regulation. Non-REM sleep is usually recognized by the appearance of sleep spindles and K-complexes, the hallmarks of the light non-REM sleep (stage 2 sleep). The deepest stage of non-REM sleep, called slow-wave sleep (SWS), is defined by the presence of large-amplitude, low-frequency EEG waves. The power density of these slow waves is maximal at sleep onset and decreases exponentially during the night (Borbely, 1982).

Rapid eye movement sleep, also called paradoxical sleep (PS), is characterized by low amplitude, relatively fast rhythms on EEG recordings, ocular saccades and muscular atonia interspersed by muscular twitches. REM sleep typically occurs by periods of about 20 min, recurring every 90 min. In contrast to non-REM sleep, the duration of REM sleep episodes increases as the night progresses.

REGULATION OF CIRCADIAN RHYTHMS

Sleep/waking cycles, like many other physiological and behavioural parameters, occur with circadian periodicity. In mammals, a large body of data proves that the suprachiasmatic nucleus (SCN) of the hypothalamus is the site which controls these circadian rhythms, especially sleep/wakefulness cycles.

First, in animals, lesions of the SCN abolish the rest/activity rhythmicity and alter sleep/waking patterns (Ibuka and Kawamura, 1975; Mouret *et al.*, 1978). Second, circadian rhythms are reinstated by SCN transplants, the restored rhythms being derived from the donor SCN (Ralph and Lehman, 1991). Third, individual SCN cells maintain for long periods a near 24-h periodicity in their firing rates (Welsh *et al.*, 1995). This observation suggests that the periodicity of the SCN activity does not emerge from local networks but reflects the genuine pacemaker properties of the SCN cells. This hypothesis was confirmed at the molecular level. The circadian rhythms are generated by autoregulatory feedback loops of transcription and translation of a set of clock genes and their gene products (for review, see King and Takahashi, 2000; Wager-Smith and Kay, 2000). Manipulation of these clocks genes can lead to mutant individuals with intrinsic circadian rhythms different than the wild type (King and Takahashi, 2000; Vitaterna *et al.*, 1994).

In addition, the clock of the SCN does not tick only on its own. It is entrained to the night/day cycle by light. Anatomically, SCN is in position both to receive light signal and synchronize several physiological rhythms. The SCN receives light signal from the retina, mainly through the retino-hypothalamic tract (Dai *et al.*, 1998; Morin, 1994). It projects primarily to hypothalamic nuclei and, to a smaller extent, to limbic, thalamic and mesencephalic structures (van Esseveldt *et al.*, 2000). The SCN can influence sleep/waking cycles via the secretion of melatonin, using a specific polysynaptic pathway (paraventricular nucleus, intermedio-lateral column of the spinal cord, superior cervical ganglion, and pineal gland) (see Moore, 1996).

Biological rhythms in humans seem to be generated by similar molecular and cellular mechanisms, which thus have important implications in sleep or circadian disorders. SCN is described in humans and, as in other mammals, it receives fibres from the retina and projects extensively to other hypothalamic nuclei (Dai *et al.*, 1998). The disturbances of biological rhythms in demented patients have been attributed to structural modifications of the SCN (Swaab *et al.*, 1985). As in other mammals, circadian rhythms in humans can be entrained by light (Lewy and Sack, 1996; Shanahan and Czeisler, 2000) and by melatonin (Cagnacci, 1997; Lewy and Sack, 1996). Blind people are known to suffer from sleep disorders due to free-running circadian rhythms (Nakagawa *et al.*, 1992), with a circadian period rather longer than normal subjects (Sack *et al.*, 2000). Melatonin may help these patients to entrain circadian rhythms and improve their condition (Sack *et al.*, 2000). Finally, polymorphisms have been identified in several human clock genes.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

A link was reported between such a polymorphism and human diurnal preferences (Katzenberg *et al.*, 1999). Likewise, probands of a familial advance sleep-phase syndrome have been shown to have an intrinsic circadian rhythm of 23 h (Jones *et al.*, 1999), 1 h less than normal (Czeisler *et al.*, 1999). This trait segregates as an autosomal dominant with high penetrance. These examples provide a clear evidence of the direct effect of genotype on the phenotype of human biological rhythms.

GENERATION OF WAKEFULNESS, NON-REM-SLEEP AND REM SLEEP

The Hypothalamic Control of Sleep and Wakefulness

Wakefulness and sleep are generated continuously, in an ordered succession, through the action of interacting structures of the brainstem and the diencephalon. In particular, the anterior hypothalamus and the posterior hypothalamus play an important role in the generation of sleep and wakefulness, respectively. Two neuronal populations seem critical in this respect, the ventrolateral preoptic nucleus (VLPO) in the anterior hypothalamus and the tuberomammillary nucleus (TMN) in the posterior hypothalamus.

Lesions of the anterior preoptic area of the anterior hypothalamus (POAH) and adjacent basal forebrain (BF) cause prolonged insomnia in mammals (for review, see Szymusiak, 1995; for the most recent study using lesions restricted to the VLPO only, see Lu *et al.*, 2000). In contrast, local stimulation of this region induces sleep (McGinty *et al.*, 1994; Sterman and Clemente, 1962). In this area, electrophysiological studies have detected neurons with firing rates two or three times higher during sleep than during wakefulness (Szymusiak *et al.*, 1998). It was also shown that the number of Fos-immunoreactive cells in VLPO increases after sleep and is proportional to the duration of sleep episode during the preceding hour (Sherin *et al.*, 1996). These data indicate that VLPO plays an instrumental role in the generation of sleep. VLPO receives a sparse projection from the SCN, thereby allowing the modulation of sleep by circadian rhythms (Novak and Nunez, 2000). VLPO neurons in turn project to the tuberomammillary nucleus of the posterior hypothalamus (Sherin *et al.*, 1998) and to other wakefulness-sustaining structures such as the locus coeruleus (LC) (Steininger *et al.*, 2001).

By contrast, the posterior hypothalamus seems to sustain arousal. Lesions of the posterior hypothalamus (Von Economo, 1926), as its inactivation (Lin *et al.*, 1988; 1989; 1990; 1994), decrease wakefulness and favour sleep. Within the posterior hypothalamus, a population of histaminergic neurons in the tuberomammillary nucleus have been particularly involved in wakefulness (Lin *et al.*, 1988; 1989; 1990; 1994). It is also a common clinical observation that antihistaminic drugs induce somnolence (Meltzer, 1990). Histaminergic neurons project to a wealth of structures (such as cortex, POAH, thalamus, and mesopontine tegmentum) thereby controlling the arousal state of the whole brain (Lin *et al.*, 1996).

It seems that feedback loops exist between the anterior and the posterior hypothalamus and regulate the succession of sleep and wakefulness periods. The GABAergic VLPO neurons probably have an inhibitory effect on TMN cells (Sherin *et al.*, 1998) but are themselves inhibited by wakefulness-sustaining neurotransmitters such as 5HT and NA (Gallopin *et al.*, 2000). Moreover, enhancement of histaminergic neurotransmission in the POAH decreases sleep and favours wakefulness periods (Lin *et al.*, 1994).

Finally, a small hypothalamic neuronal population was recently the subject of great experimental scrutiny. Located in the lateral posterior hypothalamus, they project throughout the brain and, importantly, to arousal-related structures (LC, raphe nuclei, and thalamus) (Peyron *et al.*, 1998). They secrete two newly described peptides, the hypocretins 1 and 2 (de Lecea *et al.*, 1998). Their effect is essentially neuroexcitatory and is mediated by two different receptors (hypocretin receptors 1 and 2), which are differently expressed in the cerebrum (Kilduff and Peyron, 2000). The presumptive functions of hypocretins concern eating behaviour and sleep (Sutcliffe and de Lecea, 2000). Local administration of hypocretin 1 into the LC suppresses REM sleep and increases wakefulness in a dose-dependent manner (Bourgin *et al.*, 2000) while perfusion of hypocretin 2 receptor antisense in the pontine reticular formation increases REM sleep (Thakkar *et al.*, 1999). These discoveries bear directly on one major sleep disorder, narcolepsy. In narcoleptic dogs, a mutation of the hypocretin 2 receptor gene leads to a truncated receptor protein (Lin *et al.*, 1999). Furthermore, systemic administration of hypocretin-1 reduces cataplexy and normalizes sleep/waking cycles in these dogs (John *et al.*, 2000). Likewise, knockout mice in which the hypocretin gene was inactivated suffered from cataplectic attacks, a hallmark of human narcolepsy (Chemelli *et al.*, 1999). Finally, perfusion of hypocretin 2 receptor antisense in the pontine reticular formation induces cataplectic attacks in rats (Thakkar *et al.*, 1999). It is unlikely that human narcolepsy is due, as in the dog, to a mutation of a single gene, because epidemiological studies do not point to a simple genetic transmission (Mignot, 1998). However, it was recently found that hypocretin concentration in the cerebrospinal fluid was undetectable in seven out of nine narcoleptic patients (Nishino *et al.*, 2000). Moreover, post-mortem examination of the narcoleptic hypothalamus revealed a decreased number of hypocretin cells (Thannickal *et al.*, 2000). It remains to be shown whether human narcolepsy is caused by a defect in hypocretin production, secretion or signalling. These pathological mechanisms could be due to genetic, viral or autoimmune causes (van den Pol, 2000).

HOW IS WAKEFULNESS MAINTAINED?

Besides hypothalamic sites, the generation of wakefulness depends on the mesencephalic reticular formation, and on the modulation of cerebral activity by the aminergic neurotransmission: acetylcholine (mesopontine reticular formation and basal forebrain), serotonin (raphe nuclei) and noradrenaline (locus coeruleus) (for review, see Steriade and McCarley, 1990).

The mesencephalic reticular formation, as well as the cholinergic neurons of the mesopontine tegmentum, maintain wakefulness by tonically bombarding the thalamic nuclei, thereby supporting a tonic firing in thalamocortical neurons and, consequently, a cortical arousal (Datta and Siwek, 1997; Datta *et al.*, 2001; Steriade and McCarley, 1990).

The cholinergic magnocellular neurons of the basal forebrain project directly to the whole cortex and are thought to be critical for the cortical arousal. Ibotenic acid lesions of the BF reduce acetylcholinesterase cortical staining and result in an ipsilateral increase in slow waves (Buzsaki *et al.*, 1988). In contrast, electrical and chemical BF stimulation elicits a shift of the spike discharge pattern of cortical neurons from phasic to tonic and consequently leads to EEG activation (Metherate *et al.*, 1992). By the same token, the unit activity of cortically projecting BF neurons (most of which are cholinergic) increases their discharge rate during EEG activation (Detari and Vanderwolf, 1987).

Serotonergic cells of the raphe nuclei and noradrenergic neurons of the locus coeruleus can also influence the firing pattern of thalamic cells, maintaining a tonic firing in thalamocortical neurons. They also project to widespread areas of the cortex, thereby influencing the activity of large neuronal population in the telencephalon.

THALAMOCORTICAL LOOPS AND THE GENERATION OF NON-REM SLEEP

Current theories of non-REM sleep generation put a strong emphasis on the activity patterns in the thalamocortical loops. Several rhythms and activities coalesce during non-REM sleep: spindles, delta rhythm, slow rhythm and K-complexes. All these rhythms occur through complex interactions between the reticular thalamic cells, the relay thalamic neurons and cortical networks. For didactic reasons, they are described as separate processes but, in practice, these oscillations coexist (spindles and slow rhythm, delta and slow rhythm [Steriade and Amzica, 1998]) or smoothly alternate (spindles and delta rhythm [Merica and Fortune, 1997]).

In animals, it is known that thalamic neurons become hyperpolarized because the activating brainstem structures described above decrease progressively during their firing rate at sleep onset. Due to this disfacilitation mechanism, thalamic neurons change their firing mode from tonic to phasic (Steriade and McCarley, 1990). First, due to their intrinsic membrane properties, GABAergic cells of the reticular thalamic nucleus burst in the spindle frequency range and entrain thalamocortical neurons in spindle oscillation (Steriade and McCarley, 1990; Steriade *et al.*, 1993b). As sleep deepens, thalamic neurons get more hyperpolarized and a clock-like delta rhythm appears in thalamocortical cells, due to their intrinsic membrane properties (Steriade *et al.*, 1993a). This delta rhythm arises from the interplay between a low threshold calcium current (It) and a hyperpolarization-activated K^+ current (Ih) (Steriade *et al.*, 1993a). Thalamic delta rhythm is conveyed to the cortex, which further reorganizes it and incorporates it into a cortically-induced, slow rhythm (Steriade and Amzica, 1998).

Neuroimaging data support the role of thalamic nuclei in non-REM sleep generation. A significant regression was found between thalamic blood flow and the power density within the spindle frequency band (Hofle *et al.*, 1997). Likewise, significant changes in thalamic blood flow and glucose metabolism is the most consistent feature reported in human non-REM sleep (Maquet, 2000). The observation of patients with thalamic lesions also confirms the role of thalamic nuclei in non-REM sleep. Thalamotomized Parkinson patients show significant changes in their pattern of spindles (Roth *et al.*, 2000). Likewise, fatal insomnia, a prion disease characterized by a severe loss of sleep, is related to thalamic lesions and a decrease in thalamic metabolism (Cortelli *et al.*, 1997).

The slow rhythm relies on the properties of the cortical networks and the alternate silent periods of hyperpolarization with activity periods (Steriade *et al.*, 1993a; Steriade *et al.*, 1993c). The slow rhythm was recently identified in humans (Achermann and Borbely, 1997). Moreover, K-complexes, a hallmark of human stage 2 sleep, are viewed as an expression of the slow rhythm (Amzica and Steriade, 1997; Amzica and Steriade, 1998). The long-lasting silent periods appear to be due to a cascade of disfacilitation (Contreras *et al.*, 1996). Activity periods depend on aminoacidergic neurotransmission (Steriade *et al.*, 1993a). The participation of intracortical inhibitory neurons (Steriade *et al.*, 1993a), as well as cortico-cortical connection fibres (Amzica and Steriade, 1995a; Amzica and Steriade, 1995b), has also been emphasized. Recent data suggest that the slow rhythm is actively generated in the cortex. The depolarization state is related to recurrent excitatory interactions between pyramidal cells, regulated by inhibitory networks. The hyperpolarization state is characterized by an after-hyperpolarization in pyramidal cells and the withdrawal of synaptic barrages (Sanchez-Vives and McCormick, 2000).

REM SLEEP: BRAINSTEM MECHANISMS AND LIMBIC/PARALIMBIC ACTIVATION

Two aspects of REM sleep are worth describing: its generation by brainstem nuclei and the characteristic activation of limbic and paralimbic structures.

The widely held theory on REM sleep generation relies on the balance between, on the one hand, the activity of cholinergic REM sleep-on neurons of the mesopontine tegmentum (laterodorsal tegmenti [LDT], pedunculo-pontine nucleus [PPT], and peri-locus coeruleus alpha [periLCa]) and, on the other hand, the noradrenergic cells of the LC and serotonergic neurons of the raphe nuclei (Hobson *et al.*, 1975). The reciprocal interaction model is based on the observation that, during REM sleep, raphe nuclei and LC cells remain silent while, at the same time, mesopontine cholinergic cells increase their firing rate (Steriade and McCarley, 1990). The inhibition of LC and raphe nuclei cells could be due to a direct effect of cholinergic cells, but other mechanisms are possible, such as the inhibition of LC by GABAergic or glycinergic periaqueductal grey (PAG) neurons (Gervasoni *et al.*, 2000; Rampon *et al.*, 1999). Recently, it was also shown that the midbrain structures responsible for REM sleep generation were themselves modulated by higher structures, such as the central nucleus of the amygdala (Morrison *et al.*, 1999).

The activation of cholinergic mesopontine neurons leads to the three characteristics of REM sleep: the cortical activation, the muscular atonia and rapid eye movements. Mesopontine neurons project monosynaptically to the thalamic nuclei. The thalamic activation is then conveyed to the cortex. The ensuing cortical activation would explain the small-voltage, relatively high-frequency EEG activity characteristic of REM sleep (Steriade and McCarley, 1990).

The characteristic muscular atonia observed in REM sleep also depends originally on cholinergic mesopontine neurons (Lai and Siegel, 1999). Cells in or near the periLCα project and stimulate the bulbar reticular formation, directly or via a polysynaptic pathway through the pontine reticular formation. Bulbar reticular formation in turn projects and inhibits motoneurons in the spinal cord, through glycinergic neurotransmission, leading to a tonic decrease in muscle tone. In animals, lesions in the pontine reticular formation lead to REM sleep without atonia. A similar condition, the REM sleep behaviour disorder, was recently described in humans (Schenck *et al.*, 1986). It is characterized by movements of the limbs or body associated with dream mentation and at least one of the following criteria: dreams that appear acted out or sleep behaviour that disturbs sleep continuity (American Sleep Disorder Association, 1997). This condition is related to extrapyramidal disorders (Parkinson's disease, multiple system atrophy). In some of these patients, symptoms have been related to the marked neuronal loss in brainstem nuclei, such as the locus coeruleus, that usually inhibit cholinergic mediated atonia during REM sleep (Turner *et al.*, 2000).

Finally, ocular saccades in REM sleep also depend on cholinergic mesopontine neurons, especially the peribrachial region (Datta, 1999). In animals, saccades are related to ponto-geniculo-occipital (PGO) waves, prominent transient activities that are readily (although not exclusively) recorded in the pons, the lateral geniculate nucleus and the occipital cortex (Datta, 1999). These PGO waves have not been directly recorded in humans, but many arguments suggest that they exist in humans (Peigneux *et al.*, 2000).

The other striking aspect of REM sleep is the predominant activation of limbic and paralimbic structures. Although described in animals for some time (Lydic *et al.*, 1991; Ramm and Frost, 1986), this aspect of REM sleep was recently emphasized in humans by functional neuroimaging studies (Maquet, 2000). Activation in both amygdala and hippocampal formation was reported. Moreover, amygdalo-cortical functional relationships specific to REM

sleep were observed. These results suggest that brain function during REM sleep is mainly driven by an interplay between the limbic areas and posterior (temporal and occipital) cortices. The relation between this cortico-limbic interplay and the dreaming activity, although sensible, remains to be formally assessed (Maquet, 2000).

CONCLUSIONS

Sleep is not a state of complete cerebral quiescence. The patterns of brain activity certainly are different in sleep than during wakefulness but do not correspond to the absence of brain activity. The understanding of sleep mechanisms is crucial since they probably underlie some important — or even vital (Rechtschaffen *et al.*, 1989) — function.

Functional Neuroimaging in Sleep and Sleep Disorders

Pierre Maquet

INTRODUCTION

Functional neuroimaging characterizes the human brain function in time and space, using various techniques such as electroencephalography (EEG), positron emission tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI) or near infrared spectroscopy (NIRS). In this chapter, we review the studies of human sleep using PET, SPECT or fMRI, all techniques which allow us to investigate the whole cerebral volume. In the following sections, we consider successively studies performed in normal subjects and in several sleep disorders.

FUNCTIONAL NEUROIMAGING OF NORMAL HUMAN SLEEP

The regional organization of brain activity is completely different in sleep than in wakefulness and reflects cellular processes similar to the ones described in sleeping animals.

Functional neuroimaging by PET has recently yielded original data on the functional neuroanatomy of human sleep. A more comprehensive discussion of these results, which is beyond the scope of the present chapter, can be found in a recent review paper (Maquet, 2000). These recent data describe the very reproducible functional neuroanatomy in sleep. The core characteristics of this 'canonical' sleep may be summarized as follows. In slow-wave sleep (SWS), the most deactivated areas are located in the dorsal pons and mesencephalon, cerebellum, thalami, basal ganglia, basal forebrain/hypothalamus, prefrontal cortex, anterior cingulate cortex, precuneus and the mesial aspect of the temporal lobe. Briefly, these findings are in keeping with the generation of non-rapid eye movement (REM) sleep in mammals, whereby the decreased firing in brainstem structures causes hyperpolarization of the thalamic neurons and triggers a cascade of processes responsible for the generation of various non-REM sleep rhythms (spindles, theta, and slow rhythm; see Chapter XXIV-7). The human data showed for the first time that the pattern of cortical deactivation was not homogeneous but predominated in various associative cortices, particularly the dorso-lateral and orbital prefrontal cortex. There seems to be a functional link between these cortical regions and sleep processes. Indeed, these areas are known to be involved in mood regulation and in various cognitive functions (such as planning or probability matching) that help to adapt individual behaviour and are known to deteriorate after a short deprivation of sleep (Harrison and Horne, 1998, 1999; Horne, 1988, 1993; Pilcher and Huffcutt, 1996).

During REM sleep, significant activations were found in the pontine tegmentum, thalamic nuclei, limbic areas:amygdaloid complexes (Maquet *et al.*, 1996; Nofzinger *et al.*, 1997), hippocampal formation (Braun *et al.*, 1997; Nofzinger *et al.*, 1997), and anterior cingulate cortex (Braun *et al.*, 1997; Maquet *et al.*, 1996; Nofzinger *et al.*, 1997). The posterior cortices in temporo-occipital areas were also activated (Braun *et al.*, 1997) and their functional interactions are different in REM sleep than in wakefulness (Braun *et al.*, 1998). In contrast, the dorso-lateral prefrontal cortex and parietal cortex, as well as the posterior cingulate cortex and precuneus, were the least active brain regions (Braun *et al.*, 1997; Maquet *et al.*, 1996). Once again, these regional distributions of brain activity are in good accordance with the knowledge already acquired on sleep in animals (see Chapter XXIV-7). REM sleep is generated by neuronal populations of the meso-pontine reticular formation that monosynaptically activate the thalamic nuclei and in turn the cortex. Although early animals studies had mentioned the high limbic activity during REM sleep (Lydic *et al.*, 1991), functional neuroimaging in humans highlighted the contrast between this activation of limbic, paralimbic and posterior cortical areas, and the relative quiescence of associative frontal and parietal cortices. This particular pattern of activation has been thought to account for the main characteristics of human dreaming activity (Hobson *et al.*, 1998; Maquet, 2000; Maquet *et al.*, 1996). The perceptual aspects of dreams may be related to the activation of the posterior (occipital and temporal) cortices and the emotional features to the activation of the amygdalar complexes and related mesio-temporal areas. In contrast, the lack of insight, the loss of time perception, and the amnesia on awakening may be related to the relative hypoactivation of the prefrontal cortex.

Sleep as a Period Favourable to Brain Plasticity

In the adult brain, it is believed that sleep periods participate in memory trace consolidation (Hennevin *et al.*, 1995; Smith, 1995). If this were the case, the regional brain activity in sleep would not be fixed and stereotyped but would depend on previous waking experience. It was recently shown that waking experience indeed influences regional brain activity during subsequent sleep (Maquet *et al.*, 2000). During REM sleep, several brain areas, activated during the execution of a serial reaction time (SRT) task during wakefulness, are significantly more active in subjects previously trained on the task than in non-trained subjects. The functional connectivity of these brain regions was also examined (Laureys *et al.*, unpublished data). One of the reactivated areas, the left premotor cortex, was functionally more tightly correlated with the posterior parietal cortex and the supplementary motor area (SMA) during post-training REM sleep than in 'typical' REM sleep. It was hypothesized that this increase of functional connectivity during post-training REM sleep reflects some processing of the memory traces recently acquired during wakefulness and embodied in the parietal-premotor-SMA network. It remains to be shown that these processes lead to memory trace consolidation.

The Brain's Reactivity to External Stimulation in Sleep

During sleep, the brain remains able to process external stimuli (see, for instance, Perrin *et al.*, 1999). During non-REM sleep, as during wakefulness, several areas continue to be activated by external auditory stimulation: the thalamic nuclei, the auditory cortices and the caudate nucleus (Portas *et al.*, 2000). However, in contrast to wakefulness, no activation is observed in the left parietal, or in the prefrontal and cingulate cortices. Furthermore, in sleeping normal subjects, the activation related to the subject's own name, as compared to beeps, involved the amygdala and the prefrontal cortex (Portas *et al.*, 2000). This demonstrated the persistence during sleep of specific responses to meaningful or emotionally loaded stimuli.

Sleep Drugs and Regional Brain Function

Functional neuroimaging can also be used to explore the effect of a therapeutic agent on brain function. For instance, during REM sleep, zolpidem administration decreased regional blood flow in the anterior cingulate cortex during REM sleep, and in the prefrontal cortex and the insula during non-REM sleep. The results indicate that some differences in regional cerebral blood flow (rCBF) from wakefulness to sleep are modulated by zolpidem (Finelli *et al.*, 2000).

SLEEP DISORDERS

Sleep is deteriorated in a wide range of conditions, ranging from environmental situations (such as jet lag, shift work, and noisy environment) to medical diseases (such as endocrine disorders, chronic pain, brain lesions, sleep apnoea) and psychiatric disorders (such as anxiety and depression). Only a handful of these situations have been explored by functional neuroimaging. Our relative ignorance of the pathophysiology of most sleep disorders and the technical difficulties related to sleep studies probably explain why neuroimaging techniques have not been widely used in the exploration of human sleep disorders and certainly less than in other neurological conditions such as epilepsy or degenerative diseases. In this chapter, we will cover only a few disorders of sleep. We exclude single-case reports, however interesting they may be in their own right (see, for instance, the report on Kleine-Levine syndrome by Lu *et al.*, 2000). Depression is extensively dealt with elsewhere in this book and will be only briefly mentioned here in the context of sleep and sleep deprivation studies.

Narcolepsy

To our knowledge, the voxelwise functional neuroanatomy of the waking state, REM sleep or SWS is not yet described in narcoleptic patients. Nor have been the brain areas related to the other cardinal symptoms of diseases — cataplectic attacks and hypnapompic/hypnagogic hallucinations or sleep paralyses — characterized.

Early observations using ^{133}Xe inhalation showed that during wakefulness, brainstem and cerebellar blood flow was lower in narcoleptic patients than in normal subjects (Meyer *et al.*, 1980). During sleep (3 out of 13 subjects in REM sleep), the cerebral blood flow increased in all regions, and particularly in the temporo-parietal regions. This pattern was putatively attributed to dreaming activity. More recently, a HMPAO-SPECT study compared the waking state to REM sleep (Asenbaum *et al.*, 1995). The global uptake was similar in both conditions. Analysis by regions of interest indicated again an activation of parietal regions. These parietal activations are not in agreement with the parietal deactivation observed by PET studies during normal REM sleep (Maquet, 2000). Further observations are required, using present technology of the acquisition and analysis of functional neuroimaging data, to characterize better the functional organization of the narcoleptic brain during wakefulness and sleep.

Some ligand studies have been reported. Because acetylcholine is an important neurotransmitter in the generation of REM sleep, it was thought that some disturbance in the cholinergic system might underlie narcolepsy. Unfortunately, no change in muscarinic cholinergic receptors could be observed in narcoleptic patients (Sudo *et al.*, 1998). Likewise, post-mortem examination of the brain of narcoleptic patients indicated an increased dopamine D2 binding (Aldrich *et al.*, 1992). This finding was not confirmed by *in vivo* measurements by PET or SPECT, three studies out of four not showing any change in dopamine receptor-binding potential in narcoleptic patients, as compared to controls (Hublin *et al.*, 1994; MacFarlane *et al.*, 1997; Rinne *et al.*, 1996; Rinne *et al.*, 1995). In one study, there was a significant increase in the uptake of ^{11}C-raclopride, a specific D2-receptor ligand, in the putamen of narcoleptic subjects older than 31 years (Khan *et al.*, 1994). Finally, although the binding of IBZM, another D2 receptor ligand, was similar in narcoleptic patients and normal controls, treatment by stimulants and antidepressants for 3 months significantly changed the ligand uptake in four out of five patients. This suggested that the post-mortem findings were more related to treatment than to the disorder itself (Staedt *et al.*, 1996).

The effects of stimulant drugs on cerebral function in narcoleptic patients was assessed in two fMRI studies. The first one tested the effect of modafinil, a sleep-preventing drug (Ellis *et al.*, 1999). First, it was observed that the activation related to visual or auditory stimulation was dependent on the time of day. Normal subjects show higher levels of activation at 10 am than at 3 pm. In a group of 12 narcoleptic patients, the reverse pattern was observed. The administration of modafinil did not modify the average level of activation in either normals or narcoleptics ($n = 8$). However, in both populations, the post-drug activation level was inversely proportional to the pre-drug activation level. This finding is not easily interpreted, but it suggests that modafinil can modulate the brain activation to external stimuli.

Finally, an fMRI study assessed the effects of amphetamines in a small sample of patients with narcoleptic syndrome ($n = 2$, Howard *et al.*, 1996). As compared to three normal control subjects, the activation related to auditory and visual stimulation was decreased in extent after amphetamine administration in normal subjects. The reverse pattern was observed in patients. Once again, these findings are difficult to interpret, and larger samples should be studied before any generalization can be made.

Following the advances made recently in the understanding of narcolepsy (see Chapter XXIV-7) and the discovery of the implication of the hypocretin system in this disorder, it is expected that new neuroimaging studies will soon appear that provide a better description of regional brain function in the various aspects of the disease, such as excessive daytime somnolence, cataplexy and hypnapompic/hypnagogic hallucinations.

Periodic Leg Movements

Periodic leg movements during sleep (PLMS) are characterized by repetitive flexion of the extremities. PLMS can occur in isolation or together with other sleep disorders (narcolepsy, sleep apnoea syndrome or REM sleep behaviour disorder [RBD]). In any case, PLMS disturbs sleep, being responsible for repeated brief arousals. A disinhibition of the descending inhibitory pathways, involving the dopaminergic, adrenergic and opiate systems, is thought to cause PLMS (Wetter and Pollmacher, 1997). Among other therapeutic possibilities, dopaminergic drugs were shown to relieve PLMS (Montplaisir *et al.*, 1991). Only one group has tested the hypothesis of a decreased dopaminergic activity in PLMS patients. In a

series of reports, they mention a decreased IBZM striatal uptake, indicating a lower D2 receptor occupancy in PLMS patients (Staedt *et al.*, 1993; Staedt *et al.*, 1995a; Staedt *et al.*, 1995b). Treating patients with dopamine replacement therapy increased the IBZM binding and improved the sleep quality in these patients (Staedt *et al.*, 1995b).

REM Sleep Behaviour Disorder (RBD)

This condition, which has been described only recently (Schenck *et al.*, 1986), is characterized by movements of the limbs or body associated with dream mentation and at least one of the following criteria: dreams that appear to be acted out or sleep behaviour that disturbs sleep continuity (American Sleep Disorders Association, 1997). Patients with REM sleep behaviour disorder are likely to develop extrapyramidal disorders (Schenck *et al.*, 1996) as multiple system atrophy (Plazzi *et al.*, 1997), i.e., degenerative disorders related to alteration in the central dopaminergic system.

With SPECT and IPT (a ligand of striatal presynaptic dopamine transporter), it was recently shown that IPT binding in RBD patients ($n = 5$) is lower than in normal controls but higher than in Parkinson patients ($n = 14$; Eisensehr *et al.*, 2000). These results suggest that the number of presynaptic dopamine transporters is decreased in both Parkinson and RBD patients. It remains to be shown whether this alteration plays a causal role in the pathophysiology of RBD. Although there is evidence that some Parkinson patients do show excessive nocturnal movements (Trenkwalder, 1998), it is intriguing that not all Parkinson patients develop full-blown RBD. This suggests that modifications of other systems of neurotransmission are probably necessary for RBD to occur.

Depression: Studies of Sleep and Sleep Deprivation

There are good reasons to study brain function during sleep in depressed patients. Sleep disturbances are an integral feature of depressive disorders, ranging from hypersomnia to marked difficulty in maintaining sleep. The architecture of sleep itself is modified and characterized by a reduced SWS, an early onset of the first episode of REM sleep, and increased phasic REM sleep (Thase, 1998).

Sleep deprivation had rapid beneficial effects on about 60% of depressed patients (Wirz-Justice and Van den Hoofdakker, 1999). Responders to sleep deprivation are usually patients with high behavioural activation and low levels of tiredness (Bouhuys *et al.*, 1995; Szuba *et al.*, 1991). The hypothesis has been put forward of an increased arousal in depressed patients. Functional neuroimaging lends support to this hypothesis. Beta activity was proposed as a marker of arousal during sleep (Nofzinger *et al.*, 2000). Beta power is negatively correlated with subjective sleep quality, in both normal and depressed individuals. Depressed patients tend to have increased beta activity during the night as compared to normal controls. Finally, beta power is correlated with the glucose metabolism of ventro-medial prefrontal cortex, one of the most deactivated regions during consolidated SWS (see above).

Brain activity during sleep differs in several aspects from normal human sleep. Early studies indicated that cerebral metabolism during non-REM sleep in depressed patients is higher than in normal subjects (Ho *et al.*, 1996). The greatest increases was observed in the posterior cingulate, the amygdala, the hippocampus, and the occipital and temporal cortex (Ho *et al.*, 1996). During REM sleep, more recent data showed that the anterior paralimbic areas (anterior cingulate cortex, right insula, right parahippocampal gyrus) were less active, as compared to wakefulness, in depressed patients than in normal subjects (Nofzinger *et al.*, 1999).

Sleep deprivation has profound effects on brain metabolism, in both normals and depressed subjects. After 24 h of total sleep deprivation in normal subjects, cerebral glucose metabolism decreases by 8% (Thomas *et al.*, 2000). This decline involves the brain as a whole but is particularly prominent in the thalamic nuclei and associative cortices of the frontal and parietal lobes. No brain area increases its glucose metabolic rates after 24 h of continuous wakefulness. In depressed patients who respond to sleep deprivation, the baseline brain activity (measured in the awake patient) is higher in the anterior cingulate cortex (Wu *et al.*, 1992) or nearby mesial frontal cortex (Ebert *et al.*, 1994; Wu *et al.*, 1999) than in non-responders. This feature normalizes after sleep deprivation. The same pattern was observed in elderly depressed patients, the normalization of anterior cingulate metabolism persisting even after recovery sleep (Smith *et al.*, 1999).

These data suggest a close link between the mood alteration and the activity in limbic and paralimbic structures. In particular, it is as if the anterior cingulate cortex were hyperactive in depressed patients during wakefulness, masking any further increase in REM sleep. Sleep deprivation would decrease both the activity in the anterior cingulate cortex and depression ratings. Further studies are needed to understand the causes and consequences of these mesial frontal metabolic disturbances.

CONCLUSIONS

Functional neuroimaging provides unprecedented possibilities to explore the brain function during sleep. In the near future, it should help to clarify the functions of sleep and the mechanisms underlying sleep disorders.

Genetics of Sleep and Sleep Disorders

Paul Linkowski

INTRODUCTION

The relationship of genes to behaviour has always been a major topic of research and interest in the neurosciences. In the study of sleep, the traditional way to determine whether distinct phenotypes have a familial component was to study family pedigrees or to investigate sleep in monozygotic (MZ) and dizygotic (DZ) twins, a classical method in human and psychological research. In animals, the inheritance of sleep traits was previously studied by Valatx *et al.* (1972) in cross-breeding mice strains. The developments of molecular genetics and gene technology favoured a renewed interest in the behavioural neurobiology of sleep, leading to an increasing number of papers on the genetics of sleep and the molecular aspects of sleep disorders.

Current scientific investigations address various phenotypic dimensions, including the genetic components of rapid-eye-movement (REM) sleep and delta sleep, and the circadian components of human sleep.

In the present paper we will review some of the classical genetic studies of sleep and summarize important recent results.

GENETICS OF SLEEP IN NORMAL MAN: TWIN STUDIES

The importance of the investigation of the genetic aspects of sleep was demonstrated in some early studies that focused mainly on the investigation of twin pairs in man. In 1937, Geyer (quoted in Vogel, 1958) reported that concordance for a number of sleep characteristics was much better in MZ than in DZ twins. Other pioneering efforts were made by Vogel (1958), who was the first to study the sleep EEG in MZ twins, and by Zung and Wilson (1967), who performed computations of the sleep EEG of three pairs of MZ and three pairs of DZ twins. They reported that the all-night-sleep EEG and REM patterns of MZ twins were similar, whereas those of DZ twins were dissimilar and variable.

It should be noted, however, that some further studies relied mainly on questionnaire investigations of sleep habits (duration of sleep, subjective reports of sleep timing and quality) in MZ and DZ twins (Partinen *et al.*, 1983; Heath *et al.*, 1990). These studies were conducted mainly in adult twins, and, in general, correlations were higher for MZ than for DZ twins, with a significant synchronizing effect of cohabitational status on sleep length (Partinen *et al.*, 1983). Heath *et al.* (1990) found that genetic influences accounted for at least 33% of the variance in sleep quality and sleep disturbance, and 40% of the variance in sleep pattern. A substantial genetic effect was also reported for some parasomnias such as sleepwalking and nocturnal enuresis (Kales *et al.*, 1980).

The hereditary components of sleep were also suggested by some polygraphic twin studies of newborns (Gould *et al.*, 1978), of a limited number of adolescent twin pairs, and of single nights of identical and fraternal twins. In the study of Webb and Campbell (1983), measures of awakening and REM sleep amounts were found to be significantly correlated in identical twins. In a study of seven twin pairs, Hori (1986) suggested that sleep spindles were determined by a genetic trait.

The inheritance of properties of the wake EEG has also been a focus of interest in recent years, since the pioneering observations of Vogel (1958). Stassen *et al.* (1987) reviewed 22 twin studies and noted that MZ co-twins were generally more alike than DZ co-twins, indicating the presence of genetic influences on the spontaneous EEG. In a more recent study, Van Beijsterveldt *et al.* (1996) measured four frequency bands (delta, theta, alpha, and beta) and reported that the average heritability of brain functioning, as indexed by rhythmic brain electrical activity, is one of the most heritable characteristics in humans.

Finally, a large number of animal studies also indicate unequivocally that certain aspects of sleep might be genetically determined.

These studies have mainly suggested a genetic determination of sleep length in rodents (Valatx *et al.*, 1972; Friedman, 1974; Franken *et al.*, 1999) as well as a significant genetic effect on REM sleep in mice (Valatx *et al.*, 1980; Valatx, 1984).

Taken together, most studies that addressed the issue of genetic aspects of sleep in normal men have relied on the twin method, which allows the determination of heritability estimates and is frequently used to partition variance of phenotypic quantitative traits into environmental and genetic components.

The twin design has also been frequently used to evaluate the heritability of other primary sleep disorders such as sleepiness, nightmares and sleepwalking. This will be reviewed later in the chapter. We will first present the results of the Brussels twin study, which was conducted between 1986 and 1990 (see Table XXIV-9.1) (Linkowski *et al.*, 1989; 1991).

In this study of two samples of 26 pairs of male twins, we have found that stages 2, 3, $3 + 4$ and 4 were significantly determined by genetic components. This was also the case for REM density. No genetic effect was found for total sleep period, period of sleep, total sleep time, sleep onset latency and REM latency. Waking was found to be significantly determined by genetic factors in one of the two samples.

Therefore, our results substantiate previous reports suggesting that some components of human sleep might be genetically determined (Partinen *et al.*, 1983; Webb and Campbell, 1983). In our study, stages 2, 4 and delta sleep (stages $3 + 4$) unequivocally show a strong genetic component: the same is true, but is less pronounced for REM density measures. It is of interest that the stages with the strongest genetic component show the best relative stability from night to night (Merica and Gaillard, 1985). This is also supported by previous reports of substantial within-subject, night-to-night correlation of stage 4 (Webb and Agnew, 1968) and a greater inter- than intraindividual variation of stage 4 (Merica and Gaillard, 1985).

Table XXIV-9.1 Selected heritability estimates of markers of sleep-wake homeostasis

Parameter	Authors	No. of pairs	Gender	Age range (years)	Heritability 2 ($r_{MZ}-r_{DZ}$)
Minimum of stages 2 + 4	Linkowski *et al.*, 1989	14 MZ 12 DZ	M	16–35	0.50
REM density	Linkowski *et al.*, 1991	11 MZ	M	20–36	0.95
Minimum of stages 3 + 4		15 DZ			0.52
REM density	Linkowski *et al.*, 1998	9 MZ	M	16–35	0.64
Minimum of stages 3 + 4 (with catheter)		8 DZ			0.90
Minimum of stages 3 + 4 (with catheter)	Linkowski *et al.*, unpublished	11 MZ 11 DZ	M	16–35	0.68

More recently, Franken *et al.* (2001) have reported that the increase of slow-wave sleep need after sleep deprivation is under strong genetic control in the mouse. Our data also show that regulation of REM stage variability shows substantial environmental determination rather than evidence of significant genetic effect, in opposition to what is observed in animals (Valatx, 1984).

GENETIC ASPECTS OF SLEEP DISORDERS

For most of the disorders of sleep, twin or family studies support a genetic component in a majority of sleep disorders such as sleepwalking nightmares, hypersomnia, restless legs syndrome (RLS), insomnia, obstructive sleep apnoea and narcolepsy. With reference to the last disease, the gene responsible for dog narcolepsy has recently been cloned (Lin *et al.*, 1999), also implicating the dysfunction of orexins (hypocretins), neuropeptides active in energy homeostasis and arousal (Thannickal *et al.*, 2000; van den Pol *et al.*, 2001).

FAMILY ASPECTS OF INSOMNIA

A family history of insomnia is a well-known symptom among patients with a complaint of chronic insomnia (Hauri and Olmstead, 1980; Bastien and Morin, 2000). In the study of Bastien and Morin (2000), 35% of the patients consulting for insomnia had a positive family history of sleep disturbances. Insomnia was the most common type of sleep disturbance identified (76%), and the mother was the most frequently afflicted family member.

The reported sleep disturbances among family members were more prevalent when the onset of insomnia was before 40 years of age than when it was later in life. These findings are supported by other reports such as that of Dashevsky and Kramer (1998), which shows that 42% of patients with psychiatric disturbances have a positive family history of insomnia.

Another major contribution to the genetic studies of insomnia came from the studies that explored the clinical and molecular genetics of a new syndrome: fatal familial insomnia (FFI) (Lugaresi *et al.*, 1986; Cortelli *et al.*, 1999). FFI is a rare autosomal dominant disease clinically characterized by sleep loss that inevitably proves fatal, disordered sleep-wake cycle, dysautonomia (increased perspiration and salivation, impotence, constipation, tachycardia, systemic hypertension and fever progressively worsening), and motor signs (ataxia, dysarthria, astasia-abasia and myoclonic jerks). At autopsy, both in the thalamus and in the cortex, the limbic structures (the orbito-frontal cortex, the cingulate gyrus and the mediodorsal and ventral thalamic nuclei) are those most consistently and severely involved.

Genetically, the disease is characterized by a missense mutation at codon 178 coupled with methionine at the polymorphic codon 129 of the prion protein gene (Goldfarb *et al.*, 1992; Medori *et al.*, 1992). The selective atrophy of the limbic thalamus that characterizes FFI might be due to the binding of toxic prion proteins to specific receptors on thalamolimbic neurons, leading to this rare but well-characterized inherited prion disease in humans.

SLEEPINESS

Carmelli *et al.* (2001) have explored the responses to the eight-item Epworth Sleepiness Scale obtained from 1560 World War II male veteran twin pairs to determine the extent to which genetic influences are involved in self-reported daytime sleepiness in the elderly. The heritability of responses to the Epworth Sleepiness Scale was estimated to be 38% while environmental influences not shared by twin brothers accounted for the remaining variance in daytime sleepiness. The authors interpreted the heritability of the responses to the Epworth Sleepiness Scale as related to a genetic susceptibility to disordered breathing during night sleep.

NIGHTMARES, SLEEPWALKING AND SLEEPTALKING

The twin design was also applied to quantify the genetic influences affecting the liability to nightmares, sleepwalking, night terrors and sleeptalking.

Nightmares are frightening dreams that usually awaken the sleeper from REM sleep. They are usually long and complicated, exhibiting a progressive content that becomes increasingly frightening toward the end (Broughton, 1994).

Sleepwalking belongs to the group of parasomnias characterized by a series of complex behaviours that are initiated during slow-wave sleep and result in walking during sleep.

Talking, screaming, striking out or walking during the nightmare rarely occurs, distinguishing the nightmare from sleep terror and REM sleep behaviour disorder (ASDA, 1990). No firm evidence for a familial basis of nightmares was available until the study of Hublin *et al.* (1999), who investigated 1298 MZ and 2419 DZ twin pairs by questionnaire. They showed a persistent genetic effect on the disposition to nightmares in both childhood and adulthood. Of the phenotypic variance, the estimated proportion of genetic effect in childhood was 44% in males and 45% in females. In adults the values were 36% in males and 38% in females. Nightmare frequency and psychiatric disorders were linearly associated.

The same authors explored the prevalence a genetic predisposition to sleepwalking in the same population of twins and reported a substantial genetic effect in both childhood and adulthood (Hublin

et al., 1997). The proportion of total phenotypic variance attributed to genetic influences was 80% in men and 36% in women. The same values were 60% in men and 57% in children for sleepwalking.

RESTLESS LEGS SYNDROME (RLS)

RLS is a common sleep disorder, present in about 6% of the adult population. It is characterized by motor restlessness and painful sensations during sleep in the legs. RLS has been reported to be familial: 30–64% of RLS patients have positive family history (Lazzarini *et al.*, 1999). It has been shown that familial RLS follows an autosomal dominant mode of inheritance with variable expressivity (Becker *et al.*, 1993). It is also important to note that genetic anticipation (increased severity with age and an earlier age of onset of the illness in successive generations) has been suggested for RLS indicating a possible trinucleotide repeat expansion in the molecular mechanisms of the disease (Lazzarini *et al.*, 1999).

NARCOLEPSY

Narcolepsy is a disabling sleep disorder which typically arises during adolescence and early adulthood, and affects 0.02–0.18% of the general population (Mignot, 1998). This syndrome is characterized by excessive daytime sleepiness and pathological manifestations of REM sleep. These include cataplexy (a sudden loss of muscle tone generally caused by a strong emotion), sleep paralysis (muscle atonia when falling asleep or at awakening) and hypnagogic hallucinations, a complex state that occurs between waking and sleep. The full tetrad of excessive daytime sleepiness, cataplexy, sleep paralysis and hypnagogic hallucinations is present in only 15% of the patients (Aldrich, 1998).

Familial narcolepsy is rare (sporadic cases are more frequent) and the risk to first-degree relatives is estimated at 1–2%; only 8–10% of narcoleptic patients identify another member of the family as having the narcolepsy-cataplexy syndrome. Furthermore, a risk of 2% is 10 times higher than what is observed in the general population, suggesting the existence of predisposing genetic factors (Mignot, 1998).

The importance of environmental factors is supported by the fact that up to 30% of MZ twin factors are concordant for narcolepsy. This led some authors to suggest that undefined environmental factors act on a susceptible genetic background to initiate the disease. Several studies have reported a strong association between certain HLA haplotypes on human chromosome 6 and human narcolepsy; HLA DQB1*0602 and DQA1*0102 are found in 90% of narcoleptics, but in only 30% of the general population, suggesting that autoimmunity plays a role in the disorder (Kadotani *et al.*, 1998).

The major breakthrough, however, occurred recently, shedding new light on the physiopathological and molecular basis of the disease. In 1998, two peptides were identified in the hypothalamus, and were termed hypocretin-1 (HCRT-1) and hypocretin-2 (HCRT-2), reflecting their hypothalamic origin. They project to monoaminergic and cholinergic components of the ascending reticular activating system (Kilduff and Peyron, 2000). The sleepiness in narcolepsy appears to reflect lack of hypocretin excitatory inputs on histaminergic, dopaminergic and cholinergic components of the ascending reticular activating system, which normally promote thalamo-cortical arousal (Silber and Rye, 2001).

Other recent molecular and post-mortem studies further support the role of hypocretins, indicating a mutation in a case of early-onset narcolepsy and a generalized absence of hypocretin peptides in human narcoleptic brains (Peyron *et al.*, 2001). These studies are paralleled by similar studies in mice (Hara *et al.*, 2001) and canine narcolepsy (Hungs *et al.*, 2001). HLA and hypocretin findings can be integrated into a concept of immunologically mediated destruction of hypocretin-containing cells in human narcolepsy (Mignot *et al.*, 2001). The genetic contribution of HLA to narcolepsy might also be estimated by the use of the lambda statistic (Risch, 1987), which computes the relationship between increased risk in relatives and population prevalence. The results indicate that complex HLA-DR and -DQ interactions contribute to the genetic predisposition to human narcolepsy but that additional susceptibility loci are also probably involved.

HCRT-1 was undetectable in the CSF of seven of nine patients with narcolepsy (Nishino *et al.*, 2001). In an autopsy study, hypocretin neurons were damaged in 95% of narcoleptic brains (Thannickal *et al.*, 2000). Finally, Dalal *et al.* (2001) confirmed low to absent HCRT-1 concentrations in the CSF of narcoleptic patients and demonstrated that serum HCRT-1 was normal in narcolepsy.

These results add further fascinating details to the neurochemical aspects of sleep and offer a new potential for the discovery of pharmacological tools targeting hypocretin receptors in order to cure the disorders of excessive sleep.

CONCLUSION

Current research suggests that both normal sleep and various sleep disorders either have a genetic basis or are influenced by genetically determined physiological or environmental predispositions. Identifying the genes that influence the various components of sleep may ultimately contribute to a better understanding of the processes that control normal sleep, and also to the understanding of sleep disorders, and might add new pathways to the development of interventions to alleviate these disabling conditions.

Gender Issues Related to Sleep

Joyce Walsleben

Sleep is an active cyclic process that involves both physiological and behavioural changes. There are two major states of sleep: rapid-eye-movement (REM) sleep, commonly known as 'dream sleep', and non-REM (NREM) sleep. In the adult, these states cycle every 70–90 min across the night, usually beginning with NREM sleep. The state of NREM is divided into four stages: stages 1–4, which denote the 'depth' of sleep, based upon one's ability to respond to stimulation. Stage 1 is thought to be transitional and the lightest. Stage 2 fills approximately 50% of the night and is frequently felt to be the first definite stage of sleep. The deepest stages are 3 and 4, called delta sleep, or slow-wave sleep (SWS). SWS is felt to be the most restorative stage. The depiction of these states and stages of sleep in a histogram shows the structure or architecture of one's sleep at any given time point.

Originally, scoring of sleep stages was performed visually only by comparison to standard guidelines which evaluated the EEG frequency and amplitude (Rechtschaffen and Kales, 1968) of the electroencephalogram (EEG), electro-oculogram (EOG) and electromyogram (EMG). For instance, delta sleep is represented by an EEG frequency of 0.5–4 Hz and an amplitude $>75\,\mu V$, with steady EOG and decreased EMG, and it is further delineated into stages 3 or 4 by the percentage of a 30-s epoch which displays this frequency and amplitude. More recently, with the advent of computer scoring and spectral analysis, more definitive changes of EEG power can be documented, allowing subtle changes across and between stages of sleep to be noted.

Two main biological drives regulate the timing and amount of sleep. They are the circadian drive, or 24-h sleep/wake cycle, and the homeostatic drive, which may represent the accumulation of sleep factors or toxins produced during wake. These drives change as we age, altering the normal flow of sleep across our 24-h 'day'.

We begin to form the various stages of sleep around the fourth month of life. Sleep architecture continues to evolve throughout childhood and adolescence, and subtle differences of architecture between sexes may exist at times during this period. Sleep then reaches a fairly stable period until mid-life when gender differences begin to be more noticeable and suggest a female advantage. Sleep architecture continues to change subtly with ageing, sometimes affected by health and lifestyle.

Besides the biological changes that occur in sleep across age and gender, sleep disorders may develop, and certain of these have a higher prevalence or impact in one sex than the other. Furthermore, females' sleep is often affected by significant hormonal influences that may cause day-to-day alterations from menarche through menopause. Some women are more sensitive to these influences than others. Finally, psychosocial issues, particularly stressful lifestyle, affect one's ability to sleep well and cannot be ignored in a discussion of gender differences in sleep. Females, perhaps secondary to hormonal influences, appear to be more affected by stress than men. In addition, the psychosocial demands of mothering and caregiving frequently have a negative impact on woman's sleep.

SLEEP CHANGES ACROSS AGE AND SEX

A seminal work examining sleep in normal subjects was reported by Williams *et al.* (1974), who showed sleep architectural changes across ages and between genders (Table XXIV-10.1)

Table XXIV-10.1 Comparison of gender differences in sleep characteristics (Williams *et al.*, 1974)

Age (years)	Females	Males
3–5	Increased SWS, decreased stage 2	Increased TIB, SPT, TST
6–9	Increased SWS	
10–12	Increased SWS, no. of stage changes	
13–15	Same, begin to see decreased TIB, TST and TSP	
16–19	Same, decreased REM	
20–29	Increased stage 2	Increased awakenings
30–39	No differences	
40–49	Increased TST, SE	Increased WASO, decreased SE
50–59	Increased SWS, REM	
60–69	Increased SWS (50% have it)	Increased wake, only 10% have SWS
70–79	Increased stage shifts, SWS, REM	Increased TIB

SWS = slow-wave sleep, TST = total sleep time, TSP = total sleep period, TIB = time in bed, REM = rapid-eye-movement sleep, WASO = wake after sleep onset.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Non-complaining sleepers, categorized by decade and gender, were studied with full laboratory-based polysomnography. While not all variables that could influence sleep were controlled for at this early time in the science, this work did attempt to control for the influence of the menstrual cycle by studying only adult women in their follicular phase. Sleep differences between males and females were seen to begin around 9–10 months of age, with female babies sleeping longer. Around the age of 3 years, males showed greater time in bed (TIB), longer total sleep time (TST), longer REM cycle length and higher percentage of stage 2 sleep. Females demonstrated a trend toward increased SWS that continued throughout most of their lives. Teenage females tended to show less TIB, and in the later teens females slept less than males. In their twenties, females demonstrated more TST than men and continued to do so throughout life. Additionally, they showed more stage 2 sleep. Males began to show increased levels of arousal and decreased SWS toward the end of the second decade. The decline of SWS continued throughout their life, but it did not begin in females until the fourth or fifth decade. Males continued to show increased levels of arousal and decline in REM sleep during their fourth decade. Women began to show less SWS in their fifties and began to exhibit patterns like those of men in their thirties. Sleep became fragmented in women during the perimenopausal years with increased arousal. During the sixth decade, larger differences were seen in the amount of SWS; only 10% of males showed SWS while 50% of females did 50. In their seventh decade, women showed more stage changes than men did, perhaps simply because they continued to show all stages of sleep. By seventy, few men showed appreciable amounts of SWS. In addition, they tended to show shorter REM cycles. The REM cycles of younger adults showed increasing length across the night such that the last REM cycle of the night was the longest. This pattern changed in the elderly, with REM cycles becoming more even in length across the night.

While numerous smaller studies have confirmed these findings using visually scored sleep staging, many have resulted in controversy, particularly regarding the sleep of infants. Some studies of infants have shown no gender-related differences (Parmalee *et al.*, 1961, Hoppenbrowers *et al.*, 1989). Others have shown increased variability in males (Moore and Ucko, 1957) or females (Cornwell, 1992). The environment is one influence that could alter findings. To examine infant sleep and the influence of environment, Bach *et al.* (2000) examined the relationship between gender-related sleep differences with a thermal challenge. Healthy preterm neonates were studied (21 males/17 females) during three consecutive morning sleep sessions while sleeping in their closed, convectively heated incubators. The first morning served as a screen at thermoneutral conditions. The second session provided baseline data at thermoneutral conditions. The experimental condition, day 3, monitored sleep at cool conditions ($<1.5^{\circ}$C from baseline). Sleep continuity and architecture were altered in both males and females. Active sleep (AS) increased at the expense of quiet sleep (QS). Males exhibited a larger variability in their sleep than females, sleeping less, waking more frequently and showing more AS. Since QS is believed to be highly controlled by developing brain centres, the investigators suggested that stable QS might mark the more advanced development of the female infants. The investigators also proposed that the increased variability seen in male infant sleep might be similar to that seen in older males. Furthermore, they suggested the need to consider the role of environmental factors in the variability noted in infants' sleep.

Few differences have been noted among young adults by visual scoring. However, Dijk *et al.* (1989) studied gender differences in young adults aged 19–28 years (13 males/15 females), using computer-quantified spectral analysis of EEG. He noted no change between sexes in the distribution of sleep stages but saw an increase of delta power in the EEG (0.25–11 Hz) of women during NREM sleep and higher power densities in women during REM sleep that was consistent across the night. The changes were independent of those seen after sleep deprivation or increased homeostatic drive for sleep, which should have dissipated across the night. The authors suggest that these differences may reflect gender differences in skull size or thickness, which has previously been shown to be negatively correlated to EEG amplitude (Pfefferbaum and Rosenbloom, 1987) rather than physiological differences between the sexes. Unfortunately, nine of the females in this study used oral contraceptives, which may have acted to blunt the temperature changes that affected sleep.

Also using visually scored staging and period-analysis algorithms, Armitage (1995) studied young men and women (mean age 25 years, 11 men/11 women) to examine EEG frequencies during sleep. She evaluated EEG in five conventional frequency categories: delta (0.5–4 Hz), seen in SWS; theta (4–8 Hz), predominantly seen other stages of sleep; alpha (8–12 Hz), found in quiet wakefulness; sigma (12–16 Hz), seen in spindle activity of stage 2; and beta (16–32 Hz), seen in lighter stages of sleep and wake. No striking gender-related differences were noted. However, when the global delta power of NREM was examined, females again showed significantly more delta across the sleep period. Unfortunately, all the women were taking oral or injectable contraceptives, a factor that may have altered the findings. As we will see, this may have an important impact on the findings.

To examine the effects of ageing on the EEG, Ehlers and Kupfer (1997) studied young adults aged 20–40 years, using visually scored sleep staging and spectral analysis of EEG characteristics. No gender differences in SWS or delta wave activity were seen among subjects in their twenties. Both sexes had a decline in the spectral power of spindles with age. No significant change of a visually scored sleep variable was noted for women across the groups. However, significant reductions of delta activity and percent SWS were noted for men in their thirties. Additionally, males showed significant reductions of REM time, and REM density, activity and intensity, with an increase of stage 2 sleep. These authors suggested this might indicate that men and women age differently over the second and third decade.

To avoid confounds of the laboratory environment, numerous studies have evaluated sleep in the subject's home. Kobayashi *et al.* (1998) studied 18 older subjects (8 males/10 females, mean age 60.6 and 61.7 years, respectively) during two 36-h sleep/wake periods. Full polysomnography was obtained in the home. They noted that men napped more frequently, had lower sleep efficiency, more stage 1 sleep, less stage 3/4 sleep, less REM sleep, and more state changes than females. However, no mention was made of concomitant sleep disorders, such as apnoea, that could be expected to produce similar patterns.

In another small study, Fukuda *et al.* (1999) evaluated sleep in older subjects (8 males/8 females, aged 54–72), also using full polysomnography in their homes. Visually scored sleep staging and spectral analysis of two frequency bands (0.5–2 HZ and 2–4 Hz) were done. No significant gender differences were noted in the following visually scored sleep parameters (percent wake, stages 1 and 2 sleep, REM sleep and REM latency, TIB, TST, sleep efficiency (SE), and awakenings). However, females had a higher percentage of SWS (stages 3 and 4). With spectral analysis, the investigators report females had larger amounts of delta power across the night than men. Furthermore, the females maintained clearer periodicity of delta power across the night. The authors suggest that the SWS generator is better conserved in middle-aged and elderly females than in males of the same age.

In another home-monitored study, Reyner and Horne (1995) studied 400 adults (211 female/189 males) aged 20–70 years for 15 consecutive nights, using sleep logs and actigraphy. Actigraphy provides objective confirmation of sleep length and timing as well as sleep continuity. Subjects were divided into three age groups: young, 20–34 years; middle-aged, 35–49; and older, 50–70. Home

environmental factors were not controlled in this field study. Overall, there appeared to be minimal effects of ageing in both the subjective and objective parameters. However, women, particularly the older ones, tended to go to bed earlier than men and stay in bed longer, but they reported worse sleep with frequent awakenings, a report which was confirmed by actigraphy. They also reported longer sleep latency (time needed to fall asleep). There was also a significant difference in rising time between middle-aged men and women, with men rising earlier. Both men and women awoke earlier with age. Young men slept longer than both their middle-aged and older counterparts and middle-aged women slept longer than middle-aged men. Women in all age groups had significantly more awakenings than men. Many of these awakenings were noted to be environmental (children's needs).

CIRCADIAN RHYTHMICITY

As previously noted, sleep is regulated in part by our circadian cycle, with input from the pacemaker located in the suprachiasmatic nuclei, as well as from exogenous factors such as food, light and ambient temperature. Body temperature also has a circadian rhythm, oscillating between a nadir at night and a maximum in the afternoon, and is thought to influence sleep onset and offset. There has been interest as to whether the circadian rhythm of temperature and sleep is disrupted in ovulatory women who have a menstrual cycle, with increased body temperatures in the luteal phase, or in women taking oral contraceptives.

To examine this question, Baker *et al.* (2001) studied eight normally cycling women, eight women taking birth-control pills, and eight men (all aged 21–22). All subjects had a screen/adaptation night in the laboratory. Women were alternately studied in their mid-follicular and mid-luteal phases over a 3-month period. Polysomnography and continuous core body temperature were measured along with levels of estradiol and progesterone in the women. Both subjective and objective sleep measures were compared. Rectal temperatures of the normally cycling women were elevated, as expected in the luteal phase of the menstrual cycle compared to that in the follicular cycle, and they had blunted nocturnal drops of temperature compared to men, but not compared to the follicular phase. Both groups of women attained temperature minima earlier than men, suggesting a gender effect. The temperatures of the women taking exogenous hormones were similar to that of the luteal phase in normally cycling women. Therefore, hormonal supplementation may render these women poor subjects for sleep evaluations since the hormones alter the temperature phase. There was no significant difference in the sleep architecture (macrostructure) of men and women except that more SWS was seen in the luteal phase of normally cycling women. Those women on exogenous hormones demonstrated less SWS than normally cycling women.

Buysee *et al.* (1993) studied 17 healthy, 20–30-year-old men ($n = 9$) and women ($n = 8$) and 18 healthy 80-year-olds (11 men/7 women) during a 36-h constant routine paradigm to evaluate temporal patterns of unintended sleep episodes. The constant routine followed a 24-h adaptation period of normal routines. During the constant routine, balanced nutrition was supplied every hour. Core body temperatures were tracked on line, and cortisol and melatonin levels were sampled over the entire period. All subjects had continuous EEG with measurement of mood and sleepiness every hour. Women showed stronger rhythmic trends for sleep than men, and the older women in this study showed higher temperature amplitudes than the younger women. All temperature measurements of the younger women were taken during their follicular menstrual phase. However, three of the younger women were taking oral contraceptives, and this could have served to blunt the temperature curves for younger women.

To examine further the relationship between age-related changes in sleep and the circadian timing system, Campbell and Murphy (1998) studied 60 subjects (32 females/28 males) aged 40–84. For some analyses, the group was divided by age: a group of 40–60 middle-aged subjects, and two older groups of 65–81. One of the older groups was a subset that had experienced sleep difficulties for at least 1 year prior to the study. Polysomnography and measures of core body temperature were performed at an adaptation and baseline night. There was no difference between the sleep quality of non-complaining older subjects and that of those middle-aged; however, there was an advance of minimum body temperature in older subjects. Complaining older subjects had decreased TST, SE, and REM with increased wake after sleep onset (WASO) compared to non-complaining older subjects. There was no difference in the rhythm of body temperature between complaining and non-complaining older subjects. With age controlled for, women showed significantly higher temperature amplitude than men. In addition, there was a significant age effect on amplitude in women, but not men. According to the authors, these findings argue that older women maintain a stronger circadian rhythmicity than older men, as measured by temperature curve amplitude, and that age-related sleep disturbances may have multiple causes.

Parry *et al.* (1997) studied the nocturnal patterns of melatonin in women with premenstrual dysphoric disorder (PMDD) and controls, and noted a delay in the secretion of melatonin and a decrease in melatonin secretion during the luteal menstrual phase, as compared to the follicular phase in women with PMDD. The authors suggest that the circadian pacemaker of women with PMDD is more responsive to the hormonal changes of the menstrual cycle. Furthermore, they postulate that this sensitivity may render these women more subject to mood, cognitive and sleep disturbances as a result of endogenous and exogenous stimuli.

HORMONAL INFLUENCES: MENSTRUATION, PREGNANCY, LACTATION, AND MENOPAUSE

Limited data suggest that secretions of gonadal hormones influence/modulate sleep physiology in animals, and both the physiology and disorders of sleep in humans. Neuroendocrine function is influenced at both the pre- and postsynaptic levels. However, most animal studies have been carried out in males of species where the direct influence of exogenous hormones may differ from that endogenously produced. Animal studies show that neurosteroids (oestrogen, progesterone and testosterone) play a pivotal role in the mediation of stress and the effect on brain functions. In humans, studies examining the role of these hormones have been small-scale, and few studies have taken even menstrual cycling into consideration in any systematic way. Nevertheless, both animal and human studies indicate neurosteroidal effects at both the genomic and nongenomic levels. Furthermore, effects have been noted in brain regions related to the control of sleep and wake (medial preoptic nuclei, medial hypothalamus) and limbic areas such as the hippocampus and amgydala.

For instance, oestrogen has been shown to increase the turnover of norepinephrine in the brainstem, hypothalamus, nucleus accumbens and locus coeruleus, as well as to alter expression of c-fos proteins in A2 adrenergic neurons. These effects act to decrease REM sleep, but the action appears to depend on the phase of the circadian cycle. Temperature phase may be altered, suggesting that oestrogen may weaken the coupling between the core body temperature and the sleep/wake cycle, or otherwise modulate circadian rhythms (Dijk, 1989).

Oestrogen acts as an excitatory stimulus by increasing the production and receptor concentrations of neurotransmitters such as serotonin, norepinephrine and dopamine, as well as the B-endorphins, and increasing the availability of glutamate, which

stimulates the excitatory *N*-methyl-D-asparate system (NMDA) (Arpels, 1996). In theory, increased levels of oestrogen occurring as a consequence of oestrogen hormone replacement therapy (HRT) could increase activity and irritability and lessen sleep. However, studies evaluating HRT in post-menopausal women demonstrate increased sleep times; that is, less fragmentation and enhanced REM sleep compared to baseline and placebo controls (Leproult *et al.*, 1998).

Progesterone and its metabolites act directly on the $GABA_A$ receptor and, through a complex mechanism, this action results in either a hyperpolarization and decrease in neuronal excitability (allopregnanolone and pregnanolone) or an antagonistic reaction that limits GABA-induced chloride transport (pregnenolone sulphate) (Mellon, 1994). The sedating action of progesterone is comparable to that of the benzodiazepines and is dose-dependent (Lancel *et al.*, 1997). Progesterone has been shown to decrease sleep latency, decrease wakefulness and increase EEG spindle activity in both REM and NREM sleep, in both animal and human studies. Furthermore, the progesterone antagonist, mifepristone (RU-486), has been shown to produce an increase of wake time, longer sleep latencies and decreased REM and SWS when administered to healthy men (Wiedemann *et al.*, 1998). Progesterone also acts as an anti-oestrogen and downregulates the oestrogen receptors.

Antonijevic *et al.* (1999) note the likelihood that ovarian steroids, such as estradiol and progesterone, may modulate GABA receptors, as well as the adrenergic system, thus effecting changes in sleep between the sexes. Women secrete more cortisol early in the night and show a pulsatile pattern of release of growth hormone (gH) across the night as compared to men, who typically show a single peak at the start of sleep.

Researchers have also detected changes in cellular immune function across the menstrual cycle that appear to be associated with fluctuations of progesterone. Moldofsky *et al.* (1995) have shown that there is less natural killer (NK) cell activity during the luteal phase, when progesterone is high. During the follicular phase, the NK responses are the same as in men. This suggests that progesterone may modify immune function and may affect women's risk of lupus and rheumatoid diseases that also alter their ability to sleep.

Human sleep changes during the perimenopausal years may therefore reflect the impact of fluctuating and ultimately decreasing levels of oestrogen and progesterone. Additionally, sleep across the menstrual cycle, for those women sensitive to subtle hormonal changes, can be problematic. Numerous studies and surveys of subjective complaints of sleep disturbance demonstrate large numbers of women with occasional, menstrual-related sleep difficulty (National Sleep Foundation, 1998). However, few objective studies confirm these complaints. This may be partly because few studies have accurately measured hormonal levels, many dividing the menstrual cycle into a variety of phases that could not be matched for meta-analysis, and most studies having few subjects. Furthermore, the two well-controlled studies that follow illustrate the subtlety of sleep changes across the menstrual cycle in healthy, non-complaining women.

Ito *et al.* (1995) studied seven women aged 18–19 who spent three consecutive days in each of five successive weeks in the laboratory. The investigators studied the plasma melatonin circadian pattern under controlled conditions with measurements every hour for 24 h on the third day of each week. They divided the menstrual cycle into four phases. Plasma melatonin was raised in the late luteal phase, and the rise time was delayed on the first of the three days in the laboratory. Additionally, SWS was increased in the follicular phase as was TIB and TST, suggesting that the menstrual cycle did affect melatonin and sleep/wake rhythm.

In a study of nine menstruating women free of oral contraceptives, Driver *et al.* (1996) evaluated 138 sleep episodes spaced every other night throughout a 36-day period. Menstrual status was measured with biphasic temperature rhythms, to capture pre/postovulatory phases, urinary luteal hormone (LH), and mid-luteal plasma levels of oestrogen and progesterone. Lighting, activity, and alcohol and caffeine intake were controlled. Subjective and objective measures of sleep showed no significant change over the menstrual cycle, with the exception of an increase of spindle (14.25–15 Hz) activity that had large variations across the cycle, reaching a high in the luteal phase in parallel with body temperature.

Animal work also suggests that the androgens (testosterone) play a role in the sexual dimorphism of REM sleep during a critical period of brain development around the perinatal time (Manber and Armitage, 1998). The administration of exogenous testosterone to adult animals has been shown to have little effect on sleep. However, it is felt that in humans it is the lessening of progesterone, as well as the change in the ratio of oestrogen to testosterone, that may influence the sleep changes around the perimenopause.

Pregnancy

Significant changes in sleep occur during pregnancy, in part due to hormonal changes and changes in the woman's girth. Profound sleepiness occurs during the first trimester secondary to elevated levels of progesterone. Progesterone also affects smooth muscle and the resultant urinary frequency disturbs sleep. Restless legs and pain begin to disrupt sleep during the second trimester. In the third trimester, women are uncomfortable due to the gravid uterus.

Using quantitative EEG, Brunner *et al.* (1994) studied nine healthy pregnant women, on two consecutive nights during each trimester. WASO was elevated across the pregnancy. No other significant differences were noted by visual scoring, but the quantitative techniques revealed significant changes across trimesters. There was an increase in WASO from trimester 2 to trimester 3, a decrease in REM sleep from trimester 1 to trimester 2, and a progressive reduction in NREM power density of spindle bands of $>14.25–15$ Hz across the pregnancy.

A second study of this type confirmed a loss of SWS as the pregnancy progressed. Schoor *et al.* (1998) studied four pregnant women and four non-pregnant controls with polysomnography in each trimester. There were no differences between groups on comparing time until sleep onset, latency to stage 2 and latency to REM. There were no differences in cardiopulmonary indices. However, there was a decrease in SWS even during the first trimester, and alpha intrusion into SWS was noted in the pregnant women.

Not only does pregnancy affect sleep but also sleep problems continue into the post-partum phase for many women. Lee and Zaffke (1999) followed 24 primiparous and 18 multiparous women to evaluate perceived levels of fatigue and energy before, during and after pregnancy. Studies were carried out in the subjects' homes during the follicular and luteal phase of menstruation prior to conception that served as baseline. Studies were repeated during each trimester and again at months 1 and 3 of the post-partum period. The measures included polysomnography, and scales such as the Lee Fatigue Scale, the POMS and the Dupuy General Well-Being and Vitality subscale. Serum chemistries included iron (Hg, HCT, ferritin, B_{12} and folic acid); progesterone; and thyroid serum T3, serum T4, T3 resin uptake, free T4 index, and thyroid antimicrosomal antibody titre. Complaints of fatigue during the first trimester were related to younger age and lower levels of iron, haemoglobin and ferritin. Haemoglobin levels remained low normal throughout the pregnancy while ferritin levels dipped more slowly across trimesters. During the third trimester, fatigue was related to decreased TST. Post-partum, fatigue was related to decreased sleep, ferritin and haemoglobin. Even at 3 months post-partum, these women still felt less energy than their baseline levels. The

perception of energy appeared to be influenced by parity, with multiparas having less energy throughout pregnancy. This suggests that pregnancy takes a significant toll on the sleep patterns and energy levels of women. Poor sleep may incline women to profound mood changes and depression during the post-partum period. Some believe the 'baby blues' may be a consequence of prolonged sleep deprivation.

Additionally, during pregnancy, changes in respiration and airway mechanics occur. Snoring and apnoea are not uncommon. To evaluate the extent of this problem, Loube *et al.* (1996) carried out a large survey of pregnant women, determining snoring status and comparing infant outcomes to examine the impact of self-reported snoring on infant health. A total of 350 pregnant women and 110 age-matched women as controls answered a survey about snoring and daytime sleepiness. Those with reported daytime sleepiness and snoring were given full sleep evaluations. Fourteen percent of pregnant women snored versus 4% of the non-pregnant. Eleven women reported anecdotal apnoea. Of these, only four were recorded. Two of them met the criteria for mild apnoea; one had positional apnoea and the other only snored. There were no significant differences between infants from either group.

In contrast, Franklin *et al.* (2000) noted in a study of 500 Swedish women that habitual snoring was a sign of pregnancy-induced high blood pressure (preeclampsia), and was associated with lower birth weights and lower Apgar scores. The study also noted that women started to snore before any sign of hypertension appeared, and that snoring was related to sleep apnoea. While it may seem reasonable to suppose that the increased abdominal girth of pregnancy (with or without excessive weight gain) underlies the increase in apnoea, there is little evidence to support this. A more likely explanation is that the frequent nasal congestion experienced by pregnant women predisposes to upper airway collapse due to the large negative pressure in the airway needed to overcome the nasal obstruction.

Perimenopause and Menopause

Many researchers and clinicians have noted an increase in complaints of fragmented sleep secondary to the hot flashes of menopause. Women complain of difficulty in falling asleep and experience disrupted sleep, as hot flashes occur frequently at night. The hot flash typically is characterized by peripheral vasodilatation, profuse sweating, and subsequent chilling, and is thought to be a disorder of thermoregulation. Alterations in central catecholamines occur; specifically, levels of plasma 3-methoxy-4-hydroxyphenylgylcol (MHPG) are higher in women who experience hot flashes (Woodward and Freedman, 1994). In a sense, the hot flash is a general alerting mechanism which interrupts sleep and requires time to settle before sleep can comfortably recur, resulting in sleep loss and daytime consequences such as loss of concentration and memory. The addition of oestrogen and oestrogen HRT reduce the hot flash and have been seen to increase SWS in post-menopausal women (Leproult *et al.*, 1998). Furthermore, oestrogen HRT has been shown to reduce the respiratory disturbances more common in post-menopausal women (Pickett *et al.*, 1989).

Menopause is preceded by many years of hormonal changes. This period, called the perimenopause, can stretch for 5–10 years before the onset of the menopause. Perimenopausal women frequently note mood changes and sleep disruption during this time. Baker *et al.* (1997) confirmed these complaints in a study of 15 perimenopausal and 13 premenopausal women. Perimenopausal women had higher anxiety levels and lower vigour than premenopausal women, as measured by the State-Trait Anxiety Inventory (STAI) and the POMS. There was a significant correlation between the STAI scores and sleep arousals, and it was clear that sleep disruption had a mediating role in mood changes.

In another interesting paper, Shaver and Paulsen (1993) reported on subjective and objective studies of 135 healthy women aged 37–59. Women were grouped as premenopausal and menopausal, each with and without 'poor' sleep. The authors noted that women with objectively documented poor sleep had higher psychological distress rather than active menopausal symptoms. This suggests that the sleep disruption in the menopausal years may not be totally due to hormonal changes. This is also an age of life-altering changes that can produce stress. Children are leaving, parents are requiring more care, marriages are being renegotiated and women may be redefining their roles. These stresses add to a hormonally volatile time in women's lives.

DREAMING

Gender differences in dream content begin to emerge during adolescence. Males show more aggression than females, who dream about relationships and pleasant emotions. This difference continues into adulthood, depending upon the socialization developed (Hall *et al.*, 1982). Working women's dreams, especially those of women in traditionally male professions, become more male-like than do those of the homemaker. This suggests that dreams have a role in reflecting experiences of the waking state (Lortie-Lussier *et al.*, 1985).

PREVALENT SLEEP DISORDERS

Insomnia

Far more women than men complain of insomnia; that is, difficulty in falling or staying asleep (Table XXIV-10.2). This increase may be related to the increase of depression in women or at least the reporting of somatic symptoms related to sleep difficulties, which is increased among depressed women both acutely (Angst and Dobler-Mikola, 1984) and chronically (Kornstein *et al.*, 2000). This association has been noted in epidemiological studies (Bliwise *et al.*, 1992). The causation of symptoms is still unclear, that is, whether sleep difficulties precede mood symptoms or not (Browman *et al.*, 1996). Furthermore, women may be subject to the entrainment of poor sleep habits first developed during years of parenting.

The increase of reports of insomnia among women is especially marked during the perimenopausal years when hormone levels are rapidly shifting, and this disorder continues to be prominent as women age. Maggi *et al.* (1998) evaluated by questionnaire 2398 (867 males/1531 females) community-living older (>65 years) subjects. The prevalence of insomnia was 54% in women compared to 36% in men. There was an increased odds ratio for insomnia (1.69) and depression (1.93) in women, even when results were controlled for potential risk factors such as health status and smoking and alcohol habits. Night waking was the most common complaint.

The causes of insomnia are usually multi-factorial and include the major categories of physical changes such as poor health; hormonal status; physiological changes such as jet lag; and psychological, psychiatric, and pharmacological influences. Because sleep loss has a profound effect on quality of life and daytime functioning, recognition and treatment of insomnia are important.

Treatments should be designed to alleviate the cause when possible. In cases of depression, adequate treatment of the depression usually heralds improvement in sleep, as long as poor sleep habits have not begun. In this event, short-term use of hypnotics may be appropriate while better sleep habits and behavioural changes are being reinforced. Ultimately, long-term improvement is best achieved with behavioural techniques (Morin *et al.*, 1999).

Fibromyalgia

Frequently, pain syndromes, more common in women, can negatively influence sleep. In a study of 11 women with fibromyalgia

Table XXIV-10.2 Sleep disorders prevalent in women compared to men Diagnostic Classification Committee, 1990)

Females	ICSD code	ICSD code	Males
Psychobiological insomnia		780.53	Obstructive sleep apnoea
Sleep state misperception	307.49	780.54	Hypersomnia
Restless legs syndrome	780.56	780.51	Central alveolar hypoventilation
Adjustment sleep disorder	307.41	780.55	Delayed sleep phase
Hypnotic dependent syndrome	780.52	307.46	Sleep terrors
Nightmares	307.49	307.3	Rhythmic movement disorders
Familial sleep paralysis	780.56	307.47	Somniloquy
Headaches	346	780.59	REM behaviour disorder
Fibromyalgia	729	788.36	Sleep enuresis
Nocturnal sleep-related eating disorders	780.52	780.59	Sudden unexplained nocturnal death syndrome
		786.09	Primary snoring
		798	SIDS

and 11 matched controls, Shaver *et al.* (1997) studied subjective reports as well as physiological indicators of stress. The study showed that sleep in the early part of the night is more fragmented, with increased arousal but no prominent EEG change in subjects with fibromyalgia. The 11 women with fibromyalgia reported worse sleep and higher psychological stress, as measured with SCL-90, on the somatization, obsessive-compulsive and anxiety subscales, although the scores were still within the normal range, despite showing no changes on measures of sympathetic activity, such as morning levels of cortisol and catecholamines from urine spills. The authors speculate that a disturbance of nocturnal growth hormone secretion may be related to these complaints.

Restless Legs Syndrome

Restless legs syndrome (RLS) is a common sleep disorder affecting more women than men, and it may affect the ability to fall asleep (Lavigne and Montplassir, 1994). RLS is characterized by the irresistible need to move one's limbs (particularly the legs). Feelings can be described as 'creepy crawling' or 'bubbling in the veins'. The constant need to move disrupts sleep. Unfortunately, the circadian rhythm of RLS worsens the symptoms in the evening. Many sufferers also demonstrate periodic leg movements (PLM) during sleep, further disrupting the continuity of sleep. Symptoms generally increase with age but occur frequently during pregnancy as well.

Recent research suggests the association of RLS with low brain ferritin levels (Early and Connors, 1999). Increasing serum levels of iron may be therapeutic. Furthermore, dopaminergic drugs and antispasmotic medications have also proven useful in treating this disorder.

Sleep Apnoea

Another common sleep disorder, the prevalence of which differs between men and women, is obstructive sleep apnoea. Apnoea, or hypopnoea, refers to the cessation of airflow during sleep, usually as a result of complete (apnoea) or incomplete (hypopnoea) closure of the airway. The closure is brief, lasting $\geq$10 s, but may be repeated every minute across the night. Sleep in this condition is disrupted by brief arousals at the end of each respiratory event. Furthermore, depending on the extent of apnoea and the cardiopulmonary health of the subject, significant oxygen desaturations may occur.

The estimated prevalence of sleep-disordered breathing, which is defined as an apnoea-hypopnoea score over 5/h sleep, is 24% in men and 9% in adult women. Four percent of males and 2% of females have the apnoea-hypopnoea syndrome, which includes daytime sleepiness (Young *et al.*, 1993).

The symptoms of obstructive apnoea in both men and women include dramatic snoring (although many women do not know whether they snore), gasping during sleep, restlessness and daytime sleepiness. Unfortunately, despite giving the classic symptoms of apnoea to their health-care provider, many women go undiagnosed. It is not clear whether this results from the bias of the health-care worker or the concurrent reporting of psychologically oriented symptoms, such as insomnia, depression and anxiety, which attract more attention in women (Young *et al.*, 1996). In fact women with sleep apnoea report far more symptoms of depression and anxiety, as measured with the SCL-90, than men regardless of the severity of their apnoea. Furthermore, complaints of depression and anxiety were higher in women with severe apnoea than women with mild apnoea (Pillar and Lavie, 1998).

Much speculation has occurred as to why there is a sexual dimorphism in this disorder. Popovic and White (1998) studied 12 pre- and 12 post-menopausal women. They found an increase in pharyngeal dilator muscle activity, probably related to levels of progesterone in awake females, such that the genioglossis tone is increased in the luteal menstrual phase, as well as in those post-menopausal women taking oestrogen HRT. However, during sleep, Thurnheer *et al.* (2000) noted no such difference. This group studied two age groups (18–35 years and 40–70 years) of both men and women with nocturnal polysomnography, measuring airway resistance during sleep, and saw no differences in airway tone between genders and across age. They did note an increase in total respiratory resistance at sleep onset in men compared to women. The authors suggested that the waking increase in upper airway resistance previously seen in women reflected the narrower size of their airway.

Obesity tends to be a major factor in the development of obstructive apnoea. However, for equal degrees of obesity, a man would probably have more sleep apnoea than a woman, perhaps because of the placement of male fat in the mid-torso area. However, women who are severely overweight are at risk at any age. They may not have apnoea from airway obstruction, but they may suffer from hypoventilation, a decreased effort to breathe, particularly in REM, allowing significant hypoxia to develop (O'Connor *et al.*, 2000). As previously mentioned, women can also develop a temporary form of sleep apnoea during pregnancy.

Treatment of apnoea is essential to good health. Recent data suggest that apnoea is an independent risk factor for hypertension and cardiovascular morbidity in the general public (Peppard *et al.*, 2000). Treatments range from weight loss and positional therapy to mechanical devices such as CPAP, a pressure of air presented to the airway which acts as a pneumatic splint to keep the airway

open, and dental devices which increase muscle tone and space in the pharyngeal airway.

CONCLUSION

Subtle differences in sleep architecture exist between males and females, particularly as they age. Most of these differences appear to be influenced by the gonadal hormones oestrogen and progesterone in females, and testosterone around the perinatal period in males. Oestrogen seems to increase REM sleep in humans and improve sleep continuity in menopausal women. Progesterone is known to be sedating and similar to the benzodiazepines in that it decreases REM sleep and increases spindling and stage 2 sleep in humans. Testosterone in males appears to influence REM sleep, and the ratio of testosterone to oestrogen in females appears to influence irritability and sleep fragmentation. Females' cyclic hormonal nature significantly influences sleep architecture across their reproductive lifetime.

Furthermore, certain sleep disorders appear to 'favour' one sex over the other. Women have a risk of depression twice that of men. Anxiety and depression increase the risk of insomnia in this group. Other sleep disorders such as apnoea appear to be twice as common in men. Significant respiratory disturbance during sleep lessens REM sleep and fragments NREM sleep, resulting in excessive daytime sleepiness.

It is sensible to take this information into consideration when attempting to evaluate or improve sleep in both men and women.

XXIV-11

Sleep Disorders — Therapeutic Armamentarium

Malcolm Lader

INTRODUCTION

We spend a third of our lives asleep and yet sleep remains an enigma. The numerous and complex disorders of sleep have been dealt with in several previous chapters. The most common complaint is that of insufficient and unsatisfying sleep. Problems with excessive sleep are much less common. Abnormal sleep is also noted on occasion, usually manifested as aberrant behaviour such as night terrors or sleepwalking.

A range of medications is available to treat insomnia, ranging from folk remedies such as valerian to the most recently introduced compound, zaleplon. Many medications possess sedative and sleep-inducing properties as a side effect, such as many tricyclic antidepressants and the first-generation antihistamines. Fewer remedies exist to treat excessive or qualitatively abnormal sleep, but progress is being made.

The purpose of this chapter is to review the available remedies, concentrating on the newest introductions that are of both theoretical interest and practical utility. The emphasis will be on the remedies for insufficient sleep — the hypnotic drugs — as these are among the most-widely prescribed medications, particularly by primary care practitioners (Simon and VonKorff, 1997).

SLEEP HYGIENE

Before dealing with hypnotic medication, it is useful to outline the stratagems that people use to induce and maintain sleep (Table XXIV-11.1). A regular bedtime routine is conducive to sleep, and many people follow a time-hallowed sequence of events, almost a ritual, before they retire at night. Regular hours for going to bed and for rising in the morning help consolidate sleep, and this routine should be maintained at the weekends and during vacations as well. Many people read before going to sleep, but arousing or disturbing material should be avoided. Rehearsing the next day's agenda or worrying about finances, family, etc. is unhelpful.

Exercise late at night is used by many people to hasten the onset of sleep although it is probably the routine that is most important. However, the optimum is moderate exercise in the afternoon or early evening, as anyone taking a vigorous sport-oriented vacation can testify. By contrast, heavy, exhausting exercise may be unhelpful (Horne, 1981).

The bedroom should be quiet, so that sound-attenuation may be needed if it abuts on a noisy street or lies under the flight path to an all-night airport. The room should not be too hot nor too cold. Many people take a milky drink at bedtime and there are many on the market. Tea and coffee may induce insomnia (Stradling, 1993). Coffee was once dubbed an 'antihypnotic' (Miller, 1722). Tolerance to the effects of the active principles, caffeine and, to a lesser extent, theobromine, tends to get lost as the individual ages.

Table XXIV-11.1 Elements of sleep hygiene

A. Regular bedtime routine
B. Standard hours of retiring and getting up
C. Avoid worry
D. Exercise in late afternoon/early, but not late, evening
E. Quiet, warm, comfortable bedroom
F. Avoid caffeine-containing drinks and too much alcohol

Table XXIV-11.2 Behavioural techniques

A. Stimulus control
B. Sleep restriction
C. Sleep hygiene education
D. Paradoxical intention
E. Attention-focusing procedures: thought-stopping, imagery training, meditation, yoga
F. Relaxation: progressive muscular relaxation, autogenic training, biofeedback

Alcohol is also used by many people, the traditional 'nightcap'. However, too much may disturb sleep due to its diuretic effect and to rebound insomnia later on.

RELAXATION AND NON-PHARMACOLOGICAL TECHNIQUES

Some people find formal relaxation techniques very helpful, especially if meditation techniques have been learnt for daytime use (Table XXIV-11.2). Nevertheless, meditation and the induction of sleep are distinct physiological and psychological processes, and it is the muscular relaxation that is most relevant. Simple relaxation exercises in which the person relaxes muscle groups progressively from toes to legs, trunk, arms, neck and head are appropriate.

More elaborate behavioural techniques have been advocated (Bootzin and Perlis, 1992; Sloan and Shapiro, 1993). Although not widely available, a variety of techniques have been developed. Morin and his colleagues evaluated 59 treatment studies involving over 2000 patients. These were predominantly women, and the mean age was 44. Most suffered from chronic primary insomnia, on average, of 11 years' duration. Most subjects received sleep-focused interventions with an average treatment time of 5 h. Follow-up lasted a mean of 6 months.

Of four outcome variables assessed, two in the meta-analysis — sleep-onset latency and time awake after sleep onset — were significantly improved following behavioural interventions. The absolute number of awakenings and total sleep time

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

were not significantly improved. The average effect size for sleep-onset latency was 0.88, signifying that patients with insomnia were better off after treatment than 81% of untreated control subjects. The average effect size for time awake after sleep onset was lower at 0.65, indicating that patients with insomnia were sleeping better than 74% of the untreated sample. Stimulus control and sleep restriction were the most effective therapy procedures given alone, whereas education about sleep hygiene was not effective when used alone. These improvements were well maintained at follow-up assessments.

What are these apparently useful therapies? *Stimulus control* comprises a set of instructions designed to help the insomniac avoid sleep-incompatible behaviours and to regulate sleep-wake schedules (Bootzin *et al.*, 1991). Such manipulations include instructions to go to bed only when sleepy; that the bedroom is to be used only for sleep and sex, and not to work or watch television; that whenever unable to sleep for 15–20 min, patients are to get up and go into another room, and return only when feeling sleepy again; that patients are to rise every morning at the same preset time regardless of quality and quantity of sleep the previous night; that there is to be no daytime napping.

Sleep restriction consists of curtailing the amount of time the insomniac is allowed in bed to the actual duration of sleep (Spielman *et al.*, 1987). Thus, the insomniac who reports sleeping only 5/8 h in bed is allowed to stay in bed for only 5 h. Once 90% sleep efficiency is achieved, the allotted time is increased by 15–20 min for the next week. If sleep efficiency is below 80%, the time window is decreased by 15–20 min. Between 80% and 90% efficiency, the time in bed is kept constant. Constant monitoring is carried out by means of a sleep diary, and appropriate adjustments are made.

Sleep hygiene education is essentially informing insomniacs about the factors that influence sleep, as set out above. It also involves exploring individual sleep expectations and setting realistic targets. A regular routine, avoidance of napping, and advice concerning substance use and medication are the components of sleep hygiene that are easiest to modify.

Paradoxical intention is somewhat akin to the implosion therapies used in phobias. It consists of persuading the insomniac to confront the feared behaviour, i.e., failing to fall or stay asleep. Often patients become 'insomnophobic', worrying about staying awake and thereby instituting a vicious circle of anxiety, insomnia and further insomnia. The theory is that if the patient stops trying to fall asleep but tries to stay awake instead, sleep will supervene more easily. However, rather like implosion treatment, paradoxical intention treatment has been disappointing.

Attention-focusing procedures use techniques such as thought-stopping, imagery training and meditation to focus the mind away from concerns about staying awake. *Relaxation* therapies focus on the body rather than cognition and comprise techniques such as progressive muscular relaxation, autogenic training and biofeedback.

Most studies evaluating non-pharmacological therapies rely on sleep diary records. This is not necessarily a limitation, as insomnia is a subjective complaint and coordinations with polysomnographic data are disappointing. Where objective techniques have been used as outcome criteria, some efficacy is still seen but less than that relating to subjective reports.

In conclusion, although psychological treatments are time-consuming and should be provided by trained personnel, benefits do accrue with some of the therapies and tend to persist. The long-term drawbacks of drug therapies do not apply. Behavioural and cognitive methods, rather than analytically based psychotherapies, are preferred. Sleep hygiene education is not enough without more specific techniques.

Table XXIV-11.3 Some benzodiazepines and similar hypnotics

Benzodiazepine	Elimination half-life (h)
Long-acting	
Nitrazepam	25–35
Flunitrazepam	10–20
Flurazepam	40–100
Quazepam	40–100
Intermediate-acting	
Temazepam	10–15
Lormetazepam	8–15
Short-acting	
Triazolam	3–5
Non-benzodiazepine	
Zopiclone	4–6
Zolpidem	2–4
Zaleplon	0.8–1.5

HYPNOTIC DRUGS

A wide range of drugs is used to treat insomnia (Table XXIV-11.3). They can be divided into two groups: a) those whose primary purpose is to induce, consolidate or prolong sleep; b) those where side effects of sedation are exploited. In the former group, the benzodiazepines still dominate the market despite misgivings concerning adverse effects, tolerance and dependence (Lader, 1994). Long experience of usage and cheapness still commend them to many practitioners. The properties of the ideal hypnotic include rapid onset of action, dependable onset or prolongation of sleep, minimal residual daytime sedation, safety in overdosage, lack of rebound dependence and abuse potential, and flexible dosage formulation. Safety in the elderly is particularly desirable, as they are heavy users of hypnotics.

Several effects of benzodiazepine hypnotics are clearly dose-related. Efficacy is increased at higher doses, as are side effects on psychomotor and cognitive function. Severe adverse reactions such as aggressive outbursts and episodes of amnesia also increase in frequency as the dosage increases: this is apparent with triazolam and flunitrazepam. Discontinuation effects, such as rebound and dependence, are also dose-dependent. Finally, abuse generally involves very high doses of hypnotic benzodiazepines.

BENZODIAZEPINE HYPNOTICS

Many of these compounds are available throughout the world, the range varying from country to country. The commonest ones encountered are temazepam, flurazepam, triazolam, nitrazepam and flunitrazepam. The last two are not available in the USA. These drugs can be divided for convenience into long-, intermediate- and short-acting, depending on their duration of action in normal dose. This in turn, mostly reflects the mean elimination half-life.

LONG-ACTING COMPOUNDS

As sleep is a night-time phenomenon, averaging 8 out of the 24 h, a long-acting hypnotic raises questions of desirability and logicality. Inevitably drug effects will persist the next day and accumulation is very likely. The development of tolerance will lessen such residual effects, but it is impossible to predict whether any particular individual will remain affected. Furthermore, objective effects may occur with subjective effects so the patient may be impaired unwittingly. The advantage of a long-acting hypnotic

benzodiazepine is that an anxiolytic effect will be present during the day. Thus, if the insomnia is a component symptom of an anxiety disorder, the latter will also receive symptomatic treatment. However, there are less contentious drug treatments for anxiety disorders (see Chapter XIX-13).

Nitrazepam was the first benzodiazepine marketed as a hypnotic. Its half-life ranges between 25 and 35 h (Breimer *et al.*, 1977). Residual effects are quite marked the next day, even after doses of 5 mg. Accumulation is likely, but, generally speaking, it is well tolerated and has been widely used in Europe.

Flunitrazepam is a similar compound with a duration of action of at least 24 h, reflecting an elimination half-life of 10–20 h (Boxenbaum *et al.*, 1978). The recommended dosage is 0.5–1 mg, but adverse events such as amnesia have attended the use of higher doses. Flunitrazepam is associated with two types of notoriety. It has a very rapid onset of action and powerful effects. It has been used as a 'date-rape drug', administered clandestinely in alcoholic drinks to unsuspecting women (and men). Usually, the victim is amnesic after the period during which the sexual assaults took place. The formulation has been changed in many countries to obviate surreptitious administration. The second problem is illicit abuse 'on the street'. In this respect, it has given rise to the greatest problem worldwide of all the benzodiazepines, even in the USA, where it is not licensed. It is taken orally, intranasally and by injection. Its scheduling has been strengthened because of its particular menace.

Flurazepam (and the closely related *quazepam*) (Ankier and Goa, 1988) are long-acting drugs with a half-life of 40–100 h. This reflects its metabolism to the long-acting *N*-dealkylflurazepam (Greenblatt, 1991). Residual daytime sedation is marked, particularly at the upper, marketed dose of 30 mg. Accumulation is also marked (Mamelak *et al.*, 1989).

Loprazolam is best regarded as a long-acting compound, as its absorption can be erratic and slow (Clark *et al.*, 1986).

INTERMEDIATE-ACTING COMPOUNDS

Temazepam is the most-widely used of these compounds. It has a half-life of about 10–15 h and is devoid of active metabolites (Greenblatt, 1991). It is generally well tolerated, and residual effects are not usually a problem even in the elderly. A wide dose range is available (7.5–30 mg). Temazepam was originally marketed in the UK in liquid-filled capsules which were extensively abused by addicts. Reformulation as a gel was unsuccessful; therefore, the drug is available in the UK only as a tablet. Its scheduling has also been strengthened.

Lormetazepam is somewhat shorter-acting but is otherwise similar to temazepam (Pierce *et al.*, 1984).

Lorazepam is also licensed as a hypnotic in many countries at higher doses than those recommended for anxiolytic effects.

SHORT-ACTING COMPOUNDS

The major member of this group is *triazolam*. This hypnotic has been the focus of much controversy since the late 1970s. It is rapidly absorbed and has a half-life of 3–5 h (Greenblatt, 1991). Residual day-time sedation is not usually a problem unless the recommended dose of 0.25 mg is exceeded. The other problem at higher dosages is an increased incidence of anterograde amnesia, and aggressive and suicidal behaviour. This resulted in much concern in the early 1990s. The UK Licensing Authority took the hardest line, withdrawing the drug from the market. It was never reinstated. In other countries, notably the USA, triazolam has remained available but with cautions regarding monitoring and recommendations that the appropriate dose be 0.25 mg in adults and 0.125 mg in the elderly.

Midazolam is generally available as an intravenous anaesthetic induction agent. In a few countries it is formulated for use orally as an hypnotic.

UNWANTED EFFECTS

These have been catalogued many times (e.g., Lader, 1994). As emphasized earlier, many adverse effects with hypnotic medication are strongly dose-related (Roth and Roehrs, 1992). The main problems are as follows:

1. There is residual sedation, which may be associated with psychomotor and cognitive impairment. Practical activities, such as driving, may be quite markedly affected so that the accident rate of benzodiazepine hypnotic users is substantially elevated (Ray *et al.*, 1992).
2. Sedation is easily detectable following administration of most hypnotics and is often associated with muscle relaxation. In its most severe form, the sedation is manifested as confusion and the muscle relaxation as ataxia. Both can present major difficulties in the elderly, who often wake at night to urinate. For this reason, some geriatricians eschew the use of benzodiazepines in the very elderly.
3. Memory, particularly for current events, can be impaired by benzodiazepines such as lorazepam. Another problem is amnesic episodes, often accompanied by nocturnal wanderings.
4. Discontinuation syndromes have been well-documented although their clinical significance is difficult to establish. Rebound insomnia and dependence syndromes can occur, the former more commonly with short-acting compounds such as triazolam, and the latter with long-acting drugs.
5. Abuse is often overlooked but can be iatrogenic with escalation of dose or as a feature of illicit use. Benzodiazepines are generally among the most important drugs of abuse, but usually in the context of polydrug abuse or alcohol problems. The combination with alcohol is particularly dangerous, with major psychological impairments, amnesia and aggressive behaviour.

OVERVIEW

The benzodiazepines continue to be the most-widely prescribed of hypnotics, having supplanted the barbiturates because of their relative safety in overdosage. They are effective drugs, at least in the short term before tolerance sets in. Residual sedation is a problem with many of these compounds but is often overlooked although the insomniac patient feels exhausted the next day. Adverse behavioural events, such as amnesia and aggression, have led to much concern. The major problems of rebound, dependence and abuse have curtailed the recommended duration of usage of these drugs. Nevertheless, long-term administration is the rule rather than the exception. Dosage is an important consideration but minimal dosage is not usually adhered to. The advent of more selective compounds has opened up the debate about the risk/benefit ratio of the various benzodiazepine hypnotics.

BENZODIAZEPINE-LIKE HYPNOTICS

Three compounds currently available as hypnotics are chemically non-benzodiazepine although pharmacologically similar; however, they are more selective. They will be reviewed in some detail.

Zopiclone

Zopiclone has been available in most countries for over a decade. The major exception is the USA, where, apparently, the company that developed the drug had no facilities for registration and marketing at the crucial time. Zopiclone can be regarded as the first of the more selective benzodiazepine-type hypnotics

Chemically, zopiclone is a cyclopyrrolone compound that potentiates the inhibitory effects of GABA at $GABA_A$ receptors. However, it differs in some ways from a typical benzodiazepine in the nature of its binding. For example, tolerance is not seen in the $GABA_A$ receptors of mice, in contrast to benzodiazepine effects (Serra *et al.*, 1996).

The other point of interest is its relatively short elimination half-life. Zopiclone is rapidly and extensively absorbed after oral administration, with a bioavailability of about 75% after the standard dose of 7.5 mg. Protein binding is low, but concentrations in the saliva can be quite high, resulting in an unpleasant, bitter taste. It is metabolized in the liver by cytochrome P450 enzymes to essentially inactive metabolites. The elimination half-life is generally accepted to be about 5 h, but it is prolonged in the elderly, particularly those aged over 75 (Gaillot *et al.*, 1987). Half-strength formulations are usually available for the elderly and for patients with impaired liver function. The main drug interaction of clinical relevance is that carbamazepine increases the plasma concentrations of zopiclone.

The hypnotic efficacy of zopiclone has been evaluated in numerous studies comparing it with placebo and with standard hypnotics, mostly benzodiazepines (for detailed reviews, see Goa and Heel, 1986; Noble *et al.*, 1998). Zopiclone shows effects on sleep induction superior to placebo and at least equivalent to short- and intermediate-acting benzodiazepines. It does not generally prolong total sleep time; therefore, some trials have shown long-acting benzodiazepines to be superior to zopiclone in this respect (e.g., Ponciano *et al.*, 1990). In general, zopiclone 7.5 mg is equivalent to 30 mg flurazepam or 5 mg nitrazepam with respect to sleep onset (e.g., Anderson, 1987). A large-scale study in primary care involving 1507 patients showed zopiclone, but not flunitrazepam 1 mg, to be significantly superior to placebo with respect to various measures of sleep quality (Hajak *et al.*, 1994). This study also included a triazolam arm: zopiclone, but not triazolam, separated from placebo. However, in general, zopiclone 7.5 mg is equivalent to or better than triazolam in the high dose of 0.5 mg (e.g., Autret *et al.*, 1987).

Zopiclone has variable effects on sleep architecture, but, in general, changes are minor (Parrino and Terzano, 1996). Tolerance to polysomnographic effects of zopiclone is usually minor, although few long-term studies have been carried out (Fleming *et al.*, 1988). An early review of short-term clinical studies lasting up to 8 weeks concluded that the hypnotic effects of zopiclone were maintained over this period for both younger and older insomniacs (Brun, 1988).

Hypnotics are generally licensed for short-term use, and a substantial proportion of users are middle-aged and elderly. Studies in elderly subjects have shown zopiclone 5 mg to be superior to placebo (Elie *et al.*, 1990), as was 7.5 mg (Klimm *et al.*, 1987). However, nitrazepam 5 mg was superior to zopiclone 7.5 mg with respect to onset latency on day 12 (Klimm *et al.*, 1987), and flunitrazepam 1 mg was superior to zopiclone 5 mg for difficulty in falling asleep (Dehlin *et al.*, 1995). Zopiclone has also shown useful efficacy in facilitating withdrawal from benzodiazepine hypnotics (Shapiro *et al.*, 1995).

Zopiclone, like the other newer hypnotics, is less likely to produce psychomotor and cognitive impairment than benzodiazepines such as nitrazepam or temazepam (Agnoli *et al.*, 1989; Ngen and Hassan, 1990). In particular, although immediate impairments can be detected following zopiclone, effects the next day are generally minor or undetectable. Subjective effects such as difficulty in waking, impaired well-being and reduced morning concentration are minimal providing a period of 5–8 h has elapsed since ingestion (Broadhurst and Cushnaghan, 1987).

Zopiclone is generally well tolerated, the commonest complaint being a bitter aftertaste (Allain *et al.*, 1991). Elderly patients tolerate the drug well, particularly in the lower doses of 3.75 and 5 mg.

Rebound following abrupt withdrawal of zopiclone is much less of a problem than with benzodiazepines such as triazolam (Bianchi and Musch, 1990). Dependence and withdrawal also seem to be far less common (Lader, 1998). However, some cases of dependence have been reported, often a transfer from a pre-existing benzodiazepine dependence. Occasional instances of street abuse have also been documented.

The usual dosage for short-term usage in patients with primary insomnia is 7.5 mg, with lower doses in the elderly. Zopiclone is now established (outside the USA) as a commonly used, well-tolerated drug with particular effects on shortening delay to sleep onset. Residual effects are generally not troublesome.

Zolpidem

The second of these new selective benzodiazepine-like hypnotic drugs is zolpidem (Holm and Goa, 2000). It has been marketed successfully for several years in many countries of the world including the USA (Langtry and Benfield, 1990). It is chemically an imidazopyridine agent and acts as a selective agonist on subtypes of benzodiazepine receptors (Sanger and Depoortere, 1998). This is believed to confer some advantage with respect to adverse effects, as compared with non-selective agonists such as the benzodiazepines.

Zolpidem has a very short half-life (Fraisse *et al.*, 1996), averaging about 2.5 h. The drug is rapidly absorbed; it has a bioavailability of around 70% and is highly protein-bound. It is largely metabolized by P450 isoenzymes, predominantly, CYP3A4, to inactive metabolites. Elimination is somewhat reduced in the elderly so that lower doses, such as 5 mg, are recommended. The pharmacokinetics are linear over the dose range 5–20 mg. The area under the curve is increased in individuals with liver or renal impairment.

The numerous clinical trials comparing zolpidem with placebo and with active comparators, mainly benzodiazepines, have been reviewed in detail by Holm and Goa (2000). The usual dosage was 10 mg in younger adults and 5 mg in the elderly. Most were primary insomniacs with sleep-onset latency beyond 30 min, and/or a total sleep time less than 6 h and/or more than three nocturnal awakenings. As is now standard, the primary outcome variables were derived from questionnaires, visual analogue scales and sleep diaries. Some polysomnographic data are also available.

Several placebo-controlled inpatient trials with acute and chronic insomnia have established the efficacy of zolpidem, mainly with respect to shortening of sleep-onset latency (Scharf *et al.*, 1991; Dockhorn *et al.*, 1996; Lahmeyer *et al.*, 1997). It was also efficacious in patients receiving concomitant selective serotonin reuptake inhibitors (SSRI) therapy (Asnis *et al.*, 1999). Zolpidem generally has equivalent efficacy to benzodiazepines. For example, the effects of 10-mg doses were similar to nitrazepam 5 mg with respect to sleep latency, number of awakenings and total sleep time (Kazamatsuri *et al.*, 1993), but it was preferred in another trial (Kudo *et al.*, 1993). Conversely, patients receiving flurazepam 30 mg reported better sleep than patients given zolpidem 10 or 20 mg (Fleming *et al.*, 1995). Comparisons with intermediate- and short-acting benzodiazepines have generally shown equivalence (e.g., Rosenberg and Ahlstrom, 1994). Studies with triazolam have used both 0.25 and 0.5 mg. In one study, zolpidem 10 mg was more effective than triazolam 0.5 mg in prolonging sleep duration (Monti *et al.*, 1994).

Zolpidem 10 mg had equivalent efficacy to zopiclone 7.5 mg in one large-scale study (see Holm and Goa, 2000: Table IV, p. 877).

In view of increasing concern about the efficacy and safety of hypnotics in the elderly, comparative efficacy data are available from some well-controlled studies in elderly insomniacs. In one placebo-controlled study, zolpidem 5 mg was equivalent to triazolam 0.125 mg and temazepam 15 mg (Leppik *et al.*, 1997). Zolpidem 5 mg is the preferred dose in the elderly (Roger *et al.*, 1993).

Zolpidem does not significantly affect sleep architecture in younger or older subjects (e.g., Blois *et al.*, 1993; Scharf *et al.*, 1991). Indeed, zolpidem tends to increase slow-wave sleep rather than diminish it. Tolerance to the effects of zolpidem was not detected in early studies (Langtry and Benfield, 1990). Later studies have tended to confirm this.

Because of concerns about long-term nightly administration of hypnotics, attempts have been made to prescribe zolpidem on an intermittent or 'as-needed basis'. Studies have shown efficacy for zolpidem in both regimens (Cluydts *et al.*, 1995).

Numerous studies have been conducted on the psychomotor and cognitive effects of zolpidem, both immediate and present the next day. Some impairments are usually detectable immediately following 10-mg doses, and they are definitely present, particularly with respect to memory at higher-than-recommended doses. As predictable from the short elimination half-life, deficits the next day tend to be minimal (Unden and Schechter, 1996). Clinical tolerability is good, as found in clinical trials and postmarketing studies (Allain and Monti, 1997). As with most of these agents interacting with the $GABA_A$ systems, the commonest adverse effects are nausea and dizziness, malaise, headache and nightmares. Reports of amnesic episodes, which have so bedevilled the use of triazolam, are rare with zolpidem.

Rebound discontinuation is uncommonly reported with zolpidem treatment (Soldatos *et al.*, 1999). Dependence and abuse are also quite rare (Lader, 1994), and probably less common than with benzodiazepines. Nonetheless, careful monitoring continues to be a wise procedure.

The recommended dosage in adults is 10 mg–5 mg in the elderly. At these doses, zolpidem is an effective inducer of sleep with little effect on sleep patterns. It is well tolerated with few residual effects. Rebound and withdrawal are not a problem. Intermittent and/or 'as-needed' administration seems feasible and widens the prescriber's choice of stratagems.

Zaleplon

Zaleplon has been recently licensed in several countries as a short-acting hypnotic. It has easily the shortest half-life of licensed hypnotics — only 1 h. This opens up new avenues for therapy, which are explored later in this chapter.

Chemically, zaleplon is quite complex; it is a pyrazolopyrimidine derivative. It has agonist activity at a subtype of the benzodiazepine receptor in the $GABA_A$–chloride-ionophore complex. This selectivity, as with zopiclone and zolpidem, may confer some clinical advantages (Hurst and Noble, 1999). It is rapidly absorbed after oral administration of the usual doses of 10 mg, with 5 mg in the elderly. Its bioavailability is about 30%. Peak plasma levels are achieved within 1 h (Greenblatt *et al.*, 1998), and the elimination half-life is about the same. Kinetics are linear within the usual dosage range (Beer *et al.*, 1994). The major metabolites, 5-oxo-zaleplon and 5-oxo-desethyl zaleplon, appear to be inactive. Pharmacokinetic parameters are only minimally altered in the elderly, but lower dosages are still recommended.

The efficacy of zaleplon was established by standardized questionnaire responses, backed up by polysomnographic data. Subjective sleep latency with 5, 10 and 20 mg of zaleplon was significantly lower than with placebo 1 week into a 4-week trial in 574 patients with insomnia (Elie *et al.*, 1998). This effect continued throughout the trial for the two high doses, but not for zolpidem 10 mg used as the active control. Similar data were obtained in another comparison of zaleplon, zolpidem, and placebo, with 20 mg of zaleplon being superior to 10 mg of zolpidem (Fry *et al.*, 1998). However, in general, zaleplon and zolpidem are equipotent with respect to effects on subjective sleep latency.

A polysomnographic comparison of zaleplon 5 or 10 mg, triazolam 0.25 mg, or placebo for 14 nights found the 10-mg, but not the 5-mg, dose to shorten sleep-onset latency (Walsh *et al.*, 1998). The effects of triazolam were significant for the first two nights only. Zaleplon leaves the sleep architecture unaffected.

A study in 422 elderly insomniac patients compared zaleplon 5 and 10 mg with placebo (Hedner *et al.*, 1998). Both doses significantly reduced subjective sleep latency during both the first and second weeks of treatment. Sleep quality was also improved.

Zaleplon 10 mg was associated with a small but significant reduction in time to return to sleep after a middle-of-the-night wakening (cited in Hurst and Noble, 1999). Flurazepam 30 mg did not show this effect but did prolong residual sleep duration.

In a phase 1 study in normal volunteers, zaleplon 10 mg and 20 mg was compared with 2 mg of lorazepam with respect to psychomotor and memory function (Allen *et al.*, 1993). The effects of zaleplon were ephemeral and also not very marked, compared with those of lorazepam.

A series of studies has examined next-day psychomotor, memory and driving ability in both normal volunteers and insomniac patients. In contrast to various benzodiazepines used as active controls, zaleplon caused no impairments in comparison to placebo (e.g., Walsh *et al.*, 1998; Ware *et al.*, 1998). Lack of residual effects occurs even when zaleplon is given 4 h prior to testing (Vermeeren *et al.*, 1998). This was in contrast to zopiclone 7.5 mg.

Zaleplon is well tolerated in general, adverse effects usually being no greater than following placebo. Headache is the commonest adverse effect, but this is a notoriously difficult complaint to assess. Subjective residual effects the next day are minimal or undetectable, even at 20-mg doses. Daytime anxiety is not increased (Elie *et al.*, 1998).

Discontinuation of zaleplon is not associated with any notable rebound or withdrawal effects. A study in subjects with histories of social drug use suggested that higher doses (25, 50 and 75 mg) significantly increased drug-liking ratings above those for placebo (Rush *et al.*, 1999). Triazolam 0.5 and 0.75 mg had similar effects.

In summary, the available published data shows that zaleplon shortens subjective sleep latency at doses of 10 mg (5 mg in the elderly). It does not alter sleep architecture. It is not associated with rebound or dependence, but abuse liability at high doses cannot be ruled out.

Because of its very brief duration of action, alternative therapeutic strategies can be adopted and are reviewed later.

IMPLICATIONS OF SUBTYPE-SELECTIVE BENZODIAZEPINE RECEPTOR LIGAND HYPNOTICS

Recent work on subtypes of benzodiazepine receptors has resulted in the discovery of numerous subtypes of receptor depending on a rather complex subunit composition (Griebel *et al.*, 2000). The commonest are designated $GABA_{A1a}$, $GABA_{A2a}$, $GABA_{A3a}$ and $GABA_{A5a}$. Benzodiazepines in general are non-selective agonists at all these receptors. Zopiclone has not yet been evaluated in detail for its selectivity but may bind somewhat atypically to a variety of subtypes.

Zolpidem and zaleplon, among the hypnotics, are selective for the $GABA_{A1a}$ subtype. A second consideration is the degree of agonism ('intrinsic efficacy') at the receptor. Zolpidem has high activity at the 1a subtype. When it does bind to the other subtypes, it does so

with low efficacy. Zaleplon is also a full agonist at the 1a subtype but also has high intrinsic activity at the high concentrations needed for binding to the other subtypes.

What benefits might the selective binding confer? The cognitive effects of zolpidem and zaleplon appear to be less than for equivalent hypnotic doses of benzodiazepines. Some animal evidence supports this notion, with the acquisition of conditional fear being disrupted at high doses only (Sanger *et al.*, 1986).

Discriminative stimulus studies also suggest that selectivity on subtypes of receptors plays a part. Zolpidem and zaleplon only partly substitute for chlordiazepoxide as a discriminative cue, and only at high sedative doses (Sanger *et al.*, 1999). Tolerance to depressant effects in animals, such as impaired locomotion, is also minimal with the selective compounds as compared with non-selective benzodiazepines (Sanger and Zivkovic, 1992). Similarly, discontinuation effects are not detectable following withdrawal of zolpidem or zaleplon (e.g., Von Voigtlander and Lewis, 1991).

The animal data outlined above are consistent with clinical findings that zolpidem and zaleplon are associated with less psychomotor and cognitive impairment, less tolerance and fewer discontinuation effects than doses of benzodiazepines equipotent for hypnotic effects. The position of zopiclone is unclear. The implication is that compounds selected for development as an hypnotic (and as an anxiolytic) should display some selectivity at the 1a subtype. The consequences of selectivity at other benzodiazepine receptor subtypes remain unexplored.

COMPOUNDS USED AS HYPNOTICS EXPLOITING SECONDARY PROPERTIES

Lorazepam is licensed both as an anxiolytic and as an hypnotic. It is quite useful as a general tranquillizer and sedative, and is even advocated for use in psychotic agitation.

Diazepam is long-acting in view of its own duration of action and that of its very long-acting metabolite, *N*-desmethyldiazepam. However, it also has a marked redistribution phase, with sedative effects lasting a few hours. These can be exploited for use as an hypnotic where daytime anxiolysis is also required.

Barbiturates are still available in some countries but are restricted to use in insomniac patients long habituated to them. They should never be used ab initio.

Clomethiazole is a powerful sedative, which is sometimes used as an hypnotic, particularly in the elderly. However, it has most of the drawbacks of the barbiturates — paradoxical excitement, confusion, dependence, and marked interaction with alcohol.

Chloral and its derivatives are cheap, obsolescent hypnotics, with a dependence liability and a high incidence of gastrointestinal upset.

Antihistamines, such as diphenhydramine and promethazine, are on sale to the public for occasional insomnia. Their prolonged duration of action may cause residual effects the next day. Tolerance is often quite marked. Although dependence does not supervene, polydrug addicts use these drugs as adjuncts to opioids.

Other drugs can be dosed in such a way that their side effects of sedation and torpor can be used to induce sleep. The classic examples are the *tricyclic antidepressants*, trimipramine, amitriptyline and dothiepin (dosulepin) in particular being given at night to help patients sleep. This is quite appropriate when insomnia is secondary to depression.

Antipsychotic drugs are sometimes used in the same way but carry the risk of extrapyramidal syndromes such as tardive dyskinesia.

Melatonin has its advocates as a 'natural hypnotic'. It is the major hormone produced by the pineal gland and is mainly secreted during the hours of darkness (Brown, 1995). Its production falls off with age, so that the elderly often secrete very little. Some preliminary trials have shown encouraging results in the elderly, mainly with respect to quality of sleep. Various formulations of melatonin are being developed, as are synthetic analogues. Melatonin has also been used, often effectively, as a phase-shift agent in sleep disorders associated with jet lag, shift work, periodic sleep disorder in the blind and brain-damaged children. Further trials are required in all these indications, but, meanwhile, melatonin preparations of variable pharmaceutical purity are available in health-food shops and pharmacies in some countries.

HYPERSOMNIA

The commonest disorder under this rubric is narcolepsy. The treatment of narcolepsy can be divided into the management of the daytime sleepiness and that of the cataplexy. Stimulant drugs such as amphetamine and methylphenidate lessen the incidence of daytime drowsiness but are attended by the usual problem of tolerance, dependence, and rebound hypersomnia and depression on withdrawal. The minimal effective dosage must be sought assiduously; for example, methylphenidate 5–20 mg, three times a day. Part of the problem is the difficulty patients have in assessing their own difficulties, and a careful observer is invaluable in establishing the extent of any therapeutic effect. As tolerance develops, the stimulant can be withdrawn to allow a 'drug holiday' before reinstitution of the drug at a lower dose.

The treatment of cataplexy is more satisfactory. Antidepressants, both tricyclics and monoamine-oxidase inhibitors (MAOIs), suppress episodes of rapid-eye-movement sleep and are effective in lessening cataplectic attacks. Clomipramine seems to be currently favoured in the usual antidepressant dosage of 25–50 mg three times a day. The usual unwanted effects are sometimes troublesome. MAOIs have also been used but are less acceptable because of their dietary and drug interactions. They must *never* be combined with clomipramine. *Modafinil* has been recently licensed for the treatment of narcolepsy. The dose is 200–400 mg^{-1} per day, but lower in the elderly. It should be used cautiously in patients with liver impairment or hypertension. The main side effects are those of central nervous system stimulation, such as insomnia, euphoria, and anxiety.

PARASOMNIAS

These comprise a wide variety of behavioural disturbances occurring at various stages of sleep. Diazepam can be used to reduce slow-wave sleep in somnambulists and children with night terrors, and to control excessive nightmares. Otherwise, drug treatments are relatively ineffective.

CONCLUSIONS

A whole range of compounds is available for the treatment of sleep disorders, particularly insomnia of various types. However, the treatment of insomnia largely revolves around drugs that act on benzodiazepine receptors. Recent developments have produced hypnotics which are more selective than the older compounds such as the barbiturates and the widely used benzodiazepines. Whether this selectivity in biochemical terms is translated into clinical advantages, such as reduced impairment of cognitive and psychomotor function and lowered dependence potential, remains to be proved in practice.

The advent of very short-acting compounds, such as zolpidem and zaleplon, has allowed different strategies for the usage of these drugs. Thus, they can be given after the patient has gone to bed and found sleep elusive. In this way, patients recover control of

their drug taking and can revert to 'as-required' medication instead of taking the medication 'prophylactically' every night on the presumption that insomnia will occur. The next step will be the use of these very short-acting compounds for middle-of-the-night wakening, when, say, a period of 4 h remains before the sufferer has to rise. Whether or not this changes prescribing practice noticeably will depend on such factors as the conservatism of the medical profession and the concern that patients have that they will have a full night's sleep.

Meanwhile, the use of hypnotics remains a controversial subject, and the development of new compounds and of new strategies to improve the benefit/risk ratio of these compounds remains an important issue.

Psychobiology of Impulse-Control Disorders Not Otherwise Specified (NOS)

Stefano Pallanti, Nicoló Baldini Rossi, Jennifer Friedberg and Eric Hollander

Impulsivity can be defined as the failure to resist an impulse, drive or temptation that is harmful to oneself or others (Hollander *et al.*, in press). Impulsivity is a measurable aspect of behaviour, manifesting as impatience (including the inability to delay rewards), carelessness, risk-taking, sensation- and pleasure-seeking, an underestimated sense of harm, and extraversion. The subjective experience of an impulse involves also an increasing sense of arousal or tension before committing/engaging in the act and an experience of pleasure, gratification or release of tension at the time of committing the act. Aggressive behaviour is a conduct that inflicts harm upon oneself or others. Behaviour can be impulsive without being aggressive (for example, a person who engages in pathological gambling is behaving in an impulsive manner, but not in an aggressive manner). Likewise, aggressive behaviour can lack impulsivity (as in a premeditated murder). Impulsive disorders cause large costs to society, and are associated with substantial morbidity, mortality, social/family/job dysfunction, accidents, suicide, violence, aggression, criminality, and excessive utilization of health-care, government and financial resources (Hollander *et al.*, in press).

Largely on the basis of the varying theoretical and clinical approaches of the myriad scientific and professional disciplines studying impulsivity and aggressive behaviours in animal models or in humans, impulsivity and aggressiveness are conceptualized and diagnosed in an unusually broad and disparate fashion. Just as anxiety and depression may be conceptualized either as symptoms or as specific disorders, impulsivity may be distinguished as a symptom or as a distinct disorder.

In psychiatric classification, impulsivity is a core symptom of a broad spectrum of disorders, including the impulse-control disorders (impulse-control disorders not elsewhere classified, comprising pathological gambling [PG], intermittent explosive disorder, pyromania, kleptomania, and trichotillomania, and impulse-control disorder not otherwise specified [NOS]), the impulsive-aggressive personality disorders (borderline, antisocial), the neurological disorders that can be associated with disinhibition of behaviour (such as epilepsy), and substance abuse (Hollander and Rosen, 2000). Of interest, addictive behaviour could also be described as conduct resulting from failure to inhibit impulses that urge and seek tension relief or pleasure. Furthermore, other psychiatric conditions also contribute to the expression of impulsivity, notably attention deficit/hyperactivity disorder (ADHD), mania, and eating disorders (Hollander and Rosen, 2000). The impulse-control disorders may belong to a family of compulsive-impulsive spectrum disorders lying at opposite ends of the dimension of risk avoidance, with impulsive disorders driven by pleasure or arousal, and compulsive disorders driven by reduction of anxiety (Hollander, 1998). Both impulsive and compulsive disorders involve a failure to resist a drive to act in a way that is potentially self-damaging, escalation of anxiety before engaging in the act, and relief of anxiety following the act. In fact, one of the few differences between the two types of disorders is that most compulsive behaviour disorders are perceived by the patient as ego-dystonic, whereas impulsive behaviours are usually viewed as ego-syntonic, at least in the impulsive setting. Rather than being the dimensional opposite of obsessive-compulsive disorders, impulse-control disorders may represent a different phenomenological manifestation of a group of disorders sharing the feature of decreased ability to inhibit motor responses to affective states.

We are at a very early stage in our understanding of the neurobiology of impulsivity and aggression (Kavoussi *et al.*, 1997). Thus, it is noteworthy that meanings and definitions of impulsivity and aggressiveness differ greatly in psychiatry and in neurobiology. Moreover, no simple extrapolation of animal subtypes to humans is possible, mainly because of the influence of complex cultural variables on behaviour. On the whole, research into the subtypes of human impulsivity has been rather limited. Much of this has been conducted in children. Clinical observation, experimental paradigms in the laboratory, and cluster/factor analytical statistics have all been used in an attempt to subdivide impulsivity and aggression. A consistent dichotomy can be identified for aggression between an impulsive-reactive-hostile-affective subtype and a controlled-proactive-instrumental-predatory subtype. Although good internal consistency and partial descriptive validity have been shown, these constructs still need full external validation, especially regarding their predictive power for comorbidity, treatment response, and long-term prognosis (Vitiello and Stoff, 1997).

In attempting to find parallels between aggression in humans and aggression in animals, Gregg and Siegel (2001) observed that whereas both humans and animals exhibit aggressive behaviour, animals do not engage in the premeditated aggressive acts that humans often display. Vitiello *et al.*, (1990), in distinguishing between affective aggression and predatory aggression, emphasize that the first is impulsive, occurring as a result of autonomic arousal, while the second is cold-blooded and premeditated, and is not a result of arousal. Due to the presence of the frontal cortex, humans have the capacity to engage in both affective and predatory aggression, while animals engage only in affective aggression, which is aggression related to survival and increased arousal. Impulsivity has been classified in to three different types: motor impulsivity, impulsivity without programming, and attentive impulsivity; the last may be represented by an exaggerated alert reaction (Barratt and Stanford, 1995).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

NEUROLOGICAL STRUCTURES INVOLVED IN IMPULSIVITY

The neurobiological basis of impulsivity is not fully understood. Frontal lobe abnormalities are associated with an inability to delay or inhibit acting on impulse, and an inability to calculate the odds of negative risk or outcome. Aspects of impulsivity are core symptoms of a number of frontal lobe syndromes, and frontal lobe hypofunction has been observed in impulsive individuals. Studies in subjects with borderline personality disorder have confirmed a fundamental, biologically based, affective hyperresponsiveness in borderline personality disorder (BPD), whereas autonomic underarousal may seriously interfere with a flexible adaptation to environmental stimuli (Herpertz *et al.*, 1999). Damasio (1996) hypothesized that 'somatic states', or emotional changes that occur in response to a stimulus, influence the cognitive process that occurs when an individual decides how to respond to the stimulus. Damasio found that patients with ventromedial frontal damage do not respond to emotionally charged stimuli, thus indicating that the frontal cortex is involved in the decision.

Bechara *et al.* (2000b), investigating gambling, have suggested that gamblers with ventromedial prefrontal cortex lesions are insensitive to future consequences, positive or negative, and are primarily guided by immediate prospects. This 'myopia for the future' in ventromedial prefrontal cortex-lesioned patients persists in the face of severe adverse consequences, as in risking future punishment or declining future reward.

Patients with lesions of the ventromedial prefrontal cortex display decision-making impairment similar to that observed in abusers of cocaine, opiates, and alcohol (Rogers *et al.*, 1999). They also evidence a disregard for or insensitivity to future consequences that is related to, but not entirely explained by, the construct of impulsivity (Bechara *et al.*, 2000a). Metabolic abnormalities have been observed in the orbital frontal, adjacent ventral medial, and cingulate cortex of impulsive-aggressive individuals (Siever *et al.*, 1999). Previous research has implicated the anterior cingulate cortex (ACC) and medial prefrontal cortex (mPFC) in impulsivity and in processes regulating choice between alternative reinforcers, and their abnormal function has been observed in some individuals with ADHD (Ernst *et al.*, 1998). Decreased regional cerebral blood flow to the ACC and frontal cortex has been observed in pathological gambling (Goyer *et al.*, 1999). Lesions of the amygdala reveal a complex modulation of aggressive and impulsive behaviours.

Recent lesion studies in animals and humans have begun to elucidate the neurocircuitry of impulsivity. Cardinal *et al.* (2001) reported induction of persistent impulsive choice in rats following lesions of the nucleus accumbens core (AcbC), a key brain region of reward and reinforcement. These lesioned rats consistently chose small or poor rewards that were immediately available in preference to larger delayed rewards. The group also exhibited locomotor hyperactivity, another sign of the hyperactive-impulsive subtype of ADHD, and so this may represent an animal model of the disorder. In contrast to earlier studies, lesions of two of the AcbC's cortical afferents, the ACC and the mPFC, did not induce impulsive choice, suggesting that ventromedial or orbitofrontal afferents may play a role. This finding complements recent work in humans with bilateral ventromedial prefrontal cortical lesions who, in a gambling test, opt for choices that yield high immediate gains in spite of high future losses (Bechara *et al.*, 2000b). Lesions in the amygdala have also been associated with impaired decision-making (Bechara *et al.*, 1999). Thus, the orbitofrontal, nucleus accumbens and amygdala regions appear to play an important role in mediating at least one aspect of impulsivity. Lesion studies to improve the localization of the neurocircuitry of specific impulsive behaviours may be helpful, and Cardinal *et al.*'s tentative localization of the neuroanatomical basis for delayed reinforcement may eventually lead to new diagnostic imaging or therapeutic procedures. Pharmacological manipulation of neurotransmitter peptide systems specifically targeted at the AcbC and/or relevant afferent pathways may moderate impulsive behaviours more specifically than do current therapies. However, while previous lesion and imaging studies suggest a role for the ACC and mPFC in impulsivity (Ernst *et al.*, 1998; Goyer *et al.*, 1999), Cardinal *et al.*'s study suggests that neither the ACC nor the mPFC contribute to the AcbC's ability to promote the choice of delayed reinforcers. Therefore, the obvious next step is to elucidate the afferent paths by which information concerning the value of delayed reinforcers is supplied to the AcbC. It has been suggested that the basolateral amygdala and/or the orbitofrontal cortex may play such a role. Orbital lesions of the prefrontal cortex have elsewhere been associated with increases in reflexive emotional responses to environmental stimuli (Luria, 1980).

NEUROLOGICAL STRUCTURES INVOLVED IN AGGRESSION

There are many literature data linking specific brain structures to aggressive behaviour in mammals and non-human primates (Hess, 1957). It is commonly observed that patients with neurological lesions may present with symptoms of aggression (Weiger and Bear, 1988). Several investigators hypothesize that, for a subgroup of chronically aggressive persons, the root of the aggressive behaviour is brain damage. Lewis *et al.* (1982) reported that every death-row inmate studied by her team had a history of head injury, often inflicted by abusive parents. Her study concluded that death-row inmates constitute an especially neuropsychiatrically impaired prison population. Although the connection between physical abuse, head injury, and aggression is uncertain, many studies do show an association between physical abuse and later aggressive behaviour. Clinical reports of aggressive patients with specific neurological lesions may help delineate the structures that mediate these symptoms. In patients presenting with aggressive symptoms, researchers have demonstrated neurological 'soft signs', a marker of subtle neurological dysfunction (Shaffer *et al.*, 1985).

It has been shown that antisocial personality disorder patients that engage in aggressive behaviour without exhibiting autonomic arousal have a reduction in prefrontal grey matter and less autonomic activity than healthy controls, psychiatric controls, and patients with substance dependence when presented with a social stressor (Raine *et al.*, 2000). Larson and Summers have recently observed that social stress from aggressive interaction is expressed differently in specific brain regions of dominant and subordinate male lizards (Anolis carolinensis). Prior to aggressive behaviour, the outcome is predictable via the celerity of postorbital colouration: dominant males exhibit more rapid eyespot darkening. Serotoninergic activation is manifested rapidly (1 h) in the hippocampus, nucleus accumbens and brainstem of subordinate males, and is expressed more rapidly in dominant males. Amygdalar serotoninergic activation responds rapidly (1 h) in dominant males, but is expressed slowly (1 week) in chronically subordinate males (Larson and Summers, 2001); these data seem to suggest that aggressive behaviour may play a role in ranking the dominance status.

We should also consider that impulsive and aggressive behaviour corresponds to a wide range of adaptative patterns, such as the self-mutilation of trapped wolves or the cannibalism of the praying mantis, and the aggressive component of reproductive behaviour in certain mammals.

Hypothalamus

The hypothalamus monitors internal status and regulates neuroendocrine responses via sympathetic arousal. It is involved in the

regulation of the sleep-wake cycle, appetite, body temperature, and sexual activity. In association with the pituitary, it is the major regulator of the autonomic nervous system. The mesolimbic dopamine (DA) pathway and the ascending serotonergic, noradrenergic, and cholinergic pathways from the brainstem have terminations in the hypothalamus.

The hypothalamus plays a major role in the expression of aggression in animals (Eichelman, 1971; Wasman and Flynn, 1962). Stimulation of the anterior hypothalamus causes predatory attacks in cats, whereas activation of the dorsomedial aspect produces aggression in which the animal ignores the presence of a rat and attacks the experimenter. Destruction of aggression-inhibitory areas, such as the ventromedial nucleus of the hypothalamus, produces permanently aggressive cats and rats (Bard, 1928; Reeves and Plum, 1969). Following cortical ablation, stimulation of the posterior lateral hypothalamus of the cat elicits sham-rage, a posture of preparation for attack. Stimulation of the posterior lateral portion of the hypothalamus shortens the latency of the attack, whereas stimulation of the medial ventral area prolongs it (Eichelman, 1971; Wasman and Flynn, 1962). Hamsters tested for offensive aggression after microinjections of arginine vasopressin (AVP) directly within the anterior hypothalamus in combination with a 5-HT_{1B} agonist have increased aggression, while those injected with AVP and a 5-hydroxytryptamine $(HT)_{1A}$ agonist have a dose-dependent inhibition of AVP-affiliated offensive aggression (Ferris *et al.*, 1999). In humans, structural lesions of the hypothalamus may be associated with unplanned and undirected aggressive behaviours that often appear to be unprovoked but may be in response to physical discomfort (Reeves and Plum, 1969; Killeffer and Stern, 1970; Haugh and Markesbery, 1983; Ovsiew and Yudofsky, 1983).

Recently, Gregg and Siegel (2001), using techniques of electrical brain stimulation, anatomical-immunohistochemical techniques and behavioural pharmacology, have investigated the neural systems and circuits underlying aggressive behaviour in the cat. The authors demonstrate that the medial hypothalamus and midbrain periaqueductal grey (PAG) are the most important structures mediating defensive rage behaviour, and that the fornical lateral hypothalamus clearly mediates predatory attack behaviour. The hippocampus, amygdala, bed nucleus of the stria terminalis, septal area, cingulate gyrus, and prefrontal cortex project to these structures directly or indirectly, and thus can modulate the intensity of attack and rage. Evidence suggests that several neurotransmitters facilitate defensive rage within the PAG and medial hypothalamus, including glutamate, substance P (SP), and cholecystokinin, and that opioid peptides suppress it; these effects usually depend on the subtype of receptor that is activated. A key recent discovery was a GABAergic projection that may underlie the often-observed reciprocally inhibitory relationship between these two forms of aggression. Recently, SP has come under scrutiny as a possible key neurotransmitter involved in defensive rage, and the mechanism by which it plays a role in aggression and rage is still under investigation (Gregg and Siegel, 2001). The possible hypothalamic role of SP in the intraspecific aggressive behaviour of isolated male mice was previously investigated by Bigi *et al.*, who evaluated the effects of a single intravenous administration of this neuropeptide on isolation-induced aggressive behaviour: SP treatment (0.25, 1.0, or $2.5\,\text{mg}\,\text{kg}^{-1}$ dose injected 15 min before testing) induced a decrease in offensive scores, a longer latency to the first attack episode and enhanced defensive displays. In no case did SP treatment affect locomotor activity levels or freezing behaviour (Bigi *et al.*, 1993).

The possible role of the hypothalamus in aggressiveness is also confirmed by Kim *et al.*, who examined the effects of intracerebroventricular injection of pertussis toxin, a specific inhibitor of G(i)/G(o) proteins, on plasma corticosterone levels, aggressiveness, and hypothalamic and hippocampal monoamines and their metabolite levels in mice. Plasma corticosterone levels were markedly increased after injection of pertussis toxin, which induced a progressive increase in aggressiveness, that is, a decrease in attack latency and an increase in number of attacks, on days 1 and 6 after injection. Brain monoamines and their metabolite levels changed on days 1 and 6 after toxin injection: in the hypothalamus, the levels of dopamine and 3,4-dyhydroxyphenylacetic acid were increased, the norepinephrine level was decreased, and the 5-hydroxyindole acetic acid (5-HIAA) level was markedly increased, with no changes in 5-HT level, whereas, in the hippocampus, the 5-HT level was significantly decreased, with no changes in 5-HIAA and catecholamines (Kim *et al.*, 2000).

According to Kim *et al.*, Van Goozen *et al.* have underlined the possible relationship between adrenal androgens and aggressive behaviour occurring in children with oppositional defiant disorder (ODD), showing that children with ODD had higher dehydroepiandrosterone sulphate (DHEAS) levels than either psychiatric control or normal control groups, and hypothesizing that the mechanism should be a shift in balance of ACTH-beta-endorphin functioning in the hypothalamic-pituitary-adrenal axis due to early stress or genetic factors (Van Goozen *et al.*, 2000).

Finally, it has been documented that maternal and mating-induced aggression is associated with elevated citrulline immunoreactivity in the hypothalamic paraventricular nucleus (PVN) in prairie voles. In the monogamous prairie vole, *Microtus ochrogaster*, the males are parental and exhibit a dramatic increase in aggression, termed mating-induced aggression, in association with reproduction. In mice, the gas, nitric oxide (NO), inhibits the males' aggression, but may have an excitatory role in the production of maternal aggression. Gammie and Nelson have combined aggressive behavioural testing of female and male prairie voles with immunohistochemistry for citrulline, a marker of NO synthesis, to examine NO synthesis indirectly during maternal and mating-induced aggression. A significant increase in the number of citrulline-positive cells was identified in the PVN of the hypothalamus in aggressive lactating females compared with unstimulated lactating females. A significant increase in the number of citrulline-positive cells was also observed in the PVN of aggressive mated males compared with nonaggressive unmated males and unstimulated mated males. In other regions of the brain, no changes in the number of citrulline-positive cells were observed. These data suggest that NO is released specifically in the PVN during both maternal and mating-induced aggression in prairie voles (Gammie and Nelson, 2000). Moreover, the intraperitoneal injections of the neuronal NO synthase (nNOS) inhibitor, 3-bromo-7-nitroindazole, significantly impaired the expression of maternal aggression in terms of the average time in aggressive encounters, the average number of attacks and the average latency to the attack first. These data suggest that the central release of NO may play an important role in the production of maternal aggression in prairie voles (Gammie *et al.*, 2000).

Amygdala

The amygdala consists of an anatomically defined region located within the temporal lobe of the brain in mammals. Along with other limbic system structures, the amygdala responds to changing environmental conditions by inducing emotive behaviours that are linked to past experiences. The amygdala is an important component of the limbic system and, as such, is considered a pivotal region for mediating the perception and the expression of fear and anxiety. The limbic system encompasses the amygdala and the temporal cortex. The amygdala activates and/or suppresses the hypothalamus and modulates input from the neocortex. It also has efferents to the extrapyramidal system. The amygdala may have a role in associating sensory experience with (hypothalamically directed) affects and behaviours, including anger (Bear, 1991). In

a study using positron-emission tomography, the amygdala was shown to be more activated during the processing of visually presented linguistic threats than during the processing of neutral words (Isenberg *et al.*, 1999).

Bilateral lesions of the amygdala tame a variety of hostile and vicious animals (Kluver and Bucy, 1939), whereas irritative lesions or electrical stimulation can lead to rage outbursts. Removal of the amygdala from monkeys results in decreased aggression (Downer, 1961). However, amygdalectomy in submissive monkeys may result in increased aggression (Dicks *et al.*, 1969). Aggressive behaviour following stimulation of the amygdala in cats varies accordingly to their pre-existing temperament (Adamac 1990). These findings suggest that the amygdala may not simply function to increase regulatory affects and behaviours, but that it may mediate and balance their control. Moreover, it seems that there is an association between intermale social aggression and cellular density within the central amygdaloid nucleus in rats with lithium/pilocarpine-induced seizures, suggesting that seizure-induced damage within proximal amygdaloid nuclei disinhibits the central nucleus and encourages aggression (Desjardin and Persinger, 1995).

Recently, it has been shown that the monoaminergic activities of limbic regions are elevated during aggression in the lizard *Anolis carolinensis* (Korzan *et al.*, 2000). In monkeys, bilateral temporal lobectomy leads to hyperorality, hypersexuality, absence of fear response, increased touching, and visual agnosia (Kluver-Bucy syndrome). Bilateral temporal lobe damage in humans leads to similar symptoms, including hypersexuality and visual and auditory agnosia. In addition, humans exhibit placidity, apathy, bulimia, and aphasia (Terzian and Ore, 1955; Marlowe *et al.*, 1975; Isern, 1987). This syndrome appears to be a disconnection between sensory information about the environment and the regulation of affects and behaviours (e.g., aggression, sex, food) that usually help the person or animal negotiate that environment.

It has been known since the classical work of Kluver and Bucy (1939) that amygdaloid lesions markedly reduce emotional responsiveness. More localized amygdaloid lesion studies indicate that a specific part of the amygdala, the central nucleus, is important for mediation of autonomic changes associated with stress. Bilateral ablation of the central amygdaloid nucleus attenuates learned heart-rate responses in the rabbit (Kapp *et al.*, 1985). Cryogenic treatment of the central amygdaloid nucleus blocked learned blood pressure and respiratory response in the cat (Zhang *et al.*, 1986). In rats, lesions of the central amygdala impede the increases in heart rate and blood pressure that occur to a tone associated with shock (Iwata *et al.*, 1986). The increases in heart rate and blood pressure to the shock alone were unaffected by amygdaloid lesions. Destruction of the central amygdala in rats also reduced stimulus-induced exaggerated increases in cardiovascular responses (Folkow *et al.*, 1982).

Seizure studies of the limbic area in humans may explain the possible neuroanatomical underpinnings of aggression. Whereas bilateral temporal lobe damage in humans may lead to Kluver-Bucy syndrome, with a decrease in regulatory affects and behaviours, disorders of temporal lobe excitation may result in increased affect and aggression (Serafetinides, 1965; Nachson, 1988). Associations between aggression and temporal lobe epilepsy has been reported: 30% of 286 patients with intermittent violent outbursts had temporal lobe epilepsy (TLE) (Elliot, 1992); 18 of 97 incarcerated delinquent boys with a history of violence presented psychomotor epilepsy (Lewis *et al.*, 1982). TLE patients may demonstrate hyperemotionality and increased aggression. Interictal aggression is much more common than ictal or postictal aggression in TLE. Interictal aggression is often characterized by intense affect in response to environmental stimuli, whereas ictal and postictal aggression is spontaneous and unfocused. In humans, reports of surgical intervention for the relief of mental or structural brain disease or epilepsy have shown that both the amygdala and other temporal lobe and limbic system structures contribute to modulation of aggression. Two patients who underwent bilateral amygdalotomy for intractable aggression showed a reduction in autonomic arousal in response to stressful stimuli and a decrease in aggressive outbursts (Lee and Coccaro, 2001). Limbic system tumours, infections, and blood vessel abnormalities have also been associated with violence and impulsivity. Although it is clear that various limbic system structures have an inhibitory or excitatory effect on aggression, the precise mechanism of the aggression pathway is still far from established.

It has been hypothesized that the amygdala probably does not function in normal homeostatic functions, as it is not active during sleep or anaesthetic states. In addition, the amygdala is not necessary for mediation of cardiovascular response to physical stressors. Rather, the amygdala probably functions to alter autonomic activity during responses to threatening or anxiety-provoking stimuli. Finally, a high density of benzodiazepine receptors has been localized within the amygdala, suggesting that it is an important site for anxiolytic drug actions (Niehoff and Kuhar, 1983). The benzodiazepine receptors are localized within the basolateral amygdaloid nucleus, an important intra-amygdaloid input to the central amygdaloid nucleus.

Prefrontal Cortex

The prefrontal cortex modulates limbic and hypothalamic activity, and is associated with the social and judgement aspects of aggression. The frontal cortex coordinates the timing of social cues, often before the expression of associated emotions. Lesions in this area give rise after minimal provocation to disinhibited anger characterized by an individual's showing little regard for the consequences of affect and behaviour. Weiger and Bear (1988) hypothesize that, whereas TLE patients may express deep remorse over an aggressive act, patients with prefrontal lesions often indicate indifference. Patients with violent behaviour have been found to have a high frequency of frontal lobe lesions (Kandel and Freed, 1989; Lishman, 1968). In a study of Vietnam veterans with a history of penetrating head injuries, patients with ventromedial lesions had higher verbal aggression scores than controls and those with lesions in other brain areas (Grafman *et al.*, 1996). Frontal lesions may result in the sudden discharge of limbic- and/or amygdala-generated affects no longer modulated, processed, or inhibited by the frontal lobe. Patients consequently respond with rage or aggression upon feelings that would have ordinarily been modulated by the individual. Prefrontal damage may cause aggression by a secondary process involving lack of inhibition of the limbic area. Dorsal lesions of the prefrontal cortex are associated with impairment in long-term planning and increased apathy. Orbital lesions of the prefrontal cortex are associated with increases in reflexive emotional responses to environmental stimuli (Luria, 1980).

Recently, neuroimaging studies suggest a role for the prefrontal cortex, along with other regions of the brain, in the expression of aggression, as shown by Lee and Coccaro (2001). Using positron-emission tomography, studies have documented reduced serotonergic function in specific brain regions in subjects with increased aggression and impulsivity. One imaging study showed that in contrast to controls, patients with borderline personality disorder have diminished response to serotonergic stimulation (*d*,1-fenfluramine) in areas of the prefrontal cortex associated with impulsive behaviour regulation, specifically the medial and orbital regions of the right prefrontal cortex, left middle and superior temporal gyri, left parietal lobe and left caudate body (Soloff *et al.*, 2000). Siever *et al.* (1999) found that impulsive-aggressive patients had significantly blunted metabolic responses in the orbital frontal, adjacent ventral medial and cingulate cortex compared to controls. Finally, impulsive murderers have been shown to have lower

left and right prefrontal functioning and higher right subcortical functioning in comparison to predatory murderers (Raine *et al.*, 1998). Van Erp and Miczek (2000) investigated the dynamic changes in DA and serotonin during aggressive confrontations in the corticolimbic areas of rats: DA and serotonin levels in the prefrontal cortex changed in opposite directions, with a sustained decrease of serotonin to 80% of baseline levels during and after the confrontation and an increase of DA by up to 120% after the confrontation. The temporal pattern of monoamine changes, which followed rather than preceded the confrontation, points to a significant role of accumbal and cortical DA and 5-HT in the consequences as opposed to the triggering of aggressive acts. The increase in accumbal DA in aggressive animals supports the hypothesis that this neural system is linked to the execution of biologically salient and demanding behaviour.

Other areas implicated in impulsivity and aggression include the midline thalamus, lateral preoptic region, mammillary bodies, hippocampus and basal ganglia.

PSYCHOBIOLOGY

Transmitter Systems

Several recent studies in genetics, neuropsychopharmacology and neuroimaging have helped to clarify the biological contributions to impulsivity and aggression in humans and animals. Various neurotransmitter systems modulate impulsive disorders. Evidence of serotonergic dysregulation and a presynaptic deficit of available 5-HT has been observed in humans with a variety of impulsive disorders, as well as animal models of impulsivity and aggression. Knockout mice lacking 5-HT_{1B} receptors display increased impulsive aggression, cocaine self-administration and alcohol consumption (Brunner and Hen, 1997), and polymorphisms of tryptophan hydroxylase (the rate-limiting enzyme for 5-HT synthesis) have been associated with impulsive-aggressive behaviours (New *et al.*, 1998). Specific impulse-control disorders, such as pathological gambling, probably involve abnormalities of DA receptors and reward pathways, as well as noradrenergic and serotonergic dysfunction (Hollander *et al.*, 2000). DA function, particularly within the mesocorticolimbic pathways, is critical in the mediation of reward and reinforcement behaviours (reviewed in Hollander *et al.*, 2000). Association studies of genes related to DA receptors have supported a genetic influence in impulsive behaviours (reviewed in Hollander *et al.*, 2000), and μ-opioid receptors are involved in the regulation of these pathways. Peptides such as vasopressin have also been implicated in aggressive behaviours. A better understanding of the role of neurotransmitters in modulating relevant neurocircuitry (i.e., the ventromedial cortex and nucleus accumbens) is needed to develop specific treatments for pathological impulsivity across various conditions.

Various approaches involving pharmacological manipulation of neurotransmitters have been undertaken in an attempt to ameliorate pathological impulsivity in several psychiatric disorders. Much research to date has focused on modulation of 5-HT transmission. Selective serotonin reuptake inhibitors (SSRIs) and other enhancers of serotonergic transmission have reduced impulsive behaviours in a wide range of different disorders, including pathological gambling, borderline personality disorder (BPD), sexual addictions and obsessive-compulsive spectrum disorders (Hollander *et al.*, 1998, Hollander and Rosen, 2000). While serotonin dysregulation and hypofunction appear to play a central role in these disorders, it is likely that impulsivity is influenced to differing degrees by the highly interconnected 5-HT, noradrenergic, dopaminergic, opiate and GABAergic systems. Nevertheless, the neuronal mechanisms producing behaviour are complex and irreconcilable with simplistic constructs, and it is impossible to manipulate one neurotransmitter system to the exclusion of surrounding neurons.

Serotonin Function

Animal and human research suggests that the central serotonin system is involved in the inhibition of impulsive behaviour, and reduced levels of cerebrospinal fluid (CSF) 5-HIAA seem to be associated with impulsive aggression.

A decrease in brain 5-HT has been found in the brainstems of muricidal rats (aggressive rats that spontaneously kill mice introduced into their cages) and other animals made aggressive by isolation. The administration of tryptophan, a 5-HT precursor, reduces or abolishes the violence (Depue and Spoont, 1987).

In primate studies, researchers have noted higher blood 5-HT and 5-HIAA CSF concentration in monkeys who tend to be dominant and high-ranking in their colonies (Higley *et al.*, 1992), and lower 5-HIAA CSF concentration as an antecedent to greater alcohol consumption (Higley *et al.*, 1996). Social stress from aggressive interaction is expressed differently in specific brain regions of dominant and subordinate male *A. carolinensis* lizards. Prior to aggressive behaviour, the outcome is predictable via the celerity of postorbital colouration: dominant males exhibit more rapid eyespot darkening. Serotoninergic activation is manifest rapidly (1 h) in the hippocampus, nucleus accumbens and brainstem of subordinate males, and is expressed more rapidly in dominant males. Amygdalar serotoninergic activation responds rapidly (1 h) in dominant males, but is expressed slowly (1 week) in chronically in subordinate males (Larson and Summers, 2001).

Mice deficient in monoamine oxidase A (MAO-A) have increased brain levels of serotonin and norepinephrine, and they show enhanced aggression (Shih *et al.*, 2000). Pruus *et al.* (2000) demonstrated that the 5-HT_{1A} receptors may be involved in the mediation of the apomorphine-induced aggressive behaviour in adult male Wistar rats; nevertheless, the prominent antiaggressive effect of the 5-HT_{1A} receptor agonist buspirone seems to be mediated by some other mechanisms, evidently via the DA D_2 receptors.

Fairbanks *et al.* (2001) provided evidence for serotonergic influences on social impulsivity in vervet monkeys. Svensson *et al.* (2000) have demonstrated that gonadectomy reduced disinhibitory behaviour in 5-HT-depleted rats, and that gamma-amino-butyric acid (A)/benzodiazepine receptor complexes ($GABA_A$/BDZ-RC) may be involved in this effect.

Studies of genetically engineered mice with targeted disruption of the neuronal nitric oxide synthase (nNOS) gene have established the inhibitory role of nitric oxide (NO) in male impulsive-aggressive behaviour. The molecular mechanism accounting for the aggressive behaviour caused by the lack of neuronally derived NO is not known; the excessive aggressiveness and impulsiveness of nNOS knockout mice is caused by selective decrements in serotonin turnover and deficient receptor function in the brain regions regulating emotion, indicating — as already mentioned — an important role for NO in normal brain 5-HT function (Chiavegatto *et al.*, 2001).

For dogs with dominance aggression, the addition of tryptophan to high-protein diets or change to a low-protein diet may reduce aggression; for dogs with territorial aggression, triptophan supplementation of a low-protein diet may be helpful in reducing aggression (De Napoli *et al.*, 2000).

Thus, there is significant evidence for the role of serotonergic (5-HT) dysregulation or dysfunction in impulsive aggression in both animals and humans (Asberg *et al.*, 1976; Brown *et al.*, 1979, 1982; Sabrie, 1986). In an attempt to dissect the contribution of individual 5-HT receptor subtypes to behaviour, Ramboz *et al.* (1996) have generated mutant mice lacking the 5-HT_{1B} receptor. These mice did not exhibit any obvious developmental or behavioural defect; however, the hyperlocomotor effect of the 5-$HT_{1A/1B}$ agonist, RU24969,

was completely absent in mutant mice, indicating that this effect is mediated by 5-HT_{1B} receptors; moreover, when confronted with an intruder, isolated mutant mice attacked the intruder faster and more intensely than wild-type mice, suggesting an involvement of 5-HT_{1B} receptors in the modulation of aggressive behaviour. These data might be related to the fact that a class of 5-HT_1 agonists, termed serenics, have antiaggressive properties, and to the findings that certain impulsive-aggressive behaviours are associated with deficits in central serotonin (Saudou *et al.*, 1994; Ramboz *et al.*, 1996). Furthermore, Brunner and Hen (1997), using a knockout mouse that lacks 5-HT_{1B} receptors, observed that this animal shows more impulsive aggression, acquires cocaine self-administration faster, and drinks more alcohol than the corresponding wild-type control; for Brunner and Hen, these impulsive characteristics are not due to a change in cognitive functions, since in a cognitive task involving a choice between a small immediate reward and a larger, more delayed reward, knockout mice showed intact choice and timing capabilities and good discrimination of reward amounts.

Scearce-Levie *et al.* (1999) have evaluated the behavioural effects of 3,4-methylenedioxymethamphetamine (MDMA), a psychoactive drug of abuse, which in rats stimulates locomotion while decreasing exploratory behaviour, on knockout mice lacking the 5-HT_{1B} receptor: these animals show a reduced locomotor response to MDMA, although delayed locomotor effects of MDMA are present in these animals. These findings indicate that the locomotor effects of MDMA are dependent upon the 5-HT_{1B} receptor, at least in part. In contrast, MDMA eliminates exploratory behaviour in both normal and knockout mice, suggesting that the exploratory suppression induced by MDMA occurs through mechanisms other than activation of the 5-HT_{1B} receptor.

Moreover, according to Ramboz, the 5-HT_{1A} receptors should be involved in the modulation of exploratory and fear-related behaviours, suggesting that reductions in 5-HT_{1A} receptor density due to a genetic defect or environmental stressors might result in heightened anxiety (Ramboz *et al.*, 1998). These results seem to be confirmed by other authors who observed that 5-HT_{1B} knockout mice are more aggressive, more reactive and less anxious than the wild types, whereas the 5-HT_{1A} knockouts are less reactive, more anxious, and possibly less aggressive than the wild types (Zhuang *et al.*, 1999).

Animal studies suggest that 5-HT_1-receptor stimulation results in a decrease in aggressive behaviour, whereas, in humans, aggressive, personality-disordered patients show a blunted prolactin response to the 5-HT_{1A} agonist buspirone. Antagonism of the 5-HT_2 receptors appears to decrease aggression, and this effect may explain the ability of newer antipsychotics agents (which, unlike older antipsychotic medications, block 5-HT_2 receptors) to produce a dramatic reduction in aggression and agitation independent of the effects on psychotic symptoms (Kavoussi *et al.*, 1997).

In humans, Asberg *et al.* (1976) initially noted an inverse relationship between violent/lethal suicidal behaviour and the 5-HT metabolite 5-HIAA CSF concentration in depressed patients. Subsequent studies on populations in eight different countries confirmed that suicidal depressed patients have lower 5-HIAA CSF than nonsuicidal depressed patients. For example, Lidberg *et al.* (2000) found that homicide offenders with a history of suicide attempts had a lower concentration of spinal fluid 5-HIAA than the remaining murderers. This correlation is particularly strong in those with violent suicide attempts. Low concentration of CSF 5-HIAA has also been shown to be related to aggressive behaviour independent of suicidal behaviour in patients with Axis I disorders (Stanley *et al.*, 2000). In addition, Brown *et al.* (1982) demonstrated a decrease in 5-HIAA CSF in patients with personality disorders and found that this decrease correlated with scores on a lifetime aggression scale. Many studies have confirmed an inverse relationship between 5-HIAA CSF level and impulsive and violent behaviours (Bioulac, 1980; Brown *et al.*, 1982; Linnoila *et al.*, 1983; Lidberg *et al.*, 1984). The individual cases and small study populations studied include psychopathic military personnel, arsonists, murderers, violent suicidal patients, and behaviourally disruptive children and adolescents. Linnoila *et al.* (1983) have reported reduced CSF 5-HIAA concentration in both impulsive violent offenders and impulsive arsonists compared with premeditated violent offenders, suggesting that it is specifically nonpremeditated ('impulsive') aggression that correlates with reduced central 5-HT function in these individuals.

Investigators have also correlated abnormal 5-HT platelet studies with impulsivity and aggression (Biegon *et al.*, 1990; Marazziti and Conti, 1991). Decreased numbers of platelet 5-HT transporter sites are found in aggressive conduct-disordered subjects and in 'aggressive' institutionalized psychiatric subjects (Stoff *et al.*, 1991). In addition, an inverse correlation between platelet 5-HT uptake and the Barratt 'impulsivity' score has been reported in aggressive adult males (Brown *et al.*, 1989). In children and adolescents with conduct disorder, there is a negative correlation between platelet imipramine binding and impulsive aggression (Stoff *et al.*, 1987). In individuals with personality disorders, platelet titrated paroxetine binding has been shown to be inversely correlated with the Life History of Aggression total score and aggression score, and with the Buss-Durkee Hostility Inventory Assault score (Coccaro *et al.*, 1996).

Researchers have noted consistently reduced imipramine binding (Brown *et al.*, 1989) and increased platelet 5-HT_2 binding in suicide victims (Biegon *et al.*, 1990). The reduced imipramine binding may reflect decreased 5-HT release. Increased 5-HT_2 binding may reflect the brain's compensatory response to a decrease in functional serotonergic neurons, with consequent upregulation of postsynaptic 5-HT_2 binding sites. Additional findings that suggest the role of 5-HT in impulsivity and aggression include reports of low serum ratios of tryptophan to other neutral amino acids in alcoholics arrested for assaultive behaviour compared with other alcoholics or nonalcoholic control subjects (Lewis, 1991). Type 2 alcoholism is associated with both violent behaviour and serotonergic deficit (LeMarquand *et al.*, 1994, Virkkunen and Linnoila, 1990). Individuals with a family history of alcoholism may be more sensitive to impulsivity in response to low serotonin levels, as tryptophan-depleted individuals with a family history of alcoholism made more errors in a modified Taylor task than did those with no family history of alcoholism (LeMarquand *et al.*, 1999).

Biver has studied gender differences in the living human brain 5-HT_2 receptor, using positron-emission tomography and a selective radiotracer: he found significantly higher 5-HT_2 receptor-binding capacity in men than in women, especially in the frontal and cingulate cortices; this finding suggests that distinct liability for men and women to suffer from some psychiatric disorders responding to serotonergic agents may be related to differences in brain serotonin receptors (Biver *et al.*, 1996).

Other Neurotransmitter Systems

Neurotransmitters other than serotonin probably influence aggressive and impulsive behaviour; for example, GABA, norepinephrine and DA (Oquendo and Mann, 2000). An alpha-amino-3-hydoxy-5-methylisoxadole-4-propionate (AMPA) receptor antagonist, NBQX, was found to increase impulsivity in rats which was restored by injection of a positive allosteric modulator of AMPA receptors, indicating that the AMPA receptor, a type of glutamate receptor, is involved in the regulation of impulsivity (Nakamura *et al.*, 2000). Some studies demonstrate that increasing norepinephrine levels correlate with impulsive aggression, whereas other studies demonstrate an opposite relationship; thus, the role of norepinephrine in impulsive-aggressive behaviour is still unclear (Oquendo and Mann, 2000).

It has been shown that brain GABA levels are involved in intermale aggression in mice, and that mice selected for differences in sensitivity to a benzodiazepine receptor inverse agonist vary in intermale aggression (Guillot *et al.*, 1999). Moreover, the acute $GABA_A$ receptor agonist THIP and the $GABA_B$ receptor agonist baclofen attenuate the apomorphine-induced aggressive behaviour, indicating the involvement of both $GABA_A$ and $GABA_B$ receptor subtypes in the neurobiology of apomorphine-induced aggressiveness, as this phenomenon is evidently subject to the general inhibitory effect of GABAergic neurotransmission (Rudissar *et al.*, 2000). The involvement of GABA as a possible neurotransmitter of aggressive behaviour is indirectly confirmed by the effect of alcohol: in fact, the aggressive behaviour of certain individual animals can be greatly increased when they are under the influence of low doses of alcohol. One of alcohol's neurochemical actions that may be relevant to alcohol-heightened aggression is its positive modulation of the $GABA_A$ receptor complex. Alcohol prolongs 'bursts' of aggressive acts, and displays and disrupts communication between the aggressive animal and the opponent who defends itself, submits or flees. Pharmacological modulation of the $GABA_A$ receptor with benzodiazepines and neuroactive steroids (allopregnanolone) results in dose-dependent biphasic changes in aggressive behaviour that mimic the dose-effect function of alcohol; benzodiazepines potentiate the aggression-heightening effects of alcohol as well as the behaviourally suppressive effects, and antagonists of benzodiazepine receptors prevent the aggression-heightening effects of alcohol (Miczek *et al.*, 1997). Although alcohol induces aggressive behaviour in mice, it has a suppressive effect upon predatory attack behaviour in the cat. Han's studies support the hypothesis that ethanol's suppressive effects in the cat are mediated, at least in part, by $GABA_A$ receptors in the lateral hypothalamus (Han *et al.*, 1997). Moreover, activation of the mesolimbic DA pathway appears to promote drug- and alcohol-seeking behaviour in laboratory animals (Hill *et al.*, 1999).

The possible role of DA in aggressiveness is suggested by the fact that the blockade of the D_1/D_2 DA receptor produces an antiaggressive action commonly associated with an impairment of other motor behaviours, and the D_3 receptor seems to present opposite actions to D_1 and D_2, since the blockade of this receptor produces a stimulation of motor activity, which has been associated with an increase in DA neurotransmission (Rodriguez-Arias *et al.*, 1999).

Several reports suggest that when there is a dysfunction in a person's brain reward cascade — a dysfunction which could be caused by certain genetic variants, especially in the DA system — leading to a hypodopaminergic trait, that person requires a DA fix to feel good. This trait leads to multiple drug-seeking behaviour. This is so because alcohol, cocaine, heroin, marijuana, nicotine and glucose all cause an activation and neuronal release of brain DA, which may satisfy the abnormal cravings. It seems certain that carriers of the DAD_2 receptor A1 allele have compromised D_2 receptors. Therefore, the lack of D_2 receptors causes individuals to have a high risk of multiple addictive, impulsive and compulsive behavioural propensities, such as severe alcoholism; cocaine, heroin, marijuana, and nicotine addiction; glucose bingeing; pathological gambling; sex addiction; ADHD; Tourette's syndrome; autism; chronic violence; conduct disorder; and antisocial behaviour (Blum *et al.*, 2000).

Shih *et al.* (2000) have observed that mice deficient in MAO-A have increased brain levels of serotonin and norepinephrine and show enhanced aggression, and that the administration of Gingko biloba extract to MAO-A knockout mice reduces their aggressive behaviour in resident-intruder confrontations; this effect on aggression is not due to sedation and may be mediated by $5\text{-}HT_{2A}$ receptors. All these contradictory results suggest the complexity of neuronal mechanisms in producing behaviour. One point to consider is that MAO is relatively nonspecific, as it is involved in the breakdown of a number of monoamines, and the activity of MAO in platelets may not reflect MAO activity in the central nervous system.

The observation that naloxone and naltrexone ameliorate self-injurious behaviour (SIB) has suggested that impairment of opioid secretion may be involved in the physiopathology of this aggressive behaviour (Richardson and Zaleski, 1983). In patients with SIB, Met-enkephalin plasma levels are increased and return to normal after improvement of the disease. Beta-endorphin plasma levels, however, are lower than normal in children with SIB and higher than normal in adults (Sandman *et al.*, 1987). There have been studies of the functional effect of enkephalins isolated from the avian brain on preoptic and hypothalamic neurons in male Japanese quails. Behavioural changes have been observed following injection of naloxone, a non-selective opioid receptor antagonist, and D-Ala2-Met5-enkephalinamide (DALA), a selective delta opioid receptor agonist, into the preopti and anterior hypothalamic regions. Naloxone treatment showed a significant increase in the frequency of several aggressive actions and the effect was dose dependent, whereas DALA treatment significantly decreased the frequency of aggressive actions in a dose-dependent manner (Kotegawa *et al.*, 1997).

Finally, it has been reported that the μ-opioid receptor upregulation in limbic areas is consistent with increased emotional and aggressive behaviours observed in enkephalin knockout mice (Brady *et al.*, 1999). Taken together, all these data seem to suggest that the opioid system may play a role in the neurobiology of aggressiveness.

NEUROENDOCRINOLOGY

Endocrine Studies

Animal studies show that the testosterone levels of male rhesus monkeys correlate positively with behavioural dominance and aggression. If a single male monkey is placed with other aggressive males, he becomes submissive and shows a decrease in plasma testosterone, revealing that endogenous hormone production can be affected by behavioural variables. King's recent data seem to support the hypothesis that early androgen treatment may support the neurobiology of animals with genetic predisposition to hyperactivity, impulsivity and inattention in a manner consistent with the enhanced expression of ADHD-like behaviours (King *et al.*, 2000).

The connection between the endocrine system and aggression and impulsivity is not clear. Some researchers have hypothesized that androgens may play a role in aggression. They suggest that the androgen insensitivity syndrome and the androgenital syndrome are examples of androgen excesses and deficiencies associated with aggressive and inhibited behaviour, respectively. In one study, plasma testosterone levels were elevated in juvenile prisoners who had committed violent crimes. CSF free testosterone has been shown to be correlated with overall aggressiveness, but not with measures of impulsivity (Higley *et al.*, 1996). Oestrogens and antioandrogens have been used to reduce aggressiveness effectively in some violent sex offenders, although these cases clearly need to be better studied. Low salivary cortisol levels have been associated with persistence and early onset of aggression in school-aged boys, suggesting that low hypothalamic-pituitary-adrenal axis activity correlates with aggressive activity (McBurnett *et al.*, 2000).

Van Goozen has recently examined the relationship between adrenal androgens and aggression in children with oppositional and antisocial behaviour, and compared their levels with those of psychiatric and normal controls. Children with oppositional defiant disorder (ODD) had higher dehydroepiandrosterone sulphate (DHEAS) levels than either psychiatric control or normal

control groups; DHEAS levels between the last two groups did not differ; in Van Goozen *et al.*'s opinion, it is possible to classify children as having either ODD or ADHD on the basis of their DHEAS levels, whereas this was not the case on the basis of the Child Behaviour Checklist (CBCL) data. These data indicate that adrenal androgen functioning is specifically elevated in children with ODD, and it is speculated that the mechanism could be a shift in balance of ACTH-beta-endorphin functioning in the hypothalamic-pituitary-adrenal axis due to early stress or genetic factors (Van Goozen *et al.*, 2000).

A positive relationship has been reported in boys between testosterone blood level and acting/receiving aggression in 'social interactions' (serious aggression), but not in playing contests (playful aggression). This indicates that radioimmunoassay testosterone samples in saliva can be a useful biological marker for the risk of serious aggression in preschool boys, reflecting that various levels of sociability are linked to different behavioural patterns (Sanchez-Martin *et al.*, 2000).

Moreover, it has been noted that the ability of estradiol to facilitate transcription from six genes whose products are important for lordosis behaviour in female mice (a typical mating behaviour) proved that hormones can turn on genes in specific neurons at specific times, with sensible behavioural consequences. The use of a gene knockout for oestrogen receptor alpha (ERalpha) revealed that homozygous mutant females simply would not do lordosis and instead were extremely aggressive, thus identifying a specific gene as essential for a mammalian social behaviour. In dramatic contrast, (ERbeta) knockout female mice can exhibit normal lordosis behaviour (Pfaff *et al.*, 2000).

A randomized, double-blinded, placebo-controlled, crossover clinical trial has been used to determine the role of sex steroids on the development of aggressive behaviours in 35 boys and 14 girls. Depot testosterone (to boys) or conjugated oestrogens (to girls) was administered in 3-month blocks, alternating with placebo at three dose levels approximating to early, middle and late pubertal amounts. The Olweus Multifaceted Aggression Inventory was administered after each placebo and treatment period to ascertain the effect of steroids on self-reported aggressive behaviours. The data demonstrated significant hormone effects on physical aggressive behaviours and aggressive impulses, but not on verbal aggressive behaviours nor on aggressive inhibitions in both boys and girls (Finkelstein *et al.*, 1997).

Finally, the impairment of the purinergic system, characterized by reduced adenosinergic activity, has been implicated in the neurobiology of aggressive behaviour. Since there are no direct adenosine agonists available for human use, inhibition of purine degradation by allopurinol was conceived as a possible strategy: Lara *et al.* (2000) reports two cases of adults with refractory aggressive behaviour due to a neurological condition with dramatic response to therapy with allopurinol, 300 mg per day p.o., suggesting the involvement of the purinergic system in the neurobiology of aggression.

Pharmacological Challenge Studies

Animal models have been used to define more clearly the role of specific 5-HT receptors in impulsivity and aggression. To define the contribution of 5-HT receptor subtypes to behaviour, mutant mice lacking the 5-HT_{1B} receptor were generated by homologous recombination. As reported above, these mice did not exhibit any obvious developmental or cognitive defects. They were, however, noted to be extremely aggressive — they attacked intruders faster and more intensely than did wild-type mice (Hen, 1994) — to have increased impulsive aggression, to acquire cocaine self-administration faster, and to exhibit increased alcohol consumption (Brunner and Hen, 1997), suggesting a role for the 5-HT_{1B} receptors in modulating aggressive, impulsive and addictive behaviour (Hen, 1994).

Another research approach involves the use of challenge agents, such as m-chlorophenylpiperazine (m-CPP), that simulate or block serotonin receptors. M-CPP, a non-selective serotonin (5-HT) receptor agonist, has a complex effect on the brain with potent binding to the 5-HT_{2C} receptors and weaker affinity for the 5-HT_{1A} receptors (Kahn and Wetzler, 1991). Neuroendocrine changes following m-CPP stimulation have been represented by increased prolactin, adrenocorticotrophic hormone (ACTH), and corticosterone/cortisol responses in rodents, monkeys and humans (Fuller, 1981; Aloi *et al.*, 1984; Yatham and Steiner, 1993; Meltzer and Maes, 1995). Postsynaptic 5-HT_{1A} and 5-$HT_{2A/2C}$ receptors are thought to mediate these effects (Meltzer and Maes, 1995).

Studies have found that aggressive antisocial subjects had significantly lower excretions of baseline urinary free cortisol and lower CSF ACTH concentration than controls. These findings suggest an inverse relationship between the activity of the hypothalamic-pituitary-adrenal (HPA) axis at baseline and aggressive behaviour (Virkkunen, 1985; Virkkunen *et al.*, 1994). Our group (De Caria *et al.*, submitted) studied 5-HT metabolism alteration, examining behavioural ('high') and neuroendocrine (prolactin and cortisol) responses to single dose ($0.5\,mg\,kg^{-1}$) oral m-CPP and placebo in pathological gamblers and matched controls, and the relationship with clinical severity. Pathological gamblers had significantly increased prolactin response compared to controls at 180 and 210 min post m-CPP. Greater gambling severity correlated with increased neuroendocrine responsiveness to m-CCP, suggesting greater 5-HT dysregulation. Pathological gamblers had significantly increased 'high' response to m-CPP compared to placebo. M-CPP challenge, via the HPA axis, provided a dynamic index of central serotonergic function. An enhanced response to direct postsynaptic serotonergic receptor stimulation is consistent with hypersensitive postsynaptic serotonergic function in male pathological gamblers compared to healthy controls. This would be consistent with a net deficiency of presynaptic 5-HT availability at baseline, and a compensatory increase in postsynaptic 5-HT receptor sensitivity.

Similar results were reported in trichotillomanic (Stein *et al.*, 1995a), alcoholic (Benkelfat *et al.*, 1991), and impulsive and antisocial patients (Moss *et al.*, 1990; Maes *et al.*, 2001). These results are also consistent with reported increased prolactin response and a prolonged peak following m-CPP administration in paedophilics, compared to placebo, relative to healthy controls (Maes *et al.*, 2001).

Pathological gamblers reported that the 'high' that they experienced in response to m-CPP was similar to the 'high' they experience while gambling. An increased 'high' response in other impulsive disorders, such as borderline personality disorder (Hollander *et al.*, 1994) and trichotillomania (Stein *et al.*, 1995a), following m-CPP stimulation has been found. These findings suggest that m-CPP elicits an increased euphoric effect in patients with various types of impulsive behaviours/disorders relative to healthy controls and placebo. In disorders of substance abuse, male alcoholics, some of whom had comorbid antisocial personality disorder (Benklefat *et al.*, 1991), cocaine addicts (Buydens-Branchey *et al.*, 1993), and alcoholics (Krystal *et al.*, 1994) also experienced increased 'high' feelings in response to m-CPP stimulation.

Hollander *et al.* (1992) observed that also a subgroup of patients with obsessive-compulsive disorder (OCD) experienced exacerbation of obsessive symptoms following m-CPP challenge studies. M-CPP has affinity for the 5-HT_{1A}, 5-HT_{2C}, and 5-HT_{1D} receptor subtypes. Patients who underwent challenge studies with MK212, a 5-HT agonist with affinity for the 5-HT_{1A} and 5-HT_{2C} receptor subtypes, but not the 5-HT_{1D} subtype, did not manifest exacerbation of obsessions and compulsions. Because there are behavioural changes in a subgroup of OCD patients following m-CPP, but not following MK212, and because the activity of these two agonists differ with regard to only one receptor subtype, the 5-HT_{1D} receptor, it

has been suggested that this receptor may modulate obsessions, of which sexual and aggressive symptoms may be prominent.

Dynamic changes of DA and serotonin have also been assessed: rats were implanted with a microdialysis probes aimed at the nucleus accumbens or medial prefrontal cortex, and, as already mentioned, DA and serotonin levels in the prefrontal cortex changed in opposite directions. Serotonin decreased to 80% from baseline levels during and after the confrontation, whereas DA increased by up to 120% after the confrontation. The temporal pattern of monoamine changes points to a significant role of accumbal and cortical DA and 5-HT in the consequences, as opposed to the triggering, of aggressive acts. The increase in accumbal DA in aggressive animals supports the hypothesis that this neural system is linked to the execution of biologically salient and demanding behaviour (Van Erp and Miczek, 2000).

NEUROGENETICS

Genetic studies in humans and animals have not yet supported a definitive association among impulsivity, aggression, and reduced 5-HT activity. The Maudsley rat study, however, was an example of genetic breeding for aggressive behaviour. Two groups of rats were bred. The first group (MNR) included rats that had low measures of impulsivity and high measures of inhibition. The second group (MR) had the opposite features. The MR strains bred from the second group were significantly more impulsive and demonstrated increased aggressive behaviour compared with the MNR rats (Eichelman, 1971). Neurochemically, the MNR strain showed lower limbic brain 5-HT levels than the MR strain (Sudack and Maas, 1964).

At the synaptic level, reuptake of serotonin is accomplished by a plasma membrane carrier called the serotonin transporter (5-HTT). The gene for 5-HTT has been mapped to chromosome 17 (Collier *et al.*, 1996). Preliminary evidence for a genetic disturbance in serotonergic function that might predispose individuals to impulsive-aggressive behaviour includes a study of the gene for the rate-limiting enzyme for serotonin synthesis, tryptophan hydroxylase (TPH). The gene for TPH has been mapped to the short arm of chromosome 11 and is one of the major candidate genes for psychiatric and behavioural disorders. Part of the gene for TPH has been discovered to exist as two alleles: U or L, with certain genotypes (UL and LL) being associated with impulsive-aggressive behaviour and suicidal behaviour, and with low levels of CSF 5-HIAA in violent offenders (Nielsen *et al.*, 1994). Persons having the TPH U allele scored significantly higher on measures of aggression than individuals homozygous for the L allele, and peak prolactin response was attenuated among male subjects, but not female subjects, having any U allele relative to LL homozygotes (Manuck *et al.*, 1999). In another study, the TPH genotype was found to be associated with impulsive-aggressive behaviours in male, but not female, patients who had personality disorders (New *et al.*, 1998). There have been reported polymorphisms in the regulatory region of the serotonin transporter, in intron 7 of the TPH gene, and in the MAO-A gene, associated with mood and anxiety disorders, impulsivity and aggression (New *et al.*, 1997; 1998). Nolan *et al.* (2000) examined these polymorphisms in schizophrenic and schizoaffective patients, suggesting the association between the TPH L allele and impulsive aggression in males with personality disorder. Turecki *et al.* (2001), instead, investigated the correlation between TPH and suicidal behaviour: haplotype analysis revealed that one haplotype (−6526G −5806T 218C) was significantly more frequent among suicide subjects than in normal controls, and this haplotype was particularly more frequent among subjects who committed suicide by violent methods. Further studies are needed to clarify the role of TPH alleles in aggression and the differences between the sexes.

Genetic studies involving the 5-HT_{1B} receptor gene in human subjects have been equivocal. In one study, a polymorphism of the 5-HT_{1B} receptor gene was linked to aggressive and impulsive behaviour in alcoholics (Lappalainen *et al.*, 1998). However, Huang *et al.* (1999) found no relationship between suicide, alcoholism or pathological aggression with 5-HT_{1B} receptor-binding indices or a genotype using two common polymorphisms. In summary, serotonin synthesis and regulation are at least partially regulated by genetic controls that probably contribute to an individual's propensity for impulsive and aggressive behaviours.

Homozygosity of a low-enzyme-activity variant of the catechol-*O*-methyltransferase (COMT) gene has been reported to be associated with aggressive behaviour in a group of schizophrenic patients. A similar tendency has been observed by Kotler *et al.* (1999) in a group of 30 schizophrenic subjects who were confined to a maximum-security psychiatric facility for homicide; significant excess (46.7% versus 21.0%) homozygosity of the low activity COMT Met/Met genotype was observed in 30, mostly male (28 of 30), homicidal schizophrenic patients compared with 415 control subjects, and no difference in COMT genotype has been found between nonviolent schizophrenic patients and control subjects. Moreover, the COMT genotype has been determined in 62 impulsive violent recidivist offenders with early-onset (type 2) alcoholism, 123 late-onset nonviolent alcoholics (type 1) and 267 race- and gender-matched controls. The allele and genotype frequencies of these groups were compared with each other and also with previously published data from 3130 Finnish blood donors. The type 2 alcoholics did not differ from either the blood donors or the controls. The low activity (L) allele frequency was higher among type 1 alcoholics than type 2. The odds ratio for type 1 alcoholism as compared with type 2 alcoholism for those subjects with the LL genotype versus the HH was 3.0 (95% confidence interval 1.1–1.84). These results suggest that the COMT genotype has no major role in the development of early-onset alcoholism with severe antisocial behaviour (Hallikainen *et al.*, 2000).

Currently, there are no controlled family history studies of individuals with impulse-control disorders (i.e., intermittent explosive disorder, kleptomania, pyromania, pathological gambling, and trichotillomania). There are studies supporting associations between major mood disorder and alcohol and substance abuse in first-degree relatives of individuals with kleptomania and in first-degree relatives of pathological gamblers (Linden *et al.*, 1986; Ramirez *et al.*, 1983; Saiz *et al.*, 1992).

The relationship between mood swing and impulse control represents a field of great relevance to the understanding and therapy of impulse-control disorders. Other findings include associations between anxiety disorders in the families of individuals with kleptomania and violent behaviour and ADHD in the families of individuals with intermittent explosive disorder (McElroy *et al.*, 1991).

Research involving monozygotic twins reveals a hereditary aspect of aggressive behaviour, with concordance rates for monozygotic twins greater than those for dizygotic twins. Twin studies suggest that antisocial behaviour in adult life is related more to genetic factors than to environmental factors (Cadoret *et al.*, 1995). Twin studies have established that there are substantial genetic influences on alcoholism in both men and women, and it seems that the heritability of alcoholism is substance-specific; the relationship between this and behaviours predisposing to alcoholism, including impulsivity, is still challenging. Refinement of clinical phenotypes and use of intermediate phenotypes will improve the changes of gene identification (Enoch and Goldman, 2001).

Chromosomal studies have looked at the influence of chromosomal abnormalities in aggression, particularly the XYY syndrome (Bioulac *et al.*, 1980). However, the link between XYY and violence has not been confirmed. Inborn metabolic disorders that affect the nervous system can be associated with aggressive personalities. These disorders, which diffusely affect the central nervous system

and are inherited, include phenylketonuria, Lesch-Nyhan syndrome, Prader-Willi syndrome, Vogt syndrome (a neuronal storage disorder), and Sanfilippo's syndrome (increased mucopolysaccharide storage).

THERAPEUTIC INTERVENTIONS

Impulsivity and aggression are behavioural characteristics that encompass a broad range of clinical problems. Studies on impulsivity and aggression have focused on a heterogeneous group of disorders with varied responses to pharmacotherapeutic interventions. In this chapter, we do not focus on the treatment of patients with epilepsy and patients with drug-induced aggression. These areas are reviewed elsewhere.

Controlled studies suggest that a number of medications may be useful in the treatment of impulsivity and aggression. Given the evidence for decreased 5-HT function in impulsive and aggressive behaviours, many, but not all, of these medications involve direct 5-HT mechanisms.

SSRIs have been shown to reduce impulsive, aggressive behaviours in various psychiatric disorders. For example, fluvoxamine resulted in improvement in gambling severity in patients with pathological gambling compared to placebo in one double-blind study (Hollander *et al.*, 2000b). However, in some disorders characterized by impulsivity, SSRIs have a quick onset, but these effects maybe transient, and some patients may require augmentation with compounds such as lithium, buspirone, and anticonvulsants (Hollander and Wong, 1995). Preliminary data from an open-label study conducted by our group reported that nefazodone (100–500 mg per day) is also an effective treatment in a sample of 12 pathological gamblers.

BPD is a common clinical problem in which researchers have used pharmacological interventions to target the characteristic symptoms of impulsivity, aggression, lability, and hostility. Fluoxetine is the best-studied SSRI for the treatment of impulsivity and aggression. A number of open trials of fluoxetine in BPD suggest its efficacy in the treatment of impulsivity and aggression in BPD. Markowitz (1990) reported that BPD patients showed significant decreases in self-injurious behaviour after treatment with fluoxetine 80 mg per day for 12 weeks. Three subsequent double-blind, placebo-controlled trials of fluoxetine confirmed the findings of the open trials (Markowitz, 1992). Overall, controlled studies of fluoxetine, sertraline, and fluvoxamine suggest that these medications are of benefit to patients with impulsivity and aggression in the context of BPD. More studies are needed to assess further which behaviours are associated with responsivity to an SSRI, and to determine the appropriate dosage, and longitudinal efficacy of those agents. The tricyclic antidepressants (TCAs) have been extensively studied in BPD for their effects on depression in BPD patients. Although clearly effective for depressive symptoms, TCAs have not been shown to be particularly helpful in decreasing aggression and impulsivity in BPD (Soloff *et al.*, 1986). Some BPD patients actually experienced increased anger, hostility, and aggression while taking imipramine (Klein, 1968) and amitriptyline (Soloff *et al.*, 1986). There are case reports of using desipramine and clomipramine effectively to treat violent outbursts in some patients, and of using amitriptyline, trazodone, and fluoxetine for aggression associated with brain injury and anoxic encephalopathy. The potential for worsening impulsive, aggressive symptoms and the danger of overdose in patients who have impaired self-control may limit the use of TCAs. The same limits apply to MAOIs, which also have not been shown to decrease the behavioural dyscontrol or impulsivity seen in BPD.

Medications that are not serotonergically mediated, such as carbamazepine and other anticonvulsant mood stabilizers, have also proven to be useful (Haller *et al.*, 1994). Although evidence suggests that impulsivity and aggression are serotonergically mediated, a 5-HT hypothesis of impulsivity is not a definitive model. The complete role of 5-HT activity and its complex interactions with other neurotransmitters and receptors in impulsivity and aggression have not yet been fully delineated. The antagonism of 5-HT2 receptors appears to decrease aggression and may explain the efficacy of newer antipsychotic agents in the reduction of aggression and agitation independently of effects on psychotic symptoms.

The neurotransmitter effects of lithium are complex and include an effect on second-messenger systems related to the 5-HT system. A recent single-blind, randomized study (Pallanti *et al.*, in press) suggests the efficacy of both lithium carbonate and valproate in the treatment of PG. Further studies on psychopharmacological treatments of pathological gambling should be performed, as preliminary studies involving medication in the treatment of this disorder have shown promising results. Researchers and clinicians have used lithium, carbamazepine, valproic acid, and, more recently, gabapentin, lamotrigine, and topiramate to treat the impulsivity, aggression, and mood instability seen in bipolar patients, and they subsequently reasoned that it might stabilize these same symptoms in BPD. In a double-blind placebo-controlled trial (Cowdry and Gardner, 1988), carbamazepine decreased impulsivity in a group of BPD patients.

Our group (Stein *et al.*, 1995b) found that valproate led to significant overall improvement in 50% of a small sample of BPD patients who completed an 8-week, open-label trial, and that valproate may be more effective than placebo was shown in a 10-week, double-blind study (Hollander *et al.*, 2001). The medication was helpful for impulsivity, anger, and irritability, as well as for mood instability and anxiety. The potential efficacy of valproate in the treatment of BPD raises the question of the neurobiological underpinnings of the core features of BPD, namely, impulsivity and aggression. A number of points are relevant. First, a link between impulsive aggression and limbic abnormality has long been postulated. Although only a small percentage of BPD patients have seizure activity, more subtle neuropsychiatric abnormalities have been found in this population, including increased neurological soft signs. The hypothesis that valproate alters limbic dysfunction by interrupting neuronal kindling is therefore of interest. Second, there is increasing evidence that 5-HT hypofunction may play a role in the mediation of BPD symptoms. Although valproate has multiple effects on neurotransmission, it is notable that it increases 5-HIAA levels. Further studies and larger sample sizes for the use of valproate in the treatment of BPD are warranted.

Neuroleptics are among the most studied medications for the treatment of BPD, and they have been effective in treating violence associated with psychosis. Although they are the most commonly used medications for violence and aggression related to psychosis, neuroleptics are often misused as chronic sedatives. In BPD patients, moreover, neuroleptics were not well tolerated and were statistically no better than placebo in the reduction of hostility, anger, and aggression (Goldberg *et al.*, 1986; Soloff *et al.*, 1986). In one 8-week, open-label, pilot study, BPD patients treated with olanzapine had lower Barratt Impulsivity Scale and Buss-Durkee Hostility Inventory scores then those treated with placebo (Schulz *et al.*, 1999). Neuroleptics may result in a number of adverse side effects. They may cause tolerance to sedation and lead to increased doses and thereby increased side effects such as akathisia, extrapyramidal side effects, and anticholinergic toxicity. These specific side effects can worsen aggression in predisposed patients, particularly those with organic brain injury.

Kim has employed the opioid antagonists in the treatment of impulse-control disorders, prescribing naltrexone for up to 9 months to 15 patients who had impulse-control disorder: naltrexone was generally well tolerated, and there were no hepatic side effects. Naltrexone appears to reduce urge-related symptoms and decrease

the problematic behaviours such as PG; the effects appear to be sustained. In general, 50 mg per day of naltrexone was not effective, and most patients required higher doses. These data suggest that naltrexone may be of use in selected impulse-control disorder patients (Kim, 1998).

Moreover, it seems that the disinhibitory behaviour of 5-HT-lesioned rats can be reversed by the commonly used opiate receptor-antagonist naloxone at doses that do not significantly affect behaviour in sham-lesioned controls. Moreover, this effect of naloxone is reversed by a low inert dose of amobarbital. Thus, naloxone may represent a new pharmacological principle for the treatment of impulse-control disorders (Soderpalm and Svensson, 1999).

SUMMARY

Impulsivity is a core symptom of a broad spectrum of psychiatric disorders including impulse-control disorders (pathological gambling, intermittent explosive disorder, pyromania, kleptomania, trichotillomania, and impulse-control disorder NOS), impulsive aggressive personality disorders (borderline, antisocial), neurological disorders that can be associated with disinhibition of behaviour (such as epilepsy), and substance abuse. Moreover, impulsive disorders entail large costs to society, and are associated with substantial morbidity, mortality, social/family/job dysfunction, accidents, suicide, violence, aggression, criminality, and excessive utilization of health-care, government and financial resources.

While the concept of impulsivity has been widely studied and reviewed in clinical psychiatry, our understanding of the neurobiology of impulsivity is still at a very early stage. No simple extrapolation of animal subtypes to humans is possible, mainly because of the influence of complex cultural variables on behaviour. On the whole, research into subtypes of human impulsivity has been rather limited. Much of this has been conducted in children, by clinical observation, experimental paradigms in the laboratory, and cluster/factor analytical statistics.

Animal models have recently helped to clarify both the neuroanatomical and biological basis of specific impulse behaviours. Brain regions such as the nucleus accumbens core, the basolateral amygdala, the hypothalamus, and the prefontal cortex may play an important role in impulsivity, as well as genetic and environmental factors. Serotonin dysregulation and hypofunction seem also to play a central role in impulse-control disorders, with the influence of the highly interconnected noradrenergic, dopaminergic, opioid, and GABAergic systems. Pharmacological therapeutic approaches have focused for this reason on serotonin transmission (serotonin reuptake inhibitors), but various classes of medication acting on different neurotransmitter systems, mood stabilizers, and opioid antagonists have also had encouraging results.

Further and more sophisticated research is needed to elucidate the localization of impulsive choice in animal and human models, and to understand this core behavioural symptom domain that cuts across various disorders and plays an important role not only in clinical psychiatry but also in everyday life.

XXVI-1

Animal Models of Personality

A.R. Cools and B.A. Ellenbroek

PERSONALITY AND ITS DISORDERS

In practice, we need to be able to assess personality in order to predict how patients will respond to illness and to treatment. We also need to be able to manage people with personalities that cause serious problems to themselves or other people. As elaborated in the next paragraph on 'basic dimensions of personality', the term 'personality' refers to the balance between various traits. If one or more dominant traits are strong enough to cause difficulties to the person or to other people, the person is said to have a personality disorder. However, the borderline between normal personality and personality disorders is hard to define. In fact, there is no reliable and valid measure that allows a cut-off for distinguishing between normality and disorder. In clinical practice, therefore, a personality is said to be disordered when it causes suffering to the person or to other people. It is evident that such a criterion is impossible to model in animals. Indeed, animal models of personality disorders are not available, unless one adheres to the traditional classification system for personality disorders: in that case, we are dealing with animal models for anxiety disorders, mood disorders, etc., as discussed in several other chapters of this textbook.

Recently, however, Cloninger *et al.* (1994) have introduced a new classification system that allows differential diagnosis of personality disorders with the help of temperament and character descriptors. As outlined below, it is possible to model a number of these temperament descriptors in animals. In this chapter, we will focus on these and related studies.

BASIC DIMENSIONS OF PERSONALITY

In the first place we should clarify what we want to model. Thus, we should delineate the basic units of personality. As elaborated by Zuckerman (1991), the basic unit in personality psychology is the trait, defined as a group of related habits that, in turn, are defined as consistent behaviours in specific situations. Using this definition, Zuckerman suggests that the term 'basic dimensions of personality' should refer to

> supertraits that have internal reliability and can be identified in terms of their constituent traits across methods, genders, and cultures; these supertraits should be identifiable in childhood but not necessarily in infancy; the basic personality traits should show consistency over time (but because the phenotype and environment interact throughout life, one would not expect perfect or even near perfect consistency over long periods of time); they should be identifiable in species other than the human on the assumption that they have been shaped by natural selection; they should show at least moderate heritability and be related to significant biological markers; and, eventually, their biological basis in the structure and physiology of the nervous system should be identifiable, though classification is a necessary first step in biological bases of traits (pp. 40–41).

Unfortunately, there is no general agreement about the kind of classification system to be used for classifying fundamental traits. In psychiatry, there are at least two types of classification systems: the traditional system that distinguishes 5–7 dimensions resulting from factor analyses of the phenotypic structure of personality, and a more recently introduced functional classification system that is based on largely hypothetical characteristics of central nervous system functioning. The traditional classification system has resulted, among others, in the three-factor model of Eysenck (1947), encompassing the factors introversion-extraversion (E), neuroticism (N) (or emotional instability), and psychoticism (P); the five-factor model of Fiske (1949) and, later, Norman (1963), encompassing the factors extraversion, agreeableness, consciousness, emotional stability, and culture; and the seven personality dimensions of Zuckerman, which are activity, sociability, impulsivity, socialization, sensation seeking, emotionality (subdivided into general, anxiety, and hostility), and social desirability (Zuckerman *et al.*, 1988). As elaborated elsewhere, this traditional classification system suffers from several shortcomings (Cloninger *et al.*, 1994; van Praag, 1986; Tuinier and Verhoeven, 1995), the most important one being the fact that the entities classified are still complex behaviours that are not yet sufficiently broken down into specific and elementary items that are mutually exclusive and, in addition, theoretically tractable in the brain. Anyhow, animal models for some of these dimensions, especially anxiety in particular and emotionality in general, are discussed elsewhere in this book.

More recently, Cloninger has developed a neurobiologically based model to guide the rational development of descriptors for temperament and character (Cloninger, 1994). Temperament refers to those components of personality that are heritable, developmentally stable, emotion-based, or uninfluenced by sociocultural learning (Goldsmith *et al.*, 1987), whereas character refers to those components of personality that are weakly heritable, and are moderately influenced by sociocultural learning (Loehlin, 1982). His model is based on the synthesis of information from twin and family studies, studies on longitudinal development, and neuropharmacological and neurobehavioural studies of learning in human and other animals, as well as psychometric studies of personality in individuals and twin pairs. Though the neurobiological processes are not yet identified, he proposes four temperament dimensions on the basis of individual differences in associative learning that are postulated to be genetically homogeneous and independent of one another: 'novelty seeking', which is associated with the behavioural activation system; 'harm avoidance', which is associated with the behavioural inhibition system; 'reward dependence', which is associated with the behavioural dependence system; and 'persistence', which is associated with the behavioural persistence system. The dimension 'novelty seeking' nicely corresponds with Zuckerman's dimension 'sensation seeking' (McCourt *et al.*, 1983). Cloninger complements his model of personality with three character dimensions, self-directed behaviour, cooperativeness, and self-transcendence.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Because this definition of character refers to self-concepts and individual differences in goals and values, which influence voluntary choices, intentions, and the meaning of what is experienced in life, it is evident that these character dimensions are difficult to model in animals. For that reason, they are not considered in this chapter.

The authors of this chapter regard Cloninger's classification system as a very powerful model that provides four temperament dimensions that fulfil all criteria summarized by Zuckerman (1991): among others, they are moderately heritable, stable from childhood through adulthood, and structurally consistent in different cultures and ethnic groups (Cloninger *et al.*, 1994). Furthermore, it is interesting to note that Cloninger's four temperaments to some extent correspond to the four basic emotions of anger (*novelty seeking*), fear (*harm avoidance*), love (*reward dependence*), and tenacity (*persistence*), as well as with a modern interpretation of the ancient temperaments the choleric (*novelty seeking*), the melancholic (*harm avoidance*), the sanguine (*reward dependence*), and the phlegmatic (*persistence*). The model of Cloninger *et al.* (1994) is especially powerful, because it has given rise to the development of a validated guide that allows a clear-cut definition of personality disorders with the help of the so-called 'temperament and character inventory' (TCI) scales. In other words, each individual personality disorder is defined as a configural function of all seven temperament and character dimensions. The correlations between TCI scales and various symptoms for individual personality disorders according to DSM-IV classification are illustrated in Table XXVI-1.1 (Svrakic *et al.*, 1993). This table also shows that individuals can fall into disorders in multiple clusters because the temperament dimensions are independent, not mutually exclusive. To what extent Cloninger's dimensions of temperament are identifiable in species other than the human is discussed below. We will also discuss whether the biological basis of these dimensions can be identified in the structure and physiology of the nervous system.

CRITERIA FOR ANIMAL MODELS

Modelling aspects of human personality in animals should result in animal models that meet criteria that allow validation of the models. Though such generally accepted criteria for animal models of normal human behaviour are missing, such criteria are formulated for animal models of abnormal human behaviour. In the latter field, it is quite common to subdivide animal models by specifying the presumed validity of the models. This has led to three different sets of models, which are hierarchically related (Willner, 1984):

1. animal models with predictive validity of the lowest class
2. animal models with face validity of the second class
3. animal models with construct validity of the highest class.

By modifying the set of criteria for each of these models, we can try to formulate criteria for animal models of normal human behaviour. By analogy with the predictive validity of the animal models for human disorders (that is, predicated on the prediction they make with respect to pharmacotherapy), the predictive validity of animal models for normal human behaviour should be based on the prediction they make with respect to treatments and/or environmental conditions that are known to alter specifically the behaviour in question. Though early environmental factors, brain injury, delay in brain development, childhood experience, and the use of alcohol or drugs are assumed to contribute to the occurrence of abnormal behaviour in people with personality disorders, there is no convincing evidence that these factors alter a particular behaviour in a specific and selective manner. Indeed, animal models with predictive validity for normal human behaviour are not yet available. By analogy with the face validity of animal models for human disorders (which are predicated on symptom similarity), the face validity of normal human behaviour should be based on convincing similarity of the behavioural phenomenon between the model and the target behaviour. As mentioned below, there are animal models that fit into this category. Finally, by analogy with the construct validity of animal models for human disorders, the construct validity of animal models for normal human behaviour should be based on convincing similarity of causes and (neuro)biology of the behavioural phenomenon between the model and the target behaviour. In our opinion, the animal models of *novelty seeking* that are discussed below, appear to fit into this category.

Table XXVI-1.1 Correlations between Cloninger's Temperament and Character Inventory (TCI) Scales and number of symptoms for individual personality disorders (Modified from Svrakic *et al.*, 1993)

TCI scale scores Personality disorder symptoms	NS	HA	RD	P	SD	C	ST
Antisocial (adult)	H	—	L	—	L	L	—
Histrionic	H	—	—	—	L	L	—
Borderline	H	H	—	—	L	L	—
Passive-aggressive	H	—	—	L	L	L	—
Avoidant	L	H	—	—	L	—	—
Obsessive-compulsive	—	H	—	—	L	L	—
Dependent	—	H	H	—	L	—	—
Schizoid	—	—	L	—	L	L	L
Schizotypal	—	H	L	—	L	L	—
Paranoid	H	—	L	—	L	L	—

H = high scores.
L = low scores.
P = persistence.
NS = novelty seeking.
SD = self-directedness.
HA = harm avoidance.
C = cooperativeness.
RD = reward dependence.
ST = self-transcendence.

INDIRECT APPROACHES IN ANIMAL STUDIES

In the traditional biological approach to personality, the independent variables are behavioural and the dependent variables biological. Because there are also other approaches in this field that can shed light on selected aspects of personality, it is worthwhile to consider these approaches as well.

Gene-Oriented Approach

Following human studies on the association of various gene alleles with a particular trait or temperament dimension, animal models are developed by assessing behavioural or molecular genetic strategies to trace the genes and their involvement in the trait or dimension under study. The following can illustrate this approach. Studies on the association of dopamine-receptor genes and human behaviour including personality traits have provided evidence that the *Taq* I A D2 dopamine-receptor (DRD2) minor (A1) allele and the 7-repeat (7R) allele of the D4 dopamine-receptor (DRD4) gene D2 polymorphisms individually associate with *novelty-seeking* behaviour (Benjamin *et al.*, 1996; Noble *et al.*, 1998; Noble, 2000; cf. Herbst *et al.*, 2000). Predicated on these findings, two types of animal models are of interest. By the quantitative trait loci (QLT) technique in recombinant inbred mouse strains, it has become possible to show that the QTLs for alcohol preference drinking are localized in the region of the DRD2 (Tarantino *et al.*, 1998). The next question, of course, is whether or not this gene is also associated with the animal counterpart of human novelty

seeking. Another animal model in this respect involves mice that lack functional dopamine D2 receptors: such mice are marked by a severe reduction of alcohol- and opiate-related behaviours (Maldonado *et al.*, 1997). In this case, it is also important to know whether these mice are marked by a reduced amount of the animal counterpart of human novelty seeking. These models can be very helpful in laying the foundation for new hypotheses about the involvement of particular genes in personality dimensions, but at the same time they are less suitable for elucidating the genetic complexity of personality dimensions, because the independent variables are biological rather than behavioural.

Substrate-Oriented Approach

Following human studies in which biological correlates and/or substrates of a particular behaviour, trait, or temperament dimension have been mapped, animal models are developed by manipulating the biological correlate or substrate in question, in the hope that the resulting models can help to elucidate the biological mechanisms of the phenomenon under study, and even to discover new treatments for abnormal behaviours that are inherent in a disorder of that trait or temperament dimension. For example, human studies have shown that there is relationship between sensation seeking (*novelty seeking*), violent suicide, homicide, arson, psychopathology or substance abuse with decreased cerebrospinal fluid levels of the main serotonin metabolite 5-hydroxyindoleacetic acid (Lewis, 1991; Virkkunen *et al.*, 1994). Given these findings, together with the notion that serotonin (5-HT) deficiency may be associated with impulsive, disinhibited, and aggressive behaviours (cf. Soubrie, 1986), two kinds of animal models have been developed. One model involves extensive depletion of brain 5-HT by means of 5-HT synthesis inhibition or selective neurotoxic lesioning of 5-HT neurons (Söderpalm and Svensson, 1999). Given the therapeutic efficacy of the opiate receptor antagonist naloxone in this model, it is suggested that this drug may represent a new pharmacological principle for the treatment of impulse-control disorders (Söderpalm and Svensson, 1999). Another animal model involves the selective breeding of rat lines that show a differential physiological response to stimulation of the 5-HT1A receptors, namely, the high and low sensitivity responding lines (HDL and LDS, respectively), since these receptors have been implicated in a variety of disorders, including anxiety and alcoholism. This approach has generated data suggesting that the HDL line is a useful model for a type of high trait anxiety linked to susceptibility to depression (Knapp *et al.*, 1998). Though such models can certainly provide new insights into the relevance of certain biological mechanisms involved in the traits or temperament dimensions under discussion, they are primarily of heuristic value because the independent variables are biological, but not behavioural. Nevertheless, these models can be very helpful in laying the foundation for new hypotheses about the biological mechanisms that underlie the particular personality dimension under discussion.

Physiology-Oriented Approach

Following the finding in human studies (Zuckerman *et al.*, 1974) that high sensation seekers (*high novelty seekers*) show increasing amplitudes of visual evoked potentials (VEP) as a function of flash intensity (VEP augmenters), in contrast to low sensation seekers (*low novelty seekers*), who show decreasing VEP amplitudes as a function of flash intensity (VEP reducers), Siegel and co-workers have looked at animals with a bimodal distribution of certain behavioural features. Initially, VEP responses were compared in cats that vary in terms of their behavioural response to novel and threatening stimuli: active and explorative cats showing approach behaviour even to threatening stimuli turned out to be VEP augmenters, whereas less active cats showing withdrawal responses turned out to be VEP reducers (Saxton *et al.*, 1987a). An additional interesting finding was that VEP augmenter cats learn a novel and simple bar press task much faster than VEP reducer cats (Saxton *et al.*, 1987b). In this context, it is interesting to note that high responders to novelty, considered as the rodent counterpart of novelty seekers (see below), also learn a simple radial-maze task much faster than low responders to novelty (Cools *et al.*, 1993c). Siegel later reported that the Swiss line of the Roman high avoidance (RHA) rats are VEP augmenters, in contrast to the Swiss line of the Roman low avoidance (RLA) rats, who are VEP reducers (Siegel *et al.*, 1993). Again, these animal models are primarily of heuristic value, because in these models the independent variables are biological rather than behavioural. Still, these models can help us to formulate new hypotheses about the biological mechanisms that underlie the particular personality dimension under discussion.

Behaviour-Oriented Approach

Given the enormous individual variation in human behaviour, traits, or temperaments, animal research has focused attention on individual differences in behaviour in its broadest sense. In practice, three research strategies are assessed:

1. comparing features of individuals belonging to different inbred strains of animals, usually rodents (e.g., RHA vs. RLA rats [Driscoll *et al.*, 1998], Lewis vs. Fischer rats [Sternberg *et al.*, 1989] or C57BL/6 vs. DBA/2 mice [Cabib and Puglisi-Allegra, 1988]);
2. comparing features of intrastrain individuals that are selected on the basis of a particular behaviour or trait (e.g., winner vs. loser rats [Masur *et al.*, 1995]);
3. comparing features of intrastrain individuals that differ in terms of behaviour because of known individual-specific features of the physiological state of the brain (Cools *et al.*, 1990).

The first approach has the disadvantage that one is dealing with different inbred strains, each of them marked by a genotypic uniformity that is not only greater than it is in the initial outbred population, but also accompanied by a loss of the originally present variation that is necessary for survival in changing environments. This does not match the human situation. The second approach is far better in this respect, but has the disadvantage that it remains unknown whether the variable used for the selection is a primary feature or just an intervening variable. The final approach lacks these shortcomings, since in this strategy the behavioural variable that is used for the selection is not an intervening variable but, instead, a basic feature, the consequence of a well-delineated and known physiological state of the brain. As discussed in the next paragraph, the latter approach has resulted in an animal that seems to be a highly interesting animal counterpart of the human novelty seeker. In general, the behaviour-oriented approach has provided a large amount of data that are primarily descriptive and correlative by nature. In principle, individual animals, related lines, or related strains are selected on the basis of a particular behavioural variant. The extent to which the behavioural variant is associated with other behavioural features that are considered to be features of a particular trait or temperament dimension is then investigated. Apart from this, one commonly investigates to what extent the behavioural variant is associated with physiological, neurochemical, and neuroendocrine and pharmacological variables. Using this approach, Gentsch *et al.* (1988) have shown that three distinct kind of pairings of rats resulted in a remarkably similar dichotomy across these pairings: RHA, spontaneously hypertensive (SHR) rats and individually housed Wistar rats are marked by lower emotionality (shown in factors such as decreased defecation and corticosterone secretion) than their respective counterparts, RLA,

Wistar-Kyoto rats and group-housed rats. Of course, the question arises why rats selected for extremes in the shuttle box performance (RHA/RLA), blood pressure (SHR/Wistar Kyoto rat), or variation in housing conditions show similar intrapair differences. Though these findings may lead to the hypothesis that these rats are all characterized by a similar idiosyncrasy in relation to emotionality, the similarities in the differences between the various pairings have to be considered as merely coincidences if there is no evidence that the distinct variables used for the selection are part of a cross-situational consistency in brain and behavioural physiology. Thus, the animal models that belong to this category can provide very useful information, although these models should not be considered as animal models for aspects of personality.

Construct-Oriented Approach

Though this approach does not deal with animal models as such, it assesses animal studies to provide insight into neurobiological processes that underlie various aspects of personality. In general, basic constructs about the functioning of the brain and body that are based on theoretical and empirical knowledge are used to relate temperament dimensions to processes and circuitries in the body and brain. Once such a relationship is hypothesized, animal experiments can be performed to (in)validate such hypotheses. An example that clearly illustrates this approach is provided by studies recently reviewed by Davidson (1999). In short, on the basis of a large number of human studies, Davidson developed a model that features individual differences in prefrontal asymmetry as a reflection of a diathesis that modulates reactivity to emotionally significant events. It was then hypothesized that if individual differences in prefrontal asymmetry are associated with a dispositional affective type, such differences should be related to cortisol levels, since individual differences in baseline cortisol levels have been related to various aspects of trait-related stressful behaviour (Davidson, 1999). They indeed found that individual differences in cortisol levels in nonhuman primates predict biological measures that are related to affective style (Kalin *et al.*, 1998). Though our present-day knowledge about the functioning of the brain is limited and, consequently, the available hypotheses in this respect are by definition speculative, this approach is very promising, because it helps us to develop new constructs about the functional anatomy of fundamental dimensions of personality.

DIRECT APPROACH IN ANIMAL STUDIES

As already mentioned above, in the traditional approach to personality the independent variables are behavioural and the dependent variables biological: we label this strategy the 'trait-oriented approach'. A description of the behavioural features of a particular trait or temperament is used to model these features in animals. The demonstration of a convincing similarity in the behavioural phenomenon between the model and the target behaviour provides an animal model with face validity and perhaps even with construct validity.

As clarified above, the authors of this chapter regard the classification system of Cloninger as the most powerful system for two reasons. First, the resulting four temperaments meet all criteria that are set for basic dimensions of personality. Second, the classification system provides the basis for differential diagnosis of personality disorders. Below we consider animal models for the four temperament dimensions delineated by Cloninger (1994).

Persistence

This dimension is hypothesized to be a heritable tendency to maintain behaviour in response to a) signals of anticipated reward, b) intermittent punishment, and c) intermittent frustrative non-reward. Today, animal models of *persistence* are not yet available. According to Cloninger, this dimension is mediated and modulated by the behavioural persistence system that encompasses the hippocampal subiculum, the anterior cingulate cortex and the orbitomedial cortex. Assessment of the above-mentioned construct-approach might help us to develop new constructs about the functional anatomy of this fundamental dimension of personality.

Reward Dependence

This dimension is hypothesized to be a heritable tendency to respond intensely to signals of reward and to maintain or resist extinction of behaviour that has previously been related to rewards or relief from punishment. It can be suggested that individuals of the monogamous vole species serve as animal model, because they show a greater social affiliation with their partner, a larger distress in response to isolation, and a larger sensitivity to social cues than individuals of the polygamous vole species (cf. Insel *et al.*, 1993). According to Cloninger (1994), this dimension is mediated and modulated by the behavioural dependence system that encompasses the lateral amygdala, the bed nucleus of the stria terminalis, the nucleus accumbens, the midline thalamus, and the prelimbic cortex in which oxytocin plays a key role. Thus, a theoretical and empirical analysis of the function of these structures might help us to develop new constructs about the functional anatomy of this fundamental dimension of personality.

Harm Avoidance

This dimension is hypothesized to be a heritable tendency to respond intensely to signals of aversive stimuli, thereby learning to inhibit behaviour in order to avoid punishment, novelty, and frustrated non-reward. If one regards high frequency of defecation under bright lights in a novel environment and/or immobility with bradycardia in response to foot shock as indicators of *harm avoidance* in animals, one can suggest that individuals of the Maudsley reactive rat line (MR) (cf. Broadhurst, 1975) serve as animal models for a high degree of harm avoidance, because they are higher defecators in a novel environments (MR) than their counterparts, individuals of the Maudsley nonreactive rat line (MNR). In this context, it is interesting to note that the MR share this feature with individuals of the Syracuse low avoidance rat line (SLA) (cf. Brush *et al.*, 1988), the Roman low avoidance rat line (RLA) (cf. Driscoll and Bättig, 1982), the Tsukuba high emotional rat line (THE) (Fujita and Nakamura, 1976), and the Flinders sensitive rat line (FLS) (Russell *et al.*, 1982), although the latter rat lines were selected for a different biological variable, namely, performance in a two-way active avoidance task (SLA and RLA), entering a bright runway (THE) and sensitivity to the anticholinesterase dipropyl fluorophosphates (FLS). Although there is hardly any information about the neurochemical, neuroendocrine, physiological, behavioural, and pharmacological features of the MR, Driscoll and his colleagues have invested an enormous amount of research in analysing these features in the RLA (Driscoll *et al.*, 1998). Ongoing research with the RLA and their counterparts, the RHA, investigates to what extent the biological features in question should be conceptualized as substrates of the various traits of these animals rather than just biological correlates. The finding that neonatal handling produces changes in certain behavioural and endocrine responses of the RLA that are line-specific (Escorihuela *et al.*, 1995) strongly suggests that at least these responses reflect basic aspects of the underlying psychobiology of the feature in question. Still, it is important to note that none of these rat lines are selected for *harm avoidance*: they are selected for a feature of which breeding has resulted in a correlated difference in behaviour that is related to *harm avoidance*. Thus, it remains to be proven

that the feature used for the selective breeding is consistently and causally coupled to *harm avoidance* or to related aspects of this dimension. If so, the available knowledge about the neurochemical, neuroendocrine, physiological, behavioural, and pharmacological differences between the RLA and their counterparts, the RHA, provide unique information for constructing a functional anatomy of the temperament dimension, *harm avoidance*.

Novelty Seeking

This dimension is hypothesized to be a heritable tendency to intense excitement in response to novel stimuli or cues for potential reward, and it is quite likely to correspond with Zuckerman's *sensation seeking* (McCourt *et al.*, 1983). At least two important animal models are available: a) mice that are selectively bred on the basis of their behavioural response to novelty (Gerschenfeld and Paul, 1998; Hall, 1938; Simmel and Bagwell, 1983; Walsh and Cummins, 1976), and b) Wistar rats that are selected on the basis of their behavioural response to novelty (Cools *et al.*, 1990; Dellu *et al.*, 1996; Piazza *et al.*, 1990). Whereas the mouse model can help us to trace the contribution of the heritable component, the rat model can help us to study the biological processes that underlie this trait. Because the latter model is a very basic one that has provided a wealth of biological data, it will be discussed below under a separate heading. Here we discuss the mouse model, a relatively simple behavioural assay, in which the mouse is placed in a brightly lit, novel environment, and its behaviour serves as indicator. The mouse model is generally seen as an animal model for temperament or emotionality. Zuckerman has rejected the possibility that the mouse behaviour actually models *sensation seeking*, because of the negative correlation usually found between activity and defecation at both the phenotypic and genotypic levels. The reader is referred to Zuckerman for a detailed discussion about the pros and cons of open-field activity in mice as a model for *sensation seeking* (Zuckerman, 1984; cf. Gershenfeld and Paul, 1998). Irrespective of the precise nature of the temperament dimension that is modelled by open-field activity in mice, there is little doubt that it does reflect a particular aspect of personality. Although the interpretation of mouse behaviour under these conditions is difficult and ambiguous, it has been found to represent a well-defined, innate behavioural response, and to have broad generalization across species from chickens to infants. In addition, it has been found to differ between individuals and strains, due to heritable components. With this mouse model, it has become possible to partition the behavioural variance into genetic, environmental, and interaction components, and the heritable component has been further demonstrated by selectively breeding mice that differ in their open-field behaviour. By the above-mentioned QTL technique, it has even become possible to map the QTLs for initial ambulation in the open field: these are localized on chromosomes 1 and 15 (Flint *et al.*, 1995; Gershenfeld and Paul, 1998). This approach should help us to narrow down the human chromosomal regions in order to define human candidate genes and to define polymorphisms.

ANIMAL MODEL OF NOVELTY SEEKING

The best animal model for the temperament dimension *novelty seeking* is the so-called high responder to novelty (HR) (Cools, 2000; Dellu *et al.*, 1996), namely, rats that are selected for their intense behavioural response to novelty in an open-field test. According to Cloninger, the following traditional personality dimensions are marked, among others, by a high degree of novelty seeking: antisocial, histrionic, passive-aggressive, and explosive (Cloninger *et al.*, 1994). When in childhood such a high degree of *novelty seeking* is associated with low *reward dependence*, low *harm avoidance* and high *persistence*, these persons are likely to display antisocial behaviour, to become addicted to alcohol and other drugs of abuse, and to develop criminal behaviour as adults (Cloninger *et al.*, 1994). Because the HR are also marked by low *reward dependence*, low *harm avoidance*, and high *persistence*, we regard these animals as a very important source of information for understanding the psychobiology of humans with a predisposition to the latter behaviours. For that reason, particular attention is paid to this animal model.

The animal studies in question are performed with the HR and their counterparts, the low responders to novelty (LR). These two types of rat occur in any population of Wistar rats, and are characterized by individual-specific differences in the structure, function, and reactivity of the limbic-mesolimbic-striatal axis and the hypothalamic-pituitary-adrenal (HPA) axis. These differences underlie the fully distinct behavioural, physiological, and endocrine responses to stress shown by the HR and the LR, respectively. Genetic factors direct the way to cope with stressors during the early postnatal and, probably, prenatal period: the nature and intensity of the stressor to which the individual is exposed, during the perinatal period, appears to direct the structure and function of the brain and the body of these individuals. The available animal studies reveal that three factors direct the behaviour of this personality variant: a) genetic predisposition, b) the early postnatal and, probably, prenatal factors that direct the phenotypic expression of the genotype in question, and c) the degree of stress to which the individual is exposed immediately before, and during the onset of, the performance of the behaviour (Cools and Gingras, 1998). Knowledge about the structure, function, and reactivity of the brain and the body of the HR and the LR might help us to understand which factors can underlie the behavioural lapses that occur in certain individuals under particular conditions. Below we will provide a short summary of the outcome of animal studies on the HR and the LR.

Selection Procedure

The Nijmegen outbred population of Wistar rats has been found to contain at least two distinct types of individual, each of them marked by their own structure, function, and reactivity of the brain and body. There are three validated methods to select these types of rat.

First, we have the assessment of the open-field test (Cools *et al.*, 1990; Cools *et al.*, 1993c; Cools and Gingras, 1998; cf. Piazza *et al.*, 1989), which allows the separation of the HR and the LR. Both the dimensions of our open field — 160 × 160 cm — and the absence of external cues are important features of this open-field test. The HR and the LR behave differently in this novel environment: the HR are bound to the only available external stimulus, the edge of the open field, and they continue their exploratory behaviour for a very long period of time (>840 s). As in the intruder test (see below), the HR interrupt their ongoing behaviour only when a change in their environment occurs: this is considered to reflect a high degree of context-dependency. In contrast, the LR start to explore their novel environment and, after about 480 s, stop their exploratory activity in an otherwise undisturbed environment. Thus, as in the intruder test, the LR can interrupt their ongoing behaviour by themselves: this is considered to reflect a high degree of self-control.

Second, we have the assessment of the so-called intruder test in which 'freezing', defined as 'sitting motionless for over 45 s' and 'fleeing', defined as 'number of fleeing spells seen during the whole observation period of 6 min', serve as dependent variables (Cools, 1988; Cools *et al.*, 1990; Schuurman, 1981). This test allows the separation of rats that primarily flee (FLEE rats) and rats that primarily freeze (NON-FLEE rats). Since FLEE rats — being

the intruders — primarily flee during the direct confrontation with the resident (coping situation), but freeze as long as the intruders can only see and smell the resident without being able to attack him (non-coping situation), and because NON-FLEE rats freeze during the coping situation, but actively explore during the non-coping situation, the nature of the selected coping strategy (active or passive) varies according to the context and therefore is not a trait of the individual.

Third, we have the apomorphine test (Cools *et al.*, 1990), which allows the separation of apomorphine-susceptible rats (APO-SUS) and apomorphine-unsusceptible rats (APO-UNSUS): APO-SUS display more than 500 gnawing spells/45 min following an injection of 1.5 mg kg^{-1} apomorphine (s.c.), and APO-UNSUS display less than 10 gnawing spells/45 min following such an injection. Since 1985, the latter rats have also been bred, using a particular breeding schedule to prevent inbreeding and to maintain the original genotypic heterogeneity, apart from the alleles at the loci (or locus) involved in the determination of the chosen traits. Nevertheless, inbreeding, which reduces the genotypic heterogeneity and, ultimately, creates new substrains and strains, cannot be prevented in the long run; given our interest in the individual variability that occurs within a single strain in order to maintain a situation that approaches the human situation as closely as possible, it became necessary to restart the breeding of these lines, once every 5–8 years.

We have been able to show that the bimodal variation in apomorphine-susceptibility, the original selection criterion for the breeding, is consistently coupled to a bimodal variation in various neuroanatomical, neurochemical, endocrinological, immunological, and behavioural features. Evidence has been provided that rats marked by a high apomorphine-susceptibility (APO-SUS) are high responders to novelty in terms of both their behavioural response and their endocrinological responses, and that rats marked by a low apomorphine-susceptibility (APO-UNSUS) are low responders to novelty in terms of their behavioural and endocrinological responses (Cools *et al.*, 1990, 1993a–c; Rots, 1995; Rots *et al.*, 1996a–c). This individual consistency in behaviour and physiology has revealed that any of the biological or behavioural variables known to differ between these rats can be used as a criterion for selecting these two types of rat. For example, APO-SUS and APO-UNSUS rats can be selected from outbred strains of Wistar rats by establishing their response to novelty and selecting the HR and LR rats, respectively (Cools *et al.*, 1990; 1993). In sum, the male HR, FLEE rats and APO-SUS are marked by idiosyncratic features of one and the same type of individual; the same holds true for male LR, NON-FLEE rats and APO-UNSUS. In other words, there are two distinct types of individuals whose genetic make-up is reflected in the above three responses (Cools *et al.*, 1990).

The HR and LR are not tails of the population, but each group (HR and LR) represents a major part (40–45%) of our outbred strain of Nijmegen Wistar rats; the remaining 10–20% of rats form a heterogeneous group of rats, showing a mixture of HR and LR features, of which no details about the behavioural, neurochemical, and endocrinological features are known. As mentioned below, the ultimate neurochemical and behavioural phenotype of these two types of animal is determined, among others, by early postnatal factors. Owing to this factor and owing to distinct selection procedures, one has to be aware of the fact that the HR and LR that are studied in different research centres are not necessarily fully identical. Nevertheless, it is important to note that the HR/LR studied in other laboratories (Exner and Clark, 1993; Piazza *et al.*, 1989, 1991; Rouge-Pont *et al.*, 1993; Hooks *et al.*, 1991, 1991) share the following features with the Nijmegen HR/LR (Cools *et al.*, 1997; Saigusa *et al.*, 1999; Rots, 1995; Ranaldi *et al.*, 2001):

1. There is a positive correlation between the locomotor response to novelty and the acute behavioural response to dexamphetamine.
2. Environmental or pharmacological stressors produce a greater increase in the extracellular concentration of accumbal dopamine in the HR than in the LR.
3. The HR show a greater release of corticosteroids in response to stressors than the LR.
4. The HR acquire self-administration of psychostimulants such as cocaine and dexamphetamine much faster than LR.

In this chapter, we use the labels HR and LR for the Nijmegen HR (APO-SUS) and the Nijmegen LR (APO-UNSUS), respectively, whereas we refer to 'high responders to novelty' and 'low responders to novelty', respectively, when we refer to the studies of other groups.

CHARACTERISTIC FEATURES OF THE ANIMAL COUNTERPART OF THE *NOVELTY-SEEKING* PERSONALITY DIMENSION: GLOBAL SURVEY

Adult HR and LR animals are male rats that normally occur in every outbred strain of Wistar rats: these rats are neither mutants nor members of different substrains or strains. As mentioned above, these rats are marked by the genotypic heterogeneity that is originally present in every outbred strain of Wistar rats. However, characteristic features differ remarkably between these rats. The most characteristic ones are mentioned below.

1. *Novelty seeking*. The HR explore unfamiliar novel objects and novel environments: they enter the open arms of an elevated plus-maze to an extent that is only displayed by the LR when treated with benzodiazepines (Cools *et al.*, unpublished data). They readily self-administer cocaine (Ranaldi *et al.*, 2001). In sum, there are many features that are characteristic of the high novelty seekers.
2. *Reward dependence*. In studies on the intake of a variety of rewarding solutions, we found that HR consume far less sucrose than LR, possibly indicating that HR respond far less intensely to signals of reward than LR do. In other words, HR may have a low degree of *reward dependence* (Gingras, 1997).
3. *Persistence*. If one regards the repetition of aimless behaviour in response to novelty or psychostimulants as an indicator of *persistence* in animals, it is evident that HR have a high degree of *persistence*, because they show a far more stereotyped response to novelty and dexamphetamine than LR do (Gingras and Cools, 1997a).
4. *Harm avoidance*. If one regards a high frequency of defecation under bright lights in a novel environment and/or immobility with bradycardia in response to foot shock as indicators of *harm avoidance* in animals, HR have a relatively small degree of harm avoidance, because HR produce far fewer droppings in a novel open field than LR (Sluyter *et al.*, unpublished data). In addition, HR show also far less immobility in this open field than LR do (Cools *et al.*, 1990).
5. *Stress-sensitivity*. HR are more stress-sensitive in terms of behavioural (locomotor activity) and endocrine (release of ACTH and corticosteroids) responses than LR. In this context, stress refers to novelty-induced stress as well as to stress measured in the so-called conditioned emotional test (Rots, 1995; Rots *et al.*, 1995, 1996): the locomotor response to novelty, as well as the release of plasma release of ACTH and corticosteroids in response to stress, is far greater and longer-lasting in HR than LR.
6. *Rate of acquiring a new task*. HR that are not habituated to a four-arm radial-maze start to learn a simple cued four-arm radial-maze task during the three initial test days, whereas LR only later start to acquire that task: the overall rate of acquisition, however, does not differ between HR and LR (Cools *et al.*, 1993c, 1994). In fact, it seems that HR need stress

in order to acquire a new task, in contrast to LR, which need to be habituated to stress before learning. This holds especially for tasks known to involve the basolateral part of the amygdala (Tuinstra, 2000).

7. *Retrieval of recently stored information*. Once HR have learned to find a platform that is invisible and submersed in a so-called Morris water maze, with the help of cues around the swimming pool, they have severe difficulty in retrieving the stored information when returning to the pool 24 h after the last trial on the first test day; however, after 2 min, they perform very well. In contrast, LR have no problem in retrieving the stored information under these conditions: in fact, their performance is even better than that shown on the first day. In sum, it seems that stress inhibits HR in retrieving recently stored information, in contrast to LR, in which stress facilitates the retrieval of recently stored information. This holds especially for tasks known to involve the ventral subiculum of the hippocampus (Tuinstra *et al.*, 2000c).
8. *Context-dependency*. HR are very dependent on spatial and contextual stimuli, whereas LR are relatively independent of these stimuli (see sections on Selection procedure and on Early life events).
9. *Self-control*. HR have less self-control than LR do (see sections on Selection procedure and on Early life events).
10. *Predisposition to mental illness*. HR, but not LR, show patterns of behaviour in animal models with construct validity for certain cognitive deficits of schizophrenic patients (Ellenbroek *et al.*, 1995). HR show a reduced latent inhibition as well as a reduced pre-pulse inhibition, whereas LR show normal latent inhibition and pre-pulse inhibition. However, HR display less parkinsonian symptoms in animal models of Parkinson's disease than LR (van Oosten and Cools, unpublished data).
11. *Predisposition to somatoform diseases*. HR respond negatively in animal models for autoimmune diseases such as experimental allergic encephalomyelitis (EAE model), whereas LR respond positively in such models (Cools *et al.*, 1993b; Kavelaars *et al.*, 1997). However, HR show a vigorous, Th2-dependent IgE response after infection with the nematode *Trichinella spiralis*, whereas LR do not (Kavelaars *et al.*, 1997). In other words, HR are relatively insensitive to autoimmune diseases, but very sensitive to infections, whereas LR reveal the opposite pattern.
12. *Predisposition to 'therapeutic' and unwanted effects of drugs*. HR are more sensitive to anti-parkinsonian agents than LR, whereas LR are more sensitive to antipsychotics than HR (Cools *et al.*, 1990; 1993c): systemic administration of dopaminergic agonists such as apomorphine produce a greater and longer-lasting behavioural response in HR than in LR, whereas intra-accumbens administration of neuroleptics, such as sulpiride, produces a behavioural response in HR that is smaller than that seen in LR.
13. *Sensitivity to psychostimulant and/or reinforcing effects of orally or otherwise administered agents*. During absence of stress, HR are far less sensitive to psychostimulant and/or reinforcing effects of ethanol, dexamphetamine, sucrose, and quinine than LR (Cools and Gingras, 1998; Ellenbroek and Cools, 1993; Gingras and Cools, 1995, 1997). Under stress, however, the situation is fully reversed: HR are behaviourally far more sensitive to ethanol, dexamphetamine, and cocaine, and under stress, HR self-administer far more cocaine than LR (cf. Cools and Gingras, 1998).
14. *Structure of the brain*. There are numerous differences in number of receptors (e.g., mineralocorticoid and dopamine receptors: [Rots, 1995; Rots *et al.*, 1995, 1996a–c; Sutanto *et al.*, 1989]), concentrations of neurotransmitters (e.g., noradrenaline and dynorphin: [Cools *et al.*, 1993c; Rots, 1995]), number of synapses (nucleus paraventricularis hypothalami: [Mulders *et al.*, 1995a–b]), etc.
15. *Reactivity of the brain*. The reactivity of both the limbic-mesolimbic-striatal axis and the HPA axis is far greater in HR than in LR. These differences underlie, among others, the fact that during stress HR have a relatively active basolateral part of the amygdala and a relatively inactive ventral subiculum of the hippocampus, with the consequence that HR can easily acquire new information, but have difficulty with retrieving recently stored information. In contrast, LR have a relatively inactive basolateral part of the amygdala and a relatively active subiculum of the hippocampus, with the result that LR show the behavioural mirror image under these conditions (Roozendaal and Cools, 1994; Tuinstra, 2001; Tuinstra *et al.*, 2000b).
16. *Early postnatal development*. A rat of the LR genotype that is deprived of its mother for 24 h on the ninth postnatal day develops into an adult animal with characteristic features of the HR, whereas a rat of the HR genotype raised with an LR foster mother develops into an adult animal with characteristic features of the LR phenotype (Ellenbroek and Cools, 1996). These findings show that the biological variables in question have to be considered as biological substrates rather than biological correlates. These findings also indicate that each distinct genotype is sensitive to a type-specific set of stressors: what is fully harmless for one type appears to have large consequences for the other type. In sum, the nature of the stressors that are present during the early postnatal period have a far-reaching influence upon the phenotypic expression of the genotype.

CHARACTERISTIC FEATURES OF THE ANIMAL COUNTERPART OF THE *NOVELTY-SEEKING* PERSONALITY DIMENSION: BRAIN, BODY, AND BEHAVIOUR

Given the role of telencephalic dopamine and that of corticosteroids in the neurochemical and behavioural responses to novelty (stress) and drugs of abuse (Cools, 1988; Di Chiara and Imperato, 1988; Fahlke *et al.*, 1994, 1995; Goeders and Guerin, 1996; Marinelli *et al.*, 1994; Roberts and Koob, 1982; Shoaib *et al.*, 1995; Wise and Rompré, 1989; Yoshimoto *et al.*, 1991), the most salient type-specific differences in this respect are summarized.

As mentioned, HR are far more sensitive to the dopaminergic agonist apomorphine than LR (Cools *et al.*, 1990). Furthermore, unchallenged HR are more sensitive to noradrenergic agonists. In fact, unchallenged HR behave as if they were sensitized by dexamphetamine; Piazza *et al.* (1990) have also found that their 'high responders to novelty' show this phenomenon. Surprisingly, HR are less sensitive to dopaminergic antagonists such as sulpiride than LR (Cools *et al.*, 1993c). In fact, there are neurochemical features that can explain these differences in susceptibility to aminergic agents (Cools *et al.*, 1990, 1993a; Rots, 1995; Rots *et al.*, 1995, 1996a and c); for example, unchallenged HR have a smaller amount of mesolimbic noradrenaline in the nucleus accumbens than unchallenged LR (Cools *et al.*, 1990; Rots *et al.*, 1996c). As discussed elsewhere in detail (Cools *et al.*, 1987), this explains why unchallenged HR are more sensitive to the accumbal administration of the alpha-adrenergic agonist phenylephrine (Ellenbroek and Cools, 1993). Furthermore, unchallenged HR have more striatal dopamine D1 receptor mRNA and more tyrosine hydroxylase mRNA in the A9 (substantia nigra, pars compacta) and A12 (nucleus arcuatus) cell groups than unchallenged LR, implying that the capacity to enhance the formation of dopamine in response to stress is greater in HR than in LR. Indeed, when the rats are challenged by novelty or tested in the conditioned emotional response test, behavioural and physiological responses mediated by

dopamine are greater in HR than LR (Cools *et al.*, 1990; Rots, 1995; Rots *et al.*, 1995, 1996a). The following example nicely illustrates this dopamine hyperreactivity in HR: the dopaminergic, tuberoinfundibular system that arises in A12 normally inhibits prolactin, and this response is far more strongly inhibited in HR than in LR, when the rats are exposed to stress (Rots, 1995; Rots *et al.*, 1996a).

Given the difference in the behavioural response to stress, it could be predicted that this difference extends to the HPA axis. This is indeed the case. First, the amount of corticotrophin-releasing hormone (CRH) mRNA in the nucleus paraventricularis hypothalami (PVN) of HR is greater than that in the PVN of LR (Rots *et al.*, 1995), implying that these cells in HR have also a greater capacity to generate CRH. Because CRH, which is under the stimulatory control of dopamine (Plotsky *et al.*, 1989), stimulates the release of plasma ACTH, especially during exposure to stress, it is logical to expect a HR-LR difference in the ACTH plasma release in response to stressors such as novelty. This is indeed the case: the stress-induced release of ACTH as well as that of plasma corticosteroids, of which the release is stimulated by ACTH, are greater and longer-lasting in HR than in LR (Rots *et al.*, 1995), a finding that fits in with those reported by Piazza *et al.* (1991). Apart from these data, we found that plasma levels of ACTH in HR are greater than those in LR under baseline conditions, but that the plasma release of free corticosteroids in HR is lower than those in LR under these conditions (Rots *et al.*, 1995; 1996a).

NOVELTY AND THE NEUROCHEMICAL STATE OF THE NUCLEUS ACCUMBENS IN THE ANIMAL COUNTERPART OF THE *NOVELTY-SEEKING* PERSONALITY DIMENSION

As elaborated elsewhere in detail (Cools *et al.*, 1991, 1993a, 1994; Cools and Gingras, 1998; Roozendaal and Cools, 1994), there is anatomical, electrophysiological, pharmacobehavioural, and neurochemical evidence that the neurochemical state of the nucleus accumbens of an unchallenged HR is marked by the following features when compared with LR:

1. The functional activity at the level of beta-adrenergic receptors that can stimulate the release of dopamine at the level of dopamine D2 receptors is relatively low.
2. The functional activity at the level of these dopamine D2 receptors, presynaptically localized on glutamatergic hippocampus-accumbens neurons, is relatively low.
3. The functional activity at the level of alpha-adrenergic receptors that can inhibit the release of dopamine at the level of so-called inhibitory dopamine receptors (DAi) — a subtype of dopamine receptors not yet linked to the two more recently discovered families of dopamine D1 and D2 receptors (Cools and van Rossum, 1980) — is relatively low.
4. The functional activity at the level of these DAi receptors — localized on glutamatergic amygdala-accumbens neurons — is relatively high.
5. The neurochemical state of the nucleus accumbens of an unchallenged HR greatly differs from that of an unchallenged LR: for all neurotransmitters, functional activity that is relatively low in HR is relatively high in LR, and vice versa.

Very recently biochemical evidence gained by the microdialysis technique has shown that the noradrenaline-dopamine interaction in the nucleus accumbens differs completely between HR and LR (Saigusa *et al.*, 1999; Tuinstra and Cools, 2000a and b). Finally, under challenge by a mild physiological, pharmacological, or environmental stressor, the neurochemical state of the nucleus accumbens and, probably, of other parts of the brain and body as well, is temporarily reversed (Roozendaal and Cools, 1994; Tuinstra and Cools, 2000a and b). Thus, the state of a challenged HR goes in the direction of that of an unchallenged LR, whereas that of a challenged LR goes in the direction of that of an unchallenged HR.

EARLY LIFE EVENTS AND THE DEVELOPMENT OF THE ADULT PHENOTYPE OF THE ANIMAL COUNTERPART OF THE *NOVELTY-SEEKING* PERSONALITY DIMENSION

Before discussing the consequences of early postnatal life events, it is important to consider characteristic changes that occur during the normal development of HR and LR (Rots *et al.*, 1996b). In 10-day-old rats, type-specific differences in dopaminergic variables (e.g., D1 receptor mRNA and TH mRNA) and in variables of the HPA axis (e.g., ACTH and corticosteroids) are not yet present. However, in 18-day-old rats, variables of the HPA axis already show some type-specific differences known to occur in 60-day-old, adult rats. For instance, the ACTH plasma level under baseline conditions is greater in HR than in LR, and a trend towards lower free corticosterone plasma levels is present in HR; in contrast, there are still no type-specific differences in the dopaminergic variables in 18-day-old rats (Rots, 1995; Rots *et al.*, 1996b). Thus, the divergence in the dopamine phenotype of HR and LR develops subsequent to distinct differences in the HPA axis.

To investigate to what extent early experiences direct the development of the adult phenotype, two paradigms were used (Ellenbroek *et al.*, 2000): cross-fostering on day 1 and maternal deprivation on day 9. These manipulations are chosen because they are known to function as mild stressors at that time. Remarkably, cross-fostering influences only the adult phenotype of HR, and not of LR (Ellenbroek and Cools, 1996), whereas maternal deprivation influences only the adult phenotype of LR (Ellenbroek *et al.*, 2000). In fact, cross-fostering reverses HR into LR, whereas maternal deprivation reverses LR into HR, as far as their apomorphine-susceptibility is concerned. In addition, we found that maternal deprivation affects various characteristics of the biochemical phenotype: adult rats that were deprived show a higher ACTH plasma level under baseline conditions and a greater amount of TH mRNA in A9 cells than their controls (Rots, 1995; Rots *et al.*, 1996b). Very recently, we found that this reversal also holds for the individual-specific sensitivity to diseases such as periodontitis (Sluyter *et al.*, unpublished). These data together suggest that this early life experience reverses the biochemical, immunological, and behavioural phenotype of LR into that of HR.

EPILOGUE

This review reveals that there are many animal studies that deal with animal analogues of various aspects of personality dimensions of the recently introduced functional classification system of personality. However, most of the approaches are indirect in the sense that the independent variables are biological, but not behavioural. Nevertheless, these animal models can be very helpful in laying foundations for new hypotheses about the biological mechanisms and substrates that underlie particular personality dimensions. However, there is only one mouse model and one rat model that use behavioural measures as independent variables, and biological ones as dependent variables. These two models deal with *novelty seeking*. The available mouse model has made it possible to partition the behavioural variance into genetic, environmental, and interaction components. However, the available rat

model has made it possible to provide basic insights into various biological processes and substrates that underlie the personality dimension in question. As summarized below, the rat model also helps us to understand to what extent genetic background, perinatal conditions, and the currently present environment determine the individual-specific set of personality dimensions of an individual.

The rat studies on *novelty seeking* show that the animal counterpart of a high novelty seeker, namely, the high responder to novelty (HR), and the animal counterpart of a low novelty seeker, namely, the low responder to novelty (LR), are characterized by individual-specific differences in structure, function, and reactivity of both the limbic-mesolimbic-striatal axis and the HPA axis. These differences underlie the individual-specific manner of coping with stress. The features of these individuals at adult age are determined by a) genetic predisposition, b) early postnatal and, probably, prenatal factors that direct the phenotypic expression of the genotype, and c) the degree of stress to which the individual is exposed immediately before, and during the onset of, the performance of the behaviour.

Available data show that the structure, function, and reactivity of the brain, the endocrine system, and the immune system differ completely between both types of individual. Analysis of behaviour as in the open-field test, the intruder test, the swimming task, the radial-maze task, etc., has clearly revealed that these two types of individuals organize their ongoing behaviour in a fully distinct manner: HR predominantly display extrinsically directed behaviour: they have a very well-developed capacity to use external cues for organizing their behaviour and are, in practice, dependent on these cues. In contrast, LR predominantly display intrinsically organized behaviour: they have a very well-developed capacity to control their own behaviour and are relatively independent of external cues. It is due to these features that HR perform optimally in tasks in which contextual stimuli have to be used for solving problems, but have severe problems with tasks in which internal cues have to be used for solving the problem. This also explains why LR display the mirror behaviour in these tasks. In other words, each of these types has its own optimal niche in which it can flourish, but also its own niche in which it will perish. This explains why this disruptive selection, in which more than just one phenotypic expression of a particular trait has surplus value, is present in such a stable balance within non-selected strains of Wistar rats. This makes it possible that dimorphisms, such as HR and LR, in rat populations and polymorphisms in humans exist.

One of the most remarkable findings is that both these types of individuals deteriorate as soon as they end up in each other's niche. This illustrates that certain stressors are harmful for one type, but not for the other. Nevertheless, one should not forget that a challenged HR behaves as an unchallenged LR, and vice versa. In short, the statement 'once a HR, always a HR' is incorrect. The key message of these findings is that genetic predisposition and early life events are decisive for the psychobiology of the personality dimensions, but that it is ultimately the current situation that gives rise to behavioural lapses.

Finally, HR are marked not only by a high degree of *novelty seeking*, but also by low degree of *harm avoidance*, a low degree of *reward dependence*, and a high degree of *persistence*. The coexistence of this particular configuration of scores on these dimensions is rather unexpected, because the human counterparts of these dimensions are genetically independent. To what extent these findings imply that one is dealing with a species-specific difference in this respect remains to be investigated. Anyhow, persons with a high degree of novelty seeking are marked, among others, by traditional personality dimensions such as the antisocial, histrionic, passive-aggressive, and explosive. When in childhood such a high degree of novelty seeking is associated with low *reward dependence*, low *harm avoidance*, and high *persistence*, these persons are likely to display antisocial behaviour, to become addicted to alcohol and other drugs of abuse, and to develop criminal behaviour at adult age. In view of these considerations, we believe that HR might help us to understand the biological processes and substrates that underlie the behaviour of persons marked by this particular (dys)balance of personality dimensions.

Neurotransmitter Systems in the Personality Disorders

Matt Eks, Harold W. Koenigsberg and Larry J. Siever

INTRODUCTION

According to DSM-IV (American Psychiatric Association, 1994), a personality disorder is 'an enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual's culture'. This enduring pattern is 'inflexible and pervasive over a broad range of personal and social situations'. It 'leads to clinically significant distress or impairment in important areas of functioning'. The pattern is 'stable', 'of long duration' and 'its onset can be traced back to adolescence or early adulthood'.

Personality disorders represent a relatively new field of research within psychiatry, particularly with a neurobiological approach. People intuitively react and adapt differently to their surroundings. Hippocrates explained these differences in terms of the 'four humors', different combinations and balances of which led to different personality traits. Bumps on the head, shape of the skull, hair colour, and body stature are among other traits that have been studied in the search for biological correlates of personality. Biological factors, such as the ones mentioned above, and environmental factors, such as family environment, social class, or early life experiences, have been considered to be factors which contribute to 'create' our personalities. Psychoanalysts point to 'drives' and defence mechanisms to explain individual differences. Psychologists have defined psychometric dimensional factors in normal personality and proposed that their measures correlate with biological differences. Investigators are now focusing on finding these biological correlates in relation to different temperamental and character traits. This does not necessary imply that personality disorders are explainable by biology alone. A more likely perspective is that we inherit basic traits or endophenotypes that predispose to psychiatric disorders in interaction with the environment.

Clearly defined diagnostic criteria are an important prerequisite for studying the role of biology and environment in the personality disorders. To clearly demarcate them from the more symptom-oriented psychiatric disorders, personality disorders were placed on Axis II in the DSM axial system. Personality disorders are categorized into three clusters: A, B, and C. Cluster A represents a group of personality disorders that are marked by isolation and eccentricity. Disorders in Cluster B are characterized by behaviours of acting out in a dramatic, emotional, and erratic way. Diagnoses in Cluster C include individuals who are anxious and fearful. It is important to emphasize that the DSM criteria are clinically derived schema for categorizing personality disorders. While we seek external validators for the diagnostic system, our knowledge of the biological correlates, pathophysiology, genetics, or aetiological factors has not yet progressed to the point that we can obtain biological validation of the personality disorder diagnoses. The DSM has, however, made it possible to diagnose personality disorders in a more uniform way and in that way identify more homogeneous patient populations for research studies. The advances in neuroscience and its adaptation to study the pathophysiology of the Axis I disorders also have benefited these research efforts. With the help of neuroimaging and neuroendocrine measurements, the mapping of the brain and the activity of its neurotransmitters is possible.

What makes this area interesting and difficult is the fact that what we are trying to study is the essence of what makes all of us who we are. What are the underlying reasons for the extreme problems some people have in relation to themselves and/or their surroundings? These are fundamental questions regarding personality and particularly personality disorders. As our knowledge about the central nervous system is increasing rapidly, evidence of correlations between personality traits and brain function is also increasing. We can see resemblances between Axis I disorders and personality disorders on Axis II, both in personality traits and in brain function (or dysfunction). We can see the therapeutic effects of medication on dysfunctional personality traits, but we still do not have a comprehensive knowledge of the exact mechanisms underlying personality and personality disorders.

DIMENSIONAL APPROACHES TO PERSONALITY

Personality dysfunction may be conceptualized from either a categorical or a dimensional perspective. The categorical model defines a set of specific personality disorder diagnostic categories to which an individual belongs or does not belong. DSM-IV uses this approach with a polythetic system in which individuals may fit into a diagnostic category if they possess a subset of criteria characteristics from a larger set. Thus, individuals with differing clusters of symptoms may share the same diagnosis. In contrast to a categorical system, a dimensional approach identifies a set of features which vary in magnitude among individuals. Individual personality disorders are characterized by high levels of one or more of these dimensions. The temperamental traits that are critical in the different personality disorders show strong evidence of heritability (Torgersen, 1994). Patients rarely represent 'clear-cut' cases; they often demonstrate a mix of traits that do not fit under one single diagnosis. This makes it more fruitful to evaluate personality traits rather then specific disorders to identify such associations. However, the nature of the key traits or dimensions in personality and personality disorders and the specific neurotransmitters and brain systems that can be associated with these key dimensions have not been definitively established. While researchers do not fully agree on what dimensions are critical to the study of personality, there is a fair correspondence between different dimensional systems. Our knowledge of abnormalities in neurotransmitter function in psychiatric disorders such as depression, bipolar disorder, and anxiety has suggested avenues of approach in understanding the biology of the personality disorders (Ressler and Nemeroff, 2000).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

There are a number of dimensional approaches to personality disorder. Some of these are derived from studies of normal personality such as the systems of Eysenck (Eysenck, 1991) or the five factor model of personality (Costa and Widiger, 1994). Other approaches have identified key dimensions from analyses of personality disorders. Finally, other schema, such as the temperament and character (TCI) model of Cloninger (Cloninger *et al.*, 1993), are based on a theoretical construct of the psychobiology of personality disorder as well as a framework for describing the relationship of character to temperament. For the purposes of this review, we employ a broad, face-valid model of key domains of personality disorders that may be dimensional and that cut across the boundaries of specific disorders. For example, cognitive disorganization is the hallmark of Cluster A, the schizophrenia spectrum personality disorders, including schizotypal, schizoid, and paranoid personality disorder, and is manifest in traits of suspiciousness, social isolation, and paranoid thinking, and, in some cases, psychotic-like phenomena. More extreme forms of cognitive disorganization are found in schizophrenia, where reality testing is severely distorted. Cluster B is characterized by impulsivity, defined as a relative disinhibition of action-oriented, particularly aggressive responses to the environment, and affective instability, defined as intense affective shifts in response to environmental precipitants. Anxiety, defined as apprehension and anticipation of negative consequences of behaviour often associated with autonomic arousal, is most characteristic of the anxious cluster, Cluster C. These dimensions have been related to specific neurotransmitters in brain systems on the basis of research of Axis I disorders (Siever and Davis, 1991; Kirrane and Siever, 2000). These clinical domains are consistent with those derived from factor models of personality disorders. They may also be related to other models of personality disorders, such as the temperament and character model of Cloninger, in that low harm avoidance could be considered to be coincident with impulsive aggression, while high novelty seeking may map into impulsivity and high reward dependence into affective instability (see Chapter XXVI-6).

THE ECCENTRIC CLUSTER

The eccentric cluster (Cluster A) consists of paranoid, schizoid, and schizotypal personality disorders. Patients that are diagnosed with these disorders share odd and eccentric behaviour as well as unusual thinking. The temperament and character model characterizes this group as having a temperament of low reward dependence (Cloninger *et al.*, 1993; Svrakic *et al.*, 1993). Cognitive disorganization in these patients is a central problem because it interferes with effective interaction with others in social and occupational arenas. Research suggests that the dopaminergic system, an important neurotransmitter system, is involved in cognition. Cognitive function in schizotypal personality disorder has been studied because these patients have a well-demonstrated association with schizophrenia, in both their cognitive symptoms (Siever and Davis, 1991) and their genetic basis (Kendler *et al.*, 1981), yet they are free from the potential confounding effects of chronic neuroleptic treatment and downward social drift. The major metabolite of dopamine, homovanillic acid (HVA), measured in plasma and cerebrospinal fluid (CSF), has been shown to correlate with psychotic-like symptoms in both schizotypal and non-schizotypal personality disorder subjects (Siever *et al.*, 1991a; 1993). Studies using SPECT imaging of IBZM displacement by amphetamine-stimulated dopamine release and studies of plasma HVA responses to 2-deoxyglucose (2-DG) indicate that subcortical dopamine activity in schizotypal patients is comparable to or lower than that seen in normal subjects, and is markedly lower than that seen in schizophrenic patients (Siever *et al.*, 2002). Thus, schizotypal personality disorder patients may be spared from psychosis because of reduced subcortical dopaminergic activity. Among schizotypal patients, those with higher dopaminergic activity tend to have more psychotic-like symptoms.

THE DRAMATIC CLUSTER

The dramatic cluster (Cluster B) consists of antisocial, borderline, histrionic, and narcissistic personality disorders. Common to these disorders are dramatic, emotional, and erratic behaviours. Individuals with these disorders are impulsive and aggressive, as well as affectively unstable. The TCI describes their temperament as one of high novelty seeking and low harm avoidance (Cloninger *et al.*, 1993; Svrakic *et al.*, 1993). Associations have been found between the traits of impulsivity, aggression, and affective liability and the monoaminergic systems, but other systems, such as the cholinergic system, also seem to play a role (Gurvits *et al.*, 2000).

IMPULSIVITY AND AGGRESSION

Aggressive behaviour is common in the personality disorders (Berman *et al.*, 1998), in part because of the interaction between irritability and the interpersonal environment. Borderline personality disorder (BPD) is characterized by prominent impulsive/aggression.

Early evidence suggested that borderline personality disorder (BPD) runs in families (Loranger *et al.*, 1982). Later it was shown that it is not BPD, but the personality trait of impulsive aggression, common in BPD, that is heritable (Torgersen, 1994). Impulsive aggression has been shown to be heritable in the general population through identical twin studies (Coccaro *et al.*, 1993; 1994), adoptive studies of criminal offenders and antisocial personality-disordered subjects (Cloninger *et al.*, 1975; Crowe, 1974), and family studies. The risk of having affective and impulsive personality disorder traits is greater in relatives of BPD than in relatives of people with other personality disorders (Silverman *et al.*, 1991). In order to understand the underlying biology of impulsivity and aggression, a number of neurotransmitter systems have been studied.

Serotonin

Serotonin is involved in self-directed, restitutive behaviours, such as grooming, feeding, and sleeping. Animal studies show that these behaviours are associated with increases in the firing of serotonergic neurons, neurons that normally fire at a consistent, continuous rate (Jacobs and Fornal, 1995). Low levels of the serotonin metabolite 5-HIAA in the CSF have been associated with impulsive, violent crimes and suicide attempts, examples of externally and internally directed aggressive behaviour.

Violent offenders who committed impulsive crimes had a lower concentration of 5-HIAA in the CSF than violent offenders who committed premeditated crimes (Linnoila *et al.*, 1983). It is interesting that the lowest levels were found in the subjects who had attempted suicide. Later several other studies confirmed the hypothesis that a low level of serotonergic activity correlates with an increased risk of suicide or parasuicide. Asberg *et al.* (1987) showed that low serotonin metabolite levels increased the risk of later suicide attempts. This association was confirmed in a short-term prospective study (Nordstrom *et al.*, 1994) and appears to occur regardless of psychiatric diagnosis (Siever *et al.*, 1991b). Reduced 5-HT levels were also found in parasuicidal patients (Coccaro and Astill, 1990). A meta-analyses of 27 research reports (Lester, 1995) and later a review of 20 studies (Asberg, 1997) concluded that low levels of 5-HIAA in the CSF are strongly correlated to suicidal behaviour. Mann *et al.* (1996d) found that low 5-HIAA correlated

with a history of planned suicide and with suicide attempts that resulted in greater medical damage, suggesting a more violent method.

Externally directed aggression also correlates to reduced serotonergic metabolites, although not as consistently. Subjects with antisocial personality disorder responded with more aggression when using alcohol than subjects without antisocial personality disorder (Virkkunen and Linnoila, 1993; Moeller *et al.*, 1998b). Finnish alcoholic, impulsive, habitually violent offenders have been found to have low brain serotonin concentrations (Virkkunen *et al.*, 1996). Decreased serotonin metabolism correlates with externally directed aggressive behaviour in criminal offenders and in clinical and normal populations (Coccaro *et al.*, 1990b). Lower concentrations of 5-HIAA in the CSF are found in people with a history of problematic aggressive behaviour (Brown *et al.*, 1979; 1982). Other studies have, however, shown the opposite, that is, that aggression scores correlate with high levels of 5-HIAA in the CSF (Moller *et al.*, 1996). The same study found that low levels of 5-HIAA in the CSF correlate with internally directed aggression scores (Moller *et al.*, 1996). Another study found that homicide offenders did not differ from control subjects in the concentrations of 5-HIAA in the CSF (Lidberg, 2000). However, the group of homicide offenders that had made one or more suicide attempts had a significantly lower concentration of 5-HIAA in the CSF than the rest of the group, with the exception of subjects with impulse-control disorder, suggesting that serotonin regulates suicidal tendencies and impulse control. Thus, the most consistent finding is that serotonergic activity has a strong inverse relationship with internally directed aggression.

It is relatively difficult to obtain CSF samples in order to study serotonergic activity, and these measures reflect only the presynaptic component of serotonergic activity. Since prolactin secretion is regulated by serotonergic neurotransmission (Coccaro *et al.*, 1998a), measurement of prolactin in response to a serotonergic agent could provide an indirect measure of serotonergic activity. It has been suggested that this method might be a more sensitive measurement of serotonergic activity than the measurement of 5-HIAA levels in the CSF in that it also reflects the postsynaptic responsiveness of the serotonergic system (Coccaro *et al.*, 1997a). Studies using the neuroendocrine paradigm report a consistent correlation between blunted prolactin response to serotonergic agents and impulsivity or aggression in the personality disorders.

A blunted prolactin response to *d*-fenfluramine, a serotonin releaser and reuptake inhibitor, was found in personality disorder subjects compared to controls and was associated with a history of suicide attempts and impulsive aggression in the personality disorder subjects (Coccaro *et al.*, 1989; Coccaro, 1989; Siever and Trestman, 1993). A blunted response to fenfluramine was also found in subjects with antisocial personality disorder convicted of murder (O'Keane *et al.*, 1992), and it correlated to both self-reported and behavioural measures of aggression (Coccaro *et al.*, 1996a). In a study employing m-CPP (*m*-chlorophenylpiperazine), a 5-HT_{1a} and 5-HT_{2c} agonist, the prolactin response varied inversely with assaultiveness (Coccaro *et al.*, 1997c) and was blunted in antisocial personality disorder (Moss *et al.*, 1990). Buspirone and ipsapirone, two 5-HT_{1a} agonists, also produced blunted prolactin responses that varied inversely with aggressiveness (Coccaro *et al.*, 1990a; Moeller *et al.*, 1998a). Thus, a blunted prolactin response to a serotonergic challenge seems to be a consistent correlate of impulsive aggression in personality disorder patients.

The 5-HT_{2a} and -$_{2c}$ receptors appear to mediate the prolactin response to *d*-fenfluramine (Coccaro *et al.*, 1996c), while 5-HT_3 receptors seem to play little if any role in the prolactin response (Coccaro *et al.*, 1996b; Mann *et al.*, 1996a). An increase of 5-HT_2-receptor density has been reported in depressed patients and in suicidal patients (Pandey *et al.*, 1990). The increase was localized to the prefrontal cortex in a group of suicide victims (Arango *et al.*, 1990). This could reflect a compensatory increase due to reduced 5-HT release (Mann *et al.*, 1990). The density of 5-HT postsynaptic receptors correlates with the tendency to assaultive behaviour in non-criminally aggressive, personality-disordered subjects (Coccaro *et al.*, 1997c). The density of 5-HT_{2a} receptors positively correlates to assaultiveness in personality-disordered subjects. However, the affinity seems to be decreased (Coccaro *et al.*, 1997b). The number of 5-HT transporter (SERT) sites has been shown to vary inversely with self-mutilation in patients with personality disorder (Simeon *et al.*, 1992). The SERT sites in the brain are coded for by the same single-copy gene as the platelet 5-HT uptake site (Lesch *et al.*, 1993), a fact which makes it possible to study SERT in psychiatric disorders by studying platelets. Coccaro and colleagues have found a correlation between life history of aggressive behaviour and a reduced number of platelet 5-HT transporter sites in personality disorder patients (Coccaro *et al.*, 1996d).

These studies of serotonergic activity pointed the way to candidate gene studies of serotonin-related genes. One candidate gene (Burmeister, 1999) codes for the rate-limiting enzyme, TPH, in the synthesis of serotonin. A particular polymorphism of the TPH gene has been found to be associated with suicide, but not with CSF 5-HIAA concentration, in criminal offenders (Nielsen *et al.*, 1994; 1998). However, this association with suicide was not duplicated in a more general suicidal population (Abbar *et al.*, 1995). There are two alleles of the TPH gene, the 'L' and 'U' alleles. One study has shown that the 'L' allele of the TPH gene appears to be associated with impulsive aggression (New *et al.*, 1998). However, another study contradicted this by showing an association between the presence of at least one 'U' allele of the TPH gene and overt aggression in men (Manuck *et al.*, 1999). Thus, it remains unclear to what extent the TPH gene is involved in aggression. Other studies have shown association between the 'G' allele of the 5-HT_{1b} receptor gene and a history of suicide attempts in Caucasian patients with personality disorders (New *et al.*, 2001), and an association between alleles of the 5-HT_{2a} receptor gene and self-directed aggression (New *et al.*, 1999).

Positron emission tomography (PET) studies can demonstrate activity in regions of interest in the brain through measuring glucose metabolism. Patients with impulsive-aggressive behaviours show decreased activity in orbital frontal cortex at baseline and after fenfluramine compared to controls (Goyer *et al.*, 1994; Siever *et al.*, 1999). By giving subjects fenfluramine, a serotonin releaser and reuptake inhibitor, and measuring the metabolic activity of regions of interest with a PET scan, one can obtain an index of that region's serotonergic responsiveness. Fenfluramine caused an increase in metabolic activity in an area centred on the anterior cingulate and an area in the lateral prefrontal cortex involving the inferior, middle, and superior frontal gyri in the left prefrontal cortex and in the left temporoparietal cortex in normal subjects (Mann *et al.*, 1996c), but no increase in activity was found in depressed inpatients by the same method (Mann *et al.*, 1996b). Raine *et al.* (1994) showed that seriously violent offenders pleading not guilty by reason of insanity or incompetent to stand trial had a reduced metabolic activity in both the lateral and medial prefrontal cortex. Patients with impulsive-aggressive personality disorders have reduced metabolic activity compared to healthy volunteers in the orbital frontal, ventral medial frontal, and cingulate cortex after administration of *d*,l-fenfluramine (Siever *et al.*, 1999).

Pharmacotherapeutic studies have shown that fluoxetine hydrochloride, a selective serotonin-uptake inhibitor, reduced the aggressiveness in impulsive-aggressive personality disorder subjects (Coccaro and Kavoussi, 1997; Salzman *et al.*, 1995), again supporting a relationship between serotonin and aggression.

Dopamine

Animal studies have suggested a connection between dopaminergic activity and aggression (Coccaro, 1996). Human studies show either

a negative correlation or no correlation between the dopamine metabolite HVA in the CSF and aggression. CSF HVA levels have been observed to be closely linked to 5-HIAA levels in the CSF, which are known to be reduced in impulsive aggression (Coccaro, 1998), and CSF HVA may thus be reduced as well (Linnoila, 1983). A positive correlation between plasma HVA and novelty seeking among subjects with an anxious cluster personality disorder has been found in our laboratory (Siever *et al.*, unpublished data). The dopamine receptor D4DR gene has been shown to relate to novelty seeking in volunteers in some studies (Benjamin *et al.*, 1996; Ebstein *et al.*, 1996), but not in others (Malhotra *et al.*, 1996). In schizotypal and non-schizotypal personality disorder subjects, HVA concentrations in the CSF and plasma correlate with psychotic-like symptoms rather than aggressive behaviours (Siever *et al.*, 1993; Siever *et al.*, 1991a).

Vasopressin

Animal studies report a correlation between CSF vasopressin levels in the central nervous system (CNS) and aggression (Ferris and Delville, 1994). Vasopressin is associated with aggressive behaviour in humans in that a positive correlation has been reported with a life history of aggression even when controlling for the decreased serotonergic activity (Coccaro *et al.*, 1998b).

Other Peptides

While opiate withdrawal often elicits aggressive behaviour, there has been little study of the relationship of opiates to aggression although some inconsistent correlations have been found (Coccaro and Siever, 2002). Testosterone appears to play a facilitative role for aggressive behaviours in non-psychiatric subjects (Archer, 1991; Rubinow and Schmidt, 1996).

Norepinephrine

While lower concentrations of the serotonin metabolite (5-HIAA) have been found in the CSF of people with a history of problematic aggressive behaviour, a higher level of the norepinephrine metabolite [methoxy-4-hydroxy-phenylglycol (MHPG)] has been found in aggressive subjects than controls, and is correlated with a life history of aggression (Brown *et al.*, 1979; 1982). Plasma norepinephrine has also been correlated with self-reported impulsivity in personality disorder patients (Siever and Trestman, 1993), but reductions in CSF MHPG have also been reported in one study (Virkkunen *et al.*, 1987), although this was not replicated in another later study by the same group (Virkkunen *et al.*, 1994). Increased responses to clonidine were reported to be associated with self-reported 'irritability', but not with assaultiveness (Coccaro *et al.*, 1991).

AFFECTIVE INSTABILITY

In bipolar and depressed patients, PET studies have shown decreased activity in the prefrontal cortex, ventral to the genu of the corpus callosum, a finding partly explained by a corresponding reduction in the grey matter, raising the possibility of reduced cortical activity in relationship to affective symptoms (Drevets *et al.*, 1997). Pleasant and unpleasant emotions both increased cerebral blood flow (CBF) in the vicinity of the medial prefrontal cortex (Brodmann's area 9), thalamus, hypothalamus, midbrain, and head of the left caudate nucleus in healthy women (Lane *et al.*, 1997a; 1997b). Unpleasant affects also activated the bilateral occipito-temporal cortex and cerebellum, and left parahippocampal gyrus, hippocampus, and amygdala (Lane *et al.*, 1997a). Thus, intense affects have been associated with limbic and subcortical activity. Both in healthy sadness and in depressive illness, there is a decrease of CBF in the neocortical (right dorsolateral prefrontal, inferior parietal) and the limbic-paralimbic (subgenual cingulate, anterior insula) regions (Mayberg, 1997; 1999). In remission of depression, a decrease of paralimbic blood flow and an increase of neocortical blood flow was observed (Mayberg, 1997; 1999). These considerations suggest that the cortex may play an inhibitory modulatory role in relation to limbic activation associated with intense affects. Thus, affective instability in patients with BPD may reflect increased paralimbic activity, possibly in response to poor modulation by higher cortical structures.

Acetylcholine

Cholinergic neurons are found in limbic structures, paralimbic structures, the cortex, and the nucleus basalis (Ketter *et al.*, 1996). Acetylcholine is ubiquitous in the CNS and is involved in modulating REM sleep and autonomic nervous system activity. Animal studies suggest a role for central nicotinic receptors in depression (Tizabi *et al.*, 1999).

Procaine activates limbic structures, in part, by means of cholinergic activation (Kellner *et al.*, 1987; Kling *et al.*, 1987). When procaine was administered to healthy volunteer subjects, it induced fear in one-third and euphoria in one-third of the subjects. These effects correlated with the degree of activation of the left amygdala in PET studies (Ketter *et al.*, 1996). When physostigmine, a cholinesterase inhibitor, was given to healthy male volunteers, it induced a dysphoric and cardiovascular response that correlated with high emotional lability, high irritability, feelings of stress, and low life contentment (Fritze *et al.*, 1990). Physostigmine also induced a stronger depressive response in BPD patients than in normal controls and non-BPD patients (Steinberg *et al.*, 1997). The depressive symptoms in response to physostigmine correlated to BPD traits related to affective instability (affective instability, identity disturbances, chronic feelings of emptiness and boredom, and turbulent relationships), but they did not correlate to traits related to impulsivity. Exaggerated affective responses to cholinergic agonists have been shown in affective disorder patients compared to normal controls (Janowsky *et al.*, 1994). BPD patients without current depression showed a decrease in REM latency, similar to depressed patients, as compared to non-BPD and non-psychiatric controls (Akiskal *et al.*, 1985; Bell *et al.*, 1983; McNamara *et al.*, 1984). This is consistent with the possibility of altered cholinergic activity in BPD.

Norepinephrine (NE)

Animal models show an increase of noradrenergic activity in the locus coeruleus when the rodent is confronted with threatening stimuli (Levine *et al.*, 1990). Noradrenergic neuronal function is increased in anxiety and fear states in human subjects (Charney *et al.*, 1992). Administration of dextroamphetamine, a norepinephrine and dopamine releaser/reuptake inhibitor, to healthy subjects induces a dysphoric response (Kavoussi and Coccaro, 1993). This response correlated proportionally to measures of affective lability. By using the neuroendocrine measure of growth hormone response to a clonidine challenge, Coccaro *et al.* (1991) showed that central alpha$_2$-adrenergic receptors play a role in irritability, but not in assaultiveness. Gerra *et al.* (1999) found a positive correlation between sensation seeking, and NE and NE-dependent hormones.

GABA (Gamma-Aminobutyric Acid)

GABA-receptors are found in the amygdala and seem to be involved in the intense affects induced by procaine (Ketter *et al.*, 1996). Medications that successfully treat patients with affective instability,

such as lithium, valproate, and carbamazepine, increase GABAminergic neurotransmission (Shatzberg and Nemeroff, 1989), suggesting that GABA plays a role in affective instability.

CLUSTER C

The anxious cluster consists of avoidant, dependent, and obsessive-compulsive personality disorders. Anxious and fearful personality features are common to these disorders. Individuals with these disorders try to avoid situations that can lead to embarrassment, but at the same time they want to be part of their social group and long for close relationships. According to the TCI, they have a temperament of high harm avoidance (Cloninger *et al.*, 1993; Svrakic *et al.*, 1993). Harm avoidance has been hypothesized to be associated with the neurotransmitters serotonin and dopamine.

Serotonin

Blunted prolactin responses to fenfluramine were found in males with compulsive personality disorder compared with males with non-compulsive personality disorders, but these responses correlated with impulsivity in these patients (Stein *et al.*, 1996). A blunted prolactin response to fenfluramine has been shown in obsessive-compulsive disorder (OCD) patients and in patients with major depression compared to normal controls (Lucey *et al.*, 1992). An inverse correlation between harm avoidance and 5-HT_2 receptor sensitivity has also been demonstrated (Pierson *et al.*, 1999). The s/s genotype, but not the s/l or l/l genotypes, of the serotonin transporter is associated with higher scores of neuroticism on the NEO personality inventory, a measurement that includes anxiety (Greenberg *et al.*, 2000; Murakami *et al.*, 1999).

CONCLUSIONS

In general, surprisingly strong correlations have been shown between neurotransmitter activity and the personality disorders, particularly dimensions of personality such as impulsive/aggression, cognitive disorganization, and affective instability. New imaging techniques may permit more specific delineation of the circuits that may be altered in relation to these disturbances in neurotransmitters. As the genome is mapped in more detail, we may have better means of identifying specific candidate genes. Linkage techniques may also help to develop specific identification of altered genes. Not only will such studies inform our clinical interventions with these difficult-to-treat individuals, but they may also help us to understand better the relationship between individual differences in behaviour and personality and neurotransmitter activity.

XXVI-3

Neuroendocrinology of Personality Disorders

Roger T. Mulder and Peter R. Joyce

INTRODUCTION

Disorders of personality are currently defined as categories of deeply ingrained and enduring behaviour patterns that are persistently maladaptive and encompass multiple domains of behaviour and psychological functioning. Personality types were described in ancient Greece, yet, despite this lengthy history, it may be argued that we are still far from adequate in describing the phenomena that constitute the clinical core of personality disturbance (Tyrer, 1995). Personality pathology has been conceptualized in a number of ways, including categories, dimensions and clusters, but none of the classification systems have been validated from an aetiological or a biological perspective. We begin by discussing ways of classifying personality pathology and measurement of central nervous system monoamines since the patterns of association are critically influenced by these factors.

CLASSIFICATION OF PERSONALITY PATHOLOGY

Personality Categories

The separation of personality disorders (PDs) as a discrete axis of classification by the American Psychiatric Association (APA) in DSM-III (American Psychiatric Association, 1980) has focused attention on this neglected group of disorders and stimulated research in this area. However, the large increase in literature (Gorton and Akhtar, 1990) has not been accompanied by a corresponding increase in systematic models to aid in understanding the underlying behavioural abnormalities. The 10 current DSM-IV categories — paranoid, schizoid, schizotypal, antisocial, borderline, narcissistic, histrionic, avoidant, dependent and obsessive compulsive — are derived from a mixture of theory, opinion and historical precedent. The *10th Revision of The International Classification of Diseases* (World Health Organization [WHO], 1992) has replicated most features of DSM-IV. Diagnoses in both systems involve a list of operational criteria, of which a specific number must be present for an individual to receive a diagnosis of personality disorder.

Although it is implied that the categories group patients into mutually exclusive diagnostic entities, most studies have reported high rates of co-occurrence (e.g., Pfohl *et al.*, 1986; Joffe and Regan, 1988; Mulder *et al.*, 1994), and the measured behaviours appear to be distributed dimensionally with no evidence of the discontinuity a categorical model would imply (Zimmerman and Coryell, 1990). The overlap and clinical heterogeneity which result hamper attempts to link personality disorder diagnoses with specific neurobiological processes.

Personality Dimensions

Unfortunately, the dimensional models have fared little better. Many have emerged from academic psychology, the most important being the work of Eysenck and the five-factor model currently being refined by Costa and McCrae (1992). Eysenck's model initially consisted of two dimensions labelled introversion/extraversion (E) (sociability, stability, activity) and neuroticism (N) (temperamental sensitivity to negative stimuli). His model included a biological explanatory schema based on autonomic nervous system reactivity and ease of conditionability. He suggested that arousal stems from the ascending reticular activating system and is linked with E, while N reflects activation from the limbic system (Eysenck, 1967). Later critics have noted that these two systems of brain circuitry are interconnected and are thus unlikely to explain two supposedly independent dimensions (e.g., Claridge, 1986; Gray, 1982), but it remains an initial attempt to link behavioural dimensions to underlying biological processes. In 1976, Eysenck added a third dimension, psychoticism (P), defined as tender-minded versus tough-minded (high P is similar to psychopathy) (Eysenck *et al.*, 1976).

Costa and McCrae's (1992) five-factor model consists of five dimensions — neuroticism, extraversion (both similar to Eysenck's dimensions), agreeableness (trust, altruism), conscientiousness (self-discipline, competence, order) and openness to experience (aesthetics, fantasy, values). Although this model is being increasingly related to the DSM PD classification (Nestadt *et al.*, 1994; Widiger and Costa, 1994), it has only recently been linked with biological processes, and then mainly genetics.

More recently, a model of temperament with specific theoretical relationships to neurobiology was proposed by Cloninger (1986; 1987). This model began by postulating brain systems based on animal and genetic studies and then worked out their behavioural manifestations (Carey and DiLalla, 1994). There are three temperament dimensions, namely, novelty seeking (NS), harm avoidance (HA) and reward dependence (RD). Initially, NS was hypothesized to reflect heritable differences in the behavioural activation system and to be associated with central nervous system (CNS) dopaminergic activity, HA was said to reflect individual differences in behavioural inhibition and to be associated with serotonergic neural firing, and RD was held to reflect differences in behavioural maintenance and was associated with noradrenergic activity. More recently, Cloninger's theory has been modified, so that HA is related to gamma-aminobutyric acid (GABA), as well as serotonin; RD is related to serotonin (median raphe) as well as noradrenaline; and persistence (a new temperament dimension based on a reward-dependence subscale) is related to serotonin (dorsal raphe). The tridimensional model of

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

temperament has been related to DSM PD categories (Cloninger, 1987; Svrakic *et al.*, 1993; Mulder *et al.*, 1999) and has been useful in describing personality pathology (Svrakic *et al.*, 1993; Mulder and Joyce, 1997) and comorbidity (Mulder *et al.*, 1994; Battaglia *et al.*, 1996).

Clusters and Factors

A third approach to classification has been to group PD diagnoses into broad clusters with the aim of decreasing redundancy and creating more valid categories. At one extreme, Rutter (1987) suggested that, since all PDs have a pervasive and persistent abnormality in maintaining social relationships, there should be one overall category defined in terms of relationship abnormalities. More commonly, researchers, using a variety of factor and cluster-analytical methods, have identified three or four major groups with reasonable consistency (Walton and Presly, 1973; Tyrer and Alexander, 1979; Kass *et al.*, 1985; Hyler and Lyons, 1988; Tyrer and Seivewright, 1988; Dowson and Berrios, 1991; Schroeder and Livesley, 1991; Livesley and Jackson, 1992). DSM has also suggested three clusters named A, B and C. In a recent study, we identified four factors we named the 'Four As' — antisocial, asocial, asthenic and anankastic — from an item level factor analysis of DSM-III-R Axis II symptoms (Mulder and Joyce, 1997).

The possible relationships of these four factors to other empirically derived groups and the DSM-IV clusters are shown in Table XXVI-3.1, while the relationship of the 'Four As' to dimensional models of personality is shown in Table XXVI-3.2.

In this chapter, we will present the neuroendocrinology of PDs using the four groups — antisocial, asocial, asthenic and anankastic. This retains the accumulated clinical experience and meaning to clinicians of PD symptoms and signs, as well as a relationship to dimension models. The prototype PDs of the Four As are borderline PD (antisocial), schizoid PD (asocial), avoidant PD (asthenic) and obsessive-compulsive PD (anankastic).

NEUROENDOCRINE MEASUREMENT

Accessing brain function in human subjects presents significant methodological problems. Despite this, a variety of approaches have been used, including measuring monoamines and their metabolites in cerebrospinal fluid (CSF), plasma and urine; neuroendocrine probes of monoamine function; and the use of platelets and other cells as models for CNS monoamine function. Each technique has limitations, and they are all indirect estimates of what it is occurring in the CNS.

Many studies do not consider potentially important interactions between neurotransmitters or physiologically significant relationships with other compounds (Linnoila *et al.*, 1988). For example, CSF 5-hydroxyindoleacetic acid (5-HIAA), a serotonin metabolite, and CSF homovanillic acid (HVA), a dopamine metabolite, are usually significantly correlated. This suggests that when studies report serotonergic abnormalities related to PDs, there are probably dopaminergic abnormalities as well.

If monoamine measures are to be used as an index of personality, they should represent stable biological traits. It is not always clear whether such measures reflect temporary reactions to stressful or pleasant events, that is, state rather than trait.

Finally, there is evidence that neuroendocrine measures are influenced by seasonality, clinical variation, diet and weight,

Table XXVI-3.1 Relationship of Four As to DSM clusters and other factor analyses

Four As 1997	DSM-III R PDs (Mulder and Joyce, 1997)	DSM-III R Clusters	Walton and Presly (1973)	Tyrer and Alexander (1979)	Schroeder and Livesley (1991)
Antisocial	Antisocial Borderline Narcissistic Histrionic Paranoid	B Antisocial Borderline Narcissistic Histrionic	Hysterical	Sociopathy	Psychopathic entitlement
Asocial	Schizoid	A Paranoid Schizoid Schizotypal	Social avoidance	Schizoid	Social avoidance
Asthenic	Avoidant, Dependent	C Avoidant Dependent Obsessive-compulsive	Submissiveness	Passive Dependent	Dependent emotionality
Anankastic	Obsessive-compulsive		Obsessional/schizoid	Anankastic	Compulsiveness

Table XXVI-3.2 Relationship of Four As to personality dimensions

Four As	Descriptors	Eysenck (Mulder and Joyce, 1997)	Cloninger (Mulder and Joyce, 1997)	Costa and McCrae, 1992 (theoretical)
Antisocial	Impulsive, unstable, easily bored	↑Psychoticism	↑Novelty seeking	↓Agreeableness ↓Conscientiousness
Asocial	Socially indifferent, lacks empathy	↑Psychoticism	↓Reward dependence	↓Extraversion
Asthenic	Fearful, anxious, insecure	↑Neuroticism ↓Extraversion	↑Harm avoidance	↑Neuroticism ↓Extraversion
Anankastic	Rigid, conscientious, perfectionistic		↑Persistence ↓Reward dependence	↑Conscientiousness

gender, and menstrual cycle, as well as other variables (Mulder, 1992). Given all these factors, results need to be viewed sceptically, and these considerations may, in part, also explain some of the inconsistencies and contradictory results found in this review.

ANTISOCIAL FACTOR

Most neuroendocrine research into PDs is focused on subjects who would fall within the antisocial personality factor. The behaviours studied have been impulsivity, aggression and affective lability. The principal finding, indeed the major finding, in the neuroendocrinology of PDs, is in the relationship of impulsivity and aggression to CNS serotonin. Much of the initial evidence of a link came from animal studies that had repeatedly demonstrated that serotonin-depleted animals are more aggressive, impulsive and disinhibited (e.g., Brody, 1969; Miczek *et al.*, 1975). The first published study in humans was in 1976, when Asberg *et al.* (1976) reported lower levels of CSF 5-HIAA in those who had made violent suicide attempts than in a control group. Since then, there have been a number of studies linking reduced levels of CSF 5-HIAA in personality-disordered men with a history of aggressive behaviours (Brown *et al.*, 1979), violent prison offenders (Linnoila *et al.*, 1983), impulsive arsonists (Virkkunen *et al.*, 1987) and impulsive suicide attempters (Roy, 1996). Pharmacochallenge studies have reported similar results. Coccaro and others reported a blunted prolactin response to fenfluramine in depressed patients with a history of suicide attempts and/or aggression (Coccaro *et al.*, 1989), and in aggressive and personality-disordered men (Coccaro *et al.*, 1996). There have been reports of reduced prolactin response to fenfluramine in patients with PDs (New *et al.*, 1997) and criminal offenders (O'Keane *et al.*, 1992).

There are some conflicting results. Wetzler *et al.* (1991) failed to find a relationship between self-reported aggression and the prolactin response to fenfluramine in depressed and panic disorder subjects, while Fishbein (1989) reported a positive relationship between prolactin response to fenfluramine and aggression in substance abusers. We have recently found no relationship between repeated self-harm, antisocial or borderline PD, and the prolactin response to fenfluramine in depressed subjects (Mulder and Joyce, 2002, in press).

Another neurotransmitter increasingly studied in relation to antisocial and impulsive behaviour is CNS dopamine. Overall, the evidence is weaker, with some studies showing a relationship between CSF HVA and antisocial and recidivist violent offending (Linnoila *et al.*, 1983; Virkkunen *et al.*, 1989), while others have demonstrated no relationship between this measure and aggression (Brown *et al.*, 1979; Virkkunen *et al.*, 1987). As discussed earlier, this evidence is complicated by the fact that CSF 5-HIAA and CSF HVA are usually correlated. There is some debate over which metabolite is more relevant. Agren (1983), for example, has suggested that suicidal behaviours correlated more closely with low CSF HVA than with low CSF 5-HIAA levels. Animal studies clearly suggest a direct relationship between dopamine function and aggression (Coccaro *et al.*, 1996).

Cloninger's dimension of NS, which is correlated with the antisocial factor, should also theoretically be related to dopaminergic activity. One study (Wiesbeck *et al.*, 1995) reported an association between growth hormone response to apomorphine (an indirect measure of CNS dopamine) and NS scores, but a later study by Hansenne and Ansseau (1998) failed to replicate this finding. Patients at risk of Parkinson's disease have low premorbid NS scores (Menza *et al.*, 1995), a finding which can be seen as support for the importance of dopamine in incentive activation of pleasurable activity. Other behaviours associated with the antisocial cluster, such as hyperactivity, sexual hedonism, drinking and smoking, have also been associated with high NS scores (Bardo *et al.*, 1996; Fergusson and Lynskey, 1996; Downey *et al.*, 1996). However, there is very little study of the relationship of these behaviours to indices of dopaminergic functioning. A study in depressed patients found a correlation between CSF dopamine and extraversion (King *et al.*, 1986).

There have also been some reports linking decreased dopamine β-hydroxylase (DBH) (an enzyme that catalyses the conversion of dopamine to noradrenaline in the brain) with unsocialized conduct disorder in boys (Rogeness *et al.*, 1982; Rogeness *et al.*, 1987; Bowden *et al.*, 1988).

Hyperactivity of noradrenergic functioning has been found to correlate with aggressive behaviour in human beings as well. Increased beta-adrenergic receptor binding has been found in the brains of violent suicide victims compared with accident victims (Stanley and Mann, 1983). Brown *et al.* (1979) reported a positive correlation between CSF 3-methyl-4-hydroxyphenolglycol (MHPG) concentrations and a history of aggression in male subjects with PDs. CSF MHPG levels have also been reported to be elevated in violent suicide attempters compared with non-violent suicide attempters (Traskman-Bendz *et al.*, 1992).

Androgens may also play a role in aggressive behaviour. Violent criminals appear to have higher testosterone levels than criminals who commit non-violent crimes, and are also more aggressive in prison settings (Dabbs *et al.*, 1995). Among violent alcohol offenders, those with antisocial personality disorder (ASPD) and increased aggressiveness appear to have higher CSF testosterone concentration (Virkkunen *et al.*, 1987).

In summary, all three major neurotransmitters and male androgens have been implicated in the impulsive and aggressive behaviour found within the antisocial cluster. The most convincing evidence is for serotonin abnormalities. These biological abnormalities may be confined to individuals with extreme and persistent impulsive/aggressive behaviours.

ASOCIAL FACTOR

The most interesting findings related to asocial behaviour come from animal studies, particularly those on prairie voles (Insel, 1997). The neurohypophysial neuropeptides, oxytocin and vasopressin, appear to be important for the formation of long-term social attachments and some aspects of infant attachment behaviour. For example, blocking oxytocin neurotransmission results in a significant inhibition of maternal behaviour, while a vasopressin antagonist administered to male prairie voles blocks the development of particular mate preference and selective aggression. The pathways appear to be species-specific, but these data suggest that the study of these neuropeptides in highly asocial individuals might be rewarding. There are some inconsistent findings that oxytocin levels may be abnormal in subjects with autism (Gilberg and Coleman, 1992).

There are also suggestions that opioid pathways may be involved in social attachment. There is some literature on an opioid model of autism, although therapeutic trials with opiate agonists have been disappointing (Insel *et al.*, 1996).

The asocial factor may be associated with low reward dependence (Mulder and Joyce, 1997). One study has reported that the noradrenaline metabolite MHPG was significantly correlated with TPQ reward-dependence scores (Garvey *et al.*, 1996). Another has related higher reward dependence scores with increased excretion of harman (a by-product of monoamines) in alcoholics (Wodarz *et al.*, 1996). Neither of these studies utilized measures of asocial behaviour.

Overall, despite the evidence that asocial behaviour or social indifference is consistently reported as a stable and persistent human personality trait, there is remarkably little research on its underlying neurobiology.

ASTHENIC FACTOR

The pathophysiology of this cluster of PDs has also seldom been investigated and is poorly understood (Kirrane and Siever, 1998). There are a few studies in social phobia, which, it could be argued, overlaps with and may not be distinct from avoidant PD. Patients with social phobia may have a greater fenfluramine-induced rise in cortisol than controls (Uhde, 1994), suggesting serotonin receptor supersensitivity. The hypothalamic-pituitary-adrenal (HPA) axis appears to be normal (Tancer *et al.*, 1990), but reduced dopamine metabolism has been suggested in one study (Potts and Davidson, 1992). The fact that the monoamine oxidase inhibitors (MAOIs) and selective serotonin reuptake inhibitors (SSRIs) sometimes reduce symptoms of avoidant personality disorder has led some to suggest that the monoamines, particularly serotonin, are implicated, although the evidence beyond this is vague.

The asthenic cluster is consistently associated with higher Eysenck's neuroticism (N) scores and Cloninger's harm-avoidance (HA) scores. Despite the importance of these dimensions, particularly in predicting the severity and course of mood and anxiety disorders, their neuroendocrinological underpinning has barely been researched. Two studies (Nelson *et al.*, 1996; Pfohl *et al.*, 1990) reported no significant correlation between platelet imipramine binding (an indicator of serotonergic function) and TPQ scores. However, in the Nelson *et al.* study, an alternative measure of serotonin functioning, L-lysergic acid diethylamide (^{125}L-LSD), was strongly related to HA scores. In patients with eating disorders, there was no relationship between blood serotonin and HA (Waller *et al.*, 1993).

Studies of the relationship between biochemical measures and N scores are few. Ballenger *et al.* (1983) reported that serum cortisol correlated negatively with N, as did plasma MHPG and CSF calcium. Recently, McCleery and Goodwin (2001) reported that individuals with high N scores had a smaller cortisol response to the combined dexamethasone–corticotrophin-releasing hormone (CRH) test. This suggests that individuals with a high N may have downregulation of the HPA axis.

ANANKASTIC FACTOR

Specific neurobiological research into the anankastic, or obsessive-compulsive, personality is essentially non-existent. There is some research into the obsessive-compulsive spectrum disorders, which include anankastic personality as well as obsessive-compulsive disorder, Tourette's syndrome, and other stereotypic movement disorders. Whether this characterization of such a varied range of psychopathology is valid remains contentious (e.g., Rasmussen, 1994), but it does hint at possible directions for further research into anankastic personality.

The possible importance of the serotonin system is supported by the response of this obsessive-compulsive spectrum, including anankastic personality, to clomipramine and SSRIs. However, the few studies using CSF 5-HIAA measures or pharmacological challenge techniques do not show evidence of a consistent serotonergic abnormality (Stein, 2000). Although dopamine metabolism may play a part in tics and abnormal movements associated with the obsessive-compulsive spectrum, it seems less likely to have a role in anankastic personality (Stein, 2000).

One interesting hypothesis is that, while impulsivity is associated with decreased serotonergic function, compulsiveness is associated with hyperresponsivity of the serotonergic receptors. This contrast may be overly simplistic in that both impulsive and compulsive disorders have been reported to show neuroendocrine blunting on serotonergic challenge and both respond to serotonergic antidepressants (Stein, 1996).

Millon and Davis (1996) have speculated that the neural connections in the limbic system that control fear and anger may contribute to the indecisiveness and excessive conflict that characterizes decision-making in this personality style. This is an interesting but untested speculative hypothesis.

DISCUSSION

We have noted limitations to formal classifications of personality pathology. These limitations have restricted identification and quantification of behaviours that may be associated with neuroendocrinology. PDs, as currently defined, are non-specific diagnostic categories with no theoretical relationship to neuroendocrinology. Trying to find patterns of associations between such categories and specific neurochemical processes is unlikely to be successful.

Grouping PDs into clusters such as the 'Four As', creates more valid categories from a psychometric point of view, but there is limited evidence that these clusters are related to neuroendocrine abnormalities. The monoamine abnormalities reported in violent, impulsive individuals seem to relate to a broad cluster of personality pathology, including antisocial, borderline, narcissistic, histrionic and paranoid symptoms, rather than to individual personality disorder categories, so that the 'antisocial' cluster has superior face validity. However, the lack of biological research into the other personality groups (i.e., asocial, asthenic and anankastic) means that we do not know whether each has a distinct neuroendocrinology, and whether such groups are likely to be helpful for biological research.

Dimensional classifications appear to offer the most promising model for biological processes. However, most current models are derived through the statistical modelling of answers to questionnaires with little thought given to underlying biological principles. The exception is Cloninger's tridimensional model, which was specifically designed to encompass knowledge about the biology of behaviour. However, there is only limited evidence that CNS neuroendocrinology is related systematically to Cloninger's dimensions, as we have already reported. More convincing evidence is in the neuroanatomical and genetic studies related to TPQ measures (Cloninger, 1998).

It may be time to question whether biological research is building on an adequate base. There are increasingly accurate and sophisticated means for measuring brain processes, but what seems to be lacking is an adequate system for personality description. The current DSM categories may be useful for certain tasks, but they reflect simplistic static notions that seem to relate distantly, if at all, to the core processes involved in psychopathology. The self-report questionnaires used in dimensional models are more self-representations than accurate personality descriptions (Kagan, 1994; Hogan, 1996) and lack any behavioural observation.

The move toward objectification in psychiatric diagnosing was a necessary first step but appears to have come to a premature closure (van Praag, 1992). To advance research into the biology of PDs, detailed scrutiny outside our current symptom representation may be necessary. There are some hints of this already. For example, the serotonin abnormalities correlated with impulsive aggression are largely found in individuals whose aggressive behaviour is not premeditated (Linnoila *et al.*, 1983; Virkkunen *et al.*, 1987). This suggests that the key component may be lack of behavioural inhibition rather than aggression or impulsivity.

It may be better to have skilled clinicians closely observing behaviour and assessing detailed personality pathology rather than using structured interviews and questionnaires. Hypotheses derived from clinical models, genetic studies and brain imaging could provide more specific testable models for linking behaviour

and neuroendocrinology. For example, selecting a group of very socially indifferent individuals for study, regardless of their clinical psychopathology (some may have adapted very well to their temperament), might be useful. This could involve using a screening tool such as low RD scores on Cloninger's TPQ questionnaire and then validating these scores by behavioural observation. Animal and genetic studies suggest that neurochemicals such as vasopressin, oxytocin, serotonin and the opioids would be of interest.

The potential significance of finding consistent links between neurochemistry and personality lies in three main areas. First, if maladaptive personality traits can be shown to be shaped by neurotransmitter functions which relate to an individual's ability to regulate impulse, anxiety, mood, sociability and so on, then a sound theoretical basis for pharmacotherapy becomes possible (Soloff, 1990). Rather than targetting PDs, medications could target specific biological trait vulnerabilities and help to modify and regulate the particular behavioural symptoms that make up the psychopathology of PDs.

Second, there is the possibility that much of the relationship between neuroendocrinology and Axis I disorders is mediated by personality traits. There is considerable evidence that certain Axis I disorders are associated with specific personality pathology. For example, individuals with antisocial personality traits are more likely to have alcohol and substance-abuse disorders but less likely to suffer from generalized anxiety disorder, while those with anankastic personality traits are more likely to have obsessive-compulsive disorder, and anxiety and mood disorders but less likely to have alcohol or substance-abuse disorders (Nestadt *et al.*, 1989). These associations may reflect neuroendocrine abnormalities. For example, the serotonergic abnormalities sometimes reported in depressed patients may be largely confined to those with impulsive suicidal behaviours (De Meo *et al.*, 1989). Samples with a high proportion of such individuals report differences in serotonin functioning compared with a control group; those with a low proportion do not. In other words, serotonin disturbances may be non-specific from a functional/categorical perspective but specific from a functional/dimensional perspective, correlating with particular personality traits such as aggression, impulsivity or obsessionality across diagnoses (van Praag, 1986).

Third, linking personality with neuroendocrinology may be a way to integrate biology and psychosocial experience. There is a small but increasing literature reporting associations between negative early life experiences and abnormalities in adult neuroendocrinology. Measuring urinary catecholamine excretion showed that sexually abused girls secreted greater amounts of HVA (De Bellis *et al.*, 1994), and that abused children had higher concentrations of noradrenaline and dopamine than healthy controls (De Bellis *et al.*, 1999). Hospitalized boys who had experienced neglect in the first 3 years of life have been found to have reduced DBH (Galvin *et al.*, 1991), a finding also associated with antisocial cluster behaviour (Galvin *et al.*, 1995; Rogeness *et al.*, 1987), and, in particular, a low valuation of authority and peer-derived rules of conscience (Galvin *et al.*, 1995). Here is a link between an experience (neglect), through a particular behaviour (lack of conscience), to a personality abnormality (conduct disorder).

HPA axis regulation also appears to be related to the quality of early maternal care (Caldji *et al.*, 1998). De Bellis *et al.* (1994) found a reduced adrenocorticotrophic hormone (ACTH) response to CRH stimulation in their sexually abused girls, and Stein *et al.* (1997) reported enhanced dexamethasone suppression in women with a history of childhood sexual abuse. High neuroticism (and its associated reduced cortisol response to dexamethasone-CRH), while partly heritable, may be a measurable vulnerability factor linking such experiences with later post-traumatic stress disorder (PTSD) and depression (McCleery and Goodwin, 2001).

SUMMARY AND CONCLUSION

Over the past 20 years, there has been increasing interest in the neuroendocrinology of PDs. Early results related CSF monoamine metabolites to specific behaviours. There has been a gradual expansion in the types of neuroendocrine measures and behavioural subtypes studied. Despite this, most research has focused on the broad area of antisocial behaviour, particularly impulsivity and lack of inhibition. These behaviours have been linked with abnormalities in all three major CNS biogenic amines and changes in male androgens. Other consistently identified human behavioural traits — asociality or social indifference, asthenic or neurotic behaviours, and anankastic or obsessive-compulsive behaviour — have been much less studied.

Plausible, testable, aetiological models of personality pathology are a necessary step for the science of neuroendocrinology to contribute to an integrated understanding of personality. Attempts to find patterns of association between current DSM PD categories and specific neurochemicals have had limited success. Broader empirical groupings with less overlap such as the 'Four As' may be more useful, but until increased research on the non-antisocial factors is undertaken, it is difficult to be sure. Cloninger's biosocial model is the most sophisticated attempt so far to construct a theoretical, testable model relating biology to behaviour. Results have been somewhat inconsistent, but it offers a base for future research. New developments in measuring the temperament dimensions while incorporating behavioural factors may lead to more valid parameters. Results from animal and imaging studies have already helped refine the initial model of the three monoamines as 'emblematic' neurotransmitters into more complex theoretical relationships between neurochemistry, neuroanatomy and behaviour.

The neuroendocrine abnormalities associated with some adverse early life experiences offer another potentially important model for research. Personality pathology might form the link between such experiences and later psychopathology. Enduring changes in CNS neurochemistry and HPA axis function associated with abuse may be correlated with personality characteristics such as high N or conduct disorder, which in turn make an individual vulnerable to PTSD, depression and ASPD as an adult. Screening a large population for high and low behavioural measures, such as N, NS or RD, and studying these individuals' neurochemistry, early life experiences and current psychopathology might lead to useful results.

The neuroendocrinology of PDs remains an important area of psychiatric research. It could lead to more rational treatment for both Axis I and Axis II disorders, help construct a more valid classification for psychopathology, and provide a link between early life experience and adult development.

The Psychophysiology of Personality Disorders

Angela Scarpa and Adrian Raine

The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (American Psychiatric Association, 1994), defines a personality disorder (PD) as 'an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment (p. 629)'. In general, PDs involve personality traits that have become severe and rigid enough to be dysfunctional or maladaptive, and are typically manifested in at least two of the following areas: cognition, affectivity, interpersonal functioning, or impulse control.

The DSM-IV distinguishes 10 specific PDs that are grouped into three broad clusters, based upon similarities in descriptive features. Cluster A includes the paranoid, schizoid, and schizotypal PDs, which describe individuals who often appear odd, eccentric, or suspicious. Cluster A PDs are also thought to be part of the schizophrenia-spectrum disorders due to their similarity in symptoms with schizophrenia, though milder in form. Cluster B includes the antisocial, borderline, histrionic, and narcissistic PDs, which describe individuals who appear dramatic, emotional, impulsive, or erratic. Finally, Cluster C includes the avoidant, dependent, and obsessive-compulsive PDs, which describe individuals who often appear anxious or fearful. Clusters B and C have been described as reflecting externalizing (i.e., dramatic, reactive, and aggressive) or internalizing (i.e., anxious, avoidant, and withdrawn) dimensions of personality, respectively, based upon their primary symptomatology (Scarpa *et al.*, 1999).

Psychophysiology involves the study of cognitions, emotions, and behaviour as related to physiological principles and events (Cacioppo and Tassinary, 1990; see also Chapter IX in this volume). As such, psychophysiology can provide unique information on the cognitive, affective, interpersonal, and impulsive features of PDs that is relatively objective in nature. This chapter will describe psychophysiological studies of PDs, as grouped by cluster. Although such studies provide rich information on psychological processes related to PDs, relatively few PDs have been examined by psychophysiological techniques. Specifically, the schizotypal and antisocial PDs have been most abundantly studied in relation to psychophysiology; thus, this chapter must necessarily focus on these two. Whenever possible, this information will be supplemented with psychophysiological studies of the other PDs. Findings related to characteristics associated with the Cluster C PDs are also discussed.

CLUSTER A PERSONALITY DISORDERS

As described above, Cluster A includes the paranoid, schizoid, and schizotypal PDs, which are thought to reflect psychosis-proneness or schizophrenia-spectrum disorder. In the DSM-IV, paranoid PD is defined as a pattern of suspiciousness whereby others' motives are interpreted as hostile or malevolent; schizoid PD is defined as a pattern of social detachment or indifference with a restricted range of affect; and schizotypal PD is defined as a pattern of cognitive and perceptual distortions, interpersonal deficits, and odd behaviour (American Psychiatric Association, 1994). Indeed, schizotypal and paranoid PDs are found with greater frequency in the relatives of probands with schizophrenia, although not all studies have been consistent (see Webb and Levinson, 1993 for a review).

Schizotypal PD, in particular, has been a focus of attention due to its symptoms seeming to reflect a milder form of those seen in schizophrenia. These include negative (or deficit) symptoms, such as social withdrawal or blunted affect, and positive (or excess) symptoms, such as perceptual aberrations or magical ideation. Social anhedonia (i.e., social indifference) and magical ideation seem most predictive of later psychosis (Chapman *et al.*, 1995). As such, researchers have focused on comparing schizotypal PD to findings in schizophrenia, with the hope of discovering either a common genetic marker for vulnerability or a factor protective against the progression to full-blown schizophrenia. In this vein, the primary psychophysiological variables that have been studied in schizotypal PD are the skin conductance orienting response (SCOR), smooth pursuit eye movement (SPEM), and event-related potential (ERP), all of which have been found to be deviant in individuals with schizophrenia. Each of these variables and research on their relationship to schizotypal PD will be summarized in turn below.

The Skin Conductance Orienting Response (SCOR) and Schizotypal PD

Changes in the electrical activity of the skin generally occur in response to the presentation of novel stimuli in one's environment. For example, the presentation of a new tone generally causes an orienting response that is accompanied by increased electrical activity in the skin, and thus, a change in skin conductance levels called the SCOR. One useful model for understanding the SCOR has been that of template-matching (Ohman, 1979; 1985). In this model, novel stimuli are stored in short-term memory where they create neural 'templates'. Subsequent stimuli are matched against the template currently stored in short-term memory. If the two stimuli differ, preattentive mechanisms will fail to recognize the newly presented stimulus, thus requiring controlled processing of the new stimulus. However, if the stimuli match, habituation occurs. In addition to cases in which there is a mismatch between the 'stored' stimulus and the novel stimulus, controlled processing also occurs when the novel stimulus is recognized as significant, necessitating further processing. In either case, augmented controlled processing of information would produce a SCOR. Thus, the SCOR is a useful index of how one attends to and processes novel environmental stimuli (Dawson and Nuechterlein, 1984; Dawson *et al.*, 1989).

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

A review of previous studies that have assessed the relationship between SCOR and schizotypy reveals diverse and sometimes inconsistent findings (see Raine *et al.*, 1995 and Yaralian and Raine, in press, for reviews). As in findings with schizophrenia (Dawson and Nuechterlein, 1984), significant effects have shown that negative-symptom schizotypy is marked by hyporesponding while positive-symptom schizotypy is marked by hyperresponding. For example, Simons (1981) and Bernstein and Riedel (1987) both found a greater incidence of SC non-responding in a group of individuals characterized by high scores on physical anhedonia. Whereas neither of these studies found associations with positive symptoms, others have indeed found a significant association between hyperresponsive SCOR amplitudes and positive symptoms of schizotypy, such as cognitive distractibility and distortions (Lipp and Vaitl, 1992; Nielsen and Petersen, 1976). However, significant findings also indicated that positive-symptom schizotypy, as reflected by schizophrenism, perceptual aberrations, and cognitive distortions, is also sometimes associated with non-responding or hyporesponding (Lencz *et al.*, 1991; Raine, 1987; Simons *et al.*, 1983). While the above findings clearly indicate some abnormal orienting in individuals with schizotypal features, it must be noted that none of these studies directly assessed for the syndrome or diagnosis of schizotypal PD. This is particularly noteworthy for studies of negative-symptom schizotypy, where the primary index of physical anhedonia is not even listed as a DSM-IV symptom of schizotypal PD. Thus, the finding of most relevance to DSM-IV symptoms of schizotypy is that either hypo- or hyper-SC responding may characterize cognitive and perceptual deficits.

There is also evidence of a link between erratic responding and schizotypy. One example involved an analysis of SCORs over nine orienting trials for normal subjects characterized by high scores on schizophrenism and physical anhedonia and a group of controls (Wilkins, 1988). The results indicated normal habituation over trials 1–3 for the control and schizophrenism groups, but increased response amplitudes from trials 1–2 in the physical anhedonia group. Similarly, the physical anhedonia group showed an increase in amplitudes, rather than normal habituation, from trials 4–5, which comprised a reorienting set of trials. Thus, negative-symptom schizotypal subjects, characterized in this study by physical anhedonia, failed to display the expected SCOR habituation patterns seen in normal controls. As mentioned above, physical anhedonia is not a DSM-IV symptom of schizotypal PD, and thus it was unclear how these results might generalize to the categorical classification of schizotypy.

To address this issue, this study was replicated, using both a sample of 13 DSM-III-R clinically diagnosed schizotypals (i.e., categorical approach) and a sample of 30 subjects who self-reported on a screening scale for schizotypy (i.e., dimensional approach) (Raine *et al.*, 1997a). The results indicated a similar failure to habituate over orienting trials, regardless of whether schizotypy was defined categorically or dimensionally. Cluster analysis of the 13 diagnosed schizotypals revealed two subclusters, the cognitive-perceptual and the interpersonal deficits subclusters, which respectively reflect positive and negative symptoms of schizotypal PD. The failure to habituate was noted only for the cognitive-perceptual subcluster, as reflected by an initial low orienting response followed by increasingly larger responses for both an orienting trial (i.e., over trials 1–3) and a reorienting trial (over trials 4–6). The interpersonal deficits subcluster, however, showed an expected pattern of habituation, with a large initial SCOR followed by diminished responses. This suggests that erratic SCORs may be associated primarily with positive, rather than negative, symptom features of diagnosed schizotypal PD.

Several interpretations of SC orienting abnormalities have been proposed (see Raine *et al.*, 1995 for a review). One interpretation involves deficits in working memory and frontal brain systems, since reduced SC orienting has been shown to be correlated with both of these indices. In addition, template mismatching has been speculated to underlie abnormal orienting. Template mismatching may result from either the degradation of the accurate representation of the initial stimulus, or from difficulty in initially generating the neuronal template. Inhibitory deficits have also been proposed to explain abnormal orienting. It is possible that the underlying deficit lies in the balance between excitatory and inhibitory processes; too much inhibition would account for the high incidence of SC non-responding in schizotypals, while a failure of inhibitory mechanisms would explain erratic orienting and hyperresponding. It is also thought that the balance between these two contrasting processes affects the particular syndrome. Positive syndrome schizotypy may result from disinhibition, while negative syndrome schizotypy may occur because of an excess of inhibition.

Smooth Pursuit Eye Movement (SPEM) and Schizotypal PD

SPEM measures an individual's visual tracking of a smoothly moving target, such as a pendulum. It can be assessed either qualitatively (by visually inspecting the number of saccadic intrusions and visual lags) or quantitatively (by computerized assessments of tracking accuracy, such as the log of the signal-to-noise ratio). SPEM has been thought to reflect cognitive difficulties with nonvoluntary attention and inhibition (Holzman *et al.*, 1976; 1978) and with working memory and prefrontal disorder (Park *et al.*, 1991), all of which are often seen in schizophrenia.

Indeed, impaired SPEM is one of the most consistent findings in schizophrenia, having been observed in 50–85% of patients with chronic schizophrenia compared with 8% of a control population (Holzman *et al.*, 1974; 1984). Impaired SPEM is also greater in relatives of probands with schizophrenia (Holzman *et al.*, 1974) and in patients whose schizophrenia has remitted (Iacono *et al.*, 1981), and is thus speculated to be a genetic marker or diathesis for schizophrenia-spectrum disorders. As such, an interest arose in its relationship to schizotypal PD.

A relationship between SPEM impairment and schizotypal PD first came from studies of individuals selected from the general population on the basis of either poor tracking ability (Siever *et al.*, 1984) or physical/social anhedonia and perceptual aberration scores (Simons and Katkin, 1985). In the former study, volunteers who were selected on the basis of qualitatively poor eye-tracking accuracy had a greater prevalence of diagnosed schizotypal PD than a control group with high eye-tracking accuracy (11% versus 29%). The difference was even more pronounced for individuals whose eye tracking was reassessed quantitatively, with a prevalence rate of 54% with schizotypal PD. No differences were observed between the two groups on other non-schizophrenia psychopathology, including other PDs. This finding suggested that impaired SPEM was specific to the schizophrenia-spectrum disorder of schizotypal PD.

In the study by Simons and Katkin (1985), subjects were selected by dimensional scores on anhedonia and perceptual aberration. Those with high scores on anhedonia demonstrated heightened prevalence of poor SPEM compared to those with low anhedonia, a finding which suggests a relationship of SPEM to negative symptoms of schizotypy. However, impaired eye tracking has also been noted in relationship to positive psychotic symptoms (Siever *et al.*, 1989). Since this study was not conducted on individuals with clinically diagnosed schizotypal PD, it was still unclear how findings would generalize to the classification of the disorder.

To address the issue of eye-tracking abnormalities in clinically identified schizotypal PD, a study was conducted that compared patients who met DSM criteria for the disorder with three other comparison groups — a group with other non-schizophrenia-related PDs, a group with no psychopathology, and a group with schizophrenia (Siever *et al.*, 1990). The results indicated that the

groups with schizotypal PD and schizophrenia displayed greater impairment of SPEM than the other PD group and the normal control group. This finding of poor SPEM in diagnosed schizotypal PD was replicated by Lencz *et al.* (1993), who showed impaired eye tracking in a group of undergraduates who met DSM criteria for the disorder.

In the study by Siever *et al.* (1990), an analysis of specific symptoms showed that impaired SPEM was predicted only by the criterion of social isolation, with low accuracy trackers also reporting reduced desire for social contact. This would seem to support the notion of impaired SPEM in relation to negative-symptom schizotypy. Other studies, however, show a relationship between eye-tracking abnormalities and positive-symptom schizotypy. Raine *et al.* (1995), for example, reported a reanalysis of the data by Lencz *et al.* (1993), finding that those diagnosed with schizotypal PD who displayed cognitive/perceptual symptoms showed significantly poorer eye tracking than those with interpersonal deficit symptoms. These same individuals exhibited a loss of normal SC habituation (described in the above section on SCOR), and Raine *et al.* speculated that this reflected a loss of inhibitory functions related to both saccadic intrusions in eye tracking and SC attentional deficits.

On the basis of these studies, it is still unclear whether impaired SPEM is specific to certain types of symptoms (i.e., negative versus positive) or instead reflects the entire schizotypal syndrome more generally. It is clear, however, that poor eye tracking is consistently found in individuals with clinically diagnosed schizotypal PD. Together with the literature on SPEM in schizophrenia, this finding supports the notion of impaired SPEM as a marker for schizophrenia-spectrum disorders that may reflect a common genetic vulnerability.

Event-Related Potentials and Startle-Blink

Despite the emphasis on SCOR and SPEM presented above, there has more recently been research on event-related potential (ERPs) and eye-blink correlates of Cluster A PDs. Perhaps the best-replicated electrophysiological correlate of schizotypal personality is reduced amplitude of the P300 ERP. At least five studies find evidence of P300 amplitude reduction in DSM diagnosed schizophrenia-spectrum disorders (Salisbury *et al.*, 1996; Trestman *et al.*, 1996; Black *et al.*, 1992) and individuals high on schizotypal personality (Kimble *et al.*, 2000; Klein *et al.*, 1999). However, Blackwood *et al.* (1992) did not find reduced P300 in individuals who had been diagnosed as schizoid in childhood, suggesting that schizoid PD, unlike schizotypal and paranoid PDs, may not be part of the schizophrenia-spectrum of disorders. P300 deficits have been repeatedly found in schizophrenics and relatives of schizophrenics, and reflect a broad attentional deficit.

Three other ERP findings are of note. First, high scorers on the schizotypal personality questionnaire have failed to show the right-sided predominance in the post-imperative negative variation (PINV) observed in normals (Klein *et al.*, 1998). Second, individuals with schizotypal PD show less gating (suppression) of the P50 ERP to the second of a pair of click stimuli than controls (Cadenhead *et al.*, 2000), indicating a failure of sensory gating at a relatively early stage of information processing, and consequently reduced central nervous system (CNS) inhibition. The same deficits have been observed in both schizophrenics and their relatives. Third, there is growing evidence in schizotypal individuals of a deficit in N400, an ERP component that reflects the degree of search for a semantic match to a word. Two recent studies have shown reduced N400 amplitudes in both individuals high on schizotypy and those with schizotypal PD (Kimble *et al.*, 2000; Niznikiewicz *et al.*, 1999). These two studies suggest a language-processing deficit in schizotypals that is similar to that observed in schizophrenics.

Research has also been conducted on startle eye-blink modification (SEM) and psychosis-proneness (Cadenhead *et al.*, 1993; Dawson *et al.*, 1995; Simons and Giardina, 1992). These findings again show some consistency with findings in schizophrenia, whereby SEM is impaired in subjects with schizotypal features. Findings are inconsistent, however, regarding whether the deficits occur in the controlled or automatic attentional components of SEM. Nevertheless, deficits in sensorimotor gating are consistent with the P50 ERP deficit outlined above, indicating a failure to gate stimuli.

Summary

Overall, two primary findings emerge on the relationship between psychophysiological measures and schizotypal PD. First, they are generally consistent with those found in schizophrenia. That is, SCOR hyporesponding and hyperresponding; failure to habituate; and deficits in SPEM, P300, P400, P50, and SEM have paralleled the literature on schizophrenia. These findings imply an underlying psychophysiological commonality between schizophrenia and schizotypal PD, and suggest that the latter does indeed reflect part of the schizophrenia-spectrum of disorders. Second, all of these psychophysiological measures tap some cognitive capacity, primarily related to attentional, inhibitory, and working-memory processes. They converge in suggesting specific deficits in such cognitive processes in individuals with schizotypal PD. The findings are not consistent, however, in regard to whether the impairments are related to positive or negative symptoms, and this issue needs to be further examined. It is possible, for example, that three-factor models of symptomatology in schizophrenia and schizotypal personality may provide clearer findings than the two-factor positive-negative model (Raine *et al.*, 1994). Moreover, the relationship to the other Cluster A PDs is still understudied.

CLUSTER B PERSONALITY DISORDERS

Cluster B includes the antisocial, borderline, histrionic, and narcissistic PDs. Antisocial PD is defined as a pattern of disregarding and violating the rights of others; borderline PD is defined as a pattern of unstable relationships, self-image, affect, and behaviour in the form of impulsivity; histrionic PD is defined as a pattern of excessive emotionality and seeking of attention; and narcissistic PD is defined as a pattern of grandiosity, need for admiration by others, and lack of empathy with others (American Psychiatric Association, 1994). These PDs seem to share symptoms that reflect dramatic, erratic, and highly emotional behaviours, although antisocial PD may also be associated with a lack of emotionality.

Of this cluster, antisocial PD has been most extensively studied in relation to psychophysiology, especially in regard to heart rate (HR), skin conductance (SC), and electroencephalogram (EEG) as a reflection of underarousal (see Chapter 7 in Raine, 1993 for a comprehensive review). As such, this will be the focus of the following review. It should be noted, however, that the majority of these studies do not use DSM criteria for measurement of PD, but instead use measures of psychopathy or repetitive antisocial behaviour. Thus, though obviously related, the exact nature of the findings in regard to clinically diagnosed antisocial PD is blurred. There has also been some limited psychophysiological research on borderline PD and one known psychophysiological study of narcissism, and this information will be included as well.

HR Studies and Antisocial Behaviour

HR reflects both sympathetic and parasympathetic nervous system activity and can be measured both tonically (i.e., beats per

minute at rest) or phasically (i.e., change in response to a stimulus). Accelerations in HR to a stimulus are thought to reflect sensory rejection or 'tuning out' of noxious environmental events, while decelerations are thought to reflect sensory intake or an environmental openness (Lacey and Lacey, 1974). Emotionally, HR has been associated with the experience of anxiety. As such, high tonic HR is thought to reflect fear, while low tonic HR may reflect fearlessness.

Regarding studies on tonic HR, one of the best-replicated findings to date is that of reduced resting HR in antisocial individuals. In his review of this topic, Raine (1993) noted that of 14 relevant studies, there were no failures to replicate the finding of reduced resting HR in the antisocial groups. Low HR is a robust marker independent of cultural context, with the relationship having been established in the UK (e.g., Farrington, 1987), Germany (Schmeck and Poustka, 1993), New Zealand (Moffitt and Caspi, 2001), the USA (e.g., Rogeness *et al.*, 1990), Mauritius (Raine *et al.*, 1997b), and Canada (Mezzacappa *et al.*, 1997). It is also diagnostically specific (i.e., it is not found in other disorders), and multiple confounds have been ruled out (Raine *et al.*, 1997b).

All of these studies used child or adolescent samples, but consistent with this finding, low HR recently has also been associated with self-reported aggression in uninstitutionalized young adults (Scarpa *et al.*, 2000). In addition, 21 adult individuals from the community with a diagnosis of antisocial PD were found to have low HR during a social stressor (Raine *et al.*, 2000). However, this effect seems specific to antisocial behaviour and personality in general rather than psychopathic personality in particular. Reviews by Hare (1970; 1975; 1978) revealed no successes and at least 15 failures to obtain low resting HR in institutionalized, psychopathic criminals.

Low resting HR has recently been found to characterize life-course persistent offenders (Moffitt and Caspi, 2001), as well as those with diagnoses in institutionalized psychopathy, indicating that low HR is related to a pervasive pattern of severe rule violations. It also characterizes milder forms of antisocial and aggressive behaviour in children and adolescents that preface more serious criminal violations later in life. For example, in one of the few prospective studies examining this issue, psychophysiological measures were obtained at age 15 years in an unselected sample of male students, and government records were obtained 9 years later to measure any criminal violations. Only relatively serious offences were registered, ranging from theft to wounding, with the most common offence being burglary. By this criterion, 17 of the 101 subjects were found to have a criminal record. These 17 criminals were found to have significantly lower resting HR than the non-criminal controls, indicating reduced cardiovascular arousal as measured 9 years earlier. Low HR at age 3 years is also predictive of aggressive behaviour at age 11 years in both males and females (Raine *et al.*, 1997b). Reduced HR may reflect autonomic underarousal, as suggested by Raine *et al.* (1990a), or, alternatively, fearlessness in novel situations (Kagan, 1989; Venables, 1987), which theoretically could predispose a child to early social transgressions that cycle into later serious antisocial behaviour.

Regarding studies on phasic HR changes, the literature is less extensive, but suggests that psychopathic criminals exhibit anticipatory HR acceleration prior to an aversive event. In general, the findings of early studies indicated that psychopaths gave significantly larger acceleratory HR responses in anticipation of a signalled aversive stimulus such as a loud noise or electric shock, followed by reduced SC responses to the aversive stimulus itself (Hare, 1982; Hare and Craigen, 1974; Hare *et al.*, 1978). Hare (1978) interpreted these findings to suggest that psychopathic individuals have a very proficient active coping mechanism that allows them to 'tune out' aversive events. Although interesting, there has been very little further research on this phenomenon. Again, the relationship has not been studied specifically in relationship to antisocial PD, but it would be predicted that these individuals may engage in similar sensory rejection of aversive events. In terms of theories of socialization, this pattern may lead to poor conditioning in response to cues of punishment and thus decreased learning of appropriate social behaviour (Eysenck, 1977).

SC Studies and Antisocial Behaviour

Besides measuring SC phasically, as discussed above in the description of the SCOR, SC can also be measured tonically or in a resting state. In this regard, SC is measured in terms of resting level (SCL) or number of nonspecific SC fluctuations (NSF). NSFs are changes in SC that look like orienting responses, but do not occur in response to a known stimulus. Both SCL and NSF are thought to reflect some baseline level of physiological sympathetic arousal, and thus have often been associated with fear emotions in the fight/flight response.

Recent reviews of SC studies (Raine, 1993; Scarpa and Raine, 1997) indicate that

1. There is some evidence for SC underarousal in antisocial individuals, particularly with respect to nonviolent and non-impulsive forms of crime.
2. SCOR deficits seem specific to antisocial individuals with concomitant schizotypal personality features.
3. Prior findings up to 1978 of reduced SC responsivity to aversive stimuli in psychopaths generally have not been observed in more recent studies, either in psychopathic or non-psychopathic antisocial populations.
4. The strongest findings lie with respect to reduced SC classical conditioning in antisocial populations.

These findings are summarized below.

With regard to SC underarousal, both SCL and NSFs have been found to be reduced in antisocial groups in a number of studies, though this has not been entirely consistent. As with HR, the findings are primarily in uninstitutionalized subjects with mild forms of aggressive or other antisocial behaviour. Again, however, in the prospective study by Raine *et al.* (1990a), it was found that a reduced number of NSFs at age 15 years predicted criminal behaviour 9 years later. Raine and colleagues suggested that this pattern, along with low resting HR, reflected autonomic underarousal in criminals-to-be. In an early review of the literature on psychopathy, Hare (1978) concluded that these individuals are characterized by reduced SCL, but not NSFs. Thus, it is possible that reduced SC arousal is also related to antisocial PD in adulthood. This has recently been confirmed in a study showing that individuals with antisocial PD show reduced SC activity during a social stressor (Raine *et al.*, 2000).

Regarding SCORs, Hare (1978) had concluded that the research to that date showed reduced SC responses to aversive, but not neutral tones (i.e., a reduced defensive response, but no difference in orienting response). This pattern of findings, however, has not been consistently replicated in research conducted after that review. Nevertheless, deficits in SCOR have been consistently observed in individuals who display both antisocial behaviour and features of schizotypal PD. For example, antisocial adolescents with schizotypal features had significantly lower SCORs than those with only schizotypal features (Raine and Venables, 1984). In his review, Raine (1993) also noted that, with the exception of one study, reduced frequency of SCORs was found only in studies where antisocial behaviour was combined with schizotypal or schizoid characteristics. Thus, it seems that SCOR deficits may be specific to schizotypal criminals. Since the number of SCOR responses may be related to frontal lobe functioning (Raine *et al.*, 1991), Raine interpreted these results as possibly reflecting frontal dysfunction in this particular subgroup of antisocial individuals. Further support for interpreting reduced SC activity in terms of prefrontal deficits

comes from a recent study showing that individuals with antisocial PD have both reduced prefrontal grey matter and reduced SC activity (Raine *et al.*, 2000). Furthermore, when antisocials were divided into those with and those without reduced prefrontal grey, it was the subgroup with prefrontal grey deficits who showed SC deficits compared to those without prefrontal deficits.

Perhaps the strongest findings for SC activity lie with respect to reduced classical conditioning in antisocial populations. Classical conditioning involves learning that an initially neutral event (i.e., a conditioned stimulus [CS]), when closely followed in time by an aversive event (i.e., an unconditioned stimulus [UCS]), will develop the properties of this UCS. Eysenck (1977) argued that the socialization process and development of a 'conscience' stems from a set of classically conditioned negative emotional responses to situations that have previously led to punishment. In this way, socialized individuals develop a feeling of uneasiness at even contemplating antisocial behaviour, presumably because such thoughts elicit representations of punishment earlier in life. Furthermore, according to Eysenck's theory, arousal levels are related to conditionability, such that low levels of arousal predispose to poor conditionability and high levels to good conditionability.

The central idea in Eysenck's theory is that antisocials are characterized by poor classical conditioning. Classical conditioning has frequently been assessed with SC: a neutral tone (CS) is presented to the subject, followed a few seconds later by either a loud tone or an electric shock (UCS). The key measure is the size of the SCR elicited by the CS after a number of CS-UCS pairings. In a review by Hare (1978), 13 out of 14 studies reported significantly poorer SC conditioning in antisocial populations. In a review of studies since 1978 by Raine (1993), all six studies showed some evidence of significantly poorer SC conditioning in antisocials, including psychopathic gamblers, other psychopaths, conduct-disordered children from high social-class backgrounds, and criminals from good homes. These results are also consistent with findings of reduced SC arousal in antisocial populations, as presented above.

EEG, ERPs, and Antisocial Behaviour

The EEG reflects the electrical activity of the brain recorded from electrodes placed at different locations on the scalp according to the standardized international 10–20 system. The EEG can be broken down into different frequency components, most commonly delta (0–4 Hz), theta (4–8 Hz), alpha (8–12 Hz), and beta (13–30 Hz). Alpha and beta are also often subdivided into slow and fast components. The EEG can be either clinically scored by observing the chart record to detect excessive theta or slow-wave activity, or subjected to a more quantitative computerized analysis, which more objectively delineates the EEG into different components.

EEG frequency has been aligned with a continuum of consciousness, with delta associated with sleep, theta associated with drowsiness and low levels of alertness, alpha associated with relaxed wakefulness, and beta associated with alertness and vigilance. As such, individuals with a predominance of theta or slow alpha activity would be viewed as having relatively reduced levels of cortical arousal, while those with relatively more fast alpha and beta activity would be viewed as relatively more aroused.

In a review by Mednick *et al.* (1982), the authors concluded that there is a high prevalence (25–50%) of EEG abnormalities in violent criminals, especially recidivistic offenders, compared with the 10–15% normally found in the general population. Volavka (1987) and Milstein (1988) drew similar conclusions for crime in general and violent crime in particular. Reviews of the EEG literature on psychopathy are less consistent. Hare (1970) initially concluded that psychopaths are characterized by excessive slow-wave activity. Later reviews, however, concluded that the evidence of EEG abnormalities in psychopaths is inconsistent (Blackburn, 1983; Syndulko, 1978), with one study even showing the opposite pattern that primary psychopaths were *more* aroused than secondary (schizoid) psychopaths.

The ERP refers to averaged changes of electrical activity of the brain in response to specific stimuli. ERP responses typically follow a sequence of early, middle, and late components which are thought to reflect the psychological processes of environmental filtering, cortical augmenting, and attention, respectively. ERP studies of antisocial behaviour have primarily involved psychopathic populations, and a review of this literature (conceptually broken down into early, middle, and late latency studies) was presented by Raine (1989). The main conclusions of this review are findings of

1. long early latency brainstem averaged evoked responses, reflecting excessive environmental filtering and reduced arousal
2. increased middle latency ERP amplitudes to stimuli of increasing intensity, which has been linked to sensation seeking
3. enhanced late latency ERP P300 amplitudes to stimuli of interest, suggesting enhanced attention to stimulating events.

Raine suggested that these processes may be causally linked, such that individuals with chronically low levels of arousal (possibly caused by excessive filtering of stimuli) would seek out stimulating events (including risky situations) in order to increase their levels of arousal to more optimal levels. This stimulation-seeking may partly account for the enhanced attention shown to events of interest.

While the evidence is unclear in terms of antisocial PD, there is again some reason to believe that impaired EEG and ERPs may reflect an early risk of later criminal behaviour. As reflected in the prospective study by Raine *et al.* (1990a; 1990b), criminals had significantly more slow-frequency EEG theta activity and larger N100 ERPs to target stimuli, as measured nine years earlier, than non-criminals. These findings are consistent with notions of underarousal and enhanced early stimulus attention in criminals and psychopaths.

Psychophysiological Study of Borderline PD

There are only two known studies examining the psychophysiological correlates of borderline PD. In the first study, a group of female patients with borderline PD were compared to female controls with no psychopathology on emotional reactions to pleasant, neutral, and unpleasant slides as measured by self-report, HR, SC, and eye-blink startle response (Herpertz *et al.*, 1999). In the second study, a comparison group of patients with avoidant PD was added to the borderline PD and normal control groups (Herpertz *et al.*, 2000). It is unclear whether the same individuals were used in both studies to form the borderline PD and normal control groups. The eye-blink startle response measures the automatic blink response that occurs to a startling probe, and is typically magnified when viewing unpleasant stimuli, but diminished when viewing pleasant stimuli. On the basis of previous theories of borderline PD, the authors predicted heightened affective responsivity in the subjects with this diagnosis.

Contrary to predictions, the borderline PD and control groups did not differ in startle response or HR responsivity in both studies, and the borderline PD group exhibited significantly reduced SC responses to all three stimulus categories. Moreover, the borderline PD group reported less pleasant affect to pleasant and neutral stimuli and less arousal to neutral stimuli. Self-report ratings on impulsivity, sensation seeking, and aggressiveness also did not account for the findings of SC hyporesponsivity. The authors speculated that this finding of decreased electrodermal responsiveness instead reflected problems in attentional processing.

Psychophysiological Study of Narcissism

There is one known study relating psychophysiological variables to narcissism (Kelsey *et al.*, 2001). As with many of the other studies reviewed here, narcissism was measured by a dimensional scale in this study, and the diagnostic syndrome of narcissistic PD was not assessed. Nonetheless, this study provides an initial peek at the psychophysiology of the major features of this disorder, including egocentricity, grandiosity, arrogance, a need for admiration, and a lack of empathy.

In this study, 40 undergraduate men who scored high or low on the Narcissistic Personality Inventory were compared on measures of pre-ejection period (PEP), frequency of SC responses, and HR reactivity in anticipation of an aversive stimulus. PEP was included as a measure of beta-adrenergic cardiac reactivity, primarily reflecting sympathetic cardiac activity; SC was included as a measure of sympathetic activity; and HR was included as a measure of both sympathetic and parasympathetic influences. Because narcissism has been posited to be an underlying feature of psychopathy, the authors hypothesized reduced sympathetic activity overall and enhanced parasympathetic control of the heart.

The results indicated greater PEP shortening, HR deceleration, and SC response habituation in the high narcissism group in anticipation of the aversive stimulus. Consistent with one hypothesis, the cardiac deceleration was interpreted as reflecting parasympathetic dominance. Contrary to the other hypotheses, however, the PEP and SC results suggested a fractionation of the sympathetic response. Shortened PEP reflects heightened sympathetic reactivity, while reduced SC activity reflects reduced sympathetic activity. The authors interpreted these findings according to a model of arousal proposed by Pribram and McGuinness (1975), suggesting that low SC activity in narcissism reflects physiological underarousal, HR deceleration reflects internally generated attention and activity, and PEP reactivity reflects heightened effort during the processing of aversive information.

Summary

For antisocial, psychopathic personality, the psychophysiological results suggest several conclusions. First, psychophysiological underarousal may reflect an early predisposition to mild antisocial behaviour that cycles into more serious recidivistic crime later in life. Second, as suggested by poor SC classical conditioning and low tonic SC, psychopathic and antisocial personality may be characterized by poor passive avoidance learning, which would interfere with the ability to learn to avoid misbehaviour in response to the anticipation of punishment. Because SC and HR have been associated with anxiety and fear, it is conceivable that these findings, along with underarousal, may also reflect the callousness and unemotionality that is characteristic of the psychopathic personality. Parallel findings of reduced SC responsivity in borderline PD and in narcissism suggest that they instead may relate to behaviour that is characterized by impulsivity and risk-taking (common to both antisocial and borderline PD) or may reflect an attentional 'tuning out' of aversive environmental stimuli in order to manage negative affect or maintain self-esteem (common to both antisocial and narcissistic PD). Third, low resting HR is the best-replicated psychophysiological correlate of antisocial behaviour. Fourth, findings in antisocial personality using ERPs are consistent with the notions of both increased sensation seeking and focus on events of interest, a fact which could explain the increase in impulsivity and risky behaviour seen in this personality style. Lastly, findings suggest that antisocial individuals with schizotypal PD may reflect a special subgroup of criminality characterized by frontal lobe dysfunction which is reflected in SCOR hyporesponsivity. Further study is necessary to see how the above findings generalize to clinically diagnosed antisocial PD, and a clear need is present to study the psychophysiology of the other Cluster B PDs.

CLUSTER C PERSONALITY DISORDERS

Cluster C includes the avoidant, dependent, and obsessive-compulsive PDs. Avoidant PD is defined as a pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation; dependent PD is defined as a pattern of submissive and clinging behaviour related to a need be taken care of; and obsessive-compulsive PD is defined as a pattern of preoccupation with orderliness, perfectionism, and control (American Psychiatric Association, 1994). Each of these PDs has some association with underlying feelings of anxiety and internalizing behaviours. To the authors' knowledge, the only Cluster C PD that has been studied psychophysiologically is avoidant PD, which will begin the following section. Inhibited temperament in children, which includes shy and cautious behaviour, along with fear of novel or unfamiliar people and situations, is also discussed as a possible developmental precursor to avoidant PD. No studies are known that directly assess obsessive-compulsive PD in relation to psychophysiological measures, but the DSM-IV notes that many features of this PD overlap with 'type A' personality (e.g., hostility, competitiveness, and time urgency). Type A personality has been studied extensively in relation to cardiovascular disease risk. As such, a brief review of this literature is also provided.

Psychophysiological Studies of Avoidant PD

As described above, avoidant PD involves a pervasive pattern of social inhibition or avoidance of social situations that seems to revolve around feelings of being inadequate and fears of consequent criticism and rejection by others. According to DSM-IV, there appears to be a great deal of overlap between this PD and the Axis I disorder of social phobia, generalized type. As such, several studies have been conducted to assess for differences or similarities between social phobia with and without avoidant PD, and they do indeed suggest a distinction between these two forms of social phobia in terms of severity.

In general, studies which compare these subgroups of social phobia on measures of subjective and behavioural anxiety find greater reports of anxiety and behavioural impairment in those diagnosed with avoidant PD or the generalized subtype of social phobia (Herbert *et al.*, 1992; Holt *et al.*, 1992). If social phobia with avoidant PD indeed reflects a more severe form of social phobia, one would predict greater psychophysiological reactivity to fearful social situations in these individuals. There seems to be a discrepancy, however, between the subjective anxiety reported and the psychophysiological profile exhibited in this population. For example, one study compared groups with discrete social phobias, generalized social phobia with avoidant PD, and generalized social phobia without avoidant PD on HR recorded during an impromptu speech (Turner *et al.*, 1992). The results indicated no HR differences among these three groups. Similarly, two other studies showed no HR differences during a public-speaking task between socially phobic individuals with avoidant PD and normal controls, but those with a specific social phobia did show higher HR with the task (Heimberg *et al.*, 1990; Hofmann *et al.*, 1995). Interestingly, in these studies, the group with avoidant PD reported the greatest subjective anxiety and fear, although their HR responses did not differ from controls and were lower than the group without avoidant PD.

Overall, these findings indicate a discordance between the subjective and HR responses in socially phobic individuals with avoidant PD. Although the reason for this discordance is unknown, Hofmann *et al.* (1995) suggest several possibilities — that social phobias with avoidant PD have a less coherent cognitive fear structure, that other emotions may be blending with fear to attenuate HR responses, or that the tonic presence of fearful cognitions in avoidant PD may inhibit further processing of fearful material

because the feared event provides no new emotional information. A possibility that was not considered is that excessive tonic worry in avoidant PD may inhibit the information processing of feared stimuli because it simply serves as an attentional distraction, thus leading to reduced HR reactivity. Either of the latter two interpretations is supported by a study by Herpertz *et al.* (2000) in which eye-blink startle, HR, and SC responses to emotional stimuli were compared in groups with avoidant PD and borderline PD, or normal controls. Relevant to avoidant PD, the results showed increased startle magnitude relative to the borderline PD and control groups, but only at baseline (i.e., before the emotional stimuli were presented). No group differences were found for SC and HR responses. Since the eye-blink startle response is specifically sensitive to anxious/fearful mood, this finding suggests that individuals with avoidant PD may have a tonically high level of anxiety that interferes with ongoing information processing.

Psychophysiological Studies of Inhibited Temperament in Children

Behavioural inhibition in childhood reflects a temperamental style of avoidance in situations that are novel or unfamiliar. According to DSM-IV, avoidant PD is described as often starting in infancy or childhood with characteristics of shyness, isolation, and fear of strangers and new situations. Thus, inhibited temperament in children may reflect a developmental precursor to avoidant PD, although it is clear that not all children with such shyness will go on to develop the PD.

In a series of studies, Kagan and his colleagues examined children who were classified as either behaviourally inhibited or uninhibited at 21 months of age by their tendency consistently to withdraw or interact respectively across various experimental situations. At 21 months, inhibited relative to uninhibited children were found to have higher and more stable HR while looking at unfamiliar pictures and listening to unfamiliar sounds (Garcia-Coll *et al.*, 1984). These children were again examined at ages 31 months, and 4, 5.5, and 7.5 years. At every age, it was observed that the behavioural differences which originally led to the classification as inhibited or uninhibited at age 21 months were still maintained between the two groups, and the inhibited children showed higher and more stable HR to a series of cognitive procedures than the uninhibited children (Kagan *et al.*, 1984; Kagan *et al.*, 1988; Reznick *et al.*, 1986). The results were replicated on a second cohort of children who were tested at ages 2, 3.5, 5.5, and 7.5 years, suggesting a stability of inhibited/uninhibited temperament over time, with those classified as inhibited having higher HR at each age than those classified as uninhibited (Kagan, 1989; Kagan, *et al.*, 1987). Taken together, these results indicate that high HR is associated with increased behavioural inhibition.

Kagan (1989; 1994) has suggested that this heightened sympathetic reactivity in inhibited children stems from a lower threshold of excitability in limbic sites, particularly the amygdala and hypothalamus. If behavioural inhibition is thus reflected in increased sympathetic activity, other sympathetic measures should show similar group differences in inhibited individuals. Indeed, Kagan (1994) reports findings of increased sympathetic activity reflected in other measures such as salivary cortisol, urinary norepinephrine, and facial skin temperature. Furthermore, in a study of 3-year-old children, those who were inhibited exhibited heightened levels of both resting HR and SC relative to those who were uninhibited (Scarpa *et al.*, 1997), again providing support for the relationship between inhibition and physiological arousal through limbic activation.

If behavioural inhibition does developmentally precede avoidant PD in adulthood, similar sympathetic arousal and reactivity would be expected in adults with avoidant PD. As described in the preceding section, however, there is no evidence for increased sympathetic levels or responsivity in adults with avoidant PD. In fact, of the few studies examining psychophysiology of avoidant PD, all indicated similar levels and reactivity of HR and/or SC compared to normal controls (Herpertz *et al.*, 2000; Hofmann *et al.*, 1995; Turner *et al.*, 1992). It is possible, therefore, that inhibited temperament in children is not a childhood precursor of adulthood avoidant PD. Alternative explanations could also be that the physiological responses of inhibited children who grow up to develop avoidant PD differ from those who do not develop the disorder, or that their physiological responsivity changes as they grow into adulthood.

Psychophysiological Studies of Type A Personality

As originally described by Friedman and Rosenman (1959), the type A behaviour pattern is characterized by excessive competitiveness; impatience; hostility; overcommitment to work; and a loud, rapid, and pressured vocal style. This pattern has many behavioural similarities to the symptoms of obsessive-compulsive PD, suggesting a possible overlap. We are aware of no psychophysiological studies of obsessive-compulsive PD; however, psychophysiological reactivity in relation to type A personality has been extensively studied (see Houston, 1983 and Harbin, 1989 for reviews). Although other measures have been included, blood pressure (BP) and HR have been the foci of these investigations due to the link between type A behaviour and coronary heart disease (e.g., Cooper *et al.*, 1981). A brief summary of this literature follows.

Results from reviews have generally concluded that, relative to type B individuals (i.e., people who are easy-going, patient, and soft-spoken), type A individuals show greater BP and HR responses to stressors (Houston, 1983; Harbin, 1989). In a re-examination of the same data presented by Houston (1983), Holmes (1983) emphasized that the most consistent findings were with respect to systolic BP and that this effect was of small magnitude. That is, 13 out of 20 experiments revealed reliable differences in systolic BP, while only 4 of 18 experiments revealed reliable diastolic BP effects and only 6 of 24 experiments revealed reliable HR effects. Moreover, the median group difference in systolic BP was 6 mmHg, a difference that is not typically considered to be physiologically meaningful.

Despite some inconsistency in findings and the suggestion that this relationship is weak to moderate at best, the quantitative review by Harbin (1989) still showed an overall effect for increased cardiovascular activity in those with the type A behaviour pattern. It appears that more consistent findings are obtained when the individual is faced with a stressor task that is challenging, where there is an intermediate chance of failure, where there is moderate external incentive to do well, or where there is an interpersonal encounter that is annoying or harassing to the subject (Houston, 1992). Moreover, the most reliable BP responses have been found when type A behaviour is measured according to a structured interview that assesses behavioural qualities, rather than by self-report measures. Finally, it may be that not all aspects of type A personality are equally related to physiological reactivity. Hostility, for example, has been identified as the most powerful type A characteristic to predict coronary heart disease (Dembroski and Costa, 1987), and it has been associated with increased cardiovascular reactivity in response to stress (see Smith and Leon [1992] for a summary).

As summarized by Smith and Leon (1992), several psychological explanations have been posited for the increased cardiovascular reactivity found in type A personality. In general, these explanations imply that the stressor tasks activate a relevant type A characteristic that leads these individuals to increase their efforts, and this is associated with increased sympathetic nervous system activity. Such a behavioural response on the part of the person with type A personality may be due to excessively high standards for success,

perceptions of threat of loss of control over the environment or other people, or a high level of self-involvement. It is also possible that these individuals simply create more frequent stressful situations in their lives, the net result of which is more frequent physiological reactivity and consequent increased risk of coronary heart disease.

Summary

None of the Cluster C PDs have been studied extensively enough to form substantive conclusions in relation to psychophysiological variables. Nonetheless, studies on associated features, such as inhibited temperament and the type A behaviour pattern, as well as the few studies of avoidant PD, suggest some directions. Sympathetic reactivity is implicated in both inhibited temperament and type A personality. However, it is more pervasive in relation to behavioural inhibition, and seems to be primarily associated with systolic BP in relation to type A behaviour. Moreover, no studies found HR differences between avoidant PD, in particular, and normal control groups. Thus, it appears that inhibited temperamental style, avoidant PD, and type A personality (which is the closest personality analogue to obsessive-compulsive PD) are distinct constructs with distinct psychophysiological profiles. As such, one suggested direction for further research in this area includes the study of whether behavioural inhibition does indeed serve as a developmental precursor to adult avoidant PD, and, if so, why is there a change in psychophysiological response over time? Another suggested direction is to examine whether the cardiovascular findings in type A personality generalize to obsessive-compulsive PD. Lastly, more work overall needs to be done on the psychophysiology of all of the Cluster C PDs.

CONCLUSIONS

As can be seen from the above review, the psychophysiological findings with respect to PD are quite diverse. While this might be expected given the diverse characteristics of each of the 10 PDs described in the DSM-IV, it is also notable given the high degree of overlap in PD symptomatology and the resulting high PD comorbidity. As such, this psychophysiological research provides some insight into the differences that may underlie the various PDs. Caution, however, is warranted due to the fact that there has been little work on the diagnostic syndromes of *any* of the PDs. That is, what work has been done typically has focused on dimensional characteristics, specific symptoms, or associated features of the disorders rather than the clinical diagnosis as a syndrome. Further research is definitely needed in this area, but despite this major limitation, the following conclusions are suggested.

First, the psychophysiological findings generally indicate cognitive abnormalities in Cluster A disorders, especially schizotypal PD, that mirror findings in schizophrenia and thus suggest a common underlying biological marker. Second, the findings generally indicate arousal and cognitive learning deficits as well as emotional deficits in Cluster B disorders, which particularly reflect impulsive, antisocial behavioural styles. Third, primarily emotional contributions are suggested in relation to Cluster C PDs, particularly to fear in avoidant PD and to hostility/anger in obsessive-compulsive PD. These findings suggest that the behavioural similarities within PD clusters and differences across clusters may indeed be reflected in corresponding psychophysiological profiles.

It is also noted, however, that certain paradigms for measuring psychophysiology do not cut across the study of PDs. SC conditioning, for example, has in the past been extensively studied in relation to antisocial behaviour, but not in the other PDs. Similarly, SPEM has been studied in relation to schizotypal PD, but not specifically in the other PDs. As such, psychophysiology still has much to offer in terms of elucidating the cognitive and emotional psychology of PDs. This review establishes a clear need for further work on the psychophysiology of PDs.

Finally, probably the most striking and consistent finding in the field of the psychophysiology of PDs is the low autonomic arousal of antisocial behaviour and personality. Furthermore, low autonomic arousal is diagnostically specific to antisocial personality within the diagnostic subfield of PDs in that no other PD is characterized by low autonomic arousal. In particular, low resting HR is the best-replicated biological correlate of antisocial behaviour in community samples. A challenge for future research lies in placing this finding, linked to impairments of the prefrontal cortex, within a wider, neurophysiological, neuropsychological, and psychosocial context. A similar challenge exists with respect to the larger literature on the psychophysiology of PDs overall.

Neuropsychology of Personality Disorders

Martina M. Voglmaier

INTRODUCTION

Intuitively, one might expect individuals with personality disorders to have neuropsychological deficits. The hypersensitivity of the paranoid and avoidant personalities, the rigidity of the obsessive-compulsive personality, the perceptual distortions of the schizotypal personality, and the limited social and emotional responsiveness of the schizoid personality suggest areas of deficit fascinating to the researcher interested in brain–behaviour relationships. Yet the study of neuropsychological functioning in personality disorders is in its infancy, primarily because of methodological problems associated with studying these disorders. The focus of this chapter is a general review of studies of clinical neuropsychological test performance in DSM-IV personality disorders as well as a description of the methodological problems associated with their study. Information processing, psychophysiological, and structural anatomical studies are dealt with elsewhere in this text.

GENERAL METHODOLOGICAL CONSIDERATIONS

Before reviewing empirical studies of neuropsychological test performance in personality-disordered individuals, a number of general methodological concerns must be addressed. Typically, in such studies, personality disorders are diagnosed by structured clinical interview, and subjects are administered a battery of neuropsychological tests measuring one or more cognitive domains, such as attention, memory, language, visuospatial perception, executive functions, and motor skills. Test performance of a group of individuals with a personality disorder of interest is then compared to that of one or more groups of subjects with either a different personality disorder, a mixed group of 'other' personality disorders, another psychiatric disorder, or no psychiatric disorder.

Research in this area is fraught with methodological difficulties. Samples differing in selection criteria, inpatient status, medications, and gender may result in inconsistent findings. Moreover, diagnosing personality disorders is a decidedly unclear science (Strack and Lorr, 1997). The clinical definition of character traits, severity, and impact on functional ability can be subjective, and whether a personality disorder can be diagnosed by self-report to an examiner in a preset period of time has been questioned (Oldham and Skodol, 1992). The DSM-IV requires a specific number of character traits to meet clinical diagnostic criteria for a personality disorder, and some studies include individuals who have fewer than the cut-off number of traits, such as those defined as having a 'probable' disorder.

Another concern is determining the specificity of any cognitive deficits given the co-occurrence of the 10 personality disorders with each other (Stuart *et al.*, 1998), the co-morbidity of personality disorders with Axis I disorders (Oldham and Skodol, 1992), and the possibility of misdiagnosis of behavioural traits associated with neurological disorders, such as head trauma, substance abuse, and temporolimbic epilepsy (Devinsky and Najjar, 1999). For example, increased rates of depression have been associated with a number of personality disorders (Table XXVI-5.1). Even with detailed historical and diagnostic information, it could be difficult to determine whether cognitive deficits evinced by a group of subjects are related to the personality disorder under examination, to concurrent symptoms of depression, to cognitive vulnerabilities related to the predisposition to depression, or to treatments for depression. A related concern is that individuals with personality disorders may be vulnerable to neuropsychological dysfunction from secondary sources such as precursors or lifestyle behaviours associated with maladaptive personality traits. For example, risk-taking behaviours, substance use, impulsivity, and aggression in antisocial personality disorder (ASPD) may increase the risk of head trauma in this population, and childhood trauma (physical, emotional, or sexual) may predispose an individual to head injury, borderline personality traits, symptoms of post-traumatic stress, and dissociative disorders (Paris, 1997).

The battery of neuropsychological tests employed in research studies is also of importance. Often, only a few tests or cognitive domains are examined, resulting in a limited view of cognitive functioning. For example, if only executive-function tasks are employed, it cannot be determined whether any weaknesses in this domain are due to a generalized deficit associated with having a psychiatric illness, or to a domain-specific deficit associated with the personality disorder being examined. Finally, there is some evidence for sex differences in cognitive functioning in some personality disorders (Voglmaier *et al.*, submitted). Grouping males and females together in such studies may result in inconsistent findings.

DSM-IV CLUSTER A: THE ODD/ECCENTRIC PERSONALITY DISORDERS

General Findings

Schizotypal, paranoid, and schizoid personality disorders make up this cluster of odd and eccentric personalities. By far, the most research on cognitive functioning in this cluster has been on schizotypal personality disorder (SPD). SPD is characterized by oddities in appearance, perception, and behaviour, as well as marked discomfort in close relationships. On the hypothesis that this disorder is biologically related to schizophrenia, studies have focused on cognitive domains known to be impaired in schizophrenic subjects, that is, abstraction, attention, language, and verbal learning and memory (e.g., Gur *et al.*, 1991; Saykin *et al.*, 1991).

Table XXVI-5.1 Methodological considerations in the study of personality disorders

	Axis I	Axis II	Precursors	Lifestyle
Cluster A				
Schizotypal (SPD)	Depression, dysthymia, social phobia, agoraphobia	Cluster A BPD, OCP	—	—
Schizoid (SZD)	Depression, substance abuse	Cluster A APD	—	—
Paranoid (PPD)	Depression, delusional disorder, agoraphobia, bulimia	Cluster A	—	—
Cluster B				
Borderline (BPD)	Depression, bipolar, PTSD, substance abuse, dissociative disorders	Cluster B SPD, OCP, DPD	Physical/sexual abuse, emotional trauma, head trauma	Reduced impulse control, substance abuse
Antisocial (ASPD)	Substance abuse, depression, anxiety	Cluster B ADHD, OCP	Conduct disorder	Reduced impulse control, increased risk taking, violence, substance abuse
Histrionic (HPD)	Depression	Cluster B	—	—
Narcissistic (NPD)	Depression	Cluster B	—	—
Cluster C				
Avoidant (APD)	Depression, anxiety disorders, social phobia, GAD, panic disorder	Cluster C SZD	—	—
Dependent (DPD)	Depression, anxiety disorders	Cluster C	—	—
Obsessive-compulsive (OCP)	Anxiety disorders, bulimia	Cluster C SPD, BPD, ASPD	—	—

PTSD [post-traumatic stress disorder], GAD [generalized anxiety disorder], and ADHD [attention deficit hyperactivity disorder].

There have been relatively few comprehensive studies of neuropsychological function in individuals who meet full DSM diagnostic criteria for SPD. Generally, the extant studies have shown deficits in sustained attention (Roitman *et al.*, 1997), working memory (Farmer *et al.*, 2000; Roitman *et al.*, 2000), abstract reasoning (Voglmaier *et al.*, 1997), and verbal learning (Voglmaier *et al.*, 1997; Bergman *et al.*, 1998) that are similar to but less severe than those evident in schizophrenic subjects (Table XXVI-5.2). These findings have been hypothesized to reflect involvement of similar frontal, left hemisphere, and temporal-limbic brain areas.

My colleagues and I examined the neuropsychological profile of SPD (Voglmaier *et al.*, 1997). We studied a wide array of cognitive functions in 10 right-handed men with DSM-IIIR-defined SPD and 10 matched non-psychiatric comparison subjects (Voglmaier *et al.*, 1997). All subjects were unmedicated and were carefully screened for Axis I disorders, neurological disorders, and substance abuse. Cognitive domains included abstraction, verbal and spatial intelligence, language, learning, memory, attention, and motor skills. Analyses covaried the effects of general ability (IQ) and symptoms of depression, variables that were found to differ between subject groups. The resultant profile revealed a mild, general decrement in most cognitive domains, as well as more severe dysfunction in verbal learning and abstract reasoning. Specifically, SPD subjects showed significant decrements in performance on the California Verbal Learning Test (CVLT) (Delis *et al.*, 1987), a word-list learning measure which requires semantic organization for efficient performance, and on the Wisconsin Card Sort Test (WCST) (Heaton, 1981), a measure requiring concept formation, abstraction, and mental flexibility. The CVLT involves five presentations of a list of 16 'shopping items', which can be grouped into four semantic clusters (fruits, spices, clothing, and tools) to enhance learning. The SPD subjects learned significantly fewer words over the five trials, and used the clustering strategy less frequently than comparison subjects. There was no evidence of increased rate of forgetting. On the WCST, subjects were asked to sort cards by category (number of items, shape, or colour) and shift the categorical set based on limited feedback from the examiner. SPD subjects formed significantly fewer categories and made more perseverative responses than control subjects. Overall performance by male SPD subjects was similar to but less severe than in schizophrenic subjects. Females with SPD were found to have less severe cognitive deficits than males (Voglmaier *et al.*, submitted).

Questions were raised about the source of the apparent deficit in verbal learning in SPD. Because the CVLT requires intact language, verbal learning, and memory, and semantic organization skills for efficient performance, it was unclear to us whether the SPD group's reduced performance on this task reflected a primary deficit in language processes, learning, or concept formation and organization. For further examination of the verbal learning deficit in SPD, we evaluated selected components of verbal and non-verbal attention; learning and memory, including short-term retention (trigram versus pattern recall); supraspan learning (serial digit learning versus spatial block span); persistence (verbal versus design fluency); learning (CVLT versus Continuous Visual Memory Test [Trahan and Larrabee, 1988]); and memory retention (WMS-R Logical Memory versus Visual Reproductions [Wechsler, 1987]). In addition to a mild generalized deficit, 16 carefully screened and matched male SPD subjects revealed deficits on verbal measures of persistence, short-term retention, and learning (Voglmaier *et al.*, 2000). Non-verbal analogues of these tests, supraspan learning, and long-term retention of newly learned information were relatively preserved. The results suggested that the verbal learning deficit apparent on the CVLT is at least in part the result of a deficit in the early processing (encoding) stages of verbal learning, and not solely due to a primary deficit in organization or conceptualization.

Language functioning in SPD remains unclear. Standard neuropsychological tests of language ability have not revealed specific deficits in this domain, such as naming, repetition, comprehension, reading, and spelling (Voglmaier *et al.*, 1997). Reduced WAIS-R (Wechsler, 1981a) Vocabulary subtest performance was found in our group of 16 male SPD subjects, and we speculated that a primary deficit in verbal learning could account for such performance (Voglmaier *et al.*, 2000). Based on language samples, we have documented an increased amount of thought disorder in male SPD subjects that is qualitatively similar to that of schizophrenics

Table XXVI-5.2 Neuropsychological test performance in personality disorders

	General ability/IQ	Attention/working memory	Learning	Memory	Language	Visuoperception/ construction	Abstraction/executive functions	Sensory and motor skills

(+) Deficits evident in at least one study; (−) no deficits evident in at least one study; BDAE indicates Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 1983); BNT, Boston Naming Test (Kaplan *et al.*, 1983); COWAT, Controlled Oral Word Association Test; CPT-IP, Continuous Performance Test, Independent Pairs; CVLT, California Verbal Learning Test (Delis *et al.*, 1987); CVMT, Continuous Visual Memory Test (Trahan and Larrabee, 1988); HRB, Halstead Reitan Battery (Reitan and Wolfson, 1985); MAE, Multilingual Aphasia Examination (Benton and Hamsher, 1976); WCST, Wisconsin Card Sorting Test (Heaton, 1981); WAIS-R, Wechsler Adult Intelligence Scale-Revised (Wechsler, 1981b), WRAT-R, Wide Range Achievement Test-Revised (Jastak and Wilkinson, 1984); WMS-R, Wechsler Memory Scale-Revised (Wechsler, 1987); [a]Burgess (1992), mixed Cluster B 'dramatic' personality disorder.

(Voglmaier *et al.*, 1996). Overall, neuropsychological test results from our laboratory imply involvement of frontal and left temporal brain structures and suggest a specific deficit in the early processing stages of verbal learning in SPD. The results support hypotheses of a dysfunctional semantic language network in schizophrenia (Spitzer *et al.*, 1993). Dysfunction, inefficiency, or reduced inhibition of such a system could result in verbal learning deficits, deficient facilitation by semantic context, magical thinking, and thought disorder.

The paranoid and schizoid personality disorders are also thought to have some biological connection to schizophrenia, but neuropsychological test performance has not been studied independently in these groups. It is noteworthy that schizoid personality traits (e.g., limited social and emotional responses) are similar to those seen in social-emotional or 'right-hemisphere' learning disabilities (Weintraub and Mesulam, 1983), making this disorder worth a detailed study of neuropsychological test performance.

Methodological Concerns

There are several additional methodological concerns that are specific to the study of SPD. First, there is considerable overlap between SPD and major depression and borderline personality disorder (Siever, 1992) (Table XXVI-5.1), disorders that may be associated with cognitive deficits. Second, many studies have assessed neuropsychological function in populations thought to be at higher risk of developing schizophrenia, in an attempt to elucidate markers of vulnerability to the disease. Studying these groups is considered preferable because they do not include the confounding factors of chronic institutionalization and medications. These high-risk samples include the non-psychotic first-degree relatives of schizophrenic probands, and the so-called 'psychosis-prone' populations, non-clinical groups who have abnormally high scores on one or more measures thought to assess schizotypal symptoms (such as the Chapman scales [Chapman and Chapman, 1985]). These samples are often described as 'schizotypal' or their results as indicative of 'schizotypy'. However, it is not clear how such groups are related to clinically defined SPD or how many (if any) of the DSM-IV diagnostic criteria are actually met by each subject. Although the results of these studies also suggest similar deficits in information processing (Chen *et al.*, 1998), abstraction (e.g., Tallent and Gooding, 1999), and left-hemisphere function (Overby, 1992), it is possible that relatives of schizophrenics and 'psychosis-prone' samples differ from SPD in phenomenology as well as severity.

A related concern is the possibility of heterogeneous subgroups among individuals who meet diagnostic criteria for SPD. Those with a family history of schizophrenia have been found to have more 'negative' symptoms (e.g., constricted affect, anhedonia, and no close friends) than those without such a family history. Moreover, some SPD samples may share a genetic link with mood disorders. These 'familial' and 'clinical' samples may represent different SPD subtypes (Bergman *et al.*, 2000) with differing neuropsychological test profiles. Finally, it is unclear how subject groups should be matched in terms of general ability. As in schizophenic subjects, because education, IQ and verbal skills may be reduced in SPD groups as a result of the disorder, matching patient and control groups on these indices may artificially dilute the extent of any deficits (e.g., the 'matching fallacy' [Meehl, 1970], matching high-functioning patients with low-functioning controls). In our laboratory, we have found that matching groups on age, sex, handedness, parental socio-economic status, and non-verbal general ability (e.g., the WAIS-R Block Design subtest) yields the most consistent results without affecting the cognitive domains of particular interest.

DSM-IV CLUSTER B: THE DRAMATIC PERSONALITY DISORDERS

General Findings

This cluster includes the borderline, histrionic, narcissistic, and antisocial personality disorders. Burgess (1992) studied neuropsychological test performance in a mixed group of 37 subjects who met diagnostic criteria for at least one of the 'dramatic' personality disorders and 40 non-psychiatric control subjects. Of the 37 patients, 30 patients had borderline personality disorder and seven had another Cluster B disorder. On a 16-item neuropsychiatric scale, the dramatic patient group showed relative deficits on tasks requiring multistep or multielement associative procedures (Table XXVI-5.2).

Within Cluster B, only the borderline and antisocial personalities have been studied independently with regard to neuropsychological function. In patients with borderline personality disorder (BPD), the results of cognitive studies have been inconsistent, perhaps due to heterogeneous samples. Some studies have found deficits on memory and executive tasks, suggesting that the behaviours and interpersonal problems associated with BPD result from deficits in attention, impulsivity, memory, and processing complex information (e.g., O'Leary *et al.*, 1991), and have hypothesized frontotemporal brain involvement in at least a subgroup of patients (Swirsky-Sacchetti *et al.*, 1993). Performance deficits may be exacerbated by stress or increased emotional arousal (Farrell and Shaw, 1994). Stein *et al.* (1993) found increased left-sided neurological soft signs in a group of 28 patients with 'impulsive' personality disorders: all 28 subjects met criteria for BPD, and 10 subjects also met criteria for antisocial personality disorder (ASPD). Increased soft signs correlated with reduced performance on the Trail-Making Test and Matching Familiar Figures Test, and the authors suggested the possibility of right-hemisphere and/or frontal network dysfunction. However, these results are difficult to interpret given the heterogeneity of the patient group, which included males, females, inpatients, and outpatients. Eight subjects met current diagnostic criteria for major depression and 25 subjects had histories of substance abuse.

van Reekum *et al.* (1996) found evidence of a high proportion of cerebral insults among borderline patients (including developmentally based and acquired insults) and a neuropsychological profile reminiscent of traumatic brain injured patients. It is unclear whether borderline samples in earlier studies had been carefully screened for such insults. A recent study of females that carefully controlled for history of neurological insult and symptoms of depression found essentially no deficits on neuropsychological tests of frontal executive and memory tests. Sprock *et al.* (2000) studied a group of 18 women with BPD, and compared them to female depressed patients and a non-psychiatric control group. They employed a battery of tests thought to tap frontal-executive (e.g., the Trail-Making Test, Part B; Stroop Color-Word Test; Porteus Mazes; and Rey-Osterreith Complex Figure) and memory functions (e.g., Rey-Osterreith Figure immediate and delayed memory, Wechsler Memory Scale-Revised Logical Memory, Figural Memory, Digit Span subtests, Story Recall Task, and Verbal Recall with Interference). There were essentially no differences in test performance between the BPD and control groups, and only the depressed patients showed evidence of cognitive dysfunction. Similarly, in a study that revealed abnormal hippocampal volumes in females with BPD and history of trauma, neuropsychological performance was related to symptoms of depression, but not to hippocampal volume (Driessen *et al.*, 2000). The results suggest there may be considerable heterogeneity in the cognitive functioning of BPD patients. Moreover, evidence of abnormal neuropsychological test performance may be confounded by affective state and/or history of cerebral insult.

The neuropsychology of antisocial personality disorder (ASPD) is also unclear. The results of studies have been conflicting (Table XXVI-5.2), and this may also be related to sampling differences and comorbid disorders. Executive dysfunction has been associated with antisocial behaviour in adolescent females with conduct disorder (Giancola *et al.*, 1998). In another study, deficient language skills, but not executive functions, were associated with conduct disorder in a mixed group of male and female adolescents (Dery *et al.*, 1999). Some studies have indicated that ASPD may be characterized by deficits in self-modulation of executive functions and verbal skills, suggesting that frontal and left-hemisphere abnormalities may be related to impulsive aggression (Miller, 1987). A recent meta-analytical review of 39 studies supported the hypothesis that executive-function deficits (e.g., planning, organization, goal-formulation and follow-through, self-monitoring, and problem-solving) are associated with antisocial personality (Morgan and Lilienfeld, 2000), implying involvement of frontal networks and dorsolateral/prefrontal brain structures. In a community sample of adults with ASPD that were screened for neurological disorders, deficits were evident on measures sensitive to orbitofrontal function (e.g., object alternation and spatial working memory), but not on standard measures of frontal-executive function (Dinn and Harris, 2000).

Methodological Concerns

The study of neuropsychological function in BPD is complicated by the high incidence of developmental and/or acquired brain insults (van Reekum *et al.*, 1996), and comorbid disorders such as depression, bipolar illness (Atre-Vaidya and Hussain, 1999), post-traumatic stress, and substance use (McGlashan *et al.*, 2000). Many studies mix male and female subjects, and often include medicated and/or hospitalized patients or those with current mood disorders and substance abuse. Similarly, the study of ASPD is confounded by overlap with substance abuse, attention deficits, depression, and anxiety (see Widiger *et al.*, 1993). Moreover, the aggressive, violent, and impulsive lifestyle of these patients may also increase their risk of head trauma.

DSM-IV CLUSTER C: THE ANXIOUS PERSONALITY DISORDERS

This cluster comprises the avoidant, dependent, and obsessive-compulsive personality types. There has been little research on these disorders, which are often comorbid with anxiety disorders (Alpert *et al.*, 1997; Paris, 1998). Neuropsychological function has not been studied directly in this cluster, although these subjects have made up 'other' or 'mixed' personality groups for comparison. The relationship of obsessive-compulsive personality (OCP) and obsessive-compulsive disorder (OCD) is unclear, although one study found that 36% of its sample of OCD patients also had OCP (Bejerot *et al.*, 1998). Neuropsychological deficits have been found in OCD (e.g., Bolton *et al.*, 2000) and sub-clinical compulsive samples (Matai-Cols *et al.*, 1997; Roth and Baribeau, 1996). It is unclear whether similar deficits could be expected in OCP, but this represents another untapped area for neuropsychological research.

CONCLUSION: FUTURE NEEDS AND NEW RESEARCH

The DSM-IV personality disorders represent a fascinating area of study for the neuropsychologist, yet their comprehensive study is in its infancy. The available data imply involvement of frontal, temporal, and left-hemisphere structures in schizotypal personality disorder, and orbitofrontal, dorsolateral/prefrontal, and possibly left-hemisphere structures in ASPD. Findings in patients with BPD have been inconsistent, with some studies showing involvement of frontal networks. In particular, the schizoid and OCP disorders represent interesting untapped areas worthy of comprehensive neuropsychological evaluation.

Methodological concerns such as sampling criteria, gender differences, comorbid disorders, and neurological risk factors limit the interpretation of the neuropsychological performance of individuals with personality disorders, and there is evidence that some personality disorders may include heterogeneous subtypes. In future studies, detailed assessment of Axis I and Axis II disorders and careful screening for head trauma, substance abuse, and current mood disorders will help to clarify the specificity of any neuropsychological deficits. It is recommended that subject groups include unmedicated individuals who meet full diagnostic criteria for the personality disorder under study, and that multiple cognitive domains be evaluated, with attention to the possibility of gender effects in cognitive functioning. Matching study groups for age, handedness, and parental socio-economic status, rather than education or IQ, may reveal the most accurate picture of cognitive functioning. Careful evaluation of verbal ability, education, and IQ as possible areas of secondary deficit will also be informative. Use of statistical procedures such as analysis of covariance (ANCOVA) will help in evaluating the effect of these factors, as well as the variance associated with comorbid disorders. Whenever possible, use of psychiatric control groups is advised. It may be most informative to employ a comparison group of individuals who meet full diagnostic criteria for a specific personality disorder from a different diagnostic cluster than the one under study.

Functional Neuroanatomy and Brain Imaging of Personality and its Disorders

C. Robert Cloninger

People differ markedly in their personality traits, but there is a stable organizational structure of the brain circuits regulating personality traits. In this chapter, a clinical model of personality will be described that corresponds well with DSM-IV categories of personality disorder and also with available data about the functional neuroanatomy of temperament and character. Temperament refers to the emotional aspects of personality that are regulated by subdivisions of the limbic system and centrally integrated in the hypothalamus. Character refers to the higher cognitive aspects of personality that are regulated by subdivisions of the thalamo-neocortical system and centrally integrated in the frontal cortex. In this chapter, quantifiable personality traits will be related to a model of their functional neuroanatomy derived from classical and comparative neuroanatomy, along with supporting clinical data and experimental findings from brain imaging.

Temperament will be considered in terms of four dimensions of personality that are related to specific subdivisions of the limbic system. These traits are called 'harm avoidance' (anxiety-proneness versus libido, which is outgoing vigour and daring), 'novelty seeking' (exploratory impulsivity and irritable aggression versus frugality and stoicism), 'reward dependence' (social sensitivity attachment versus insensitivity and aloofness), and 'persistence' (industrious determination versus underachievement). A quantitative dimensional approach is used because this corresponds well with the functional neuroanatomy and because there is no evidence of discrete boundaries between traditional syndromes of personality disorder, as in DSM-IV. Instead, traditional syndromes emerge from the interaction of multiple dimensions, which give rise to specific configurations of temperament that distinguish developmentally stable subtypes (Cloninger, 1987; Cloninger and Svrakic, 2000).

Character will be considered in terms of higher cognitive functions that regulate an individual's goals and values. In other words, character refers to mental self-government, which includes executive, legislative, and judicial functions. These traits are called 'self-directedness' (purposeful and resourceful versus aimless and helpless in executive functions), 'cooperativeness' (helpful and principled versus hostile and opportunistic in legislative functions), and 'self-transcendence' (inventive and insightful versus unimaginative and undiscerning judgement) (Cloninger *et al.*, 1993).

Each of the seven dimensions of personality considered here has been shown to have genetic variability that is unique from all the others, indicating that a model with seven dimensions is needed to describe the organization of human personality (Gillespie *et al.*, in press). The correlations among the temperament dimensions are weak, as are the correlations among the character dimensions, but there are moderate non-linear relations between temperament and character. This is expected because character (i.e., higher cognitive functions) modulates temperament (i.e., emotionality). A well-integrated character allows coherence of personality by modulation of emotional conflicts. In contrast, to the degree that character is not well integrated, emotional conflicts arise from the interplay of competing urges from various temperament dimensions. Likewise, the dynamics of complex adaptive systems oscillates between multiple states as a result of small contextual influences on dissociable circuits whenever such circuits are coordinated by a self-organized interplay, as has been suggested as a model of brain systems (Bressler and Kelso, 2001). Consequently, different dimensions of temperament are correlated with differences in the activity of specific brain circuitry that is partially overlapping but functionally dissociated when character is not coherent in its guidance.

All individuals with personality disorders have immature character development, particularly low self-directedness and low cooperativeness (Svrakic *et al.*, 1993; Cloninger and Svrakic, 2000). Individuals with different DSM-IV categories of personality disorder are distinguished primarily by their temperament profiles. Descriptive labels for the personality subtypes defined by the temperament dimensions of novelty seeking, harm avoidance, and reward dependence are shown in Figure XXVI-6.1. For example, borderline personality disorder is associated with a temperament configuration comprising high novelty seeking, high harm avoidance, and low reward dependence. Individuals with antisocial personality disorder are also high in novelty seeking and low in reward dependence, but they are low in harm avoidance. Consequently, the brain images of individuals with antisocial and borderline personality disorder are similar in many, but not all, ways. Specifically, individuals with either borderline or antisocial personality disorder have brain images expected from low self-directedness (i.e., low activity in the medial prefrontal network) and low cooperativeness (i.e., low activity in the orbital prefrontal network) (Kuruoglu *et al.*, 1996; Raine *et al.*, 1998; London *et al.*, 2000; Soloff *et al.*, 2000). Likewise, both groups of individuals have brain images expected from high novelty seeking (e.g., high activity in the right insula) and low reward dependence (e.g., high activity in the right superior temporal gyrus) (Sugiura *et al.*, 2000; Soloff *et al.*, 2000). However, they differ in activity associated with harm avoidance, which is negatively correlated with activity in paralimbic regions such as the left parahippocampal gyrus, left orbitoinsular junction, and some neocortical regions such as the fusiform gyrus (Sugiura *et al.*, 2000). Borderline subjects have the brain correlates of high harm avoidance (Herpertz *et al.*, 2001), whereas antisocial subjects have the brain correlates of low harm avoidance (Raine *et al.*, 1998; Schneider *et al.*, 2000). Each of the dimensions of personality distinguished here has unique genetic variability and brain circuitry, so it is more informative to describe personality dimensionally than categorically. Studies of categorically defined groups of patients

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

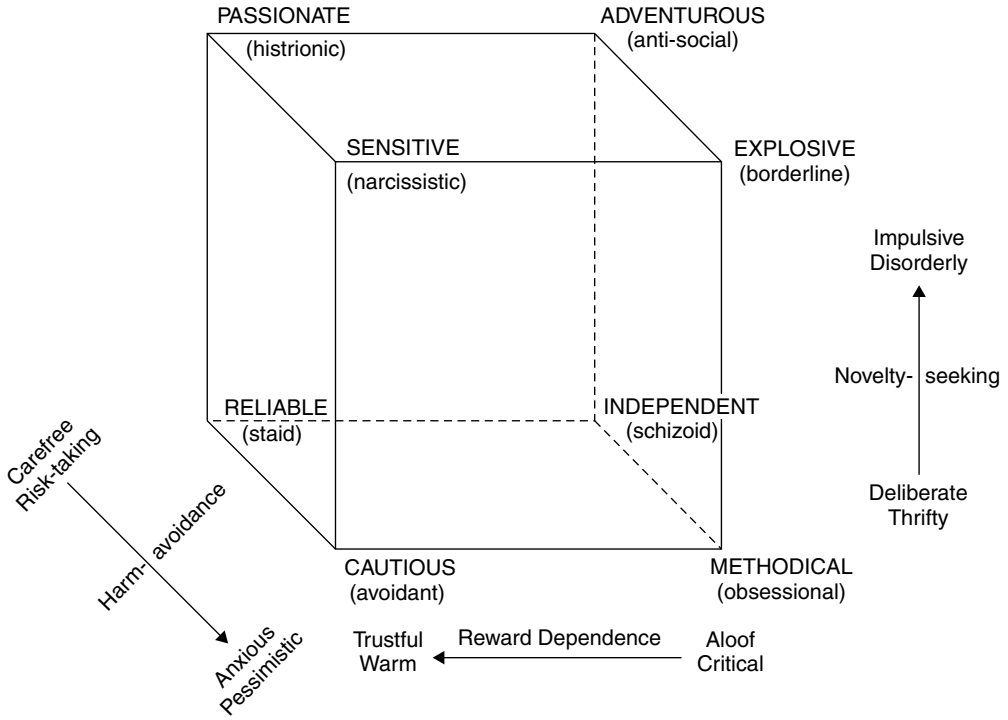

Figure XXVI-6.1 Subtypes of personality disorder defined by various combinations of novelty seeking, harm avoidance, and reward dependence (Reproduced by permission of Centre for Psychobiology of Personality, directed by C.R. Cloninger)

with personality disorder can be informative, nevertheless, and they support the findings based on dimensional studies of both clinical and general population samples.

TEMPERAMENT AND SUBDIVISIONS OF THE LIMBIC SYSTEM

Temperament is often defined as those aspects of personality that are emotion-based, heritable, and developmentally stable regardless of social and cultural influences. Four such dimensions of personality have been distinguished, and each has been shown to be moderately heritable and stable over time (Cloninger *et al.*, 1994). This same structure for temperament has been observed regardless of culture by studies throughout the world (Cloninger and Svrakic, 2000). Descriptors of individuals who score high versus low on each dimension are summarized in Table XXVI-6.1.

Activity of any or all of the brain networks involved in information processing, from sensory input to motor output, could vary with temperament. Sensory input into the primary sensory cortex is processed hierarchically, then is integrated within the multimodal association cortex, and finally reaches the limbic system via the paralimbic cortex. The limbic system is regarded as the anatomical basis for the regulation of emotion, motivation, and autonomic-endocrine functions. The paralimbic cortex plays a critical role in organizing motivated behaviour toward relevant intrapsychic and extrapersonal targets (Mesulam, 1998). Two partially dissociated networks have been distinguished in the paralimbic cortex by their connections with each another and other brain regions (Ongur and Price, 2000). The orbital network receives sensory inputs from several modalities, including olfaction, taste, visceral afferents, somatic sensation and vision. In contrast, the medial network provides the major cortical output to the visceromotor structures in the hypothalamus and the brainstem.

Table XXVI-6.1 Descriptors of individuals who score high and low on the four temperament dimensions

Temperament dimension	Descriptors of extreme variants	
	High	Low
Harm avoidance	Pessimistic Fearful Shy Fatigable	Optimistic Daring Outgoing Vigorous
Novelty seeking	Exploratory Impulsive Extravagant Irritable	Reserved Rigid Frugal Stoical
Reward dependence	Sentimental Open Warm Sympathetic	Critical Aloof Detached Independent
Persistence	Industrious Determined Ambitious Perfectionist	Apathetic Spoiled Underachiever Pragmatist

The limbic system itself has multiple subdivisions that are partly overlapping but functionally dissociable based on anatomical connections and physiology (MacLean, 1990). According to modern understanding, the limbic system is a distributed network of structures with synaptic proximity to the hypothalamus, which serves as the central integrator of the system (Nauta and Feirtag, 1986). MacLean distinguished three subdivisions of the limbic system with regulatory nodes in the septum, amygdala, and thalamus. More recent work has also distinguished a fourth subdivision involving

the ventral striatum. Here I propose the hypothesis that individual differences in harm avoidance, novelty seeking, reward dependence, and persistence are regulated by individual differences within the septal, amygdaloid, thalamo-cingulate, and striato-thalamic subdivisions, respectively.

The hypothalamus centrally integrates input from the limbic subdivisions and regulates the tonic opposition of the sympathetic and parasympathetic branches of the autonomic nervous system. The autonomic nervous system maintains homeostasis by the opposition of its parasympathetic functions (such as sexual arousal, feeding, digestion and storage of nutrients, elimination, and sleep) and its sympathetic functions (such as sexual orgasm, preparation for fighting or flight, and wakefulness). Accordingly, it is not surprising that each of the limbic subdivisions also regulates the tonic opposition of pairs of such psychodynamic drives, each of which has advantages and disadvantages depending on the context. Specifically, there are opposing drives for sexuality versus preservation of safety in the septal subdivision, feeding and aggression versus satiety and satisfaction in the amygdaloid subdivision, social attachment versus aloofness in the thalamo-cingulate subdivision, and industriousness versus impersistence in the striato-thalamic subdivision.

For clarity, I will describe each limbic subdivision individually, but it should be understood that they are partially overlapping and may be dissociated or integrated in function depending on the degree of coherence from higher cortical function. Then I will relate the functional neuroanatomy to available clinical and neurophysiological information.

THE SEPTAL SUBDIVISION AND HARM AVOIDANCE

The septal subdivision of the limbic system is hypothesized to regulate sexuality and the preservation of safety (MacLean, 1990). In humans and other mammals, stimulation of the septum, medial preoptic area, and anterior hypothalamus is pleasurable, with sexual arousal (Heath, 1963; Margules and Olds, 1962; MacLean, 1958, 1962, 1990; Mink *et al.*, 1983). Conversely, lesions in the anterior hypothalamus abolish sexual interest.

In addition, the septum projects to the entire hippocampal formation, but is strongly reciprocally connected with the giant pyramids of the CA3 and CA4 fields. The septal division also includes parts of the paralimbic cortex near the segments of the hippocampus to which it most heavily projects, namely, the caudal part of the entorhinal cortex (Brodmann's area 28) (BA 28), the postrhinal hippocampal gyrus, the presubicular part of the lingual gyrus (BA 27), and the retrosplenial cortex (BA 29) (MacLean, 1990). The septal subdivision also includes the pericallosal hippocampal rudiment and a narrow strip of preseptal cortex continuous with it. These areas are all closely interconnected with one another and the hippocampal formation in the medial aspects of the limbic system (Sanides, 1969; Reep, 1984). In turn, fibres from the hippocampal formation (primarily from the rostral subiculum) terminate in the medial prefrontal cortical network, including BA 24, 25, 32, and parts of 11 through 14 (Ongur and Price, 2000). This medial prefrontal network is the major source of cortical output to the visceromotor structures in the hypothalamus and brainstem. The hypothalamus also receives input directly from lateral septum and hippocampal formation.

Individual differences in harm avoidance have been observed to be significantly negatively correlated with individual differences in activity in the medial prefrontal network at rest (Sugiura *et al.*, 2000). This includes significant negative correlations between regional blood flow and the score for harm avoidance in paralimbic regions such as the left parahippocampal gyrus and the left orbitoinsular junction, and various neocortical regions in the frontal, parietal, and temporal cortex. Likewise, patients with familial pure depressive disorder, which is specifically associated with high harm avoidance, have a decrease in blood flow in the subgenual part of BA 24 (Drevets *et al.*, 1997). This decrease in blood flow is associated with a reduced volume of this area ventral to the genu of the corpus callosum in the medial prefrontal network. This decrease in volume is associated with a reduction in the number and density of glial cells in this area (Ongur and Price, 2000).

Gray (1982) has shown in detailed neurobehavioural studies that the septo-hippocampal-hypothalamic connections of the septal subdivision are essential in the inhibition of behaviour to preserve safety. According to Gray (1982), this circuit is essential in passive-avoidance learning, which is manifest as anticipatory anxiety in response to conditioned signals of punishment or frustrative non-reward. In particular, input to the lateral septum from the hippocampal CA3 field results in habituation and inhibition of unrewarded behaviour. Other aspects of Gray's model of anxiety involve interactions between the septal and thalamo-cingulate subdivisions, which are described later.

Key elements in the neuroanatomy of the septal subdivision include sensory input via the entorhinal cortex and internal sensory input from the midbrain limbic area, such as the dopaminergic ventral tegmental area and the serotonergic raphe nuclei. The septal connections with the dentate gyrus and hippocampal CA3 fields are involved in habituation of unpleasant or unrewarded behaviour. The connections of the subiculum and the lateral septum with the medial prefrontal network and the hypothalamus influence visceromotor output.

The significance of these neuroanatomical connections can be understood in behavioural and psychodynamic terms, which help to reveal their evolutionary and developmental significance. Individuals who are low in harm avoidance are described as outgoing, vigorous, and daring optimists, as shown in Table XXVI-6.1. Harm avoidance is hypothesized to be a behavioural manifestation of individual differences in the septal subdivision of the limbic system regulating the tonic opposition of sexual drive necessary for reproduction versus the preservation of personal safety (MacLean, 1958, 1962, 1990). Likewise, in his theory of libido, Freud (1938) described such vigorous and outgoing optimists as having a strong libido, which leads to anxiety when unsatisfied. Libido does not refer to sexual appetite or conscious sexual desires, although it does energize such desires. Rather, libido refers more broadly to quantitative differences between individuals in their vigour or energy derived from their procreative drive. Consequently, low harm avoidance is a valid measure of libido as originally conceived by Freud.

Freud noted that libido is essential for the preservation of the species by sexual reproduction. However, high harm avoidance is associated with anxiety-proneness, sensitivity to contextual stress, and concern about the preservation of personal safety. At the most basic reflex level, harm avoidance modulates the human startle reflex, which abruptly interrupts behaviour that is potentially harmful and causes withdrawal by widespread contraction of the flexor muscles (Graham, 1979; Corr *et al.*, 1995, 1997; Cloninger, 1998). When compared to the magnitude of the eye-blink startle to a loud noise while the subject is viewing a neutral foreground stimulus, high harm avoidance potentiates startle while viewing an unpleasant stimulus whereas low harm avoidance reduces startle while viewing a pleasant stimulus (Corr *et al.*, 1995, 1997). Other temperament dimensions are uncorrelated with the modulation of startle when subjects are viewing pleasant and unpleasant pictures (Corr *et al.*, 1995, 1997). Anxiety can also be induced in animals by prolonged exposure to bright light or intraventricular administration of the stress peptide corticotrophin-releasing hormone. These anxiety-producing effects depend on a brain area called the bed nucleus of the stria terminalis, rather than the central nucleus of the amygdala, which is involved in the fight or flight response (Davis *et al.*, 1999).

AMYGDALOID SUBDIVISION AND NOVELTY SEEKING

The amygdaloid subdivision of the limbic system regulates the tonic opposition of feeding and aggression versus satiety and satisfaction. Stimulation of the lateral hypothalamus is satisfying, but only if the human or other mammal is hungry (Heath, 1963; Margules and Olds, 1962; Hoebel and Teitelbaum, 1962). In contrast, stimulation of the septum is sexually arousing regardless of feeding status (Heath, 1963; Margules and Olds, 1962; Hoebel and Teitelbaum, 1962). Stimulation of the lateral hypothalamus leads to overeating, whereas stimulation of the ventromedial hypothalamus produces satiety. Conversely, lesions in these same areas have opposite results: lesions of the ventromedial hypothalamus produce hyperphagia whereas those in the lateral hypothalamus lead to aphagia and adipsia. The ventromedial hypothalamus seems to inhibit the activity of the lateral hypothalamus because destruction of both produces anorexia.

In cats and monkeys, activation of the lateral hypothalamus by stimulation of the basal amygdaloid nucleus also produces a defence reflex or rage reaction. This is characterized by pupillary dilation, snarling and aggressive gestures, piloerection, elevation of blood pressure with cardiac deceleration, generally lower amplitude and increased rate of breathing, and changes in gastric motility and acidity (Brodal, 1981; FitzGerald, 1985). This reflex prepares an individual for fight or flight by muscle vasodilation, increased muscle blood flow, and decreasing sensitivity to aversive stimulation (Kelly *et al.*, 1973; Graham, 1979; Deakin and Graeff, 1991). The defence reflex or its autonomic components are elicited from a neural circuit that extends from the basal amygdaloid nucleus, through the central nucleus and the lateral hypothalamus, and into the pontomedullary brainstem, ending approximately at the level of the dorsal vagal complex (Price and Amaral, 1981; Price *et al.*, 1987). Hypothalamic stimulation is ineffective if the amygdalas have been removed (FitzGerald, 1985). In humans, the defence response is usually more modulated, so stimulation of the amygdala most often produces a sensation of fear, occasionally anger, and rarely a full rage reaction (Brodal, 1981). However, in humans with frequent temper tantrums or severely violent rage reactions, surgical lesions in the amygdaloid or hypothalamic components of the defence reflex circuit produce clinical improvement with decreases in aggression, anxiety, restlessness, and sympathetic overactivity (Kelly *et al.*, 1973; Sano and Mayanagi, 1988).

The defence reflex circuit is also involved in fear-potentiated startle in which the startle reflex is potentiated by a conditioned aversive stimulus, as when a human subject is anticipating a painful shock. Fear-potentiated startle depends on the integrity of the central nucleus of the amygdala, and not on the bed nucleus of the stria terminalis (Davis *et al.*, 1999). Increasing the intensity of the threat of harm leads to a switch to active responses (which depend on the integrity of the dorsolateral periaqueductal grey) from more passive responses (which depend on the integrity of the ventral periaqueductal grey) (Davis *et al.*, 1999).

The amygdaloid subdivision of the limbic system receives highly processed sensory input through the orbital prefrontal network. The orbital prefrontal network in humans includes most of the areas on the posterior, central, and lateral orbital surface, including the agranular insular areas Ial, Iam, Iapl, and Iapm, and the orbital areas 11l, 12m, 12l, 13b, 13l, and 13m (Ongur and Price, 2000). Significant positive correlations are observed between scores on novelty seeking and cerebral blood flow in the orbital prefrontal network, particularly the right anterior and right posterior insula (Sugiuri *et al.*, 2000). Other temperament dimensions do not show such positive correlations.

Stimulation of the basal amygdaloid nucleus produces feeding, like the lateral hypothalamus, whereas stimulation of the central amygdaloid nucleus produces satiety, like the ventromedial hypothalamus. When hunger or hunting urges are unsatisfied, there is irritability and impulsive aggressive behaviour, so the amygdaloid subdivision is involved in both feeding and attack behaviour (Chi and Flynn, 1971; Siegel and Brutus, 1990). In cats, synaptic transmission within the amygdaloid subdivision has been experimentally manipulated to cause stable changes in fight or flight behaviour (Adamec and Stark-Adamec, 1983a; b).

The neuroanatomy of the amygdaloid subdivision of the limbic system can be considered functionally in relation to clinical and psychodynamic descriptions of novelty seeking. Individuals who are high in novelty seeking are supposed to have a strong psychodynamic drive for exploratory hunting and feeding, which leads to aggression rather than anxiety if unsatisfied (Freud, 1938). The novelty-seeking dimension is hypothesized to be regulated by the amygdaloid subdivision of the limbic system, which regulates the tonic opposition of drives for feeding and aggression versus satiety and satisfaction (MacLean, 1958, 1990; Kelly *et al.*, 1973; Kelly, 1980). Novelty seeking involves a tonic opposition of craving and desire for novel stimuli and avoidance of fear-inducing stimuli. Experimentally, the amygdaloid subdivision can be activated in humans by negative stimuli, such as exposure to faces expressing fear, or positive stimuli, such as pictures of erotic nudes (Davidson and Irwin, 1999; LaBar *et al.*, 1998). Likewise, individuals high in novelty seeking are particularly prone to thrill-seeking behaviour, overeating, and substance dependence, as well as to irritability and impulsive aggression when they are unsatisfied (Cloninger *et al.*, 1994). Individuals who are high in novelty seeking are quick-tempered, that is, they have a low threshold for the defence reflex.

THE THALAMO-CINGULATE SUBDIVISION AND REWARD DEPENDENCE

The thalamo-cingulate subdivision of the limbic system is also called the circuit of Papez in recognition of James W. Papez, who described it as the 'mechanism of emotion' (Papez, 1937). More specifically, the thalamo-cingulate subdivision is hypothesized here to regulate the tonic opposition of social attachment and aloofness by its role in selective attention to salient emotional events.

The thalamo-cingulate subdivision involves connections between the posterior hypothalamus, anterior thalamus, cingulate gyrus, and hippocampal subiculum. This subicular loop (subiculum to mammillary body to anterior thalamus to anterior cingulate and back to the subiculum) has been studied physiologically in detail (Parmeggiani *et al.*, 1971). For example in the curarized cat, conduction around the entire loop occurs within 50–60 ms and involves no other relay sites until there is transfer of information beyond this simple circuit (Parmeggiani *et al.*, 1974). The subiculum receives information from the outside world, as it is already processed when it reaches the entorhinal cortex or hippocampal CA3-CA1 fields. The subiculum compares the information it receives with what was expected, and then projects to the cingulate cortex and to the septal subdivision via the entorhinal cortex so as to select responses that should habituate and be inhibited (Gray, 1982) as well as what is useful to enter into long-term memory (Eccles, 1989). Information reaching the subicular circuit has already been extensively processed, and its potential importance or salience has already been tagged by processing in the septal or amygdaloid subdivisions (Gray, 1982). By acting as a comparator of observed and expected stimuli, the subicular circuit can modulate orienting responses.

Sensory input about the external context and internal milieu also enters this subdivision through the sensory association cortex and midbrain limbic area, respectively. Papez (1937) showed that connections among the posterior hypothalamus, anterior thalamus, cingulate gyrus, and hippocampus formed a two-way circuit by which emotions could be elicited either by ideational association in the neocortex or by visceral activation of the hypothalamus, which in turn provides central control of the autonomic nervous system.

MacLean (1990) showed that differentiation of the thalamo-cingulate subdivision in mammals is associated with the emergence of a behavioural triad of social interactions, including parental nursing, play, and audiovocal communication, to maintain communication between mother and offspring. This was a major advance in capacity for social attachment in mammals over reptiles and more primitive vertebrates.

Individuals who are high in reward dependence are sentimental and emotionally warm, whereas those who are low in reward dependence are aloof and emotionally cold. In psychodynamic terms, individuals who are high in reward dependence are sympathetic to emotional distress in others and attribute their own positive emotions onto others. However, individuals low in reward dependence do not form social attachments readily because they project or attribute their own negative emotions onto others and remain unresponsive to the positive emotions of others.

Accordingly, reward dependence is hypothesized to be regulated by the thalamo-cingulate subdivision of the limbic system (MacLean, 1990). More specifically, the subicular circuit is hypothesized to modulate the magnitude of the orienting reflex, which alerts and orients a person to information to which they need to pay selective attention (Graham, 1979; Gray, 1982). More specifically, it is hypothesized that the orienting reflex is potentiated in individuals who are high in reward dependence when they are stressed and responding to high-intensity stimuli, particularly stimuli of social interest, such as frowns and signs of distress in others. However, individuals low in reward dependence are expected to have greater orienting responses in the absence of stress when responding to low-intensity stimuli. Empirically, this expected interaction between intensity of stimulus and reward dependence is empirically supported by the results of personality measures with reward dependence as their major common correlate, such as high extraversion and low psychoticism, but not neuroticism (Fowles *et al.*, 1977; Wigglesworth and Smith, 1976; O'Gorman, 1983).

It should be noted that the initial magnitude and the rate of habituation of orienting responses are only weakly correlated (O'Gorman, 1983). Habituation of the orienting response may be more closely modulated by the septal subdivision, as proposed by Gray (1982), so harm avoidance would interact with reward dependence. Specifically, individuals with high reward dependence and low harm avoidance are expected to habituate slowly to unpleasant social cues, such as a frown, whereas individuals with low reward dependence and high harm avoidance are expected to habituate rapidly to pleasant social cues, such as a smile. Consequently, studies of the orienting reflex with extraversion as a measure may have had inconsistent results because extraversion confounds high reward dependence and low harm avoidance. More empirical research is therefore needed to test the tentative hypotheses about the orienting reflex suggested here.

Nevertheless, the hypothesis that reward dependence modulates the magnitude of the orienting reflex is suggested by the sentimentality and preference for social closeness of individuals who are high in reward dependence, in contrast to the preference for social distance in individuals who are low in reward dependence. It is supported empirically by the particular sensitivity of the thalamo-cingulate subdivision to facial cues and visceral (autonomic) variability through exteroceptive and interoceptive sensory inputs to the mesocortical ring. This concentric ring of mesocortex links the anterior cingulate (area 24) with the infralimbic (area 25), medial and ventrolateral orbital, insula, perirhinal (area 35), and retrosplenial (area 29) mesocortex (Reep, 1984). Individual differences in reward dependence are negatively correlated with cerebral blood flow in this mesocortical ring (Sugiura *et al.*, 2000).

THE STRIATO-THALAMIC SUBDIVISION AND PERSISTENCE

Persistence despite partial reinforcement has been poorly explained by the functional neuroanatomy of the preceding three subdivisions of the limbic system (Gray, 1982). Persistence can be measured by the partial reinforcement extinction effect (PREE), which means that behaviour is more persistent despite non-reward after an initial period of intermittent reinforcement than after an initial period of continuous reinforcement. This persistence effect is abolished after lesions of the nucleus accumbens, which interrupts an excitatory projection from the hippocampal subiculum to the ventral striatum (Tai *et al.*, 1991).

Phenomena that are closely related to PREE are the greater resistance to extinction after continuous small rewards than after continuous large rewards and the greater approach speeds during acquisition with intermittent rewards than with continuous rewards. The latter is called the partial reinforcement acquisition effect (PRAE) or eagerness reflex. Therefore, the temperament dimension of persistence is not simply a form of perseverative behaviour. Instead, it involves persistence in behaviour to achieve long-term goals with eagerness, enthusiasm, and industry, which may require flexible adaptation of routines. In fact, neurons in the ventral striatum selectively respond to motivationally significant stimuli that are rewarding or punishing (Rolls and Williams, 1987; Schneider and Lidsky, 1981; Schultz *et al.*, 1998). This reward-guided behaviour in animals involves activation in a circuit connecting the ventral striatum and the prefrontal cortex. In humans, this striatal-prefrontal circuit is known to include intermediate connections between the ventromedial striatum, pallidum, certain medial thalamic nuclei, and the prefrontal cortex (Knight, 1964; Kelly *et al.*, 1973; Modell *et al.*, 1989; Hay *et al.*, 1993; Joseph, 1999).

Individual differences in persistence in humans are strongly correlated with responses measured by fMRI in a circuit involving the ventral striatum, orbitofrontal cortex/rostral insula, and prefrontal/cingulate cortex (BA 32) (Gusnard *et al.*, 2001). Subjects low in persistence exhibited relative decreases in activity within this circuit whereas those high in persistence exhibited relative increases. Persistence scores also correlated with an apparent selection bias such that subjects with high persistence scores made relatively more pleasant judgements at the expense of neutral judgements when viewing pictures from the International Affective Picture System.

The neuroanatomy of this ventral striatal-prefrontal circuitry can be appreciated functionally in terms of its clinical and developmental significance for the temperament dimension of persistence. Individuals who are high in persistence are industrious overachievers. In contrast, those who are low in persistence are described as apathetic underachievers who are easily discouraged when their expectations are not quickly and consistently satisfied. More specifically, when individuals are intermittently reinforced, those who are high in persistence remain eager and industrious despite discouragement by others, whereas those low in persistence quit quickly despite encouragement by others. In terms of functional neuroanatomy, the ventral striato-thalamic-prefrontal circuit is likely to be involved in reward-guided choice behaviour (Schultz *et al.*, 1998). Striatal neurons are almost silent at rest, whereas nigro-striatal and pallido-thalamic projections are tonically active and inhibitory. The motivation to initiate behaviour is associated with increases in both striatal and pallidal activity, which selectively disinhibits thalamo-frontal activity (Penney and Young, 1983). In turn, the increased thalamo-frontal activity completes the fronto-striato-pallido-thalamo-frontal circuit, so that a positive fronto-striatal feedback loop can maintain activity in a persistent goal-directed manner. However, decreased nigro-striatal activity may lead to tonic inhibition of the pallidum, which produces akinesia, rigidity, and tremor in the dorsolateral striatum. It is hypothesized that the analogous effect of tonic

inhibition of the ventral pallidum on motivation mediated by the ventromedial striatum is low persistence, characterized by amotivation (apathy, underachievement, and discouragement), inflexibility (spoiled behaviour — wanting your way regardless of consequences and subjectively complaining without adapting efforts), and lability (mood swings).

Patients with bipolar mood swings are often low in persistence, even when euthymic (Osher *et al.*, 1996; 1999). Moreover, subcaudate tractotomy is frequently beneficial in such patients when they are chronically or recurrently depressed (Mindus and Jenike, 1992). The target of this surgery is the substantia innominata below the head of the caudate, which is the location of the ventral pallidum. The treatment produces a relief of amotivation, that is, an increase in industry with improved mood and work capacity (Strom-Olsen and Carlisle, 1971; Goktepe *et al.*, 1975; Lovett and Shaw, 1987).

HIGHER COGNITIVE FUNCTIONS OF FRONTAL CORTEX

Character has long been regarded as what human beings make of themselves intentionally (Cloninger, 1994). In contrast to temperament, which involves basic emotional responses, character involves our concepts of self and our relations with other people and the world as a whole. In other words, character involves our conceptual or propositional learning about goals and values that allow us to organize and integrate the behavioural drives motivated by temperament. The subdivisions of the limbic system produce a variety of responses, often producing conflict. For example, individuals may be high in both harm avoidance and novelty seeking, so when they encounter unfamiliar situations or strangers, they will have conflicting impulses to experience something new (thereby producing a thrill or relieving boredom) and to avoid the unfamiliar (thereby playing it safe). The way such emotional conflicts are organized and resolved defines a person's character or style of higher cognitive processing.

Empirically, individual differences in temperament do not tell us whether or not a person is integrated in character (that is, mature as opposed to having a character disorder). However, individual differences in maturity can be well described by three dimensions of character called self-directedness, cooperativeness, and self-transcendence (Cloninger *et al.*, 1993; Svrakic *et al.*, 1993). Descriptors of individuals who are high or low on each of these character dimensions are summarized in Table XXVI-6.2.

Table XXVI-6.2 Descriptors of individuals who score high and low on the three character dimensions

Character dimension	Descriptors of extreme variants	
	High	Low
Self-directed	Responsible	Blaming
	Purposeful	Aimless
	Resourceful	Inept
	Self-accepting	Vain
	Generative	Unproductive
Cooperative	Reasonable	Prejudiced
	Empathic	Insensitive
	Helpful	Hostile
	Compassionate	Revengeful
	Principled	Opportunistic
Self-transcendent	Judicious	Undiscerning
	Insightful	Superficial
	Intuitive	Dualistic
	Inventive	Unimaginative
	Spiritual	Materialistic

These dimensions allow quantitative ratings of the degree of maturity as well as the severity of personality disorder. The presence of personality disorder can be defined by those individuals who are in about the lowest 10% of the distribution of the sum of self-directedness and cooperativeness (Svrakic *et al.*, 1993). Even those in the bottom third of this distribution are noticeably immature and disorganized. However, there is more clinical information in considering the full distribution of scores. Likewise, consideration of quantitative variation in these dimensions is more helpful as a way of understanding the functional neuroanatomy of personality.

Empirical findings showed temperament and character to be interactive aspects of personality in which each influences the other. Specifically, the relations are non-linear, as expected in a self-organizing adaptive system in which temperament influences the emotional salience of events, and character influences the higher cognitive processing of the meaning of events (Cloninger *et al.*, 1997). Furthermore, character, but not temperament, was observed to be correlated with individual differences in event-related potentials of healthy adults that are characteristic of higher cognitive processes subserved by the prefrontal cortex and sensory association cortex (Fuster, 1984, 1997). Specifically, P300 is positively correlated with self-directedness and no other temperament or character dimension; in parietal leads, the correlations are $+0.3$ to $+0.4$ in healthy adults (Cloninger, 1998; Vedeniapin *et al.*, 2001). The P300 is a positive potential recorded at the scalp surface and elicited by an unexpected event that has been awaited while a subject deals with another repetitive, highly structured task. Likewise, contingent negative variation (CNV) is negatively correlated with cooperativeness and self-transcendence, and not with temperament dimensions (Cloninger, 1998; Vedeniapin *et al.*, 2001). CNV is a scalp-recorded, slow negative potential recorded at the scalp in the interval between two events that lead to a motor act. In recordings from single neurons in the prefrontal cortex, Fuster (1984, 1997) has shown that CNV originates in the prefrontal cortex. In delayed response tasks, large numbers of prefrontal neurons increase in their discharge rate, and this discharge is measured as the CNV surface potential.

It has long been recognized that higher cognitive functions depend on the integrity of the thalamo-neocortical system, and are centrally integrated in the prefrontal cortex (Freeman and Watts, 1942; Nauta, 1971; Fuster, 1984, 1997; Cloninger, 1994; Joseph, 1999). The prefrontal cortex is seen as the peak in a hierarchy of structures modulating goal-directed behaviour. These higher cognitive functions have a delayed experience-dependent maturation, just as the prefrontal cortex and sensory association areas have a delayed onset of myelination, not maturing until puberty (Sanides, 1969; Stuss, 1992). Likewise, social deprivation and psychological trauma during early childhood can disrupt normal neocortical development and higher cognitive processing (Meares *et al.*, 1999). These observations suggest the hypothesis that the maturation of higher cognitive functions, which I will call character development, involves the integration of the interactions among the areas of neocortex that supervise the individual limbic subdivisions.

A useful metaphor for the integrative activity of the thalamo-neocortical system is the government of a large and complex country. To manage a country effectively, it is useful to have executive, legislative, and judicial branches of government (Sternberg, 1990). Likewise, as previously described on empirical clinical grounds, higher cognitive functions can be measured as three dimensions of character that have been shown to distinguish individuals with personality disorder from those who are mature (Cloninger *et al.*, 1993; Svrakic *et al.*, 1993; Cloninger and Svrakic, 2000). These dimensions involve executive functions (self-directedness), legislative functions (cooperativeness), and judicial functions (self-transcendence).

Alterations in personality and cognitive processing caused by frontal lobe lesions have been described in detail (Freeman and Watts, 1942; Damasio, 1985; Milner and Petrides, 1984; Stuss and Benson, 1986; Joseph, 1999). Three syndromes of frontal lobe dysfunction have been described that can be systematically related to the three character dimensions of self-directedness, cooperativeness, and self-transcendence, as shown in what follows.

The prefrontal cortex is not homogeneous in its connectivity, cytoarchitecture, ontogeny, and phylogeny, or its function (Sanides, 1969; Nauta, 1971; Reep, 1984; Joseph, 1999; Ongur and Price, 2000). Most recent research on the prefrontal cortex distinguishes regions including the medial, orbital, dorsolateral, and polar areas (Ongur and Price, 2000; Joseph, 1999; Bechara *et al.*, 1998; Roland, 1984). The medial prefrontal network includes all the areas on the medial wall of the cerebrum (areas 25, 32, 14r, 14c, 24a, and 24b) and related areas on the orbital surface (areas 11m, 13a, Iai, and 12o). The orbital prefrontal network includes most of the areas on the posterior, central, and lateral orbital surface (agranular insular areas Ial, Iam, Iapl, and Iapm, and orbital areas 13b, 13l, 13m, 11l, 12r, 12m, and 12l) (Ongur and Price, 2000). The frontal poles and dorsolateral prefrontal cortex are designated as areas 10 and 11, respectively.

Furthermore, there are prominent functional differences related to hemispheric specialization or laterality. Whereas the left side is usually dominant for verbal analysis and speech, some observations suggest that the right side is usually dominant for the integrative and modulatory functions described here as character (Joseph, 1999). It is suggested that the right frontal lobe has a greater attentional capacity than the left and exerts bilateral inhibitory influences on arousal (Joseph, 1999; Pardo *et al.*, 1991). In contrast, the left frontal lobe appears to exert unilateral excitatory influences on arousal and attention (Davidson and Irwin, 1999). Finally, it is useful to distinguish the frontal pole (area 10) from other prefrontal regions since it has distinct patterns of development, connectivity, and coactivation (Roland, 1984), such as receiving projections from the mediodorsal thalamus, but not the amygdala (Reep, 1984).

Patients with left-sided or bilateral lesions in the medial prefrontal network show deficits suggestive of the executive functions associated with self-directedness, as indicated by apathy, abulia, or lack of initiative, and inability to organize or prioritize activities in their life (Damasio, 1985; Joseph, 1999). In recent brain-imaging research, individual differences in Self-directedness, as measured by the Temperament and Character Inventory, were strongly correlated with fMRI response magnitudes in BA 9/10 when subjects were carrying out simple executive tasks (Gusnard *et al.*, 2001). Self-directedness was also negatively correlated with reaction times in the same tasks.

Likewise, Bechara *et al.* (1994, 1996, 1997, 1998) have found that patients with bilateral medial prefrontal lesions cannot anticipate future positive or negative consequences of their actions, although their behaviour is influenced appropriately by immediately available contingencies. The same patients fail to show anticipatory electrodermal responses when confronted by a risky choice, whereas normal controls generate such anticipatory autonomic responses even before they are able to declare this explicitly. Patients with medial prefrontal lesions who were unable to anticipate future positive or negative consequences had normal working memories, whereas other patients with dorsolateral prefrontal lesions had impaired working memories but were able to anticipate future positive or negative consequences on a gambling task (Bechara *et al.*, 1998).

Right-sided or bilateral medial prefrontal lesions usually produce a deficit in a subjects' concept of temporal self-continuity in which they have difficulty thinking about themselves as having a continuity from the past to the future (Freeman and Watts, 1942). This leads to severe impairment of self-directedness and sometimes to bizarre ideation. This has led some to suggest that the right prefrontal cortex is dominant over the left in character functions (Joseph, 1999). The right-sided dominance in self-directedness is also shown by the release of inhibitory control over limbic impulses, as manifest by the emergence of impulsivity, distractibility, hypertalkativeness, and overactivity. The mood is usually hyperthymic and labile, with an increased risk of hypomania and manic episodes (Joseph, 1999). However, self-directedness, as measured by the Temperament and Character Inventory, has been correlated with medial prefrontal activity in both hemispheres (Gusnard *et al.*, 2001).

In contrast, lesions in the orbital network cause deficits in legislative function indicative of low cooperativeness. Low cooperativeness is indicated by reduced empathy and social sensitivity, ethical unreliability, and poor social judgement in which patients seem to lack principles and compassion regarding the effects of their behaviour on others (Damasio, 1985; Stuss and Benson, 1986; Joseph, 1999). This can lead to criminality, promiscuity, profane speech, and a crude, immature social manner that is inconsiderate of the feelings of others. In addition, as in right medial lesions, there is often excessive eating, drinking, and hypersexuality (Joseph, 1999).

Although right-sided lesions of either the medial or orbitofrontal cortex produce behavioural disinhibition, there is still a difference in their impact on the capacity for self-directedness (which is impaired by medial lesions) and cooperativeness (which is impaired by orbital lesions), a finding which illustrates the distinction between executive and legislative functions. Patients with low cooperativeness as a result of orbital lesions do not make rules to moderate their social interactions; they are unprincipled and opportunistic, and show pervasive impairment in social judgement according to the standards of others because they make no standards for themselves (a legislative function). In contrast, patients with only right medial lesions do have standards and principles of which they are consciously aware, but are undisciplined, have difficulty in conforming to rules (an executive function), and tend to be hyperthymic and impulsive (Joseph, 1999). Thus, there are interactions between mood and character effects.

The frontal poles are uniquely increased in human beings compared to other primates, and are the latest to myelinate of all parts of neocortex (Sanides, 1969; Eccles, 1989). Lesions to the frontal pole (BA 10 or the part of the mediodorsal thalamus that projects to area 10) may possibly impair Self-transcendence, but relevant observations are old, limited, and no studies have used the Temperament and Character Inventory (Cloninger *et al.*, 1993) to test this. Nevertheless, low self-transcendence may be indicated by early reports of impairment in creativity, spirituality, and the capacity for abstract fantasy after surgery to the frontal poles (Freeman and Watts, 1942). These are characteristics that distinguish human beings from all other primates (Eccles, 1989; Mithen, 1996). Consequently various artists, theatrical performers, writers, musicians or scientists lost their capacity for creative insight and judgement after bilateral lesions of the frontal pole, even though they remained self-directed and cooperative (Freeman and Watts, 1942). This impairment can be understood as the loss of judicial function, that is, the ability to know when a particular rule should be applied. Such judgement is intuitive in the sense that it cannot be taught algorithmically.

CONCLUSIONS

Substantial progress has been made toward the development of a functional neuroanatomy of personality and its disorders based

on classical neuroanatomy, neurophysiology, and recent brain-imaging studies using reliable quantitative measures of personality or related cognitive and emotional functions. Reliable clinical measures of temperament are available to quantify personality traits that correspond well to functional subdivisions of the limbic system. Likewise, dimensions of character may distinguish the executive, legislative, and judicial functions of different regions of the frontal cortex.

The temperament and character dimensions are now being investigated by brain imaging, but much more work is needed. Modern methods of brain imaging and psychophysiology offer excellent opportunities to relate individual differences in personality to regional brain activity. These methods can provide rigorous tests of the hypotheses and findings described here, which are often based on limited data or the synthesis of diverse observations from animals and humans. Nevertheless, the multidimensional model of temperament and character is well tested clinically and psychometrically. Accordingly, the remarkable correspondences described here between personality and available data on functional neuroanatomy are much too extensive and systematic to be coincidental.

The functional neuroanatomy of personality described here offers hope that psychiatry can progress beyond a purely descriptive approach to diagnosis and treatment. Psychiatry can become a science of functional psychobiology only when it approaches individual patients in terms of assessments based on the psychodynamics and neurodynamics of specific brain systems as described here for personality and its disorders.

Neurogenetics of Personality Disorders

Andreas Reif and Klaus-Peter Lesch

INTRODUCTION

The behavioural predisposition of an individual is commonly referred to as temperament or personality. In genetics, personality is generally defined as the characteristic manner and style of an individual's behaviour and encompasses the emotional expression, such as fearfulness, exuberance, aggressiveness, and self-restraint, as well as the vigour, temper, and persistence of the resulting behaviour (Benjamin *et al.*, 1998; Ebstein *et al.*, 2000). Personality disorder (PD) is an umbrella term covering a plethora of conditions characterized by a persistent pattern of abnormal behaviour, dysfunctioning in social contexts, and suffering of either the individual or the environment. Despite problems of classification, epidemiological research involving family, twin, and adoptee studies has gathered persuasive evidence that several categories of PD including antisocial, anxious/avoidant, and schizoid-schizotypal personalities are influenced by genetic factors, and that the genetic component is highly complex, polygenic, and epistatic (Coolidge *et al.*, 2001; Eley *et al.*, 1999; Jang *et al.*, 1996; Kendler *et al.*, 1991; McGuffin and Thapar, 1992; O'Connor *et al.*, 1998; Vernon *et al.*, 1999).

The analysis of genetic contributions to normal personality and behaviour as well as to PDs is both conceptually and methodologically difficult, so that consistent findings remain sparse. The documented heterogeneity of both genetic and environmental determinants suggests the ineffectiveness of searching for unitary causes. This vista has therefore increasingly encouraged the pursuit of dimensional and quantitative approaches to personality and behavioural genetics, in addition to the traditional strategy of studying individuals with categorically defined psychiatric entities (Plomin *et al.*, 1994). While quantitative genetics has focused on complex, quantitatively distributed traits and their origins in naturally occurring variation caused by multiple genetic and environmental factors, molecular genetics has begun to identify specific genes for quantitative traits, called quantitative trait loci (QTLs) (Eley and Plomin, 1997). In this polygenic model, behavioural disorders are extremes of continua in which various genes interact additively or nonadditively. The QTL concept thus implies that there may not be genes for psychiatric disorders, just genes for behavioural dimensions. In line with this notion, Livesley *et al.* (1998) have recently suggested that personality disorders are best classified by dimensional scales and are not qualitatively distinct from normal personality traits. Underlying genes of extremes of normal personality traits may therefore contribute to a range of psychopathology including psychoses (Tien *et al.*, 1992).

Any attempt to provide a comprehensive overview would be futile; however, an appraisal of the genetics of PDs requires the consideration of several critical caveats. This chapter therefore describes fundamental aspects of the genetics of personality and focuses on topics undergoing particularly rapid progress. Conceptual and methodological issues in the search for candidate genes of personality traits and PDs as well as for the development of mouse models of human PDs will also be reviewed.

PERSONALITY DISORDERS — A DIAGNOSTIC DILEMMA

The diagnosis of PD is evidently not as clear-cut as is desirable. In a continuum ranging from reasonably well-characterized brain disorders with a defined genetic cause, such as Huntington's disease or fragile-X syndrome, to wider and more unspecific diagnoses such as bipolar affective or schizophrenic disorders, extreme variants of personality represent disorder entities which are the least well defined and accessible to psychobiological research. DSM-IV (American Psychiatric Association, 1994) lists the following criteria of PD: a persistent pattern of abnormal behaviour, dysfunctioning in social contexts, suffering of either the patient or the environment, and early onset in childhood or adolescence. When the first three DSM-IV criteria are inverted, (pattern of normal behaviour, functioning, and no suffering), and the last is kept, one might see this as a definition of 'normal' personality, or behaviour, as human personality is mainly what is constructed from an individual's actions. It is conceivable that the DSM-IV definition of PD covers a wide range of disorders; may be subdivided in almost infinite different ways, just as human personality; and depends not only on the patient, but also the environment. The social context is of substantial importance when the diagnosis of PD is applied; individuals functioning perfectly in some societies may fail to do so in others. Thus, we have the media stereotype of a workaholic German manager, who could be indexed as neurotic and anankastic in other socio-economic models; the temperamental stereotype of a young lady from Sicily, readily regarded as highly histrionic in Norway; and that revered eccentric English gentlemen, in DSM-IV euphemisms the archetype of a schizotype personality. Accordingly, PD, in part, lies in the eye of the beholder.

What leads to the term 'disorder', is the suffering of the individual or — as is sometimes more common in PDs — the environment. Otherwise, this 'disorder' could easily be described as 'personality variation', the outer limits of a Gaussian distribution of personality traits. Thus, the presence of PDs could be viewed as an evolutionary strategy to adapt to different environmental conditions. Dysfunctioning and abnormal behaviour might be appropriate attributes for a certain kind of personality structure in a given culture; but cultures and societies vary and, even more meaningfully, constantly change, and what was abnormal or dysfunctional yesterday might be successful and perfectly normal today. PDs therefore may be the price a given society has to pay for the flexibility to adapt to different environments and for the variation of behaviour which helps it to maintain reproductive success and to ensure survival. Furthermore, the genes underlying behavioural traits have been shaped

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

throughout evolution for success in primordial societies, and not in contemporary civilization. Humans still bear the constraints of this genetic background, and it has to be kept in mind that some of the features now regarded as 'disordered', such as exaggerated anxiety, novelty seeking and risk-taking hyperactivity, or straightforward aggression, might represent behavioural strategies that were, in the evolutionarily perspective, highly successful in ancient times. For further reading, several monographs are recommended to the interested reader (Allman, 1994; Hamer and Copeland, 1998; Nesse and Williams, 1995; Weiner, 1999; Wilson, 1998).

The current classification systems of DSM-IV (American Psychiatric Association 1994) and ICD-10 (World Health Organization 1992) distinguish three distinct subgroups of PD: paranoid, histrionic, and avoidant. While an operationalized diagnostic procedure is laborious to obtain, these subgroups are familiar and intuitively comprehensible in the clinical setting. However, rating scales often fail to identify a specific PD, or the results are contrary to the experienced clinician's view. This is likely to be due to the fact that PDs arise in social contexts hardly to be reflected in standardized interviews.

Furthermore, a distinct PD, according to DSM-IV or ICD-10, does not represent a categorical unit of human behaviour but rather a blend of temperamental traits, cognitive plans, mental 'master' attitudes, patterns of behaviour, and so on. Some of these features have a substantial genetic component, while others do not. Biological background mingles with environmental factors and education — both nature and nurture shape personality and PDs alike. Due to the heterogeneity of PD diagnoses, it appears to be naive and futile to search for a single genetic cause resulting in exactly one specific PD. In DSM-IV, PDs have been grouped in three clusters (withdrawn, flamboyant, and fearful), which might be a reasonable starting point in the search for genetic influences. Several authors assign PDs of the so-called Cluster A (paranoid, schizoid, and schizotype) to the schizophrenia spectrum disorders, with an overlapping genetic background; Cluster B, the flamboyant group, appears to be influenced more by environmental than genetic factors (Kendler and Eaves, 1986). Cluster C, comprising obsessive-compulsive, avoidant, and dependent traits, seems to share genetic and environmental causes in equal parts.

In order to avoid the inherent problems of multidimensional diagnosis of PDs, it is sensible to identify the temperamental and behavioural traits, such as anxiety, novelty seeking, impulsivity, aggressiveness, and antisocial behaviour, that underlie PDs. These traits can be assessed by rating scales for humans (e.g., the Revised NEO Personality Inventory NEO-PI-R [Costa and McCrae, 1992], the Tridimensional Personality Questionnaire/Tridimensional Character Inventory TPQ/TCI [Cloninger *et al.*, 1993], and the Karolinska Scales of Personality [KSP] [Schalling *et al.*, 1987] questionnaires), as well as by specific behavioural paradigms in animal models, making it possible to investigate specific genetic influences. A specific PD could then be dissected into behavioural features, with known genetic components and non-genetic contributions, by cognitive schemes and strategies. The search for the genetics of PD thus closely resembles the search of the genetics of behaviour.

TOWARDS GENETIC DISSECTION OF PDs

It is now widely accepted that human temperament and personality is a multigene product. There is no single gene or major gene effect, respectively, for a specific behavioural trait, and, consequently, there is no single gene for a PD subtype. Rather these characteristics are polygenic, a fact which results in the failure of classical genome-wide linkage studies to detect the genes accounting for personality traits or PDs. Many genes, with only modest phenotypic effects, add up to account for the full variance of a particular personality dimension. This implies also that single variation in a given gene might lead to only a minimal change in the phenotype, but another variation in the same gene might have deleterious effects, resulting in an apparent 'one gene, one disorder (OGOD)' type of disease. This notion becomes even more complicated when gene–environment interactions and epistatic phenomena are taken into account.

A gene variant which is associated with a PD in one population may not be so associated in another ethnic group — a problem which is increasingly being encountered in behavioural genetics. Since a given gene influences distinct personality traits only to a small extent — for instance, allelic variation in 5HTT function, which is described in more detail below, accounts for approximately 8% of the genetic variance of traits related to anxiety and aggression — and since the genetic component of PD is polygenic, classical linkage analysis has failed to identify relevant genomic variation. Because the power of linkage analysis to detect small gene effects is quite limited, at least with realistic samples, QTL research relies on association analysis using DNA variants in or near candidate genes that are presumably functional. The first QTL analysis was conducted 1988 by Paterson *et al.*, who searched for the genes responsible for the phenotypes of tomato fruits (Paterson *et al.*, 1988). While this study demonstrated that a set of six genes controls fruit mass, it highly likely that personality traits are defined by sets of at least 10–20 different genes, and that both pleiotropy and epistasis play an critical role in the molecular basis of personality.

The pace of integration of quantitative and molecular genetics has been accelerated remarkably as a result of the *Drosophila*, mouse, and human genome projects, which have brought neuroscience to the threshold of the postgenomic era in which the human genome and those of other species are known. While several million DNA variations (polymorphisms) have been identified in the genomic sequence, most importantly for the analysis of complex traits, roughly 30 000–60 000 common polymorphisms are located in coding and regulatory regions of genes that are the ultimate causes of the heritability of complex traits (McPherson *et al.*, 2001; Sachidanandam *et al.*, 2001). These advances have generated new technologies, such as DNA microarrays, that make it possible to investigate the role of thousands of DNA variants in complex traits. The rate of discovery of genes associated with complex traits, such as personality and behaviour, will also increase, as systematic QTL scans can be conducted using functional DNA variants in the brain that affect coding regions or gene regulation. Of the nearly 40 000 genes, approximately 50% are expressed in the brain, but a substantial proportion of these are housekeeping genes. Thus, fewer than 15 000 tissue-specific genes may be expressed in the brain. Identifying the estimated 8000–16 000 functional DNA variants in coding regions of these genes and the DNA variants that regulate the expression of these genes is now a high priority for behavioural genetic research. Several classes of genomic variations in coding and regulatory regions of genes, commonly referred to as candidate genes, are of particular interest. The variety of these functionally relevant variations ranges from single nucleotide polymorphisms (SNPs) to microdeletions (or insertions), and polymorphic simple sequence repeats (SSRs) of 2–50+ nucleotides in length.

Quantitative genetic research on animal models consists primarily of inbred strain and selection studies. While comparisons between different inbred strains of mice expose remarkable differences in measures of anxiety-related behaviour, such as performance in the Open Field or Elevated Plus Maze paradigm, differences within strains can be attributed to environmental influences. Inbred and recombinant inbred strain studies are highly efficient in dissecting genetic influences, for investigating interactions between genotype and environment, and for testing the disposition-stress model. Selective breeding of mice for many

generations produces differences between high and low anxiety lines that steadily increase from generation to generation. Selection studies of behavioural traits strongly suggest a genetic influence and that many genes contribute to variation in behaviour. Mice strains that have been selectively bred to display a phenotype of interest are currently being used to identify genetic loci that contribute to behavioural traits. The QTL approach has been applied with some success to a trait in mice called 'emotionality' (Flint *et al.*, 1995). Crosses between the high- and low-activity selected mouse lines yielded three QTL regions that appear to be related to various measures of fearfulness. A modified QTL strategy that uses recombinant inbred mouse strains produced candidate QTLs for Open Field fearfulness (Phillips *et al.*, 1995).

Regrettably, such linkage analyses provide only a rough chromosomal localization, whereas the next step, identifying the relevant genes by positional cloning, remains a challenging task (Tecott and Barondes, 1996). Since mice and humans share many orthologous genes mapped to synthenic chromosomal regions, it is conceivable that individual genes identified for behaviour may be developed as animal models. After chromosomal mapping of polymorphic genes and evaluation of gene function with knockout mutants, behavioural parameters are investigated. Thus, the combination of elaborate genetic and behavioural analyses results in the identification of many genes with effects on the variation and development of murine behaviour; ultimately, mouse QTL research is likely to generate candidate genes for human behavioural disorders.

CANDIDATE GENES

A complementary approach to quantitative genetic studies is investigation of whether certain candidate genes are involved in the manifestation of a specific phenotype, and whether such genes are involved in the pathogenesis of disease states. While this approach was restricted until recently to a relatively small number of genes, identification of new candidates will be facilitated by the new tools of the postgenomic era. Because it is hypothesis-driven, the investigation of candidate genes is a powerful means to examine the biological basis of personality and behaviour. In this context, psychobiology accumulated a thorough knowledge of neurotransmitter networks; consequently, the first candidate genes investigated were components of the monoamine neurotransmitter pathways. Interest has primarily been focused on the serotonergic, dopaminergic, and — to a lesser extent — noradrenergic systems. Almost no information is available on the role of genetic variations of the constituents of second and third messenger pathways, transcription factors, or other morphoregulators.

Nevertheless, several caveats have to be kept in mind with respect to candidate gene studies. First of all, negative studies might be underrepresented due to publication bias, an error with declining impact, since this problem is increasingly acknowledged by scientists, reviewers, and editors. Also of importance seems to be the problem that initial false-negative association studies impede further research, as they are unlikely to be replicated (Cardon, 2001a; b). This emphasizes the importance of further research on known or hypothesized candidate genes. Further issues are the artefacts due to population stratification as well as to gene–gene and gene–environment interactions. However, as QTL loci mostly require very large sets of sib-pairs to gain enough statistical power in linkage analyses (Speer, 1998), candidate gene studies are currently more feasible despite these limitations.

Serotonergic Gene Pathway

In view of the converging lines of evidence that 5-HT and serotonergic gene expression is involved in a myriad of processes during brain development as well as synaptic plasticity in adulthood, temperamental predisposition and complex behaviour are likely to be influenced by genetically driven variability of 5-HT function. Originating from the raphe nuclei in the brainstem, the serotonergic system innervates multiple regions throughout the brain. For instance, serotonergic neurons are found in the basal ganglia, amygdala, hippocampus, nucleus accumbens, cingulum, thalamus, cortex, and many other areas. The central 5-HT system is thought to function as a behavioural inhibition system, and to be involved in the regulation of motor activity, food intake, sleep and other circadian rhythms, cognition, mood, anxiety, aggression, and impulsivity. It exerts its actions by the modulation of various other transmitter systems, such as the noradrenergic, dopaminergic, glutamatergic, GABAergic, and cholinergic systems. The 5-HT system integrates and connects these spatially separated systems and thus forms a global meta-network of distinct local networks, thereby coordinating and balancing common brain functions. Moreover, 5-HT not only acts as a neurotransmitter but is also involved in the regulation of neurogenesis and synaptic plasticity in the pre- and post-natal period, as well as in the adult brain.

Serotonergic system dysfunction has been implicated in various psychiatric disorders, including depression, bipolar disorder, panic and generalized anxiety disorder (GAD), seasonal affective disorder (SAD), obsessive-compulsive disorder (OCD), eating disorders, and possibly also schizophrenic and neurodegenerative disorders (Lucki, 1998). Regarding PDs, a pivotal role of the serotonergic system has been hypothesized in the pathogenesis of emotional instability syndrome, commonly referred to as borderline personality disorder (BPD) (Goodman and New, 2000; Gurvits *et al.*, 2000). Consequently, psychoactive drugs targetting the serotonergic neurocircuitries, such as selective 5-HT reuptake inhibitors (SSRIs) and 5-HT (ant)agonists, including atypical neuroleptics, have been proven to be beneficial in most of these diseases. Low 5-HT concentrations or turnover — as measured by the metabolite 5-hydroxyindole acetic acid (5-HIAA) in cerebrospinal fluid (CSF) — are correlated with suicide, impulsivity, aggression (Asberg *et al.*, 1986; Higley *et al.*, 1996; Higley *et al.*, 1992a), and — in neonates — a family history of antisocial PD (Constantino *et al.*, 1997). In line with these findings, patients suffering from severe PDs of the high aggression/low impulse-control type (e.g., antisocial PD) exhibit decreased 5-HIAA levels (Brown *et al.*, 1982; Brown *et al.*, 1979; Coccaro *et al.*, 1992). A landmark study by Raleigh *et al.* (1991) elegantly demonstrated that male vervet monkeys with low social status also have low CSF 5-HIAA concentrations. Correspondingly, high 5-HIAA levels are associated with high social status. Intriguingly, pharmacological alterations of serotonergic function influence social rank, a fact which further underscores the critical role 5-HT plays in controlling temperament and behavioural traits. Hence, 5-HT appears to be a stabilizer of neural circuits as well as of social networks.

In a two-step reaction, 5-HT is synthesized from the essential amino acid, tryptophan. The first and rate-limiting step, the hydroxylation at the 5-position, is catalysed by the enzyme tryptophan hydroxylase (TPH) and is restricted to raphe neurons. Decarboxylation of 5-hydroxytryptophan represents the second step, which is catalysed by an amino acid decarboxylase. This non-specific enzyme is expressed not only in serotonergic neurons but also in catecholamine-synthesizing cells. Once formed, 5-HT is transported into synaptic vesicles by a nonselective monoamine transporter (VMAT). When intracellular free calcium levels reach a certain threshold, 5-HT is released into the synaptic cleft by fusion of the vesicle with the cell membrane. It may act thereafter as a paracrine hormone with effects also on non-excitable cells, as well as a classical neurotransmitter; up to now, 14 receptor subtypes are known. The reuptake of extracellular 5-HT is performed by the selective 5-HT transporter (5-HTT). 5-HT is thereafter recycled for repetitive

release or degraded to 5-HIAA by the enzyme monoamine oxidase A (MAO-A), which is localized at the outer membrane of mitochondria. For several of the genes involved in the regulation and function of the serotonergic pathway, various polymorphisms have been identified that may influence personality traits and related disorders.

Tryptophan Hydroxylase

Tryptophan hydroxylase (TPH), the rate-limiting enzyme in the synthesis of 5-HT, is a tetrahydrobiopterin (H_4Bip)-dependent mono-oxygenase which, in the CNS, is localized exclusively in raphe neurons. It is a member of the superfamily of aromatic amino acid hydroxylases, which also comprises the tyrosine and phenylalanine hydroxylases (Ledley *et al.*, 1987). The TPH gene has been assigned to human chromosome 11p15.3-p14, comprises 11 exons, and is subject to alternative splicing (Boularand *et al.*, 1995; Craig *et al.*, 1991). Besides polymorphisms in the upstream regulatory region, intron 7 is the site of two variations, although their functional relevance remains elusive (Nielsen *et al.*, 1997). Both are A to C transversions at the base pairs 218 and 779, respectively. 779A is termed allele U, and 779 C allele L (Nielsen *et al.*, 1992). Since low 5-HT system function is known to correlate with (violent) suicide, aggression, and impulsivity, a link between TPH gene variants and these traits had been predicted.

In a pioneering study by Nielsen *et al.* (1994), it was shown in a Finnish sample that the L variant of intron 7 of the TPH gene is associated with decreased CSF 5-HIAA concentrations, and that this polymorphism may predispose to suicidal behaviour. However, no association between this genetic variation and impulsivity was found. In a replication study by the same group, the TPH L allele was again linked to suicidality, history of suicide attempts, and alcohol dependence (Nielsen *et al.*, 1998). Siever and associates (New *et al.*, 1998) reported an association of the TPH gene L allele with measures of impulsivity and aggression with the Buss-Durkee Hostility Inventory (BDHI). However, it was demonstrated that in a non-patient sample 'outward bound' aggression is correlated with the U allele of TPH (Manuck *et al.*, 1999) and low CSF 5-HIAA levels (Jonsson *et al.*, 1997a). In depressed patients, the U allele was shown to be linked to a history of suicide attempt (Mann *et al.*, 1997); in schizophrenic patients, the L allele was more frequent in male subjects with a history of violent behaviour (Nolan *et al.*, 2000b). Regarding the A218 C polymorphism, the results are similarly equivocal, with both positive (Tsai *et al.*, 1999) and negative (Geijer *et al.*, 2000) findings. Recently, a negative report on the relation between both TPH polymorphisms and suicidality was published (Bennett *et al.*, 2000) in line with the findings by Abbar *et al.* (1995) and Bellivier *et al.* (1998), who argued that TPH polymorphisms are not causally linked to suicide, but that the reported associations are due to ethnic stratification. As both investigated polymorphisms are non-coding, it seems likely that they are linked with functional polymorphisms in some, but not all, populations. This possibility may explain the observed inconsistencies and thus warrants further research. In conclusion, it seems that at least in some populations, or in connection with psychiatric disease states, TPH polymorphism may play a role in the predisposition to suicidality, aggression, and possibly alcoholism. To resolve these apparent discrepancies, studies with large and ethnically matched samples need to be conducted to clarify the role of the TPH gene in personality traits and related disorders.

5-HT Receptors

Fourteen 5-HT receptor subtypes are known and are distinguished pharmacologically, structurally, functionally, and/or by molecular biologic means (for reviews, see Hoyer and Martin, 1996; Saxena, 1995). They probably derive from a common primordial 5-HT receptor, which developed in the course of evolution more than a billion years ago. The 5-HT receptors are subdivided in seven families, the largest being the 5-HT_1 family with five 5-HT receptor subtypes termed 5-HT_{1A-F} (5-HT_{1C} has been reassigned as 5-HT_{2C}). The 5-HT_2 family has three members, the 5-HT_5 family two subtypes; with respect to 5-$HT_{4,6,7}$, only a single member is known. 5-HT_3 comprises two subunits, A and B. The diversity of 5-HT receptors is probably due to the ontogenetically old role of 5-HT in neuromodulation; the apparent complexity of serotonergic subsystems allows fine tuning. Regarding personality and behaviour, a large body of evidence suggests that 5-HT receptors are involved in anxiety, impulsivity, and aggression (Goldman *et al.*, 1996; Roth, 1994). While 5-HT_{1A} and 5-$HT_{1B/D}$ (which share a high degree of similarity), 5-HT_{2A}, and 5-HT_{2C} have been extensively investigated, little is known about subtypes 5-HT_{4-7}.

5-HT_{1A} receptors are expressed on neurons as well as on astrocytes. They act presynaptically as somatodendritic autoreceptors in the raphe complex and postsynaptically in the hippocampus, septum, and the amygdala, where they initiate neuronal inhibition by hyperpolarization. The 5-HT_{1A} receptor gene is located on human chromosome 5q11.2-q13. Studies employing pharmacological techniques suggested that 5-HT_{1A} activation decreases aggressive behaviour in humans as well as rodents (Coccaro *et al.*, 1990; De Vry, 1995; Kavoussi *et al.*, 1997). In line with these findings, mice with a targetted inactivation of the 5-HT_{1A} receptor gene display increased anxiety-related behaviours in three independent studies (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998). While other mechanisms for the observed behavioural changes could be excluded, a link between serotonergic and GABAergic transmission was recently reported. Mice with a targetted inactivation of the 5-HT_{1A} receptor consistently display a spontaneous phenotype that is associated with a gender-modulated and gene/dose-dependent increase of anxiety-related behaviours. With the exception of an enhanced sensitivity of terminal 5-HT_{1B} receptors and downregulation of GABA-A receptors (Sibille *et al.*, 2000), no major neuroadaptational changes were detected. Activation of presynaptic 5-HT_{1A} receptors provide the brain with an autoinhibitory feedback system controlling 5-HT neurotransmission. Thus, enhanced anxiety-related behaviour probably represents a consequence of increased terminal 5-HT availability resulting from the lack or reduction in presynaptic somatodendritic 5-HT_{1A} autoreceptor negative feedback function. Indirect evidence for increased presynaptic serotonergic activity is provided by the compensatory upregulation of terminal 5-HT_{1B} receptors. This mechanism is also consistent with recent theoretical models of fear and anxiety that are primarily based upon pharmacologically derived data. The cumulative reduction in serotonergic impulse flow to septohippocampal and other limbic and cortical areas involved in the control of anxiety is believed to explain the anxiolytic effects of ligands with selective affinity for the 5-HT_{1A} receptor in some animal models of anxiety-related behaviour. This notion is based, in part, on evidence that 5-HT_{1A} agonists (e.g., 8-OH-DPAT) and antagonists (e.g., WAY 100635) have anxiolytic or anxiogenic effects, respectively. However, to complicate matters further, 8-OH-DPAT has anxiolytic effects when injected in the raphe nucleus, whereas it is anxiogenic when applied to the hippocampus. Thus, stimulation of postsynaptic 5-HT_{1A} receptors has been proposed to elicit anxiogenic effects, while activation of 5-HT_{1A} autoreceptors is thought to induce anxiolytic effects via suppression of serotonergic neuronal firing, resulting in attenuated 5-HT release in limbic terminal fields.

Taken together, these findings lead to the conclusion that the 5-HT_{1A} receptor is a key player in the modulation of anxiety-related behaviour and thus behavioural inhibition. Anxiety-related behaviour in 5-HT_{1A}-deficient mice seems to be caused by an

increased serotonergic tone due to the absent negative feedback of the 5-HT_{1A} autoreceptor. Interestingly, when wild house mice were divided into those with high and those with low-aggression scores, the aggressive mice showed high levels of 5-HT_{1A} receptor expression in the dorsal hippocampus compared with low-aggression mice (Korte *et al.*, 1996). This finding supports the notion of a contraposition of aggression and anxiety and the critical role of the serotonergic system in balancing both.

The 5-HT_{1B} receptor (like the structurally similar 5-HT_{1D} receptor) serves as an inhibitory autoreceptor on serotonergic terminals but also as a postsynaptic heteroceptor on non-5-HT neurons. It is expressed in the basal ganglia, striatum, hippocampus, amygdala, and frontal cortex. 5-HT_{1B} has been assigned to human chromosome 6q13 (Demchyshyn *et al.*, 1992). Based on rather indirect pharmacological evidence, it is thought to play a role in aggressive as well as reproductive behaviour. Accordingly, 5-HT_{1B} knockout mice show increased exploratory behaviour and are more aggressive in the resident-intruder paradigm (Brunner *et al.*, 1999; Malleret *et al.*, 1999; Ramboz *et al.*, 1996; Saudou *et al.*, 1994). As for 5-HT_{1A} knockout mice, this was not due to changes in locomotor activity. Mice lacking the 5-HT_{1B} receptor were also more prone to develop cocaine (Rocha *et al.*, 1998) and alcohol dependence (Brunner and Hen, 1997), a finding which suggests a role of this receptor in the pathophysiology of substance abuse. Two polymorphisms in the human 5-HT_{1B} gene, C129T and G861C, were not associated with depression, suicidality, or alcoholism (Huang *et al.*, 1999). However, in Finnish antisocial alcoholics, as well as a Southwest Native American tribe with a high rate of alcoholism, a significant association with G861C was demonstrated (Lappalainen *et al.*, 1998).

The human 5-HT_{2A} receptor gene is located on chromosome 13q14-q21 near the genes for retinoblastoma-1 and esterase D (Hsieh *et al.*, 1990) and consists of three exons and two introns (Chen *et al.*, 1992). There is reason to assume that 5-HT_{2A} is subject to genomic imprinting; only the maternal allele is expressed (Kato *et al.*, 1996). The hallucinogenic effects of LSD have been attributed to its 5-HT_{2A} agonism (Aghajanian and Marek, 1999); consequently, an association between the T102C polymorphism of the 5-HT_{2A} receptor and schizophrenia has been suggested by several, but not all, studies (He *et al.*, 1999; Spurlock *et al.*, 1998; Williams *et al.*, 1996; 1997). However, Holmes *et al.* (1998) reported that the 102 C allele is linked to the presence of hallucinations in late-onset Alzheimer's disease. No association between suicide attempts and 5-HT_{2A} polymorphism was detected (Geijer *et al.*, 2000) when suicide attempters were split into different categories including Cluster B, but not Cluster C, PD. In a study with patients suffering from bipolar affective disorder and healthy controls, no major effect of the T102C polymorphism on the TPQ personality dimension 'harm avoidance' was found (Blairy *et al.*, 2000). All in all, there is, as yet, no clear-cut evidence for a role of this polymorphism in PDs.

The physiological function of the 5-HT_{2C} receptor, which is located in the cortex, hippocampus and striatum, remains elusive. It has been mapped to Xq24 (Milatovich *et al.*, 1992). A functional knockout mouse model, in which the carboxy-terminal half of the receptor is removed, has been generated by Tecott *et al.* (1995). In addition to increased vulnerability of these mice to die from seizures, they were also overweight, hinting at a role for 5-HT_{2C} in the regulation of food intake (Tecott *et al.*, 1995). In humans, the Cys23Ser polymorphism in the N-terminal end of the 5-HT_{2C} receptor protein has attracted considerable attention (Lappalainen *et al.*, 1995). The 23Ser allele was associated with hallucinations and, interestingly, hyperphagia in Alzheimer's disease (Holmes *et al.*, 1998). Furthermore, an association between the Cys23Ser polymorphism and violent alcoholism was reported (Virkkunen *et al.*, 1996), although failure of replication casts some doubt on the initial finding (Himei *et al.*, 2000; Lappalainen *et al.*, 1999; Schuckit *et al.*, 1999).

Based on a personality assessment with the TPQ questionnaire, an interesting gene–gene interaction between a polymorphism of the dopamine receptor DRD4 (also see below) and the 5-HT_{2C} Cys23Ser polymorphism was demonstrated. When both polymorphisms were present, they accounted for 13% of the variance of TPQ 'reward dependence' and 30% of the variance for 'persistence' — a subscore of 'reward dependence' (Ebstein *et al.*, 2000; Ebstein *et al.*, 1997c; Kuhn *et al.*, 1999). No influence of the Cys23Ser polymorphism alone was found (Kuhn *et al.*, 1999); no replication studies have been performed to date.

With respect to 5-HT_{3-7} receptors, little evidence for involvement of these molecules in behaviour has been presented to date. Clearly, more research on these, in part, poorly understood and characterized receptors is needed. An interesting finding has been presented by Grailhe *et al.* (1999), who demonstrated that 5-HT_{5A} knockout mice, just like 5-HT_{1B}-deficient mice, display increased explorative behaviour, as well as altered response to hallucinogens, such as LSD. In a Finnish group of antisocial alcoholics, an association with a polymorphism of the 5-HT_7 receptor gene has been suggested, but this finding still awaits confirmation (Pesonen *et al.*, 1998).

5-HT Transporter

In contrast to the remarkable diversity of 5-HT receptors, only a single protein, the 5-HT transporter (5-HTT), mediates the reuptake of 5-HT from the synaptic cleft and thus the termination of its action. The 5-HTT is structurally and functionally similar to the dopamine (DAT) and norepinephrine (NET) transporter proteins (Blakely *et al.*, 1994; Borowsky and Hoffman, 1995). The exchange of intracellular sodium against extracellular potassium generates the energy necessary for transport of 5-HT against the extra-intracellular gradient. When intracellular 5-HT levels are very high — for instance, as a consequence of VMAT2 inhibition following MDMA ('ecstasy') intake — the 5-HTT reverses its action by releasing 5-HT into the synaptic cleft. 5-HTT is an initial target for antidepressant drugs, either with relatively low specificity, such as the TCAs (e.g., imipramine and clomipramine) or high selectivity, such as the SRIs (e.g., fluoxetine, sertraline, and citalopram), as well as for psychostimulants, including amphetamines and cocaine (Schloss and Williams, 1998). The efficacy and versatility of 5-HTT-inhibiting drugs underscores the outstanding role of the 5-HTT in the fine regulation of the serotonergic system.

The human 5-HTT is encoded by a single gene on chromosome 17q11 adjacent to the CPD and NF1 genes (Shen *et al.*, 2000). It is composed of 14–15 exons spanning approximately 35 kb (Lesch *et al.*, 1994). In humans, the transcriptional activity of the 5-HTT gene, 5-HTT availability, and ultimately 5-HT reuptake are modulated by a polymorphic repetitive element, the 5-HTT gene-linked polymorphic region (5-HTTLPR), located upstream of the transcription start site (for review, see Lesch, 1997). Additional variations have been described in the 5′ untranslated region (5′UTR) due to alternative splicing of exon 1B (Bradley and Blakely, 1997), and in intron 2 (variable number of a 16/17-base-pair tandem repeat, VNTR-17) (Lesch *et al.*, 1994), and 3′UTR (Battersby *et al.*, 1999). Comparison of different mammalian species confirmed the presence of the 5-HTTLPR in Platyrrhini and Catarrhini (hominoids, cercopithecoids), but not in prosimian primates and other mammals (Lesch *et al.*, 1997). The 5-HTTLPR is unique to humans and simian primates. The majority of alleles are composed of either 14-or 16-repeat elements in humans (short and long allele, respectively), while alleles with 15, 18, 19, 20, or 22 repeat elements, and variants with single-base insertions/deletions or substitutions within

individual repeat elements are rare. A predominantly Caucasian population displayed allele frequencies of 57% for the long (*l*) allele and 43% for the short (*s*) allele with a 5-HTTLPR genotype distribution of 32% *l*/*l*, 49% *l*/*s*, and 19% *s*/*s* (Lesch *et al.*, 1996); different allele and genotype distributions are found in other populations (Gelernter *et al.*, 1998). Consequently, the contribution of the 5-HTTLPR to individual phenotypic differences in personality traits was explored in independent population- and family-based genetic studies (for review, see Lesch, 2001a). Anxiety-related and other personality traits were assessed by the NEO Personality Inventory — Revised (NEO-PI-R), a self-report inventory based on the five-factor model of personality ('Big Five') (Costa and McCrae, 1992), and by the 16PF Personality Inventory (Cattell, 1989). The five factors assessed by the NEO are 'neuroticism' (emotional instability), 'extraversion', 'agreeableness' (cooperation and reciprocal alliance formation), 'openess' (intellect and problem-solving), and 'conscientiousness' (will to achieve).

In an initial study, population and within-family associations were discovered between the low-expressing s allele and 'neuroticism', a trait related to anxiety, hostility, and depression, on the NEO-PI-R in a primarily male population ($n = 505$) (Lesch *et al.*, 1996). Individuals with either one or two copies of the short 5-HTTLPR variant (group S) had significantly greater levels of neuroticism, defined as proneness to negative emotionality, including anxiety, hostility, and depression, than those homozygous for the long genotype (group L) in the sample as a whole and also within sibships. Individuals with 5-HTTLPR S genotypes also had significantly decreased NEO 'agreeableness'. In addition, the group S individuals had increased scores on 'anxiety' on the separate 16PF personality inventory, a trait related to NEO 'neuroticism'. In a more recent investigation, this association was tested in an independent sample ($n = 397$, 84% female, primarily sib-pairs) (Greenberg *et al.*, 2000). The findings replicated the association between the 5-HTTLPR and NEO 'neuroticism'. Combined data from the two studies ($n = 902$), which were corrected for ethnicity and age, gave a highly significant association between the *s* allele and anxiety-related traits both across individuals and within families, reflecting a genuine genetic influence rather than an artefact of ethnic admixture.

Another association encountered in the original study between the *s* allele and lower scores of NEO 'agreeableness' was also replicated and was even more robust in the primarily female replication sample. Gender-related differences in 5-HTTLPR-personality trait associations are possible, since several lines of evidence demonstrate gender-related differences in central 5-HT system function in humans and in animals. These findings include the effects of gonadal steroids on 5-HTT expression in rodent brain and differences in anxiety-related behaviours in male and female 5-HTT knockout mice (Li *et al.*, 2000).

Analysis of NEO subscales further defined the specific aspects of personality that were reproducibly associated with the 5-HTTLPR genotype. For the NEO 'neuroticism' subscales, the combined samples from Lesch *et al.* (1996) and Greenberg *et al.* (2000) demonstrated significant associations between 5-HTTLPR S group genotypes and the facets of 'depression' and 'angry hostility', two of the three facets that showed the most significant associations in the initial sample (Lesch *et al.*, 1996). In contrast, the NEO 'neuroticism anxiety' facet, which was associated with genotype in the first study at a weaker significance level, was not significantly associated with the 5-HTTLPR genotype in the new cohort. With regard to the NEO 'agreeableness' subscales, the previously observed associations of 5-HTTLPR S group genotypes with decreased 'straightforwardness' and 'compliance' were consistently replicated. It therefore appears more accurate to state that the 5-HTTLPR is associated with traits of negative emotionality related to interpersonal hostility and depression. The relationship between these two aspects of negative emotionality is not unexpected in view of the previously observed negative correlation between 'angry hostility', a facet of 'neuroticism', and 'agreeableness' (Costa and McCrae, 1992), indicating that both measures assess a behavioural predisposition to uncooperative interpersonal behaviour (Greenberg *et al.*, 2000).

The effect sizes for the 5-HTTLPR-personality associations, which were comparable in the two samples, indicate that this gene variation has only a modest influence on the behavioural predisposition of approximately 0.30 standard deviation units. This corresponds to 3–4% of the total variance and 7–9% of the genetic variance, based on estimates from twin studies using these and related measures that have consistently demonstrated that genetic factors contribute 40–60% of the variance in neuroticism and other related personality traits. Although the genetic effect suggests that the 5-HTTLPR represents an above-average size QTL, the associations represent only a small portion of the genetic contribution to anxiety-related personality traits. If additional genes were hypothesized to contribute similar gene-dose effects to anxiety, at least 10–15 genes are predicted to be involved. Additive contributions of comparable size based on epistatic epigenetic interactions have, in fact, been found in studies of other quantitative traits. Thus, the results are consistent with the view that the influence of a single, common polymorphism on continuously distributed traits is likely to be small in humans, and possibly to influence different quantitative characteristics in other species (Plomin *et al.*, 1994).

At first glance, association between the high-activity 5-HTTLPR *l* allele and lower 'neuroticism' and related traits seems to be counter-intuitive with regard to the known antidepressant and anxiolytic effects of 5-HTT inhibitors (SRIs). Likewise, Knutson *et al.* (1998) reported that long-term inhibition of the 5-HTT by the SRI paroxetine reduced indices of hostility through a more general decrease in negative affect, a personality dimension related to neuroticism. The same individuals also demonstrated an increase in directly measured social cooperation after paroxetine treatment, an interesting finding in view of the replicated association between 5-HTTLPR genotype and agreeableness. That a drug which inhibits 5-HTT lessened negative emotionality and increased social cooperation appears to conflict with findings that the 5-HTTLPR long allele, which confers higher 5-HTT expression, is associated with lower NEO 'neuroticism' and higher NEO 'agreeableness'. However, this apparent contradiction may be due to the fact that both 5-HT and 5-HTT play critical roles in brain development that differ from their functions in regulating neurotransmission in the adult.

The conclusion that the 5-HTT may affect personality traits via an influence on brain development and synaptic plasticity is strongly supported by recent findings in rodents and nonhuman primates. Studies in rats confirmed that the 5-HTT gene is expressed in brain regions central to emotional behaviour during foetal development, but not later in life (Hansson *et al.*, 1998), hence enduring individual differences in personality could result from 5-HTTLPR-driven differential 5-HTT expression during pre- and perinatal life. In support of this notion, mice with a targetted disruption of 5-HTT display enhanced anxiety-related behaviours (also see section on mouse models of anxiety-related traits) in models of avoidance and anxiety (Wichems *et al.*, 2000).

Together with DRD4, the 5-HTTLPR is the best-investigated candidate gene polymorphism with regard to personality dimensions, with 22 studies directly or indirectly targetting this subject. The results are controversial, for manifold reasons. The limiting factor in QTL analysis often is sample size, because studies including small samples lack the statistical power to detect QTL gene effects, which account typically for 2–10% of the genetic variance. In subsequent investigations, only two attempts have been reported to replicate the original finding using large

Table XXVI-7.1 Overview of published data on the association between the 5-HT transporter gene-linked polymorphic region (5HTTLPR) and anxiety-related traits in general populations and patient samples

	n	Population and study design	Trait assessment/inventory	Association of *s* allele, *P*	Family-based studies, *P*
Lesch *et al.*, 1996	505	General, USA, males, two subsamples	NEO-PI-R, 16PF	0.02–0.002	0.03–0.004
Ebstein *et al.*, 1997	120	General, Israeli	TPQ	0.75, n.s.	—

populations with samples sizes of >400 individuals (Jorm *et al.*, 1998; Mazzanti *et al.*, 1998) (Table XXVI-7.1). Two of the three available large studies found evidence congruent with an influence of the 5-HTTLPR on 'neuroticism' and related traits (Lesch *et al.*, 1996; Mazzanti *et al.*, 1998), whereas a large population study not employing a within-family design (Jorm *et al.*, 1998) did not. Smaller population-based studies have had variable, but generally negative results (Table XXVI-7.1). Interpretation of these studies is complicated by their use of relatively small or unusual samples, and the lack of within-family designs that minimize population stratification artefacts. Other efforts to detect associations between the 5-HTTLPR and personality traits have been complicated by the use of small sample sizes, heterogeneous subject populations, and differing methods of personality assessment, that is, the use of other questionnaires as the original report, rendering between-study comparison difficult or even impossible. This may explain the conflicting results of Jorm *et al.* (1998), since this group utilized the EPQ-R questionnaire, which was not used in any of the other studies (Table XXVI-7.1). Furthermore, the subject selection in two studies (Ball *et al.*, 1997; Deary *et al.*, 1999) was unusual in that subjects at the high or low ends of the distribution for 'neuroticism' were selected on the assumption that the 5-HTTLPR affects the trait uniformly across its distribution. However, reanalysis of the data from the initial study revealed that the contribution of the 5-HTTLPR to NEO 'neuroticism' is greatest in the central range of the distribution and actually decreases at the extremes (Sirota *et al.*, 1999). This illustrates the need to obtain genotypes from individuals across the distribution of a trait, and suggests caution in the use of extreme populations in attempting to establish genetic influences on traits that are continuously distributed in the population.

Finally, difficulties in interpretation of population-based association studies due to ethnic differences in 5-HTTLPR allele frequencies have also been raised by recent studies. One found no association between the 5-HTTLPR and NEO 'neuroticism' in a sample of 191 Japanese, or between 5-HTTLPR genotype and TCI 'harm avoidance' in a subsample (Kumakiri *et al.*, 1999). In addition to its relatively small sample size, a major difficulty with this study is that the frequency of the *l*/*l* genotype (corresponding to group L) was only 6% of the total population,

giving very low statistical power to detect a genotype-related difference. Another study of association between the 5-HTTLPR and TPQ 'harm avoidance' in a Japanese population is also difficult to interpret due to differences in genotypes related to ethnicity (Katsuragi *et al.*, 1999b). In that case, the small sample ($n = 101$) had a frequency of l/l genotypes of only 4%. From an evolutionary psychological perspective, anxiety is a pervasive and innately driven form of distress that arises in response to actual or threatened exclusion from social groups (Baumeister and Tice, 1990; Buss, 1995). Notably, Nakamura *et al.* (1997) have discussed the higher prevalence of the anxiety and depression-related l/s and s/s genotypes in the context of the extraordinary emotional restraint and interpersonal sensitivity in the Japanese as a possible population-typical adaptation to prevent social exclusion (Ono *et al.*, 1996).

Nevertheless, spurious results due to population stratification cannot be ruled out entirely. It is, however, important to note that, while population stratification may lead to false-positive results, false-negative findings occur due to background factors masking QTL effects (Cardon, 2001a; Pericak-Vance, 1998). Studies which incorporate large samples of different population groups, the assessment of genetic background markers, and within-family study designs, such as the Transmission Disequilibrium Test (TDT), might help to minimize the bidirectional effects of stratification (Cardon, 2001b). In addition to regional or ethnic variations of allele frequency, epistatic and gene–environment interactions may well influence the possible phenotypic effect of a given genotype, especially in behavioural genetics, where roughly equal proportions of genetic effects and non-genetic effects contribute to trait variance. With respect to the 5-HTTLPR, further studies aiming at these questions are clearly needed to resolve these issues, which should include large, community-based cohorts of different populations. Of course, the same is true for other target genes such as DRD4.

The 5-HTTLPR has also been extensively studied in other psychiatric conditions, with both positive and negative findings (for review, see Lesch, 2001b). Especially the link between depression, suicidality, violent suicide attempts, and the 5-HTTLPR remains controversial. Seasonality and seasonal affective disorder (SAD) also seem to be associated with the 5-HTTLPR *s* allele (Rosenthal *et al.*, 1998; Sher *et al.*, 1999). This effect was shown to be independent of the gene effect on neuroticism, thus arguing for genetic pleiotropy of the 5-HTTLPR gene (Sher *et al.*, 2000). Furthermore, the 5-HTTLPR is thought to be associated with an increased vulnerability to develop nicotine (Hu *et al.*, 2000; Lerman *et al.*, 2000) and alcohol (Sander *et al.*, 1997b) dependence, the latter being comorbid with antisocial PD (Hallikainen *et al.*, 1999; Sander *et al.*, 1998).

As in the 5-HT_{1A} knockout mouse, exaggerated serotonergic neurotransmission has been implicated in the increased anxiety-related behaviours recently reported in 5-HT transporter-deficient mice (Wichems *et al.*, 2000). These findings are consistent with other evidence suggesting that increased 5-HT availability may contribute to increased anxiety in rodents, and the studies reporting that anxiety-related traits in humans are associated with allelic variation of 5-HTT function (Lesch *et al.*, 1996). Mice with a disrupted 5-HTT gene have been suggested as an alternative model to pharmacological studies of SSRI-evoked antidepressant and anxiolytic mechanisms to assess the hypothesized association between 5-HT uptake function and 5-HT_{1A} receptor desensitization (Bengel *et al.*, 1998). Excess serotonergic neurotransmission in mice lacking 5-HT transport results in desensitized and — unlike observations following SSRI administration — downregulated 5-HT_{1A} receptors in the midbrain raphe complex, but not in the hippocampus (Li *et al.*, 2000), and is suspected to play a role in the increased anxiety-related and antidepressant-like behaviours in these mice shown by the Light-Dark and Elevated Zero Maze paradigms, and the Tail Suspension paradigms. In contrast to that of 5-HT_{1A}-deficient mice, the anxiety-related behaviour, which can be reversed by anxiolytics of the benzodiazepine type, is more pronounced in female 5-HTT null mutants.

Dopaminergic Gene Pathway

While the 5-HT system exerts global, brain-wide modulatory functions, the action of the dopamine (DA) system is mediated via four distinct tracts, namely, the nigro-striatal, tubero-infundibular, meso-limbic, and fronto-cortical tract. The nigro-striatal tract, which originates in the substantia nigra and projects to the nucleus caudatus, is involved in motor control and has been implicated in the pathophysiology of Parkinson's disease; the tubero-infundibular system regulates prolactin secretion. While both systems participate in the common side effects of DA receptor antagonists, such as the classic neuroleptic drugs (e.g., dyskinesia, akathisia, and hyperprolactinaemia), they do not appear to be particularly relevant to the psychobiological aspects of dopaminergic neurotransmission. More outstanding in this regard are both the meso-limbic and fronto-cortical tracts, formerly termed the meso-cortico-limbic system. The two systems are thought to play important roles in a variety of psychiatric disease states. According to the DA hypothesis of schizophrenic disorders, functional alterations in the meso-limbic and fronto-cortical tracts underlie specific symptoms observed in schizophrenic psychoses. The meso-limbic system appears to be involved in 'positive' or 'productive' symptoms, such as hallucinations, paranoia, and delusions, whereas the fronto-cortical tract may cause 'negative' symptoms such as disorganization and lack of initiative. Furthermore, the DA system is involved in the brain's reward system and consequently in the pathogenesis of addictive behaviour. Pharmacological disinhibition of dopaminergic neurons in the ventral tegmental area, which project to the nucleus accumbens, results in the activation of the reward mechanism, while blockade of the reward system provokes symptoms similar to drug withdrawal.

Based on its functional neuroanatomy, the DA system seems to be involved in Cluster A PDs, associated in some cases with 'soft signs' of schizophrenic disorders and hence they are labelled by some authors as 'schizophrenia spectrum disorders' (Kety *et al.*, 1971), 'schizoid disease' (Heston, 1970), or 'schizotaxia'. A dysfunctional reward system in conjunction with dopaminergic abnormalities, as reflected by high novelty-seeking behaviour seems to play a role in PDs.

DA is synthesized from tyrosine in two steps. The first step is catalysed by the rate-limiting enzyme tyrosine hydroxylase, and the resulting L-DOPA is then decarboxylated by an aromatic amino acid decarboxylase (DOPA decarboxylase). Dopamine acts on at least five subtypes of receptors termed D1 to D5; the reuptake is performed by a specific DA transporter. Metabolic pathways involve two non-specific enzymes, monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). A critical appraisal of the key components of dopaminergic transmission implicated in PDs follows.

Tyrosine Hydroxylase

Tyrosine hydroxylase (TH) is central to the function of the dopaminergic as well as noradrenergic neurotransmission. In a series of elegant experiments, Zhou *et al.* (1995) showed that targetted inactivation of both TH genes results in an embryonic lethality that was prevented by prenatal administration of L-DOPA. It was also demonstrated that TH-deficient mice pups may be rescued with restored with wild-type noradrenergic cells, although marked behavioural abnormalities persist (Zhou and Palmiter, 1995): TH knockout mice remained hypoactive and refused to eat

and drink. Upon acute L-DOPA injection, the behavioural deficits were reversed, and by continuous L-DOPA administration normal growth was restored.

The human TH gene has been assigned to chromosome 11p15 (Craig *et al.*, 1986) near the insulin and IGF1 gene. Several polymorphisms have been identified in the TH gene which cause different forms of Segawa syndrome, an inborn, autosomal, recessive, parkinsonism-like disorder starting in early childhood. Linkage of TH polymorphisms to several psychiatric Axis 1 disorders, including bipolar illness or schizophrenia, has been hypothesized, but the results to date are equivocal. Recently, a seemingly functional tetranucleotide repeat polymorphism ($TCAT_n$) in intron X of the TH gene (M) has been investigated for association with personality traits as assessed by the NEO-PI-R questionnaire in a Swedish population (Persson *et al.*, 2000b). Carriers of the T8 allele of $TCAT_n$ displayed significantly elevated 'neuroticism' scores, which were most prominent in the 'neuroticism' subitems 'angry hostility' and 'vulnerability'. Furthermore, a correlation of the T8 allele with both suicide attempts among subjects suffering from adjustment disorders (Persson *et al.*, 1997) and late-onset alcoholism among other patients was reported (Geijer *et al.*, 1997). It was concluded that the $TCAT_n$ polymorphism is linked to anxiety-related traits, and that the search for gene–gene interactions between $TCAT_n$ and 5-HTTLPR could be promising.

Dopamine (DA) Receptors

Although genomic variations have been identified in all five DA receptor genes, only the role of the D_2, D_3, and D_4 receptor genes (DRD2, DRD3, and DRD4, respectively) has been studied in normal personality and PDs. However, each receptor subtype has been investigated for a possible pathogenetic role in several psychiatric disease states, especially schizophrenic disorders, with inconclusive results (Wong *et al.*, 2000).

The human DRD2 gene, which has been located on chromosome 11q22–23, is subject to alternative splicing, and comprises eight exons. Interestingly, it is able to form a heterodimer with the somatostatin receptor upon binding of the respective ligand (Rocheville *et al.*, 2000). Several polymorphisms of the DRD2 have been studied in personality genetics, especially a *Taq*I restriction fragment length polymorphism (*Taq*I A) in the 3′-untranslated region of the gene (Grandy *et al.*, 1989). Several lines of evidence indicate that the A1 allele is associated with decreased dopaminergic tone in the CNS. A second *Taq*I site, identified between the first intron and the second exon has been termed *Taq*I B (Hauge *et al.*, 1991). Furthermore, a single nucleotide polymorphism (SNP) was found in intron 6 (*Hph* I site) (Sarkar *et al.*, 1991) and a functionally relevant Ser311Cys polymorphism in exon 7, which impairs D2 signal transduction, has been described (Cravchik *et al.*, 1996).

DRD2, the target for neuroleptic agents such as haloperidol or risperidone, has been suggested to be involved in a 'spectrum of DA-related disorders', including substance abuse, pathological gambling, obesity, and Tourette's syndrome (Comings *et al.*, 1996a, b; Noble *et al.*, 1994). Although this hypothesis is controversial, especially severe alcoholism seems to be associated with the *Taq*I A1 allele (Blum *et al.*, 1990). In line with a possible association of DRD2 with addictive behaviour, DRD2 knockout mice do not respond with reward behaviour following administration of morphine (Maldonado *et al.*, 1997), in addition to locomotor disturbances (Baik *et al.*, 1995).

The DRD2 gene locus has also been studied for a possible association with personality traits as well as PDs. Corresponding with the hypothesis of a schizophrenia spectrum disorder as a result of a DA neurotransmission impairment, Blum *et al.* (1997) found an association of the DRD2 *Taq*1 A1 allele with schizoid and avoidant behaviour, suggesting an involvement of DRD2 in PDs of Cluster A. By means of the TPQ questionnaire, it was shown that *Taq*1 A1, *Taq*2 B1, intron 6 alleles alone, and, even more robustly, the corresponding haplotype resulted in higher TPQ 'novelty-seeking' (NS) scores than other allele combinations. When the 7-repeat allele of DRD4 (see below) was present, a further increase of the difference was observed. This DRD2 haplotype also resulted in higher 'persistence' scores, while no influence of DRD4 7-repeat allele was detected; neither polymorphism was associated with 'harm avoidance' (Noble *et al.*, 1998). If replicated, these findings further support the notion of a link between dopaminergic function and NS (Cloninger, 1987). However, de Brettes *et al.* (1998) failed to find any association between *Taq*1 A1 and TPQ NS scores, suggesting that reports on associations between this polymorphism and personality traits should be considered preliminary. The only study investigating the Ser311Cys polymorphism in healthy individuals also yielded negative results regarding a relationship between DRD2 and scores of the TCI, a modified version of the TPQ (Cloninger *et al.*, 1993).

An interesting gene–environment interaction was reported by Ozkaragoz and Noble (2000). Children with the A1 DRD2 allele had higher extraversion scores when living in an alcoholic home; DRD2 A2 allele subjects tended to have lower extraversion levels. This result may link the DRD2 effect on alcohol dependence to environmental factors and personality. Another preliminary finding is the report on an association between DRD2 alleles and the age at first sexual intercourse, explaining the variance by 23% alone and by 55% in combination with DRD1 alleles (Miller *et al.*, 1999). These interesting, but hitherto incompletely understood data on the impact of DRD2 on personality warrant further investigation of gene–gene as well as gene–environment interactions.

Only a few data are available concerning personality traits and DRD3, which is expressed almost exclusively in limbic structures (Sokoloff *et al.*, 1990). Preliminary findings suggest a role for a functional DRD3 polymorphism (*Bal*I) influencing the TPQ NS scores of bipolar patients (Staner *et al.*, 1998); opiate-dependent subjects with high NS scores were found to carry *Bal*I significantly more often (Duaux *et al.*, 1998). As noted above, gene–gene interactions of the Glyc/Ser substitution of DRD3 with both the DRD4-7 repeat allele and the $5HT_{2C}$ Cys23Ser substitution were demonstrated by Ebstein *et al.* (1997c) regarding TPQ 'persistence' and 'reward dependence' scores. In a large population study ($n = 2752$), the *Bal*I polymorphism was investigated for a possible association with personality traits, psychiatric symptoms, and life events (Henderson *et al.*, 2000). Since the EPQ-R (Eysenck's Revised Personality Questionnaire) (Eysenck *et al.*, 1985) and the BIS/BAS (Behavioural Inhibition System/Behavioural Activation System scales) (Carver and White, 1994) were used to assess personality scores, comparison with similar studies investigating DRD3 is difficult. In an initial subsample (including 30% of the final sample), the authors found subjects with at least one serine allele to have higher scores for neuroticism, behavioural inhibition, depression, and anxiety, when experiencing more than one life event recently. However, the gene–environment interaction became non-significant when the full sample was evaluated. A study on the association between the DRD3 polymorphism and alcoholism yielded negative results (Gorwood *et al.*, 1995). All in all, the relevance of the DRD3 in personality traits remains inconclusive, but the search for a possible association and the assessment of environmental factor such as psychosocial stress seem promising.

The potential role of the D4 receptor in the personality traits related to NS behaviour has attracted considerable attention. DRD4 has been mapped to the human chromosome 11p15.5 (Gelernter *et al.*, 1992). Several atypical neuroleptics, including clozapine and olanzapine, preferentially bind to DRD4, making this receptor an attractive therapeutic target. In exon 3 of the DRD4 gene, which codes for the third cytoplasmatic loop, a polymorphic 48-bp repeat

was found (Lichter *et al.*, 1993; Van Tol *et al.*, 1992). It varies between 2 and 10 repeat units, resulting in a corresponding length variation of the receptor protein and differential receptor function (Asghari *et al.*, 1994; 1995). The polymorphism has been termed DRD4-*n*R, with *n* being the number of repeats. The 2-, 4-, and 7-repeat alleles are most common; however, allele frequencies show substantial ethnic variability. In addition, several SNPs have been described in the upstream promoter region of DRD4 and examined with respect to their relevance for personality traits and behaviour.

Cloninger and associates have suggested that the personality trait of NS, as defined by the TPQ, is exclusively based on dopaminergic function (Cloninger, 1987). While likely to be rather simplistic, this notion provided a starting point to assess the role of DRD4 in the trait of NS. The initial study and several follow-up studies were conducted by Ebstein and co-workers (reviewed in Ebstein *et al.*,1997b; 2000). In a cohort of 124 Israeli volunteers, higher TPQ NS scores were associated with the DRD-7R allele independently of age or sex (Ebstein *et al.*, 1996) with a case-control design. No association between DRD4 alleles and TPQ 'harm avoidance', 'reward dependence', or 'persistence' was found. Simultaneously, the DRD4 polymorphism and a NS equivalent of the NEO-PI-R were studied in a North American sample that included sib-pairs to allow a complementary within-family design. The concurring results further substantiated the association between DRD4-7R and NS (Benjamin *et al.*, 1996).

These findings prompted a considerable number of groups to follow-up on these studies, with both positive and negative results (Table XXVI-7.2). Several groups succeeded in replicating the effect of the DRD4 polymorphism on NS. An association between DRD4-7R and NS could be found in populations from Finland ($n = 190$, with the TCI, a modified TPQ questionnaire [Ekelund *et al.*, 1999]), Germany ($n = 136$; TPQ) (Strobel *et al.*, 1999), and Japan ($n = 153$; TCI and $n = 69$, females, respectively) (Ono *et al.*, 1997; Tomitaka *et al.*, 1999). Noble *et al.* (1998) found an influence of DRD4-*n*R on NS alone, and an even more pronounced effect in concert with DRD2 polymorphisms.

In contrast, Gelernter *et al.* (1997) studied the DRD4-*n*R polymorphism in a North American sample of mixed ethnicity subdivided into substance-abusing, personality-disordered, and healthy individuals. As reported earlier, addicted subjects had higher NS scores; however, in neither subgroup was a relationship between DRD4 alleles and NS detected. Likewise, in a German sample, the DRD4-*n*R status did not differ between patients with alcohol dependence and controls, even when they were selected for high and low TPQ NS scores (Sander *et al.*, 1997a). Similarly, in two samples from New Zealand — one being rather small ($n = 86$) from a depression treatment trial, and the other from 14 pedigrees with alcoholism ($n = 181$) — no significant correlation between DRD4 genotype and NS was found (Sullivan *et al.*, 1998).

Moreover, in studies of populations from Finland ($n = 193$; TPQ) (Malhotra *et al.*, 1996), Sweden ($n = 126$ and 167, respectively; Karolinska Scale of Personality [KSP] [Jonsson *et al.*, 1997b; Jonsson *et al.*, 1998]), the USA ($n = 200$, NEO-PI-R [Vandenbergh *et al.*, 1997]; $n = 256$, NEO-PI-R [Persson *et al.*, 2000a]; and $n = 58$, TCI [Herbst *et al.*, 2000], respectively), Brazil ($n = 110$ patients with alcohol dependence, TPQ [Bau *et al.*, 1999]), Austria ($n = 109$, TCI [Gebhardt *et al.*, 2000]), and Germany ($n = 190$, TPQ [Kuhn *et al.*, 1999]), no association between DRD4-*n*R and the trait of NS was uncovered. The latter group, however, reported a significant interaction between DRD4 and $5HT_{2C}$ polymorphisms on reward dependence. Finally, a thorough twin study (92 monozygotic and 61 dizygotic twin pairs; TPQ and NEO-PI-R) conducted by Pogue-Geile *et al.* (1998) also did not reveal an influence of DRD4 repeat length on NS as well as positive emotional experience. Of note, several studies had been conducted in similar populations as the positive studies.

The DRD4 polymorphisms were also investigated for association with several psychiatric disorders, with substance abuse and attention deficit hyperactive disorder (ADHD) being the most extensively studied. In ADHD, several, but not all, investigators using case-control and family-based study designs found an increased disease risk associated with DRD4-7R (Castellanos *et al.*, 1998; LaHoste *et al.*, 1996; Rowe *et al.*, 1998; Smalley *et al.*, 1998; Swanson *et al.*, 1998). The findings were also inconsistent in alcoholism. While some researchers reported an association with the DRD4 exon 3 repeat polymorphism (George *et al.*, 1993; Vandenbergh *et al.*, 2000), others failed to do so (Adamson *et al.*, 1995; Geijer *et al.*, 1997; Parsian and Zhang, 1999).

Based on these inconsistent findings, it was concluded that DRD4-*n*R itself is not a susceptibility gene for NS, but rather another gene variant in linkage disequilibrium with DRD4-*n*R (Ekelund *et al.*, 1999). Indeed, a polymorphism in the DRD4 promoter region, which is located at the nucleotide position −521 of the DRD4 gene, and which comprises a C to G transition, was shown to be associated with NS scores (Okuyama *et al.*, 2000). Several follow-up studies either replicated (Ronai *et al.*, 2001) this finding or failed to do so (Mitsuyasu *et al.*, 2001; Strobel *et al.*, in press).

Evidently, efforts to detect associations between the DRD4-*n*R or promoter polymorphism and personality traits have been complicated by the use of small sample sizes (with only two of 33 studies incorporating more than 400 subjects, one being positive and one negative), heterogeneous subject populations, unusual subject selection, and differing methods of personality assessment (Table XXVI-7.2). As mentioned above, gene–gene or gene–environment interactions may also play a role, both within and among different populations. Another major concern is the lack of a within-family design in that study, raising the possibility of artefacts due to ethnic admixture. Thus, it remains controversial whether variation in DRD4 expression and function contributes to the phenotype of NS. Interestingly, DRD4 knockout mice are less active than the wild-type animals, and display supersensitivity to ethanol, cocaine, and methamphetamine (Rubinstein *et al.*, 1997). Furthermore, it was shown that DRD4-deficient mice exhibit a decreased response to novel stimuli, as tested in three paradigms including the open field, emergence, and novel objects test (Dulawa *et al.*, 1999). These results argue for a role of this receptor in explorative and addictive behaviour which appears to represent facets of NS. Whether the investigated polymorphisms are relevant to differences in NS, or whether they are in linkage disequilibrium with alternative, as yet unknown, genetic variations remains to be elucidated.

Dopamine Transporter

Similar to the 5-HT system, only a single transporter protein mediates reuptake of dopamine. The dopamine transporter (DAT, SLC6A3) is structurally similar to other monoamine transporters, and several polymorphisms, including a polymorphic 40-base-pair VNTR in the 3′ untranslated region of the DAT gene, have been identified (Byerley *et al.*, 1993; Sano *et al.*, 1993). While this VNTR-based gene variation seems to play a role in ADHD and addiction, especially cigarette smoking and alcoholism (Barr *et al.*, 2001; Daly *et al.*, 1999; Parsian and Zhang, 1997; Sabol *et al.*, 1999; Ueno *et al.*, 1999), few data are available with respect to personality traits. A weak association between the VNTR 10/10 genotype and schizoid/avoidant behaviour was found in a pilot study by Blum *et al.* (1997). In the context of research on the genetic basis of cigarette smoking, Sabol *et al.* (1999) found the SLC6A3-9 polymorphism of DAT to be associated with lower NS scores, although this was not replicated in a follow-up study (Jorm *et al.*, 2000). Thus, the role of DAT polymorphisms in personality traits is still unclear and warrants further research.

Table XXVI-7.2 Overview of published data on the association between the dopamine DRD4 polymorphisms and temperament or personality traits in general populations and patient samples

Study	*n*	Population and study design	Tested polymorphism, if different from DRD4-*n*R	Trait assessment/ inventory	Association of the polymorphism with trait, *P*	Remarks
Ebstein *et al.*, 1996	124	General, Israeli		TPQ	NS with 7R: $P = 0.013$	
Benjamin *et al.*, 1996	315	General, US, of mixed ethnicity: mostly male		NEO-PI-R	Extraversion with 7R: $P = 0.001$; consciousness, $P = 0.03$	NS (calculated) with 7R, $P = 0.002$; within-sibship analysis positive
Malhotra *et al.*, 1996	193/138	General and alcoholic offenders, Finnish		TPQ	n.s. for controls, for alcoholics *lower* NS with 7R, $P = 0.02$

Monoamine Metabolic Gene Pathway

Monoamines involved in neurotransmission (5-HT, dopamine, and norepinephrine) share common metabolic pathways: deamination, accomplished by MAO-A and, in the case of the catecholamines, methylation of the 3-hydroxy group, catalysed by the enzyme COMT. An increasing body of evidence indicates that both enzymes are relevant to genetic variation of behaviour.

Monoamine Oxidase (MAO) A

MAO, the enzyme which degrades 5-HT, dopamine, and norepinephrine by oxidative removal of the amino group, occurs in two isoforms, MAO-A and MAO-B, which are encoded by distinct genes. They are located close together on chromosome Xp11.23 (Lan *et al.*, 1989). In the brain, MAO-A is the prevailing isoform and is thought to be crucial for the catabolic metabolism of monoamine neurotransmitters. MAO-A thus links three important transmitter systems. Norrie's disease, the result of an X-chromosomal deletion which includes the MAO-A gene, causes mental retardation, autistic behaviour, motor hyperactivity, and sleep disturbances. These symptoms may, at least in part, be attributed to the lack of MAO activity in the affected individuals (Sims *et al.*, 1989).

A MAO-A-deficient mouse was found to display — as predicted by the function of this enzyme — increased brain concentrations of 5-HT (ninefold), dopamine, and norepinephrine (twofold) (Cases *et al.*, 1995). In addition, cytoarchitectural alterations of the cerebral cortex were demonstrated in these animals: like 5-HTT knockout mice, they show malformation of barrels in the somatosensory cortex (Cases *et al.*, 1996), thus highlighting the morphogenetic role of 5-HT in CNS development. MAO-A knockout mice are also characterized by markedly altered behaviour. Adult mice were more aggressive (Cases *et al.*, 1995; Shih *et al.*, 1999), as tested by the resident-intruder paradigm, and this offensive-aggressive behaviour resulted in an increased number of woundings under standard housing conditions (Popova *et al.*, 2000). Furthermore, male mice had modified sexual behaviour with enhanced "offensive" sexuality. As the behavioural changes, at least in part, could be antagonized by an inhibitor of 5-HT synthesis, parachlorophenylalanine, but not by inhibitors of catecholamine synthesis, the aggressive-offensive behavioural phenotype in MAO-A knockout mice is probably due to altered 5-HT degradation, further underscoring the role of this transmitter system in the balance of fearfulness and aggression and other outward directed behaviours.

In accordance with the observations made in the rodent model, a rare mutation in the human MAO-A gene results in noticeably changed temperament and behaviour. The disorder, termed 'Brunner syndrome' after its first describer, represents an example of transmissible genetic influence on human behaviour. In a large Dutch kindred, all affected males could be shown to suffer from mild, non-dysmorphic mental retardation along with prominent abnormal behavioural changes. This included impulsive-aggressive behaviour, sometimes shown as hypersexuality and attempted rape and exhibitionism, as well as arson and attempted suicide. The disorder is X-linked and was demonstrated to result from a point mutation in the MAO-A gene, changing a glutamine-coding triplet into a stop codon (Brunner *et al.*, 1993a; b). This leads to measurable changes in monoamine metabolism with increased 5-HT levels, as assessed by urinary examinations, as well as the absence of MAO-A activity (Brunner *et al.*, 1993b). These features largely resemble the data obtained from MAO-A knockout mice. Thus, this MAO-A mutation is the only disorder in behavioural genetics nearly to fulfil the criteria of an OGOD type of disorder, albeit there has been a considerable controversy as to the derivation of this notion (Hebebrand and Klug, 1995). Brunner (1996) later made it clear that 'the concept of a gene that directly encodes behaviour is unrealistic', and that MAO-A deficiency results in complex effects on neurotransmitter function as well as behavioural phenotypes.

At first sight, these findings contrast with the antidepressant and aggression-related effects of MAO-A inhibitors such as tranylcypromine. This apparent discrepancy is resolved when brain cytoarchitectural changes are assumed in MAO-A-deficient individuals as reported for MAO-A-deficient mice (Cases *et al.*, 1996). Moreover, drug-induced MAO-A inhibition occurs rapidly, whereas antidepressant effects require approximately 2 weeks and are probably due to neuroadaptional changes which compensate MAO-A inhibition. Nevertheless, Brunner's disease and MAO-A deficiency states are rare, as shown by a thorough screening of a large cohort (Schuback *et al.*, 1999).

The MAO-A gene consists of 15 exons and spans approximately 60 kb. Several polymorphisms have been described in the human MAO-A gene (Black *et al.*, 1991; Hinds *et al.*, 1992). Two single base-pair mutations in the last base of a triplet codon have been described that do not alter the amino acid sequence of the primary transcript but result in the absence or presence of a restriction enzyme site, thus influencing the expression of MAO-A and resulting in 30-fold increase in total enzyme activity (Hotamisligil and Breakefield, 1991). A dinucleotide repeat length polymorphism (MAOCA-1) was not associated with increased aggressivity scores (Vanyukov *et al.*, 1995). Several studies have been conducted on the association of MAO-A polymorphisms and affective disorders, but despite initially promising findings (Lim *et al.*, 1995) only controversial (Lin *et al.*, 2000) or negative results could be found (Furlong *et al.*, 1999; Muramatsu *et al.*, 1997; Parsian and Todd, 1997; Rubinsztein *et al.*, 1996).

In addition, a 30-bp VNTR polymorphism of the MAO-A promotor region has been shown to alter the expression of the enzyme (Deckert *et al.*, 1999; Sabol *et al.*, 1998) and to influence CSF 5-HIAA levels in women, but not men (Jonsson *et al.*, 2000). The longer allele (four repeats) could be shown to be associated with panic disorder in a combined German and Italian sample (Deckert *et al.*, 1999) and unipolar depression (Schulze *et al.*, 2000), both in females only. Regarding bipolar affective disorder, no association was found (Furlong *et al.*, 1999; Syagailo *et al.*, 2001). To date, only two studies have dealt with the MAO-A promotor VNTR polymorphism (MAOALPR) in PDs and provided evidence that this polymorphism is associated with antisocial behaviour in alcohol-dependent patients (Samochowiec *et al.*, 1999) and enhanced impulsivity and aggression in healthy, male subjects (Manuck *et al.*, 2000). More research is needed to clarify the apparently gender-specific effects of MAOALPR on behaviour. Nonetheless, these data again point to a role of the 5-HT system in the regulation of aggression, impulsivity, and negative emotionality.

Catechol-O-Methyltransferase

COMT is an enzyme which, alternatively or subsequentially to MAO, degrades catecholamines by methylation of the 3-hydroxy group of the catecholamine ring scaffold. *S*-Adenosylmethionine is utilized as a methyl group donor in this reaction. The human COMT gene has been mapped to 22q11.1-q11.2 (Grossman *et al.*, 1992), and three different COMT phenotypes have been described with respect to activity and stability differences resulting in low, intermediate, and high levels of enzymatic activity (Weinshilboum and Raymond, 1977). The mode of inheritance suggests the presence of autosomal dominant or codominant alleles. Accordingly, two alleles were identified (G158A). Carrying two 158A alleles results in an up to fourfold decrease of enzymatic activity when compared to homozygosity for 158G, while both alleles appear to be distributed equally (Lachman *et al.*, 1996; Syvanen *et al.*, 1997). Tiihonen and co-workers suggested an association between this polymorphism

and alcohol consumption among social drinkers (Kauhanen *et al.*, 2000) as well as the risk of developing 'late-onsets' alcoholism (type 1) (Tiihonen *et al.*, 1999), but not type-2 alcoholism, a form with severe antisocial behaviour (Hallikainen *et al.*, 2000).

Altered COMT activity in affective and schizophrenic disorders has long been suspected, but the results of studies have been equivocal (Dunner *et al.*, 1977; Fahndrich *et al.*, 1980; Gershon and Jonas, 1975; Shulman *et al.*, 1978), so that the enzyme went out of focus for a while. However, in the last 4 years, evidence has accumulated of a role for COMT polymorphisms in self- and outward directed aggression. Male schizophrenic patients were shown to have a higher risk of aggressive and dangerous behaviour when they were homozygous for the low-activity 158A allele (Kotler *et al.*, 1999; Lachman *et al.*, 1998; Strous *et al.*, 1997). Any interaction with both DRD4 and 5-HTTLPR polymorphisms could be excluded (Kotler *et al.*, 1999). Additionally, the suicidal behaviour of male schizophrenic patients again was associated with the 158A allele (Nolan *et al.*, 2000a). In females, the low-activity L allele seems to be associated with OCD (Karayiorgou *et al.*, 1997). In line with these findings, female COMT knockout mice displayed impairment in emotional reactivity; in contrast, male heterozygous mice showed increased aggressive behaviours (Gogos *et al.*, 1998), thus suggesting gender-specific effects of COMT on behaviour similar to MAOALPR variants. Because meticulous investigations of subjects who do not suffer from a psychiatric Axis 1 disorder are lacking, there is obviously a demand for further studies investigating the role of COMT polymorphisms in personality.

The influence of the COMT polymorphism on personality was investigated by Benjamin *et al.* (2000a; b) with the TPQ. An interesting gene–gene interaction was demonstrated. When the individual was homozygous for either 158A or 158G, the presence of the short allele of the 5-HTTLPR raised 'persistence' scores; COMT polymorphism alone had a significant effect as well. When the short 5-HTTLPR allele was absent in combination with both alleles of the high-activity allele of COMT, NS scores could be significantly increased by the presence of the DRD4 7-repeat allele. However, a population study from Australia failed to find any association between the COMT polymorphism (both alleles occurred in the same frequency) and personality traits or psychiatric symptoms (Henderson *et al.*, 2000). As noted above, EPQ-R and BIS/BAS were utilized, a fact which renders comparison with results derived by the TPQ or NEO-PI-R questionnaires difficult. All in all, COMT polymorphisms appear to play a role in aggressive behaviour in male schizophrenic patients and in the behavioural trait of NS, in concert with other genetic variations that have yet to be investigated in greater detail.

Miscellaneous Genes

In contrast to the remarkable amount of genetic research on the 5-HT and dopamine systems, and although there are both functional data and animal models for almost all neurotransmitter and modulator systems (e.g., noradrenergic, GABAergic, adenosinergic, and peptidergic transmission), signalling cascades as well as regulatory and structural proteins, with respect to their influence on behaviour, behavioural genetic studies of other neurotransmitter systems are largely lacking.

Noradrenergic Genes

The noradrenergic system of the brain, which originates primarily in the locus coeruleus, acts as a central arousal system and is thought to play a modulatory role in the 'fight or flight' response and, according to Cloninger, in reward dependence, albeit the latter claim requires further validation. Norepinephrine is synthesized from dopamine by the enzyme dopamine β-hydroxylase (DBH), of which the human gene is located on chromosome 9q34 (Perry *et al.*, 1991). DBH activity has been investigated as a biological marker for various psychiatric disease states, and appears to be correlated with the MMPI (Minnesota Multiphasic Personality Inventory) score (Major *et al.*, 1980). Enzyme activity varies widely among individuals, with a part of the population having very low DBH activity, a variation which has been ascribed to a functional polymorphism in the 5′-flanking region of the gene, resulting in a C to G transition and explaining up to 50% of the activity variation (Zabetian *et al.*, 2001). No linkage of DBH polymorphisms to Axis 1 disorders was found, although DBH seems to play a role in nicotine dependence (McKinney *et al.*, 2000). While DBH activity measures in serum and CSF appear to link DBH to personality traits, as well as to life events, education, and even response to psychotherapy, no data on DBH polymorphisms and personality (disorders) have been reported to date. DBH thus remains an attractive candidate gene.

Although several polymorphisms in adrenergic receptor genes have been identified, and both ADRA2A and ADRA2C gene polymorphisms have been shown to be involved in ADHD and learning disorders (Comings *et al.*, 1999), only a single study deals with the influence of adrenoceptors on personality traits. Comings *et al.* (2000c) reported that a single base-pair *Msp*I polymorphism in the promoter region of the ADRA2A is associated with irritability (as assessed by the Brown Adult Attention Deficit Disorder [BADD] scale), indirect hostility, negativity, irritability, and verbal hostility (as measured by the Buss-Durkee Hostility Inventory [BDHI]) in two populations ($n = 123$ and 204, respectively), but not with aggressiveness subscales. These results argue for a role of ADRA2A in irritability, as proposed by Coccaro *et al.* (1991). In this study, which awaits replication, the polymorphism accounted for 2–8% of the variance; however, no significant association with TCI subscales was found, underscoring the importance of using appropriate questionnaires. No studies investigating the role of norepinephrine transporter (NET1) polymorphisms in personality or behaviour have been published to date, even though NET1 is an outstanding candidate gene.

GABAergic Genes

Following ground-breaking studies by Mohler and co-workers (Crestani *et al.*, 1999), who generated mice lacking the γ_2 subunit of the GABA-A (gamma-aminobutyric acid type A) receptor, a notable body of evidence has been accumulated that GABA-A function is compromised in anxiety disorders. Preliminary data suggest that GABA receptor polymorphisms might be involved in the pathogenesis of alcoholism (Parsian and Zhang, 1999; Sander *et al.*, 1999a, b), as well as the glutamate transporter gene EAAT2 (Sander *et al.*, 2000). However, studies on PDs are largely lacking, although one group found a polymorphism in the γ_2 subunit of the GABA-A receptor to be associated with antisocial PD (Loh *et al.*, 2000).

Nitric Oxide

Nitric oxide (NO) was the first to be discovered substance in a class of novel gaseous messenger molecules, acting as paracrine and highly diffusible neurotransmitters. NO or a precursor molecule is synthesized by a family of three H_4Bip-dependent enzymes termed NO synthases (NOS-I, II, and III). NO appears to play a role in learning, memory, and long-term potentiation in the hippocampus (for a review, see Snyder and Ferris, 2000). By the modulation of oxytocin release, NO inhibits maternal behaviour in female rats (Okere *et al.*, 1996); however, male mice in which the neuronal NOS isoform has been knocked out (nNOS$^{-/-}$ rats), like mice treated with an NO inhibitor (Demas *et al.*, 1997), show a

clear increase in aggressive and sexual behaviour (Nelson *et al.*, 1995). Moreover, it was recently demonstrated that the aggressive behaviour of $NOS^{-/-}$ mice is apparently due to deficient 5-HT_{1A} and 5-HT_{1B} receptor functioning and a selective decrease in 5-HT turnover, especially in the cortex, hippocampus, amygdala, and midbrain (Chiavegatto *et al.*, 2001). NO thus seems to have a modulatory effect on the serotonergic system, a finding which functionally couples two ontogenetically old and major signalling pathways. Unfortunately, no data on NOS functioning and/or NOS polymorphisms with respect to human behaviour are available yet.

Finally, Comings *et al.* (2000a) reported that a dinucleotide polymorphism in the 5′ region of the neutral endopeptidase gene (coding for membrane metalloendopeptidase [MME]) is significantly associated with SCL-90 scores for (phobic) anxiety and obsessive compulsivity. MME is one of the major enzymes for enkephalin degradation; the report thus argues for a role of enkephalin pathway polymorphisms in the genetic variation of anxiety. Clearly, further studies are needed to strengthen this hypothesis. A tetranucleotide polymorphism of the human transcription factor AP-2β gene was shown to be gender-specifically associated with guilt, anxiety, psychasthenia, and indirect aggression, as measured by the Karolinska Scales of Personality (KSP; $n = 137$) (Damberg *et al.*, 2000). Mothers with a son suffering from fragile-X syndrome, and who themselves had a full mutation or a premutation of the FMR-1 gene, which is responsible for the fragile-X syndrome, were found to have social phobia as well as avoidant and schizotypal PD more often than controls (Franke *et al.*, 1998; Levitas, 1996; Sobesky *et al.*, 1994), although this was not evident in MMPI testing (Steyaert *et al.*, 1994).

GENE–GENE INTERACTION

Since a considerable number of genes appear to contribute to the phenotypic expression of anxiety-related behaviour, dissection of gene–gene interaction (i.e., epistasis) in the development of personality and behavioural traits is a pertinent and exciting avenue of research. Moreover, in the evaluation of complex genetic effects, it seems to be essential to control for environmental factors. Recent studies have therefore focused on the neonatal period, a time in early development when environmental influences may be minimal, and least likely to confound associations between temperament and genes. In this context, the term 'temperament' is used to refer to the psychological qualities of infants that display considerable variation and have a relatively, but not indefinitely, stable biological basis in the individual's genotype, even though different phenotypes may emerge as the child grows (Kagan, 1989).

Ebstein *et al.* (1998) investigated the behavioural effects of the VNTR polymorphism in exon 3 of the dopamine D4 receptor (DRD4), which had previously been linked to the TPQ personality trait of NS, as discussed in detail above (Benjamin *et al.*, 1996; Ebstein *et al.*, 1996), and of 5-HTTLPR, which seems to influence NEO 'neuroticism' and TPQ 'harm avoidance', in 2-week-old neonates ($n = 81$). Neonate temperament and behaviour were assessed by the Brazelton neonatal assessment scale (NBAS). In addition to a significant association of the DRD4 polymorphism across four behavioural clusters relevant to temperament (orientation, motor organization, range of state, and regulation of state), an interaction was observed between the DRD4 polymorphism and 5-HTTLPR. The presence of the 5-HTTLPR s/s genotype decreased the orientation score for the group of neonates lacking the long variant of DRD4. The D4DR polymorphism–5-HTTLPR interaction was also assessed in a sample of adult subjects. Interestingly, there was no significant effect of the L-DRD4 genotype in those subjects homozygous for 5-HTTLPR s, whereas in the group without the homozygous genotype, the effect of L-DRD4 was significant and represented 13% of the variance in NS scores between groups. Furthermore, the 5-HT_{2C} polymorphism in conjunction with DRD-*n*R accounted for 30% of the variance for persistence and 13% of 'reward dependence' assessed by the TPQ (Ebstein *et al.*, 1997c), and DRD2 and DRD4 polymorphisms seem to exert synergistic effects on NS (Noble *et al.*, 1998).

In this series of landmark studies by Ebstein and his group, temperament and behaviour of the infants were re-examined at 2 months with Rothbart's Infant Behaviour Questionnaire (IBQ) as well as at 1 year with a structured play situation and an information-processing task (Auerbach *et al.*, 1999; 2001). There were significant negative correlations between neonatal orientation and motor organization as measured by the NBAS at 2 weeks and negative emotionality, especially distress in daily situations, at 2 months of age. Furthermore, grouping of the infants by DRD4 polymorphism and 5-HTTLPR revealed significant main effects for negative emotionality and distress. Infants with long DRD4 alleles had lower scores on 'negative emotionality' and 'distress to limitations' than infants with short DRD4 alleles. In contrast, infants homozygous for the 5-HTTLPR s allele had higher scores on 'negative emotionality' and 'distress' than infants with the I/s or I/I genotypes. Infants with the s/s genotype who also were lacking the NS-associated long DRD4 alleles showed most 'negative emotionality' and 'distress', temperament traits that possibly contribute to the predisposition to adult neuroticism.

In addition, an interaction between the 5-HTT gene and the COMT gene has been shown to influence the trait of 'persistence' (RD2), a subscale of TPQ major personality factor 'reward dependence'. 'Persistence' is considered to be highly adaptive in the presence of stable intermittent reward patterns. Persistent individuals are eager, ambitious, and determined overachievers (Cloninger *et al.*, 1993). In the presence of COMT Val/Val or Met/Met homozygosity, the low 5-HTT function 5-HTTLPR *s* allele significantly raised TPQ RD2 scores, including 'perfectionism', in a sample of 577 healthy subjects (Benjamin *et al.*, 2000b). Benjamin *et al.* (2000a) also investigated the interaction of three different gene variants, DRD4, 5-HTT, and COMT, and TPQ personality factors in 455 individuals. In the absence of the 5-HTTLPR *s* allele and in the presence of the high enzyme activity COMT Val/Val genotype, NS scores were higher in the presence of the DRD4 7-repeat allele. In a within-family design, siblings who shared identical genotype groups for all three polymorphisms had significantly correlated TPQ NS scores, whereas sibs with dissimilar genotypes in at least one polymorphism showed no correlation.

Since a large number of epistatic interactions are anticipated to bear a considerable potential of false-positive findings that may lead to meaningless conclusions, gene–gene interaction analyses should at this stage be limited to polymorphisms known to be functional, preferentially within a single neural circuit, such as the 5-HT system, or demonstrated to be associated with behavioural phenotypes of interest.

GENE–ENVIRONMENT INTERACTION

It is no longer controversial whether nature or nurture shapes personality development, but it remains elusive how complex genetic and environmental factors interact in the formation of a behavioural phenotype. While genetic research has typically focused either on normal personality characteristics or on PDs, with few investigations evaluating the genetic and environmental relationship between the two, it is of critical importance to answer the questions of whether a certain quantitative trait aetiopathogenetically influences the disorder, or whether the trait is a syndromal dimension of the disorder.

Under the influence of the sociobiological concept of Edward O. Wilson (Wilson, 1978), there has also been an increasing interest in human personality, particularly the 'big five' personality

dimensions, from the evolutionary perspective (Buss, 1995). These five dimensions may define the framework for adapting to other people, a crucial task in long-term reproductive success. Extraversion and agreeableness are important to the formation of social structures ranging from pair-bonds to coalitions or groups; emotional stability and conscientiousness are critical to the endurance of these structures; openness may reflect the capacity for innovation. Since the genetic basis of present-day personality dimensions may reflect selective forces among our remote ancestors, we have recently focused our research efforts on rhesus monkeys. In this non-human primate model, environmental influences are probably less complex, can be more easily controlled, and are thus less likely to confound associations between temperament and genes.

Human and non-human primate behaviour is similarly affected by deficits in 5-HT function. In rhesus monkeys, 5-HT turnover, as measured by cerebrospinal (CSF) 5-HIAA concentrations, has a strong heritable component and is traitlike, with demonstrated stability over an individual's lifespan (Higley *et al.*, 1991; 1992b). Moreover, CSF 5HIAA concentrations are subject to the long-lasting influence of deleterious events early in life as well as of situational stressors. Monkeys separated from their mothers and reared in the absence of conspecific adults (peer-reared) have altered serotonergic function and exhibit behavioural deficits throughout their lifetimes when compared to their mother-reared counterparts.

Comparison of different mammalian species indicates that the 5-HTTLPR is unique to humans and simian primates. In hominoids, all alleles originate from variation at a single locus (polymorphic locus 1, PL1), whereas an alternative locus for a 21-bp length variation (PL2) was found in the 5-HTTLPR of rhesus monkeys (rh5-HTTLPR) (Lesch *et al.*, 1997). The fact that the 5-HTTLPR is encountered in hominoids and the cercopithecoids, represented by the macaques, indicates remarkable conservation of this part of the 5-HTT gene promoter throughout the different lineages of these two superfamilies, and suggests that a progenitor 5-HTTLPR sequence, possibly representing viral DNA, was introduced into the genome some 40 million years ago. The appearance of the 5-HTTLPR is therefore an example of a one-time event in the evolutionary history of a species. The 5-HTTLPR sequence may be informative in the comparison of closely related species, and it reflects the phylogeny of the old world monkeys, great apes, and humans. The presence of an analogous rh5-HTTTLPR and the resulting allelic variation of 5-HTT activity in rhesus monkeys provides a unique model to dissect the relative contribution of genes and environmental sources to central serotonergic function and related behavioural outcomes.

In order to study this genotype–environment interaction, the association between central 5-HT turnover and the rh5-HTTLPR genotype was tested in rhesus monkeys with well-characterized environmental histories. This sample of rhesus monkeys ($n = 177$) showed allele frequencies of 83% for the 24-repeat allele (long, [l]) and 16% for the 23-repeat (short, [s]) rh5-HTTLPR variant with a genotype distribution of 68% l/l, 31% l/s, and 1% s/s; one individual was heterozygous for a rare allele with an additional repeat unit ($\times l$) similar to longer alleles found occasionally in humans (Lesch *et al.*, 1997). The monkeys' rearing fell into one of the following categories: mother-reared, either reared with the biological mother or cross-fostered; or peer-reared, either with a peer group of 3–4 monkeys or with an inanimate surrogate and daily contact with a playgroup of peers. Peer-reared monkeys were separated from their mothers, placed in the nursery at birth, and given access to peers at 30 days of age, either continuously or during daily play sessions. Mother-reared and cross-fostered monkeys remained with the mother, typically within a social group. At roughly 7 months of age, mother-reared monkeys were weaned and placed together with their peer-reared cohort in large, mixed-gender social groups. The frequency of the l/l genotype was 70% for mother-reared ($n = 79$) and 68% for peer-reared monkeys ($n = 95$), respectively; subjects with the rare genotypes s/s and $l/ \times l$ were excluded from subsequent analyses.

Since the monkey population comprised two groups that received dramatically different social and rearing experience early in life, the interactive effects of environmental experience and the rh5-HTTLPR on cisternal CSF 5-HIAA levels and 5-HT-related behaviour was assessed. CSF 5-HIAA concentrations were significantly influenced by genotype for peer-reared, but not for mother-reared, subjects (Bennett *et al.*, 2001). Peer-reared rhesus monkeys with the low-activity rh5-HTTLPR s allele had significantly lower concentrations of CSF 5-HIAA than their homozygous l/l counterparts. Low 5-HT turnover in monkeys with the *s* allele is congruent with *in vitro* studies that show reduced binding and transcriptional efficiency of the 5-HTT gene to be associated with the 5-HTTLPR s allele (Lesch *et al.*, 1996). This suggests that the rh5-HTTLPR genotype is predictive of CSF 5-HIAA concentrations, but that early experiences make unique contributions to variation in later 5-HT functioning. This finding is the first to provide evidence of an environment-dependent association between a polymorphism in the 5′-regulatory region of the 5-HTT gene and a direct measure of 5-HT functioning, cisternal CSF 5HIAA concentration, thus revealing an interaction between rearing environment and rhHTTLPR genotype. Similar to the 5-HTTLPR's influence on NEO 'neuroticism' in humans, however, the effect size is small, with 4.7% of variance in CSF 5-HIAA accounted for by the rh5-HTTLPR–rearing environment interaction.

Previous work has shown that monkeys' early experiences have long-term consequences for the functioning of the central 5-HT system, as indicated by robustly altered CSF 5-HIAA levels, as well as anxiety and depression-related behaviour, in monkeys deprived of their parents at birth and raised only with peers (Higley *et al.*, 1991; 1992b). Intriguingly, the biobehavioural results of deleterious early experiences of social separation are consistent with the notion that the 5-HTTLPR may influence the risk of affective spectrum disorders. Evolutionary preservation of two prevalent 5-HTTLPR variants and the resulting allelic variation in 5-HTT expression may be part of the genetic mechanism resulting in the emergence of temperamental traits that facilitate adaptive functioning in the complex social worlds most primates inhabit. The uniqueness of the 5-HTTLPR among humans and simian non-human primates, but not among prosimians or other mammals, along with the role 5-HT plays in complex primate sociality, forms the basis for the hypothesized relationship between the 5-HTT function and the personality traits that mediate individual differences in social behaviour. Accumulating evidence demonstrates the complex interplay between individual differences in the central 5-HT system and social success. In monkeys, lowered 5-HT functioning, as indicated by decreased CSF 5-HIAA levels, is associated with lower rank within a social group, less competent social behaviour, and greater impulsive aggression (Higley *et al.*, 1992b; Mehlman *et al.*, 1995). It is well established that, while subjects with low CSF 5-HIAA concentrations are no more likely to engage in competitive aggression than other monkeys, when they do engage in aggression it frequently escalates to violent and hazardous levels.

Association between the rh5-HTTLPR genotype and aggressive behaviour was studied by analysing the joint effects of genotype and early rearing environment on competition-elicited aggression. Socially dominant mother-reared monkeys were more likely than their peer-reared counterparts to engage in competitive aggression. Moreover, under both rearing conditions, monkeys with the low-activity *s* allele exhibited more aggressive behaviours than their l/l counterparts. The lack of a genotype for competitive aggression in rearing interaction indicates that subjects with the *s* allele, while unlikely to win in a competitive encounter, are more inclined to persist in aggression once it begins. A role of *s*

allele-dependent low-5HTT function in non-human primate aggressive behaviour is in remarkable agreement with the association in humans between the NEO subscales 'neuroticism' (increased 'angry hostility') and 'agreeableness' (decreased 'compliance' = increased aggressiveness and hostility) and 5-HTTLPR *s* genotypes.

As the scope of human studies has been extended to the neonatal period, a time in early development when environmental influences are modest and least likely to confound gene–temperament associations, complementary approaches have recently been applied to non-human primates. Rhesus monkey infants heterozygous for the *s* and *l* variant of the rhHTTLPR (*l*/*s*) displayed higher behavioural stress-reactivity than infants homozygous for the long variant of the allele (*l*/*l*) (Champoux *et al.*, 1999). Mother-reared and peer-reared monkeys ($n = 36$ and $n = 83$, respectively) were assessed on days 7, 14, 21, and 30 of life, on a standardized primate neurobehavioural test designed to measure orienting, motor maturity, reflex functioning, and temperament. The main effects of genotype, and, in some cases, interactions between rearing condition and genotype, were demonstrated for items indicative of orienting, attention, and temperament. In general, heterozygote animals demonstrated diminished orientation, lower attentional capabilities, and increased affective responding relative to *l*/*l* homozygotes. However, the genotype effects were more pronounced for animals raised in the neonatal nursery than for animals reared by their mothers. These results demonstrate the contributions of rearing environment and genetic background, and their interaction, in a non-human primate model of behavioural development.

As in humans, the neonatal period in rhesus monkeys represents a time when environmental influences are only starting to gain influence on the genetic make-up, thus rendering relationships between temperament, behaviour and genetic variants less complex. When tested early in life at post-natal days 7–30, rhesus monkey infants with the low-expression rh5-HTTLPR *s* allele displayed higher behavioural stress-reactivity than infants homozygous for the *l* allele (Champoux *et al.*, 1999). Thus, non-human primate models are consistent with the finding in humans that it is the low-activity *s* allele that is associated with increased negative emotionality. The findings are intriguing in light of speculations that the recent appearance of the 5-HTTLPR-associated genetic variation may have helped permit more sophisticated modulation of social behaviours during the evolution of higher-order primates (Lesch *et al.*, 1997). The 5-HTT-personality association data also emphasize the advantage of the five-factor NEO-PI-R and the lexical tradition of personality theory on which it is based. This view of personality is consistent with evolutionary perspectives on personality, and the trait terms in natural language may best reflect individual behavioural differences important to group survival and reproductive success (Buss, 1995).

Another well-defined behavioural pattern among non-human primates that seems to be directly related to CSF 5-HIAA concentrations is dispersal from the natal group (Mehlman *et al.*, 1995). Most male rhesus monkeys leave their natal group and either visit or join other social groups or form small, transient all-male groups before returning to their birth group. While natal dispersal occurs at a highly variable age and is almost always associated with loss of social status and an increase in stress, injury, and mortality, its cause and intention remain controversial. Interestingly, a recent study by Trefilov *et al.* (2000) showed a gene-dose effect of the rh5-HTTLPR *s* variant on the age of dispersal, with s/s homozygotes leaving earlier than carriers of the *l* allele. This finding further supports the notion that impaired 5-HTT function resulting in low 5-HT turnover is associated with impulsive behaviour together with a high tendency to risk-taking activity that leads to early dispersal.

Taken together, these findings provide evidence of an environment-dependent association between allelic variation of 5-HTT expression and central 5-HT function, and suggest that specific genetic factors play a role in 5-HT-mediated social competence in primates. The objective of further studies will be the elucidation of the relationship between the rh5-HTTLPR genotype and sociability in monkeys, as this behaviour is expressed with characteristic individual differences both in daily life and in response to challenge. Because rhesus monkeys exhibit temperamental and behavioural traits that parallel anxiety, depression, and aggression-related personality dimensions associated in humans with the low-activity 5-HTTLPR variant, it may be possible to search for evolutionary continuity in this genetic mechanism for individual differences. Nonhuman primate studies may also be useful to help identify environmental factors that either compound the vulnerability conferred by a particular genetic make-up or, conversely, act to improve the behavioural outcome associated with that genotype.

CONCLUSIONS

The integration of emerging tools and technologies for genetic analysis will further prepare the ground for an advanced stage of gene identification and functional studies in personality and behavioural genetics. Several refined concepts should therefore be adopted.

First, future studies will require extended, homogeneous, and ethnically matched population and patient samples in conjunction with family-based designs. In order to control for non-independence within cohorts and thus to minimize the risk of population stratification bias, rigorous methods of 'genomic control' have been designed. These statistical strategies are based on the assessment of 60 SNPs or genotypes of 100 unlinked microsatellite markers spread throughout the genome to adjust the significance level of a candidate gene polymorphism (Bacanu *et al.*, 2000; Pritchard *et al.*, 2000). With recent advances in molecular genetics, the rate-limiting step in identifying candidate genes has nevertheless become the definition of phenotype.

Second, more functionally relevant polymorphisms in genes within a single neurotransmitter system, or in genes that comprise a developmental and functional unit in their concerted actions, need to be identified and investigated in large association studies both to avoid stratification artefacts and to elucidate complex epistatic and epigenetic interactions of multiple loci with the environment. Not only will DNA variants in coding and regulatory regions of genes be useful in systematic genome scans to identify genes associated with personality and behaviour, but they will also make it possible to study integrated systems of gene pathways as an important step on the route to behavioural genomics. Although great strides have been made in understanding the diversity of the human genome, including the frequency, distribution, and type of genetic variation that exists, the feasibility of applying this information to uncover useful genomic markers of behavioural traits remains uncertain. The implications of using SNPs to uncover markers for behavioural traits and disorders, as well as treatment response, such as population and patient sample size, SNP density and genome coverage, SNP functionality, and data interpretation that will be important for determining the suitability of genomic information are, however, rarely addressed. Success will eventually depend on the availability of SNPs in the coding or regulatory regions (cSNPs or rSNPs, respectively) of a large number of candidate genes as well as knowledge of the average extent of linkage disequilibrium between SNPs, the development of high-throughput technologies for genotyping SNPs, identification of protein-altering SNPs by DNA and protein microarray-assisted expression analysis, and collection of DNA from well-assessed cohorts. As more appreciation of the potential for polymorphisms in gene regulatory regions to affect gene expression is gained, knowledge of novel functional variants is likely to emerge.

Third, genetic influences are not the only pathways that lead to individual differences in personality dimensions, behaviour, psychopathology, and drug response. Complex traits are most likely to be generated by a complex interaction of environmental and experiential factors with a number of genes and their products. Even pivotal regulatory proteins of cellular pathways and neurocircuits are likely to have only a very modest, if not minimal, impact, while noise from non-genetic mechanisms obstructs identification of relevant gene variants. Although current methods for the detection of gene–gene and gene–environment interaction in behavioural genetics are largely indirect, the most relevant consequence of gene identification for behavioural traits and psychotropic drug effects may be that it will provide the tools required to clarify systematically the effects of gene–environment interaction on brain development and plasticity.

Finally, future benefits will stem from novel techniques in molecular cell biology, transgenics, and gene-transfer technologies. However, in the postgenomic world, behavioural genetic research will require integration of the entire spectrum of genomics, DNA variants, gene expression, proteomics, brain development, structure, and function, as well as behaviour, in a wide range of species. Although bioinformatics resources are evolving in most of these areas, the incorporation of these resources from the perspective of the functional genomics of personality and behaviour will greatly facilitate research.

Gene–Environment Interactions in Personality Disorders

Joel Paris

PERSONALITY DISORDERS AND THE STRESS-DIATHESIS MODEL

Personality disorders are clinical syndromes in which personality traits cause psychopathology. Disorders are diagnosed when traits interfere with occupational and personal adjustment, leading to distress and/or dysfunction. Patients meeting these criteria develop abnormalities of behaviour, affect, and cognition that begin early in life, are pervasive in many contexts, and remain consistent over time.

The roots of personality disorders lie both in genetic vulnerability and environmental adversity. Research in every category of mental disorder demonstrates genetic predispositions associated with psychopathology (Paris, 1999). These vulnerabilities are then uncovered and unleashed by environmental stressors. Predisposition and stress have an interactive relationship: genetic variability influences the way individuals respond to their environment, while environmental factors determine whether genes are expressed.

These principles describe a general theory of the aetiology of mental disorders, the stress-diathesis model (Monroe and Simons, 1991; Paris, 1999). This model provides a frame for understanding the role of gene–environment interactions in personality disorders.

One of the main problems in identifying genetic and biological factors in personality disorders concerns how to define the phenotype (Jang *et al.*, 2001). Diagnoses, as defined in the current psychiatric classification, are not very useful in this regard. Each of the present categories of personality disorders has some relationship to biological variables, but only to the extent that these disorders reflect traits. When we apply a wide range of research strategies (genetic associations, imaging, biological markers, or neuropsychological testing), relationships with measures of biological function are consistently stronger with traits, and weaker with disorders.

The relationship between traits and disorders is crucial to understanding the nature of personality pathology. Trait vulnerabilities, by themselves, do not explain why patients develop clinical symptoms. Instead, interactions between genetic and environmental factors, leading to pathological feedback loops, are responsible for the amplification of traits to dysfunctional levels.

TEMPERAMENT, PERSONALITY TRAITS AND PERSONALITY DISORDERS

Personality disorders, personality traits, and temperament have a hierarchical relationship (Rutter, 1987). Temperament refers to behavioural dispositions present at birth. Personality traits are individual differences in behaviour that remain stable over time and context. These characteristics represent an amalgam of inborn characteristics and the effects of life experiences. Personality disorders describe dysfunctional outcomes arising from traits.

In trait psychology, personality is measured as 'dimensions' with a normal distribution. Therefore, each personality profile should be common in the general population, and be compatible with normality. Disorders occur when these traits are amplified, and used in rigid and maladaptive ways.

Using current criteria, some studies (Weissman, 1993) have estimated that approximately 10% of the general population have a diagnosable personality disorder. Clearly, the precise figure depends on the cut-off point one uses. If personality is dimensional, one would expect to find no sharp break between traits and disorders. Research in clinical and community populations (Livesley and Jang, 2000) consistently supports this principle.

Personality disorders are even more common in treatment settings (Loranger *et al.*, 1994). But they are not always recognized as such, since patients present clinically when they also have Axis I symptoms. Moreover, there are serious problems in the classification of personality disorders.

CATEGORICAL AND DIMENSIONAL MODELS OF PERSONALITY DISORDERS

DSM-IV (American Psychiatric Association, 1994) divides personality disorders into 10 categories. ICD-10 (World Health Organization, 1992) uses a similar system of classification, describing most of the same types. DSM groups these diagnoses into three clusters (A, B, and C) that share common characteristics. A patient who meets the overall criteria for a disorder, but who does not fall into any specific category, is classified as 'personality disorder, not otherwise specified' (NOS). Many patients fail to fit prototypically into any single category, and about a third of all cases fall into the 'NOS' group (Loranger *et al.*, 1994).

Cluster A, described as 'odd', includes schizoid, paranoid, and schizotypal disorders, all of which lie in the 'schizophrenic spectrum' (Siever and Davis, 1991). Cluster B, which can be called either 'dramatic' or impulsive, includes antisocial, borderline, narcissistic, and histrionic disorders. Cluster C, described as 'anxious', includes avoidant, dependent, and compulsive disorders.

Many of these categories exist largely on the basis of clinical tradition, and their validity is suspect. The constructs describing schizotypal, antisocial, and borderline personality are the most useful, since each of these diagnoses communicates crucial clinical information in a compact fashion. Thus, typical patients in each of these categories have a characteristic outcome and a characteristic treatment response.

One of the most serious difficulties with the existing categories is that they overlap, with most patients earning more than one diagnosis (Pfohl *et al.*, 1986). Many (but not all) of these overlaps occur within clusters. The clusters therefore reflect underlying dimensions, which may be more valid than individual categories. In

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

support of this hypothesis, family history methods demonstrate that personality traits within clusters are often shared with first-degree relatives (Siever and Davis, 1991).

In the European tradition, personality disturbances have been thought to be milder versions, or 'formes frustes', of major mental disorders. Some evidence supports this view. For example, schizotypal personality shares biological markers with schizophrenia, suggesting that it represents a less severe form of the illness (Siever and Davis, 1991). Similarly, antisocial and borderline personality disorders share markers with substance abuse and other Axis I impulsive disorders (Zanarini, 1993). Avoidant and compulsive personality have common family histories with Axis I anxiety disorders (Paris, 1998).

The largest body of empirical research has focused on the antisocial and borderline categories. The only category to have been examined systematically in epidemiological surveys is antisocial personality. (The forthcoming International Comorbidity Survey will also measure the prevalence of borderline personality.) About 2–3% of the population (mostly males) meet criteria for antisocial personality (Robins and Regier, 1991). By indirect evidence, 2% of the population (mostly females) can probably be diagnosed with borderline personality (Swartz *et al.*, 1990).

Traits provide an alternate way to measure personality disorders. Trait dimensions are generally derived from the factor analysis of self-report data. The most influential system has been the 'five factor model' (FFM)(McCrae and Costa, 1999), which describes personality profiles with scores measuring 'neuroticism', 'extraversion', 'openness to experience', 'conscientiousness', and 'agreeableness'. In a related schema, Livesley *et al.* (1993) described personality through 18 narrow dimensions that can also be grouped into superfactors that closely resemble four of the five factors in the FFM. Cloninger *et al.*'s (1993) model attempts to unite factor analysis and biological theory. His schema describes seven factors in personality, of which four are posited to be 'temperamental' (novelty seeking, reward dependence, harm avoidance, and persistence), and three are posited to be 'characterological'.

Biological researchers tend to favour dimensional measures of personality. This preference arises from the relationship between biological variability and traits. Moreover, dimensional systems describe pathology as rooted in unusually high levels of traits, concordant with the concept that disorders are amplified versions of these characteristics. However, it is not certain which schema provides the best description of personality. To answer this question, we require more research into the mechanisms that shape traits. Although factor analytical data can be useful in searching for genetic factors, dimensions should ultimately be rooted in biology (Paris, 2000a).

GENETIC FACTORS IN PERSONALITY

To the extent that personality dimensions represent normally distributed individual differences, they should be heritable. However, single genes will not often be associated with single traits. The heritable component of personality emerges from complex and interactive polygenetic mechanisms associated with variations in multiple alleles (Livesley and Jang, 2000).

It is nonetheless striking that virtually every personality dimension that has been studied has been found to have a heritable component, with genetic factors accounting for nearly half the variance on every trait (Plomin *et al.*, 1997). This conclusion has emerged consistently from behavioural genetic studies comparing concordance in traits between monozygotic (MZ) and dizygotic (DZ) twins. Twin methodology is based on the equal-environments assumption, that is, that there is no consistent difference in the environment of MZ and DZ twins, a conclusion in accord with a large body of evidence (Kendler *et al.*, 1993). However, the percentage of the variance accounted for by genetic variability is not that precise, since twin methodology tends to exaggerate the heritable component, and is subject to error variance. Another limitation of twin studies is that they do not readily identify gene–environment correlations.

Adoption studies (Plomin *et al.*, 1997), as well as studies of twins separated at birth (Tellegen *et al.*, 1988), confirm the heritability of traits. Moreover, the degree of heritability is about the same irrespective of which schema is used to define personality dimensions. It therefore seems safe to conclude that individual differences in personality have a strong basis in heredity and temperament.

Associations between personality traits and genetic variations derive from many different genes, and are therefore measurable as quantitative trait loci. But, thus far, this line of investigation has been disappointing. Promising earlier reports (e.g., Lesch *et al.*, 1996) have not been consistently replicated (Gelertner *et al.*, 1998). The main reason is that single alleles account for only a small percentage of the variance on any trait. These studies also suffer from the lack of a precise phenotype for personality traits.

The presence of a genetic component in personality also implies that traits should be linked to biological markers. Research in this area is at an early stage. Thus far, the strongest finding has been a strong relationship, established in clinical populations, between low levels of central serotonin activity and impulsivity (Mann, 1998).

ENVIRONMENTAL FACTORS IN PERSONALITY

The other half of the variance in personality derives from the environment. Again, behaviour genetic studies shed light on the nature of this influence. The variance affecting traits is almost all 'unshared', meaning that it does not depend on being raised in the same family (Plomin *et al.*, 2001). In fact, siblings demonstrate little similarity in personality.

This finding points to the importance of gene–environment interactions. Moreover, the environment is also complex and interactive. In contrast to classical ideas in developmental and clinical psychology, parenting is not the only factor shaping personality development. Since temperament affects the response of others in the environment, parents respond differently to different children. In a recent large-scale study of adolescents (Reiss *et al.*, 2000), using a combination of twin and family methods, multivariate analyses showed that the temperament of the child was the underlying factor driving differential parenting. This interaction is one of several reasons why family environment is unshared.

The other explanation for unshared environment concerns the unique nature of each person's experience. Thus, the environmental factors affecting personality are often extrafamilial. Every child has shaping experiences with peers, with teachers, or with community leaders (Rutter and Maughan, 1997). Harris (1998), who emphasizes these importance of these factors, has criticized the traditional view of parenting in psychology, which minimizes the role of social factors in personality development.

It is also important to note that developmental psychology has often failed to take into account the influence of genetic factors on measures of environmental influence. As Harris (1998) points out, almost all the literature claiming to establish links between life experiences and personality has to be questioned in this light. Personality traits can be latent variables affecting how the environment is perceived and how it affects development. For example, Plomin and Bergeman (1991) showed that standard measures of life stress, past and present, contain a heritable component that can best be accounted for by the influence of genetically influenced traits.

GENETIC FACTORS IN PERSONALITY DISORDERS

Whereas the heritability of personality traits is firmly established, evidence for the presence of genetic factors in personality disorders has been more equivocal. Research has been limited by a lack of diagnostic precision, and by the rarity of large-scale behavioural genetic studies.

Yet if disorders are amplified traits, one would expect them to demonstrate similar levels of heritability. Some writers (Nigg and Goldsmith, 1995) have argued that disorders represent extremes on a continuum, extremes less open to genetic influence and reflecting a larger environmental component. But this supposition seems illogical, since extremes on any normally distributed dimension should be more, not less, heritable.

In any case, the concept that environmental factors are more predominant in personality disorders has been overturned by recent data. Torgersen *et al.* (2000) located a large sample of twins in which one proband met criteria for at least one categorical diagnosis in the DSM classification. All personality disorders had heritabilities resembling those observed for traits (i.e., close to half the variance). Although these numbers lack precision (due to sample size), the heritability coefficient for disorders as a whole was 0.60 (0.37 for Cluster A, 0.60 for Cluster B, and 0.62 for Cluster C). There were no antisocials in the cohort, but in the borderline category, heritable factors accounted for over 69% of the variance, while in the narcissistic category, heritability was 77%.

These observations are highly consistent with the findings of family history studies (Siever and Davis, 1991). The heritability of mental disorders is generally greater when spectra including both Axis I and Axis II diagnoses are considered. Thus, first-degree relatives of patients with personality disorders tend to suffer from disorders lying within a closely related spectrum of pathology. For example, relatives of patients with disorders in Cluster A have pathology in the schizophrenic spectrum.

Similarly, patients in Cluster B tend to have relatives with other impulsive disorders. These observations led Zanarini (1993) to describe an 'impulsive spectrum', (including antisocial and borderline personality, as well as addictive disorders such as substance abuse or bulimia nervosa). Biological markers support these relationships, with the most robust findings linking decreased serotonin levels with aggression, impulsivity, and suicide attempts (Mann, 1999), all of which are characteristic features of the antisocial and borderline categories.

Parallel findings apply to Cluster C, where first-degree relatives tend to suffer from anxiety disorders. These relationships could be described as forming an 'anxious spectrum' (Paris, 1998). Temperamental anxiety has consistent physiological correlates, and it is heritable. An ongoing prospective study by Kagan (1994), following children with 'behavioural inhibition' (unusual levels of anxiety beginning in infancy) into adulthood, will shed further light on these links.

In summary, personality disorders have biological correlates related to underlying traits. Neurophysiological and neuropsychological correlates of personality disorders confirm these relationships. For example, functional abnormalities in the prefrontal cortex are associated with traits of impulsive aggression. Raine *et al.* (2000) has reported decreases in the mass of frontal grey matter in subjects with antisocial personality. On standard measures such as the Wisconsin Card Sorting Test, patients with antisocial and borderline personality demonstrate deficits in executive function (O'Leary *et al.*, 2000).

ENVIRONMENTAL FACTORS IN PERSONALITY DISORDERS

Psychotherapists have traditionally considered personality pathology to be the outcome of defective parenting. This belief was based on the assumption that disorders that begin early in life must be the result of adversities occurring even earlier in development.

Patients with personality disorders frequently report serious adversities during childhood. In borderline personality disorder, histories of sexual abuse, physical abuse, and gross neglect are particularly common (Zanarini, 2000). The common factor behind all these experiences is usually severe family dysfunction.

However neither trauma nor family pathology, by themselves, necessarily cause personality disorders. For example, community surveys of the impact of childhood sexual abuse (Browne and Finkelhor, 1986; Rind *et al.*, 1999) and physical abuse (Malinovsky-Rummell and Hansen, 1993) show that only a minority of those exposed suffer measurable sequelae. Single traumatic events are not strongly associated with pathology, while continuously adverse circumstances lead to cumulative effects that are much more consistent (Rutter, 1987). In general, patients experiencing multiple adversities, which also tend to be associated with more severe trauma, are at the greatest risk.

The retrospective methodologies used in most studies of childhood risks of personality disorders have also made firm conclusions about causality problematic. Almost all findings reported in the literature are based on reports of life experiences occurring many years in the past. Memories are coloured by recall bias, that is, the tendency for individuals with symptoms in the present to remember more adversities in the past.

Prospective studies are clearly needed to confirm these relationships. The best available longitudinal data concern the development of antisocial personality. Robins' (1966) study showed that the strongest predictor of adult antisocial outcome among conduct-disordered children (usually boys) is parental psychopathy, usually in a father. This association was later supported by Farrington's (1998) British follow-up studies.

These findings parallel data showing that close family members of patients with borderline personality disorder have increased levels of psychopathology, usually within the impulsive spectrum (Links *et al.*, 1988; Zanarini, 1993). The presence of impulsivity in parents reflects genetic risk factors, but impulsive parents (and their partners) are also more likely to be inconsistent, neglectful, or even abusive in their parenting behaviours.

A recent prospective longitudinal study has confirmed the relationship between childhood adversity and personality disorders. The Albany-Saratoga study has been following a large community cohort of children into young adulthood. In one report, Johnson *et al.* (1999) observed that early adversities, including neglect, physical abuse, and sexual abuse, were significant predictors of the number of personality disorder symptoms. (The researchers used this continuous variable to measure outcome, since few subjects in this study had a diagnosable personality disorder.) However, this relationship accounted for only part of the variance. The study design should have obtained more data on temperamental factors, which could have helped to account more precisely for outcome.

INTERACTIONS BETWEEN RISK FACTORS FOR PERSONALITY DISORDERS

Personality disorders can best be understood by using multifactorial models. The complexity and multitude of aetiological factors in these categories requires a biopsychosocial theory and a diathesis-stress model (Paris, 1996; 1999). The diatheses for personality disorders consist of abnormal temperament, while the stressors for these disorders consist of adverse life events.

The role of temperament as a risk factor is supported by observations that children with early behavioural disturbances are more likely to develop parallel forms of pathology later in life. Strikingly, children at the age of 3 years with high levels of aggression and irritability have been shown to be at risk of

antisocial personality disorder in early adulthood (Caspi *et al.*, 1996). Moreover, when conduct symptoms during childhood begin earlier and are more pervasive, they are more likely to continue as antisocial personality (Zoccolillo *et al.*, 1992).

In the same way, infants with unusual shyness and reactivity ('behavioural inhibition') are at risk of either anxiety disorders (Kagan, 1994) or anxious cluster personality disorders (Paris, 1998). Although many in Kagan's cohort of behaviourally inhibited children eventually overcame their temperamental difficulties, none became extroverted or impulsive. When the group was followed into early adolescence, a minority still had significant social anxiety. It will be interesting to see whether this population is at risk of avoidant personality disorder in adulthood.

Some authors (e.g., Kernberg *et al.*, 2000) have suggested that personality disorders can be diagnosed in adolescence, or even in childhood. Although specific categories of disorder are unstable over time, overall personality disturbance has significant continuities. One longitudinal follow-up study (Lofgren *et al.*, 1991) showed that children with a wide range of behavioural disturbances (often termed 'borderline children') develop personality disorders in early adulthood.

The course of personality pathology over time provides a clue to its causes. Disorders beginning early in life are more likely to have a heritable biological component (Childs and Scriver, 1986). Moreover, most patients with personality disorders have a chronic course, with the exception of antisocial and borderline personality, which tend to 'burn out' by middle age (Paris, 1994).

Genetic-temperamental factors in personality disorders shed light on the relationship between childhood adversities and adult psychopathology. In community surveys of adults who report trauma and neglect during their development, associations between childhood trauma and sequelae are consistently much stronger in clinical than in community populations (Paris, 1997). While adverse events in development lead to psychopathology only in a minority of those exposed, some are more vulnerable than others (Rutter, 1989; Paris, 2000).

The explanation depends on interactions between genes and environment. The effects of adversity are greatest in individuals who are predisposed to psychopathology. In this respect, associations between reported adversities in childhood and personality disorders in adulthood are a classic example of the principle that correlation does not prove causation. Childhood adversity increases the risk of psychopathology in adulthood, but these effects are largely accounted for by vulnerable subpopulations.

Abnormal temperament is associated with a greater sensitivity to environmental risk factors. At the same time, individuals with problematic temperaments also experience more trauma and conflict during development (Rutter and Maughan, 1999). Children with difficult temperaments elicit responses from others that tend to amplify their most problematic characteristics. Specifically, those with high levels of aggression and irritability are in chronic conflict with their parents, as well as with their peers and teachers. These children respond to these conflicts with even greater aggression, creating a positive feedback loop. In a parallel fashion, children with behavioural inhibition elicit overprotective responses from their parents, which only amplify the problem (Kagan, 1994).

Thus, childhood adversities reflect positive feedback loops which are strongly influenced by personality traits. The more affected children are by these experiences, the more their traits become amplified. The more traits are amplified, the more likely children are to experience adversity.

In adult life, no specific relationship exists between stressors and symptoms (Paris, 1999). Instead, predispositions and vulnerabilities unique to each individual determine what type of disorder will develop. Personality traits lie at the core of these differences in susceptibility.

Finally, personality disorders are a social phenomenon. The prevalence of antisocial personality varies widely across cultures, suggesting that social forces play an important aetiological role in this condition. Similar considerations apply to other disorders characterized by impulsivity, such as borderline personality. The mechanisms could involve direct effects of social stressors, or indirect effects, due to the failure of the social community to buffer biological risks and/or psychological adversities (Paris, 1996).

Personality disorders are not the only possible outcome of temperamental vulnerability or psychosocial adversities. A spectra of disorders, including Axis I diagnoses, is associated with each of the Axis II clusters (schizophrenic, impulsive, and anxious). In cases where the dysfunction arising from the Axis I condition is extensive, one will not be able to diagnose a personality disorder. In other cases, Axis I and Axis II pathology will be 'comorbid'. But in either of these scenarios, common biological factors are mediated by personality trait profiles.

In summary, none of the risk factors associated with personality disorders are sufficient conditions for their development. Biological factors increase risk, but do not determine outcome. Psychosocial factors have little specificity, with similar forms of adversity being associated with many categories of disorder, or with no disorder at all.

Only a combination of risks, that is, a 'two-hit' or 'multiple hit' mechanism, can account for the data. While the cumulative effects of multiple risk factors determine whether psychopathology develops, the specific disorder that ultimately emerges depends on temperament (Kagan, 1994; Paris, 1996). Thus, only those with impulsive temperamental characteristics will develop Cluster B disorders, such as antisocial or borderline personality. Similarly, only those with introverted temperament will develop Cluster C disorders, such as avoidant personality.

SUMMARY

We can summarize the application of a stress-diathesis model to the personality disorders as follows:

1. Biological vulnerability and environmental adversity are necessary conditions, but neither is sufficient for the development of personality disorders.
2. The genetic factors in personality disorders are associated with temperamental predispositions.
3. Personality traits, which reflect both temperament and experience, are the underlying factors behind personality disorders.
4. Personality disorders are most likely to develop when environmental stressors, particularly multiple adversities with cumulative and interactive effects, amplify traits.
5. Environmental adversities have greater effects on those who are temperamentally vulnerable.
6. Once established, personality disorders are supported by positive feedback loops that lead to chronicity.

The Psychopharmacological Treatment of Personality Disorders

Royce Lee and Emil Coccaro

INTRODUCTION

This chapter will present available evidence on the psychopharmacological treatment of personality disorders. Clinical and theoretical implications of axis I/II and Axis II/II comorbidity in the treatment of patients with personality disorders will be discussed. Biological correlates of some of the major symptoms of personality disorders will provide the rationale for a review of the evidence for psychopharmacological treatment of personality disorders. These will be presented by medication class to facilitate an understanding of the evidence for the efficacy of these treatments.

PERSONALITY DISORDERS IN THE CLINICAL SETTING

The estimated prevalence of personality disorders in the community is approximately 6–11% (Samuels *et al.*, 1994; Reich *et al.*, 1989), with Cluster B personality disorders being the most common (4–5.4%), followed by cluster C (1.7–3.4%) and Cluster A (<0.1%). Evidence suggests that many personality-disordered people in the community who could benefit from treatment do not receive it. This holds true in clinical settings, where personality disorders, in general, are underdiagnosed (Zimmerman and Mattia, 1999).

Paradoxically, personality disorders may be disproportionately represented in outpatient and inpatient treatment settings (Zimmerman and Coryell, 1989). This may be due to the significant morbidity associated with them. Personality-disordered patients tend to function at lower levels than those without such disorders (Mehlum *et al.*, 1991), report more frequent adverse events in their lives (Maier *et al.*, 1992), and have elevated rates of divorce, substance abuse, and suicide (Zimmerman and Coryell, 1989). This is the case despite relatively heavy use of clinical services by some, but not all, persons with Axis II diagnoses. A recent study of treatment utilization by patients with personality disorder found that those with borderline personality disorder, compared to depressives, were more likely to have received every class of psychopharmacological medication, from twice as many trials of antidepressants to 10 times as many trials of antipsychotic medications. They had also received more psychosocial treatments than the depressive comparison group with the exception of family/couples therapy and self-help groups (Bender *et al.*, 2001). These results were consistent with earlier reports in persons diagnosed with borderline personality disorder (BPD) of more frequent hospitalization, a 20% lifetime incidence of suicide attempt (McGlashan *et al.*, 1986), and extensive use of outpatient mental health services (Perry and Cooper, 1985; Skodol *et al.*, 1983). Patients with personality disorders may also be more difficult to treat than most patients, with less treatment compliance (Bender *et al.*, 2001), less favourable Axis I treatment outcomes (Reich *et al.*, 1991), and more frequently aborted treatments. In research settings, it is not uncommon for up to two-thirds or more of personality-disordered subjects to drop out of treatment studies (Skodol *et al.*, 1983), a finding which mirrors clinical reports of their intensive but intermittent contact with outpatient services (McGlashan *et al.*, 1986).

COMORBIDITY IN PERSONALITY DISORDERS

Comorbidity in personality disorders may represent the random co-occurrence of independent disorders, co-occurrence of different disorders sharing a common aetiology or pathophysiology, or different disorders that have a causal relation between them (McGlashan *et al.*, 2000). The frequency of Axis II/Axis II comorbidity may be in part due to the fact that psychiatric nosology since DSM-III has favoured a trend towards more frequent comorbidity through the use of operationalized criteria, structured diagnostic interviews, and less stringent exclusionary rules. In some cases as well, Axis I/II and Axis II/II comorbidity could reflect the limitations of categorical diagnoses in characterizing the behavioural dimensions, that may underlie them.

Clinically, the possibility of the existence of comorbid conditions in the personality-disordered patient must be carefully evaluated for the following reasons:

1. to identify other conditions with relatively well-defined treatments — for example, the presence of a medical disorder, mood disorder, or anxiety disorder
2. to identify other conditions whose symptoms may be aggravated by proposed treatments — for example, the presence of bipolar I disorder in a patient considering the trial of an antidepressant
3. to identify disorders whose symptoms may account for the set of behaviours in questions, including such disorders as post-traumatic stress disorder (PTSD) or social anxiety disorder
4. to identify conditions whose course may be complicated by the presence of a personality disorder, such as refractory depression
5. because comorbidity may be markedly more frequent in clinical settings than community settings, as shown by comparisons between the two (Samuels *et al.*, 1994), possibly due to the selection for treatment of patients with more than one disorder and more functional impairment.

CLUSTER A

Schizotypal personality disorder is the most commonly encountered Cluster A personality disorder in clinical settings. It frequently

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

occurs in the context of other personality disorders, with most affected patients meeting the criteria for at least two other personality disorders. The most frequently comorbid personality disorder may be paranoid personality disorder, with 36.1% of patients with schizotypal personality disorder meeting the criteria for paranoid personality disorder (McGlashan *et al.*, 1986). Fulton found that 4/17 (23.5%) of subjects diagnosed by chart review with paranoid personality disorder met the criteria for schizotypal personality disorder (Fulton *et al.*, 1993). Although schizoid personality disorder is not frequently diagnosed even in clinical settings, it has been found in 10.5% of patients diagnosed with schizotypal personality disorder (McGlashan *et al.*, 1986). In contrast, Fulton found that only one out of 33 (3%) patients with schizoid personality disorder met the criteria for schizotypal personality disorder (Fulton *et al.*, 1993). Evidence suggests that despite some degree of comorbidity, schizotypal, schizoid, and paranoid personality disorders categorize distinct groups of patients. The nature and extend of the comorbidity relationships between schizoid and avoidant personality disorder (West *et al.*, 1995) and between schizotypal and borderline personality disorder are unclear.

CLUSTER B

Borderline personality disorder (BPD) is the most common of the Cluster B disorders. Like schizotypal personality disorder, BPD represents a heterogeneous group of individuals with frequent Axis I and Axis II comorbidities. The most frequent Axis I comorbidity with personality disorders is substance-abuse disorder, which is found in approximately 53% of BPD patients (McGlashan *et al.*, 2000). Affective disorders are also frequently comorbid. Approximately 41% of patients with BPD may meet research diagnostic criteria for cyclothymia (Levitt *et al.*, 1990). BPD is frequently comorbid with major depression, but major depression is frequently comorbid in nearly all personality disorders (Alnaes *et al.*, 1988), with some evidence suggesting that approximately 70–80% of patients with any Axis II disorder have at least one episode of major depression during their life (McGlashan *et al.*, 1986). However, depressive disorders associated with BPD may be more chronic and severe, and have an earlier onset (Skodol *et al.*, 2000). Curiously, some BPD patients with major depression may cope better than those without it, perhaps due to more robust medication responses (Pope, 1983).

BPD and PTSD share phenomenological and developmental risk factors, but may be separable by their longitudinal course (Gunderson *et al.*, 1993). Comorbidity is frequent. About 30–47% of patients with BPD meet the criteria for PTSD (Swartz *et al.*, 1990, McGlashan, 2000), compared to 25% of patients with schizotypal, obsessive-compulsive, and avoidant personality disorder (McGlashan, 2000).

CLUSTER C

Although measurements of personality traits are affected by state factors (Reich *et al.*, 1986), evidence to date suggests that as many as 40–90% of patients with social phobia also meet the criteria for avoidant personality disorder (McGlashan, 2000; Widiger, 1992). It remains unclear whether social phobia and avoidant personality disorder represent two frequently co-occurring conditions or different aspects of a single underlying psychopathology (Perugi *et al.*, 1999).

The extent of comorbidity between obsessive-compulsive personality disorder (OCPD) and obsessive-compulsive disorder (OCD) is unknown, with rates from 2–6% to 30–60% reported in the literature (Diaferia *et al.*, 1997). The relationship between OCD and OCPD may not be specific to OCPD but may simply reflect an overall increase in the risk of personality disorders, as approximately half of patients with OCD meet the criteria for various personality disorders (Baer *et al.*, 1990). Additionally, the majority of patients with comorbid OCD and OCPD meet criteria for at least one other personality disorder (Bejerot *et al.*, 1998).

THE ROLE OF PSYCHOPHARMACOLOGICAL TREATMENT IN PERSONALITY DISORDERS

The treatment of some personality disorders, such as BPD, with psychopharmacological agents is not uncommon in clinical practice, and in fact may be in excess of treatment in comparable populations (Bender *et al.*, 2001). Some patients, especially high-risk patients, undergo polypharmacy (Zanarini, personal communication), despite the lack of controlled evidence to validate the practice in this population. However, the severity of psychosocial dysfunction and dramatic nature of some of these patients' symptoms often warrant therapeutic intervention and may make discontinuing possibly ineffective treatment difficult.

On the whole, psychopharmacological treatments for personality disorders are considered to be adjunctive to psychotherapy, but the relative contributions of psychopharmacological treatment versus psychosocial interventions such as psychotherapy, and the interactions between the two, remain important topics for future study.

PSYCHOPHARMACOLOGICAL TREATMENT STUDIES

Three main patterns in treatment studies of personality disorders emerge. One is a relative lack of evidence for syndromal improvement, or remission, in response to pharmacological treatment. The second pattern is that pharmacotherapy may show effects on a specific range of symptoms. Modern studies emphasize treating specific symptom dimensions with agents that possess selective psychopharmacological properties. Some of these studies look within specific diagnostic categories, while others look across diagnostic categories. The third pattern that emerges is the non-specific effects that many psychopharmacological compounds have. For example, some neuroleptics seem to have a global, sedating effect on patients with personality disorders, leading to changes in a wide range of outcome measures. Even selective agents, such as the serotonin selective reuptake inhibitors (SSRIs), have effects on a range of symptoms such as mood, anxiety, obsessionality, and impulsive aggression. Sometimes these non-specific effects may also be detrimental, especially when they are unpredictable or paradoxical.

NEUROLEPTICS

The predominantly antidopaminergic effects of neuroleptics and their proven ability to treat symptoms of psychosis in schizophrenia and affective illnesses have led to studies in personality disorders with psychotic-like symptoms. These include the schizophrenia-related personality disorders of DSM-IV: schizotypal, paranoid, and schizoid personality disorders, in addition to DSM-IV BPD. The rationale for the use of dopaminergic antagonists in these patients is provided by findings of increased cerebrospinal fluid (CSF) and plasma levels of dopamine metabolites in selected schizotypal subjects (Siever *et al.*, 1991; 1993b), more frequent dyskinetic-like movements following amphetamine challenge compared to normal controls (Fenton *et al.*, 1994), genetic relationships to schizophrenia (Kendler *et al.*, 1982), and psychotic-like symptoms in BPD patients exposed to amphetamine challenge (Schulz *et al.*, 1985).

The relative rarity of paranoid and schizoid personality disorders, the frequent comorbidity of schizotypal personality disorder and BPD, the importance of psychotic symptoms in BPD and schizotypal personality disorder, and the initial conceptualization of schizotypal personality disorder and BPD as being related to each other and to schizophrenia have led to the overwhelming majority of neuroleptic trials being dedicated to these two personality-disorder populations.

Three early studies failed to find evidence for syndromal improvement with neuroleptic treatment in comparison to other medications in patients with what today would be considered Cluster B personality disorders. In a double-blind trial by Vilkin (1964) of trifluoperazine, diazepam, and meprobamate/benactyzine in BPD patients, diazepam was more effective than trifluoperazine in relieving overall symptoms, and trifluoperazine was marginally better than mebrobamate/benactyzine. Fink *et al.* (1964) reported improvement in patients with emotionally unstable character disorder (EUCD), who today might be diagnosed as having histrionic personality disorder, using relatively high doses of chlorpromazine (up to 1200 mg) when compared to placebo and imipramine. While imipramine was found to reduce affective instability and agitation, chlorpromazine's global effects were not different from those of placebo. Hedberg *et al.* (1971) noted some improvement in 22% of pseudoneurotic schizophrenics treated with moderately high doses of trifluoperazine (up to 32 mg) and in 28% of patients with trifluoperazine and tranylcypromine (up to 30 mg), but the largest number of patients in this study, as in the study of Fink *et al.* (1964), did better on the antidepressant.

The first placebo-controlled, double-blind study of a neuroleptic in DSM-III-diagnosed BPD showed some improvement with treatment on specific dimensions. In a subgroup of DSM-III-diagnosed BPD patients with at least one psychotic symptom, Goldberg *et al.* (1986) studied low-dose thiothixene (average dose 8.7 mg) compared to placebo, noting significant improvement in cognitive disturbances, ideas of reference, obsessive-compulsive symptoms, and panic-anxiety symptoms. No improvement in depressive symptoms was found, and no improvement was found in global functioning as measured by global assessment of function (GAF). The marked reductions of psychosis in this study may be partially explained by the higher levels of psychosis in the study population.

Some studies have found evidence of global improvement in BPD and schizotypal patients with neuroleptic treatment. Two controlled comparison trials in schizotypal/BPD subjects comparing low-dose chlorpromazine ($105-120\,mg\,d^{-1}$) versus loxapine ($13.5-14.5\,mg\,d^{-1}$) (Leone, 1982) and low-dose thiothixene (mean $9.4\,mg\,d^{-1}$) versus haloperidol (mean $3\,mg\,d^{-1}$) (Serban and Siegel, 1984) reported improvement in suspiciousness, hostility, depressed mood, and anxiety. An open-label study of pimozide in DSM-II personality-disordered subjects showed that pimozide was associated with good to excellent global improvement in 69% of subjects. Paranoid or schizoid personality disorder predicted response to the neuroleptic (Reyntjens, 1972).

In a randomized, placebo-controlled trial of haloperidol versus amitriptyline, Soloff *et al.* (1986) found that haloperidol at 4–16 mg per day (mean $7.24\,mg\,d^{-1}$) had significant effects on depression, anxiety, hostility, paranoid ideation, impulsive behaviour, and global function in hospitalized patients with DSM-III-diagnosed BPD or comorbid BPD and schizotypal personality disorder. Responding patients ended the study reporting clear improvement but remained moderately symptomatic by observer-rated measures. Patients' subjective reports on the Beck Depression Inventory distinguished between groups, while the observer-rated Hamilton Depression Rating Scale differences between groups were not significantly different. The patients most likely to respond to low-dose haloperidol had both affective and schizotypal symptoms. Diagnostic category did not predict outcome with haloperidol. However, a dimension of schizotypy, which included psychoticism, did predict a more favourable result with haloperidol. Haloperidol seemed to be useful for a subset of patients, but drug response could not identify a subgroup of BPD patients with an underlying 'schizotypal' illness.

Two large, placebo-controlled studies found less favourable results. Cowdry and Gardner (1988) studied alprazolam, carbamazepine (mean $820\,mg\,d^{-1}$), trifluoperazine (mean $7.8\,mg\,d^{-1}$), and tranylcypromine sulphate (mean $40\,mg\,d^{-1}$) in a double-blind, placebo-controlled trial. Patients were female; met five of eight DSM-III criteria for BPD; had histories of overdoses, self-mutilation, or physical violence; and had no current Axis I comorbidity. Physicians rated significant improvement in patient's depression and anxiety with trifluoperazine treatment, but subjective ratings were variable. Although physicians did not rate subjects on trifluoperazine as being less impulsive, they did rate suicidality as decreased. Non-significant trends were seen for less behavioural dyscontrol. On the whole, trifluoperazine seemed to be slightly less efficacious than tranylcypromine and carbamazepine on the behavioural and affective measures used in the study, and only 50% of the trifluoperazine trials could be completed due to clinical worsening or medical complications.

Soloff *et al.* (1993) compared phenelzine and haloperidol versus placebo in hospitalized, DSM-III-R-diagnosed BPD, with or without comorbid schizotypal personality disorder. Pre-treatment depression scores were high (Ham D-24 $= 25.3 \pm 5.9$). Although improvement with haloperidol therapy was seen, there were considerable residual depressive symptoms at the end of the study. Significant improvement was found with phenelzine. Surprisingly, mood reactivity increased in all three groups, although both phenelzine and haloperidol resulted in modest improvements in hostility. Only phenelzine produced a statistically significant but clinically modest improvement in impulsivity. Soloff *et al.* concluded that neuroleptic medications functions as a non-specific tranquillizer in BPD, with significant effects only in the most severely impaired borderlines (Soloff *et al.*, 1993).

A 16-week continuation follow-up study on the same group of patients also failed to find evidence for haloperidol's efficacy on syndromal measures. In fact, treatment with haloperidol was associated with a significant increase in the 'hopelessness' item of the Hamilton Depression Scale. Of the subjects treated with haloperidol, 64.3% dropped out of the continuation study, compared to 45.5% of phenlzine-treated subjects. The drop-out rate for the entire 22 weeks of study was 87.5 for the haloperidol-treated subjects. The study failed to find demonstrable value of continuation therapy with haloperidol in this population.

Although prolonged treatment with neuroleptics probably does not improve syndromal or affective measures, Montgomery and Montgomery (1982) found that over a 6-month period depot flupenthixol in comparison to placebo decreased suicidal and parasuicidal behaviour in patients with past histories of suicide attempts and self-destructive behaviour. This finding may be due to the tranquillizing effects of neuroleptics in this study population.

ATYPICAL ANTIPSYCHOTICS

The adverse side effects, high rates of drop out and non-compliance, and lack of consistent efficacy data associated with neuroleptics make the newer, atypical antipsychotics promising candidates for evaluation in the treatment of personality-disorder symptoms. Atypical antipsychotics may address affective symptoms in bipolar disorder and deficit symptoms in schizophrenia, which have similarities to the affective dysregulation in Cluster B disorders and the deficit symptoms of Cluster A disorders.

Deficit symptoms in Cluster A personality disorders are associated with impairments in working memory (Roitman *et al.*, 2000)

and sustained attention (Siever *et al.*, 1991; Meritt *et al.*, 1989). Neuropsychological evidence that the cortical deficits in Cluster A personality disorders may be selective (Raine *et al.*, 1992; Siever *et al.*, 1991) has been corroborated by neurobiological findings of altered CSF homovanillic acid (HVA) levels (Siever *et al.*, 1991) and volumetric neuroimaging findings of increased ventricular size (Raine *et al.*, 1992; Cazzullo *et al.*, 1991; Siever *et al.*, 1991), abnormally shaped corpus callosum (Downhill *et al.*, 2000), and decreased pulvinar size (Byne *et al.*, 2001). These abnormalities may be intermediate in severity between schizophrenics and normal controls (Byne *et al.*, 2001; Downhill *et al.*, 2000), indicating that these disorders may exist on a continuum with schizophrenia, and thus may be amenable to treatment with atypical antipsychotics.

The efficacy of atypical antipsychotics in the treatment of bipolar affective disorder for affective symptoms suggests they may have similar efficacy for affective symptoms in 'dramatic cluster' disorders such as BPD.

Three open trials of clozapine in BPD suggest that it may have efficacy on a range of symptom dimensions. An open trial of clozapine in 15 DSM-III-R-diagnosed BPD patients with symptoms of psychosis, seven of whom also met the criteria for schizotypal personality disorder, found significant improvement of psychosis and global function (Frankenburg and Zanarini, 1993). Benedetti *et al.* (1998) gave 12 inpatients with BPD and severe 'psychotic-like' symptoms low doses of clozapine ($25-100\,mg\,d^{-1}$) and found improvement in psychosis, depression, impulsive behaviours, and global functioning. Most patients suffered from some side effects of clozapine treatment, and on follow-up, one patient at week 24 developed reversible granulocytopaenia. Chengappa *et al.* (1999) treated seven subjects with BPD, psychosis, and a history of severe self-mutilation and/or violence serious enough to warrant hospitalization. All subjects had previous trials with conventional neuroleptics in combination with other psychotropic agents with equivocal benefits. Clozapine (mean dose $421\,mg\,d^{-1}$) led to significant improvements in self-mutilation, behavioural dyscontrol leading to seclusion, global function, and need for p.r.n. medications. However, one patient experienced leukopaenia, two patients gained 9 kg, and one patient gained 17.7 kg during the trial with clozapine. Although the study was limited by that absence of a control group, it is significant because of the severity of the subjects' borderline pathology. The risk-to-benefit ratio of the use of clozapine in personality-disordered patients remains unclear without the availability of placebo-controlled data.

No conclusive data on the newer atypical antipsychotics olanzapine, risperdal, seroquel, and ziprasidone are available yet. Their relatively low side-effect profiles and efficacy in treating psychotic as well as affective symptoms make them appealing alternatives to 'typical' neuroleptics. Preliminary data with olanzapine indicate that it shows promise as an agent that may be able to address several different symptom dimensions in patients with BPD. Case reports with olanzapine $5\,mg\,d^{-1}$ suggest it may have efficacy in reducing the frequency and intensity of self-injurious behaviour (SIB) in BPD (Hough, 2001). One open trial in BPD with dysthymia suggests that it may lead to syndromal improvement. In an 8-week open trial in BPD conducted, by Schulz *et al.* (1999), olanzapine led to decreases in psychosis, impulsivity, anger and interpersonal sensitivity, and depression, and improvements in global function. Patients in this study had comorbid dysthymia and were in continuing psychotherapy. Also notable was a low drop-out rate, and a lack of the extrapyramidal symptoms and the statistically significant weight gain of patients taking olanzapine (mean 2.7 kg). Preliminary results from a not yet published placebo-controlled trial of olanzapine in BPD outpatients show that, in comparison to placebo, olanzapine ($5\,mg\,d^{-1}$) demonstrates efficacy on a variety of symptom dimensions as well as global function, as assessed by GAF score (Zanarini *et al.*, 2002).

Controlled data in children and adolescents with borderline intellectual functioning suggest that risperidone is effective in comparison with placebo in the treatment of behavioural disturbances and aggression (Van Bellinghen *et al.*, 2001; Buitelaar *et al.*, 2001). Data regarding the usefulness of risperdone in the treatment of adult, personality-disordered patients are limited. A case report suggests that risperidone $4\,mg\,d^{-1}$ may be helpful in the treatment of self-mutilation in BPD (Khouzam *et al.*, 1997). Szigethy and Schulz (1997) found that risperdone $2\,mg\,d^{-1}$, in conjunction with fluovoxamine $200\,mg\,d^{-1}$, was helpful in treating psychosis and depression in a BPD patient with comorbid dysthymia. A single case report has described the successful treatment of a patient with antisocial personality disorder and impulsive aggression with risperidone $3\,mg\,d^{-1}$ in conjunction with 9 mg biperiden, 60 mg propranolol, and 30 mg diazepam per day to treat akathisia. In an unpublished pilot study, Schulz and associates treated BPD in a double-blind, placebo-controlled trial of risperidone versus placebo. Treatment with risperidone led to improvements in psychoticism and global function. However, the 8-week study was unable to show a statistically significant superiority of risperidone over placebo. This may have been due to the small number of subjects, robust placebo response, and coadministered weekly psychotherapy in both the placebo and treatment groups.

Atypical antipsychotics show promise and controlled data are forthcoming. In general, evidence for the use of 'typical' neuroleptics indicates that some improvement may be seen in impulsivity, aggression, and psychoticism. Improvement may depend on the severity of symptoms before treatment, with psychoticism standing out as a dimensional symptom that predicts better neuroleptic response. The value of maintenance treatment with typical neuroleptics remains unclear, but evidence suggests that the risk of worsened depression must be balanced against a non-specific sedative effect that may decrease impulsive aggressive behaviours.

MOOD STABILIZERS AND ANTICONVULSANTS

The use of lithium and the anticonvulsants carbamazepine and valproate in the treatment of acute mania has prompted interest in examining their efficacy in treating the prominent affective symptoms of the Cluster B disorders. In addition, the EEG-normalizing effect of the anticonvulsants and early studies showing the therapeutic behavioural effects of the anticonvulsant diphenylhydantoin (Klein and Greenberg, 1967; Stephens and Schaffer 1970) have made them candidates for the treatment of impulsivity in disorders with 'soft' neurological signs and personality disorders.

The rationale for the treatment of affective symptoms in Cluster B personality disorders with mood stabilizers as well as with antidepressants is based on a limited set of data. Biological studies of the affective component of personality disorders have found conflicting evidence on whether or not findings of thyroid and HPA axis abnormalities persist (Korezekwa *et al.*, 1991; Kavoussi *et al.*, 1993) or disappear (Loosen and Prange, 1982) if the presence of comorbid depression is taken into account. Similar discrepancies have been found in heritability studies (Torgersen *et al.*, 1984; Schulz *et al.*, 1986; Riso *et al.*, 2000). Affective instability, a hallmark of BPD, has been associated with cholinergic receptor responsiveness in volunteers (Fritze *et al.*, 1990) and BPD patients (Steinberg *et al.*, 1997). Evidence from a family history study suggests that trait affective lability, in conjunction with trait impulsivity, may have a greater familial relation to BPD than to affective disorders in general (Silverman *et al.*, 1991).

Lithium

Two controlled trials in two markedly different populations have found lithium to be effective at reducing anger and/or impulsive

aggression. Links compared lithium (mean dose 985 mg d^{-1}) to placebo and desipramine (mean 162.5 mg d^{-1}) for 6-week intervals with a 2-week washout period between each arm (Links, 1998). Patients in the study were moderately impaired BPD outpatients who remained in psychotherapy with their referring clinicians. Lithium was superior to desipramine and placebo on observer ratings of anger and suicidality, but the patients did not notice any change in how they felt, and no improvement was seen on objective measures of depression.

In a double-blind, placebo-controlled study of the effect of lithium on aggressive behaviour in 66 chronically aggressive prisoners in a medium-security institution, Sheard (1976) found that lithium compared to placebo was associated with a reduction in the frequency of serious aggressive incidents. Many of these patients today would be considered to have, among other DSM-IV diagnoses, antisocial personality disorder, making this one of the few controlled trials of any psychopharmacological intervention in this kind of patient population. In this study, 80–90% of the subjects had been incarcerated for longer than 1 year between the ages of 12 and 18 years; had committed crimes such as manslaughter, rape, murder, and assault; and had a history of chronic assaulting behaviour and/or impulsive antisocial behaviour. The group was described as being an 'extremely manipulative, hostile group of young men who were extroverted, highly impulsive, and action oriented' (p 1411). Lithium serum levels were maintained between 0.6–1.0 μg m^{-1}. One weakness of this study was that subjects could reliably guess which treatment they were receiving.

Two studies have found that lithium may have therapeutic effects on affective symptoms in Axis II disorders. LaWall and Cassie (1982), reported a case series of five DSM-III-diagnosed BPD patients who demonstrated relief from labile affect, decreased aggression, and decreased depression with lithium therapy. A double-blind, randomized, crossover study comparing lithium to placebo in the treatment of patients with what would today be considered BPD or histrionic personality disorder (Rifkin, 1972) found that lithium therapy significantly reduced the range of daily or hourly mood swings.

Carbamazepine

Studies to date with carbamazepine have focused on the treatment of impulsive aggression. Mattes (1990) found that carbamazepine, in comparison with propranolol, in subjects who met the first two criteria of intermittent explosive disorder but who could also have shown episodes of aggressiveness between severe outbursts, was effective at reducing the severity of outbursts by non-blind ratings by the psychiatrist, patient, and family member. Serum levels were 8–12 μg kg^{-1}. In general, a history of attention-deficit disorder predicted better response to propranolol, while a history of intermittent explosive disorder and/or epilepsy predicted response to carbamazepine. In a study more generalizable to the treatment of personality-disorder patients seen in the typical clinical setting, Cowdry and Gardner (1988), in the crossover study of tranylcypromine, carbamazepine, alprazolam, and trifluoperazine already mentioned, found carbamazepine (mean dose 820 mg d^{-1}), in a group of BPD patients with histories of self-destructive behaviour, to be beneficial in suppressing episodes of impulsive aggression, compared to alprazolam, trifluoperazine, tranylcypromine, and placebo. The authors suggested that treatment with carbamazepine produced a 'reflective delay', allowing patients to pause before reacting to an emotional stimulus. Although objective raters noted a significant improvement in mood, patients themselves did not, a finding that was attributed to a halo effect on the part of clinicians, who may have seen an improvement in impulsive aggression as improved mood. This is consistent with the additional finding that 3 of the 17 (18%) patients taking carbamazepine actually noticed worsening of their mood. Their depressive symptoms resolved after cessation of carbamazepine. Thus, carbamazepine's usefulness in treating affective symptoms of personality disorder, such as affective instability or depressive symptoms remains uncertain. However, preliminary evidence suggests that it attenuates impulsive aggression in personality-disordered patients.

Valproate

Valproate has been found to be efficacious in the treatment of bipolar disorder. There is also evidence that it might be effective in reducing impulsive aggression. A double-blind, placebo-controlled trial in 20 children and adolescents with either oppositional defiant disorder or conduct disorder found that divalproex, with a mean blood level of 82.2 μg ml^{-1}, compared to placebo, was efficacious in reducing mood lability and explosive temper (Donovan *et al.*, 2000).

Two open trials of valproate have found benefit in personality-disordered subjects. Stein *et al.* (1995) found that valproate, in 11 DSM-III-R-diagnosed BPD patients, was moderately effective at reducing anger, impulsivity, anxiety, and rejection sensitivity. The mean serum valproate level in this study was 78.8 μg ml^{-1}. Although dramatic improvements were not seen, patients at baseline were only mildly impaired with respect to depressive symptoms and aggression. Both patients and raters noted improvement in mood and irritability, with 50% of subjects taking valproate showing change scores for mood and 38% showing change scores for anxiety, anger, impulsivity, and rejection sensitivity. Kavoussi *et al.* (1998) studied valproate in 10 patients meeting DSM-IV criteria for at least one personality disorder who had failed an SSRI trial for impulsive aggressive behaviour. Patients in this trial had higher baseline OAS-M scores (mean = 27.2, SD = 17.9); met criteria for a range of Cluster A, B, and C personality disorders; had frequent Axis II comorbidity; and were treated with a maximum of 2000 mg per day of valproic acid. Systematic assessments of mood were not made in this trial. Improvements were seen on mean OAS-M scores at weeks 2, 4, 6, and 9. At week 4, OAS-M irritability scores were significantly lower. Of the eight completers in the study, six had a 50% or more reduction on the OAS-M.

A single placebo-controlled trial of valproate in BPD has been published (Hollander *et al.*, 2001). In a 10-week, parallel-group, double-blind, placebo-controlled, comparison trial, 16 outpatients with DSM-IV-diagnosed BPD received valproate, with a mean serum level of 64.57 μg ml^{-1}. Patients in this study showed global improvement as measured by global assessment of symptoms (GAS) and clinical global inventory (CGI). Significant changes in aggression were not detected in this study, perhaps because subjects did not begin the study with high aggression. Unfortunately, none of the patients randomized to placebo completed the trial. In the intent-to-treat analysis (ITT), measures made in the study failed to reach statistical significance, with the principal finding being a non-significant trend of the GAS from serious to moderate impairment.

Evidence supporting the use of valproate in personality-disordered patients for impulsivity, aggression, and mood instability is promising but incomplete. Pilot data suggests that it may have efficacy for these dimensions and may even lead to global, syndromal improvement, although this finding needs replication in a larger, controlled trial with sufficient power. A multicentre, placebo-controlled trial of valproate in a heterogeneous group of subjects with impulsive aggression is currently under way.

NEURONTIN (GABAPENTIN)

Although gabapentin's efficacy as a mood stabilizer is equivocal, a randomized, placebo-controlled study (Pande *et al.*, 1999) indicates

that it may be an effective treatment for generalized social phobia. Because of the frequent comorbidity of social phobia with avoidant personality disorder, it may be an agent to consider in patients with generalized social anxiety and avoidant personality disorder. No data is available on gabapentin's efficacy in treating impulsive aggression or affective instability. Topiramate and lamotrigene, two anticonvulsants tested in the treatment of affective disorders, have not yet been tested in personality-disordered patients.

ANTIDEPRESSANTS

Antidepressants have been studied in personality disorders because of the similarity of the mood complaints of the Cluster B disorders to affective syndromes such as cyclothymia and atypical depression, substantial comorbidity with affective disorders, the efficacy of antidepressants in treating anxiety and obsessive symptoms, and the serotonergic abnormalities linked to impulsive aggression and suicide.

The rationale for the use of antidepressants for affective symptoms in personality disorders was touched on in the section on mood stabilizers. The rationale for the use of antidepressants in the treatment of impulsive aggression is based on data relating diminished serotonergic function to impulsive aggression in personality-disordered patients. Deficits in serotonergic function have been associated with suicide in depressives (Åsperg *et al.*, 1976); aggression towards oneself and others (Brown, 1979); impulsive, rather than premeditated aggression (Linnoila *et al.*, 1983); and self-injurious behaviour (SIB) in depressives (Lopez-Ibor *et al.*, 1985) and SIB in personality-disordered subjects (New *et al.*, 1997). Neuropsychopharmacological challenge studies with the serotonergic agent fenfluramine (both *d*,l- and *d*-stereoisomer forms) have found blunted prolactin responses in association with impulsive aggression, implicating reduced serotonergic function in BPD (Coccaro, 1989a) and antisocial personality-disordered subjects (O'Keane *et al.*, 1992). Neuroimaging studies have discovered reduced metabolic activity in the areas of the prefrontal cortex in aggressive prisoners (Raine *et al.*, 1997). Using the positron emission tomography (PET) scan in personality-disordered subjects with histories of impulsive aggression, Siever *et al.* (1999) found blunted metabolic responses to *d*,l-fenfluramine in the orbital frontal, adjacent medial, and cingulate cortex when compared to matched controls, findings that were partially replicated by Soloff *et al.* (2000). These brain regions rely heavily on serotonergic neurotransmission.

In addition to abnormalities in the serotonergic system, reduced CSF levels of norepinephrine metabolites (Brown *et al.*, 1979) and dopamine metabolites (Linnoila, 1983), and increased levels of CSF vasopressin (Coccaro *et al.*, 1996) have been correlated with measures of aggression.

TRICYCLIC ANTIDEPRESSANTS

Early studies of the tricyclic antidepressants (Klein, 1968) found some efficacy in the treatment of 'pseudoneurotic schizophrenics'. Soloff *et al.* 1987 found modest benefits in depressed mood with amitriptyline (mean dose 147 mg d^{-1}) compared to placebo in a 5-week study of hospitalized BPD and schizotypal personality patients. Although some patients seemed to benefit primarily on affective measures, a subgroup of patients on amitriptyline showed increases in ratings of impulsive and aggressive behaviour. These patients were characterized as having higher levels of aggression, psychoticism, negativism, impulsivity, and schizotypal symptoms.

Three other studies (Klein 1968; Rampling, 1978; Links *et al.*, 1990) have also found that a subgroup of patients with BPD or schizotypal personality disorder seemed to worsen after treatment with tricyclic antidepressants with respect to suicidality and physical assaultiveness. This may be due to the noradrenergic actions of these agents, which could increase the likelihood of acting on aggressive impulses or increase their intensity.

MONOAMINE-OXIDASE INHIBITORS (MAOIs)

MAOIs, which are useful in the treatment of atypical depression, have been studied in personality-disorder patients in the hope that they would improve atypical mood symptoms such as the mood reactivity of histrionic personality disorder, rejection sensitivity in dependent and avoidant personality disorder, and depressive symptoms in BPD. The serotonergic effects of the MAOIs inhibitors also make them candidates for the treatment of impulsive aggressive behaviour.

The studies to date have produced conflicting results. Hedberg *et al.* (1971) found phenelzine to be effective in treating a subset of patients with pseudoneurotic schizophrenia, patients who, under DSM-IV, might be considered to have Cluster B or C personality disorders. In a retrospective study of patients with atypical depression (Parsons *et al.*, 1989), patients with comorbid BPD were three times as likely to benefit from therapy with phenelzine than imipramine in the treatment of mood symptoms. However, patients with atypical depression without comorbid BPD were no more likely to respond to phenelzine than imipramine. Cowdry and Gardner's (1989) double-blind, placebo-controlled, crossover comparison of tranylcypromine (40 mg d^{-1}), alprazolam, and carbamazepine found efficacy in mood symptoms in a group of treatment-resistant subjects with BPD without a comorbid affective disorder. Although improvement was seen in rated suicidality and impulsivity, there was no change in the severity of aggressive behaviours during the study, and the authors concluded that the improvement seen was multidimensional and mood-related, with little or no effect on impulsivity.

In a double-blind, placebo-controlled comparison of phenelzine and haloperidol in DSM-III-R borderlines, Soloff *et al.* (1993) found phenelzine (60 mg d^{-1}) to be modestly effective for symptoms of depression, anxiety, anger, and hostility compared to placebo and haloperidol. However, they did not replicate Parson *et al.* (1989) findings of efficacy against atypical depressive symptoms. The magnitude of change for all arms of the study were relatively low, leaving the patients still substantially impaired at the end. One possible explanation for their failure to replicate earlier more positive results with MAOIs was that the dose range in the study was slightly lower than previous studies due to treatment side effects. In their 16-week continuation study, Cornelius *et al.* (1993) found that continued phenelzine demonstrated only minor efficacy for treatment of the mood symptoms of irritability and depression. In these subjects, phenelzine had an activating effect, showing increased, rather than decreased, mood reactivity, although the authors note that activation was an improvement in the overall well-being of the patients suffering from anergia.

In summary, treatment of BPD patients with MAOIs may lead to improvements in mood if atypical mood symptoms are prominent, and may lead to improvements in impulsivity. Therapeutic effects may be modest, and their magnitude may be determined by the presence of comorbid atypical depression. There is no clear evidence that treatment with an MAOI leads to global or syndromal improvement.

Although not studied in the treatment of avoidant personality disorder specifically, MAOIs have been shown to be effective in the treatment of generalized social phobia. In an 8-week study comparing phenelzine to cognitive-behavioural group therapy and placebo, phenelzine treatment was more effective than either (Heimberg *et al.*, 1998). However, evidence to date suggests that

the more specific monoamine-oxidase-B inhibitor, selegiline, is not efficacious in generalized social phobia (Simpson *et al.*, 1998).

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)

SSRIs have been shown to be effective in treating depressive disorders and anxiety disorders. Preliminary evidence that SSRIs are effective in reducing impulsive aggression and affective symptoms in personality-disorder patients comes from several open trials of fluoxetine (Cornelius, 1991; Norden, 1989; Markovitz *et al.*, 1991; Coccaro *et al.*, 1990) and one of sertraline (Kavoussi, 1994).

In a double-blind, placebo-controlled trial of fluoxetine (20–60 mg), Coccaro *et al.* (1997) treated 40 non-depressed DSM-III-R-diognosed personality-disorder individuals with impulsive aggressive behaviour with fluoxetine or placebo, and found significant decreases in observed aggression scale — modified (OAS-M) irritability at week 6, and OAS-M verbal aggression and aggression against objects subscale decreases at week 10 of treatment. The effect of fluoxetine was mainly on verbal aggression, with most subjects responding at in the 20–40 mg d^{-1} dose range. No patients worsened while on fluoxetine. Notably, this study demonstrated that the treatment of a dimensional symptom (impulsive aggression) could occur across a categorical Axis II diagnosis. Patients in the study had an average of 1.8 ± 1.1 Axis II personality disorders, with the three most common diagnoses being BPD (33%), paranoid personality disorder (25%), and OCPD (23%). If SSRIs in these treatment responders were ameliorating a 'serotonin deficit', it might be hypothesized that patients with abnormalities in peripheral measures of serotonergic function would be the most likely to respond to fluoxetine. However, in a companion study, 15 of the patients underwent *d*-fenfluramine challenge prior to the start of the treatment trial. Among all of the subjects, there were positive correlations between pre-treatment prolactin response to *d*-fenfluramine challenge (PRL [*d*-FEN]) and percent improvement in the Overt Aggression Scale — Modified (OAS-M) scores in fluoxetine-treated versus placebo-treated subjects. Subjects with smaller responses to serotonergic challenge showed less improvement with SSRI treatment. Since PRL [*d*-FEN] response is thought to be an indirect measure of central nervous system serotonergic functioning, these results might indicate that impulsive aggressive subjects with the most severe serotonergic abnormalities are the ones least likely to benefit from SSRIs, possibly due to a blunted 5-HT-2 response to them (Coccaro and Kavoussi, 1997).

There is preliminary evidence that SSRIs may be able to improve depressive symptoms in BPD. Salzman *et al.* (1995) compared fluoxetine (mean dose 40 mg d^{-1}) to placebo in a 13-week, double-blind study of subjects with BPD diagnosed by DSM-III-R criteria. Patients in this study were mild to moderately symptomatic volunteers with no history of psychiatric hospitalization, recent suicidal behaviour, or self-mutilation. Significant improvement was found in anger and depression on the Profile of Mood States (POMS). There were trends for improvement in OAS and Hamilton Depression Inventory (HAM-D) scores. Although results from this trial were positive, it is unclear whether these results may be generalizable to more impaired BPD patients.

No controlled studies are available yet on the new, 'atypical' antidepressants such as mirtazepine, nefazadone, venlafaxine, and buproprion. In an open trial of venlafaxine in patients with BPD, Markovitz and Wagner (1995) found that venlafaxine seemed to be effective in treating depressive symptoms. Further work is needed with the newer antidepressants. It is unknown whether these agents, which also have effects on norepinephrine, will have tricyclic-like effects in patients with impulsive aggression.

SSRIs have been shown to be effective in the treatment of social phobia, and may be of benefit in patients with comorbid avoidant personality disorder. Controlled trials of paroxetine (Stein *et al.*, 1998), fluvoxamine (Stein *et al.*, 1999; van Vliet *et al.*, 1994), and sertraline (Katzelnick *et al.*, 1995) have all shown efficacy compared to placebo. Open trials of citalopram (Bouwer *et al.*, 1998), fluoxetine (van Ameringen *et al.*, 1993), venlafaxine (Altamura *et al.*, 1999), and nefazadone (van Ameringen *et al.*, 1999) show promising results.

BENZODIAZEPINES

Although an early comparison study of diazepam and trifluoperazine found that diazepam was more effective than the neuroleptic in relieving symptoms of BPD (Vilkin, 1964), Cowdry and Gardner found an increase in the frequency of episodes of serious dyscontrol in patients with BPD and histories of behavioural dyscontrol randomized to receive alprazolam (average dose 4.7 mg d^{-1}) in comparison to trifluoperazine, tranylcypromine, alprazolam, carbamazepine, or placebo. This troubling 'disinhibiting' effect occurred in the context of reduced anxiety and overall benefit to some patients. Although commonly used and generally considered to be safe and efficacious in the treatment of acute agitation and anxiety, the benzodiazepines remain relatively untested in the treatment of personality-disordered patients.

BUSPIRONE

There are no controlled trials to date in the use of buspirone, a 5-HT-1a selective partial agonist, in the treatment of impulsive aggression in personality-disordered patients. While it is an effective agent in the treatment of generalized anxiety disorder, its efficacy in generalized social phobia remains unclear. Although an open trial found buspirone to be effective at higher doses (average dose of responders was approximately 60 mg per day) (Schneier *et al.*, 1993), a controlled trial of buspirone at 30 mg per day in the treatment of generalized social phobia failed to find efficacy compared to placebo (van Vliet *et al.*, 1997). Further work should be done with higher doses of buspirone in patients with comorbid social phobia/avoidant personality disorder.

OPIATE ANTAGONISTS

There are no controlled data in the use of opiate antagonists to treat self-injurious behaviour (SIB) in personality-disordered patients. A few controlled data regarding the use of naltrexone in the treatment of SIB in patients with developmental disorders and mental retardation suggest that naltrexone in moderate doses (<1.5 mg per kg d^{-1}) may be effective (Pies and Popli, 1995), but not all trials to date have found positive results (Willemsen-Swinkels *et al.*, 1995).

In an open trial of naltrexone (50 mg d^{-1}), six of seven patients with histories of SIB experienced remissions of self-injury (Roth *et al.*, 1996). Patients in this trial exhibited striking self-destructive behaviours but had a heterogeneous set of diagnoses. A second open trial of naltrexone (50 mg d^{-1}) in five patients with BPD showed that treatment reduced the number of self-injurious thoughts and actions (Sonne *et al.*, 1996).

A single open trial of naltrexone for the treatment of dissociation and flashbacks in BPD patients by Bohus *et al.* (1999) found that treatment was associated with a decrease in intensity of, and total amount of time in, dissociative states in all patients. In the group of nine patients evaluated for flashbacks, six reported a reduction in

the number of flashbacks in a dose-dependent fashion, while three reported no change. Doses in this study ranged from 25 to 100 mg per day, and approximately one-third of the patients were receiving concomitant antidepressant therapy.

Open trials in the use naltrexone for the treatment of SIB and dissociation show promising results that need to be verified with placebo-controlled data.

ECT (ELECTROCONVULSIVE THERAPY)

Data on the ECT of personality-disordered patients are limited to comparisons of subjects with major depressive disorder (MDD) with a comorbid personality disorder and subjects with MDD only. These echo pharmacological treatment trials of MDD with comorbid personality disorders, which have found, in general, that comorbid personality disorders are associated with a less robust treatment response (DeBattista *et al.*, 2001).

Two prospective correlational studies have provided somewhat conflicting evidence. Pfohl (1984) found that patients with MDD + PD, as diagnosed by the Structured Interview for DSM-III Personality Disorders (SCID-P), did not differ significantly in treatment response to ECT, with 79% of MDD + PD subjects versus 75% of MDD-only subjects responding to ECT.

Zimmerman *et al.* (1986) found that at completion of ECT, 20% of MDD + PD versus 53% of MDD-only subjects had recovered at the completion of treatment. At 6 months, 33% of MDD + PD subjects versus 61% of MDD-only patients had recovered. Although most patients in both groups at the end of treatment experienced some symptomatic recovery, within 6 months, 62% of MD + PD subjects, versus only 8% of MD only subjects, were rehospitalized.

Evidence to date suggests that patients with comorbid major depressive disorder and personality disorders may respond to ECT but less robustly, may be left with considerable residual psychopathology, and may relapse at a higher rate. However, evidence also suggests that ECT may still have therapeutic effects in this population of patients, and is not contraindicated.

CONCLUSION

Evidence to date does not support the efficacy of psychopharmacological treatments in personality disorder, but does support their efficacy in treating specific symptom dimensions. There is not yet enough information available to make evidence-based treatment recommendations for every Axis II disorder. This is less true regarding BPD, which has been comparatively well studied.

For the neuroleptics, selection of appropriate patients with psychotic or psychotic-like symptoms for acute treatment produces tangible results, although these must be weighed against the lack of evidence for continuation or maintenance therapy, the risk of extrapyramidal side effects, high drop-out rates due to side effects, and possibly deleterious effects on mood with prolonged usage. The newer atypical antipsychotic agents may have better efficacy across a broader range of symptoms with fewer side effects. Mood stabilizers show promise in the treatment of impulsive aggression and possibly affective instability. These effects may occur even if subjective effects are less prominent. Benzodiazepines may help with some symptoms commonly encountered in Axis II disorders such as acute anxiety; however, they may also lead to behavioural dyscontrol in certain patients with histories of impulsive aggressive behaviour. Antidepressants may be effective in treating commonly encountered comorbid Axis I anxiety disorders in patients with Cluster C personality disorders. Tricyclics in patients with histories of behavioural dyscontrol may lead to worsening. Evidence for the efficacy of MAOIs in treating impulsive aggression, anxiety, and affective symptoms must be weighed against the risk of hypertensive crisis. For patients with histories of impulsive aggression, and without comorbid bipolar disorder, SSRIs are among the most promising agents. SSRIs may also be beneficial if mood symptoms are present. Their relatively benign side-effect profile and positive effects on mood may lead to improved compliance.

At this point, it is unclear how the effects of psychopharmacological treatment and psychotherapeutic treatment may interact. Some recent studies have kept subjects in pre-existing psychotherapy; other have not. It is also unclear whether the specific targets and efficacy measurements of the two treatment modalities are comparable. These are relevant questions, given that some patient groups with Axis II disorders are heavy utilizers of both psychotherapy and psychopharmacological treatment. It is also unclear what effect different combinations of medications may have on one another. For example, it is unclear whether the use of an SSRI or mood stabilizer lessens the risk of behavioural dyscontrol associated with benzodiazepines. Newer agents, such as the atypical antipsychotics, highly selective agents such as buspirone, and dual serotonergic/noradrenergic antidepressants, show promise for their improved side-effect profiles and atypical actions, but are untested in personality-disordered populations.

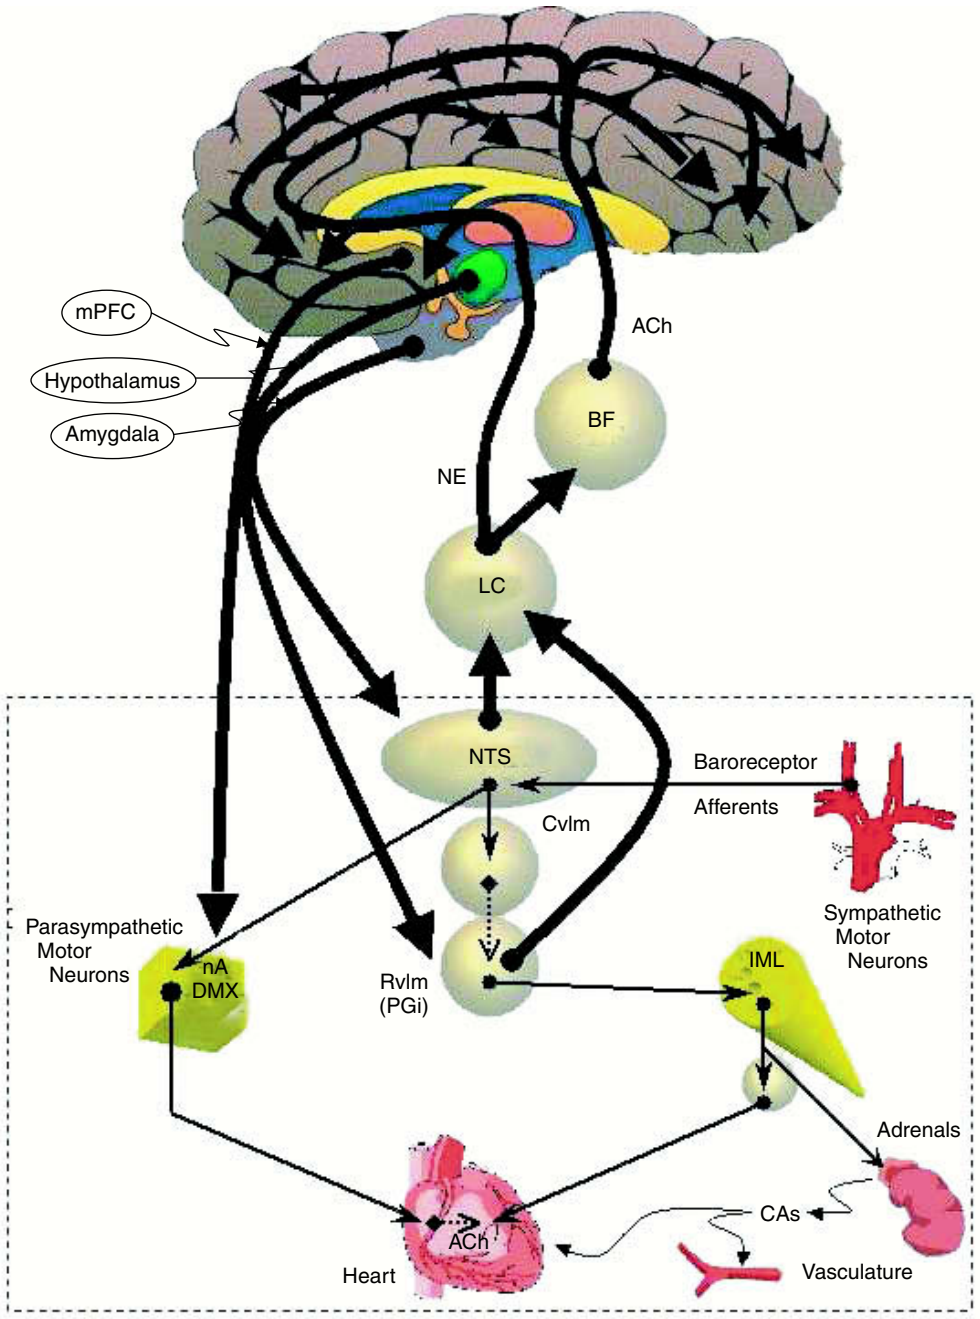

Figure IX.1 Baroreflex circuits. Dashed box: classical brainstem systems underlying baroreceptor cardiac reflex. Baroreceptor afferents project to nucleus tractus solitarius (NTS), which in turn leads to activation of parasympathetic motor neurons in the nucleus ambiguous (nA) and dorsal motor nucleus of the vagus (DMX). The NTS also activates the caudal ventrolateral medulla (Cvlm), which in turn inhibits the rostral ventrolateral medulla (Rvlm), leading to a withdrawal of excitatory drive on the sympathetic motor neurons in the intermediolateral cell column of the cord (IML). Upper section: expansion of the baroreflex circuit to illustrate the ascending and descending pathways to and from rostral neural areas, such as the medial prefrontal cortex (mPFC), hypothalamus and amygdala. Ascending systems include routes from the rostral ventrolateral medulla (Rvlm) and the nucleus of the tractus solitarius (NTS) to the locus coeruleus (LC) noradrenergic system, and indirectly to the basal forebrain (BF) cortical cholinergic system. Adapted from Cacioppo, J.T., Tassinary, L.G. and Berntson, G.G., *Handbook of Psychophysiology*, 2000, p. 466, with permission from Cambridge University Press. ACh, acetylcholine; CAs, catecholamines; NE, noradrenaline; PGi, paragigantocellular nucleus

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

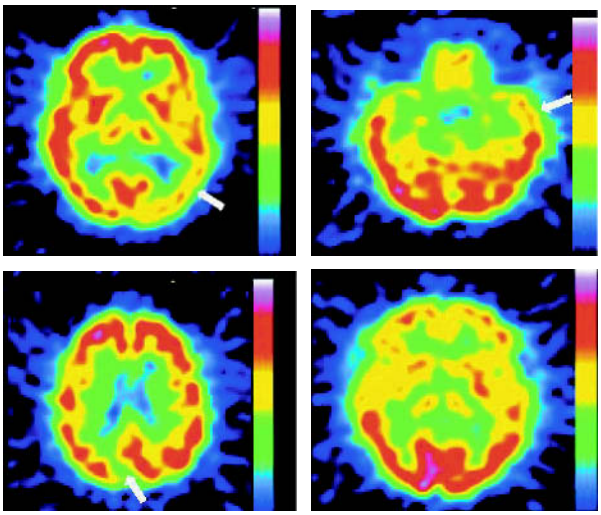

Figure XV-10.3 Perfusion brain SPECTs of four subjects with different pathologies: On the upper right: *Alzheimer disease*: 70 years old woman; MMSE = 19; performance deficit at the following tests; Boston naming test, Token test, verbal fluency and memory recall; Perfusion SPECT: Middle transaxial cut showing left temporo Parietal hypoperfusion. On the upper left: *Mild Cognitive Impairment*: 70 years old woman; MMSE = 28; performance deficit at the following tests; Grober Buschke memory recall; Perfusion SPECT: lower transaxial cut showing left temporal pole hypoperfusion. On the lower right: *Multi-infarct dementia*: 65 years old man; MMSE = 21; performance deficit at the following tests; Benton orientation/praxis/memory recall; Perfusion SPECT: Upper transaxial cut showing a right occipito parietal transcortical hypoperfusion. On the lower left: *Fronto-temporal dementia*: 61 years old woman with apathy Irritability & disinhibition; MMSE = 30; performance deficit at the following tasks; attention dual test/capture error sequencing; Perfusion SPECT: Middle transaxial cut showing a diffuse fronto-temporal hypoperfusion

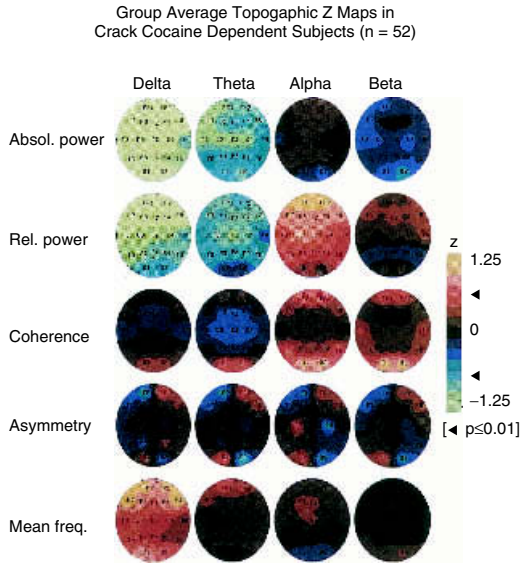

Figure XVI-5.5 Colour-coded topographic brain maps showing differences in absolute and relative power, coherence, hemispheric asymmetry and mean frequency between control subjects and recently detoxified cocaine abusers. Cocaine abusers have decreased absolute and relative slow wave and increased relative alpha power. Reprinted from Prichep, L.S., Alper, K.R., Kowalik, S., Merkin, H., Tom, M., Roy John, E. and Rosenthal, S., 1996. Quantitative electroencephalographic characteristics of crack cocaine dependence. *Biological Psychiatry* **40**, 986–993, copyright 1996, with permission from Elsevier Science

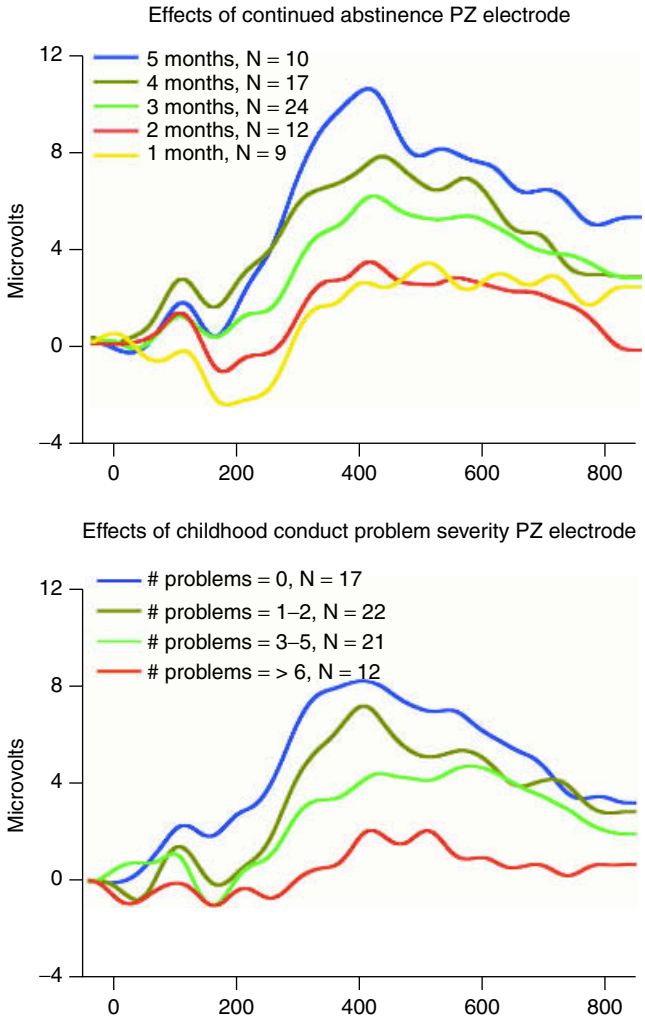

Figure XVI-5.4 Visual P3 amplitude in cocaine-, cocaine–alcohol- and opioid-dependent subjects recovers with increasing time of drug abstinence (above), but decreases with increasing number of childhood conduct disorder symptoms (below). Reprinted by permission of Elsevier Science from 'CNS recovery from cocaine, cocaine and alcohol, or opioid dependence: a P300 study' by Bauer, L.O., *Clinical Neurophysiology* **112**, 1508–1515. Copyright 2001 by the Society of Biological Psychiatry

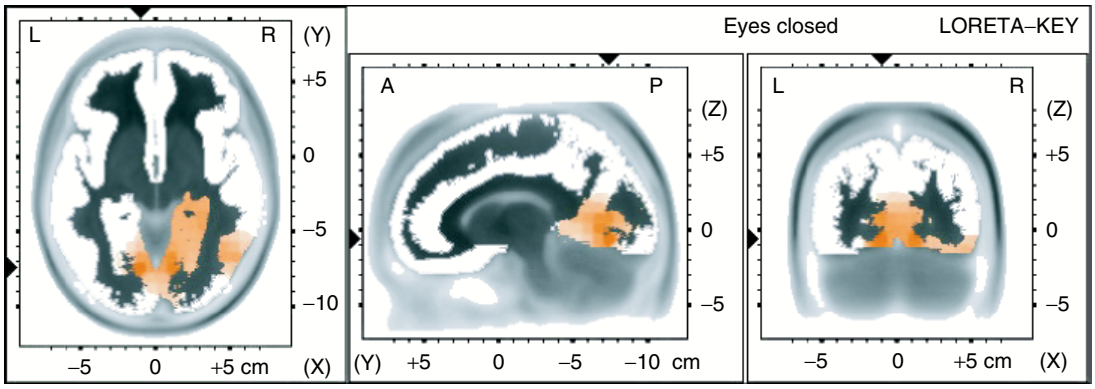

Figure XVI-5.8 Tomographic images displaying differences in fast alpha activity between MDMA ('ecstasy') users and control subjects. 'Ecstasy' users show significant increases (orange colour) in right temporo-occipital fast alpha power during closed eyes. Images have been computed from 31-channel scalp EEG recordings using low-resolution brain electromagnetic tomography (LORETA). Data from Gamma *et al.* (2000)

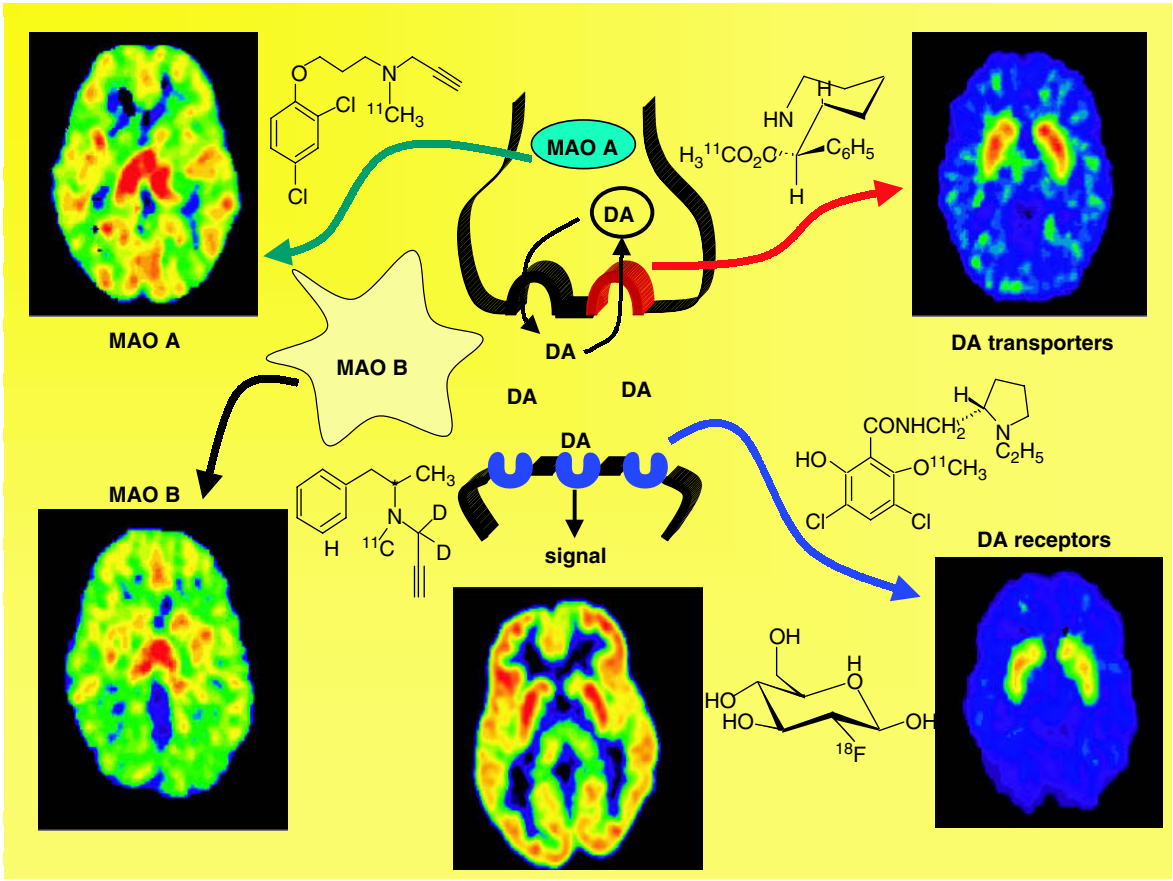

Figure XVI-8.1 Schematic of a dopaminergic synapse, indicating how PET can be used to evaluate dopaminergic function. The various ligands are ^{11}C-methylphenidate (dopamine transporter), ^{11}C-raclopride (D_2 dopamine receptor), FDG (metabolism), ^{11}C-deprenyl (MAO-B) and ^{11}C-clorgyline (MAO-A)

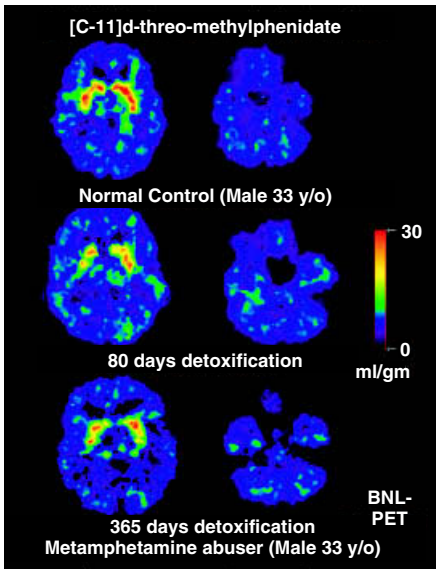

Figure XVI-8.4 Representative PET images showing ^{11}C-methylphenidate uptake to striatal dopamine transporter sites in a normal control and a methamphetamine abuser, scanned twice at 1 month and 4 months into withdrawal. Data adapted from Volkow *et al.* (2001a)

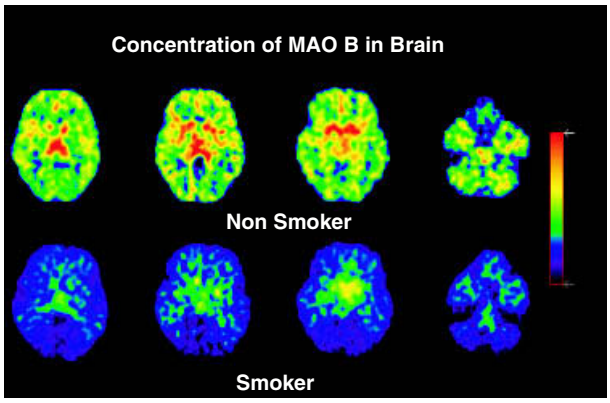

Figure XVI-8.6 Representative comparison of ^{11}C-deprenyl uptake into the brain of a nonsmoker and a smoker. Data are taken to indicate reduced MAO-B activity in the smoker. Adapted from Fowler *et al.* (1996)

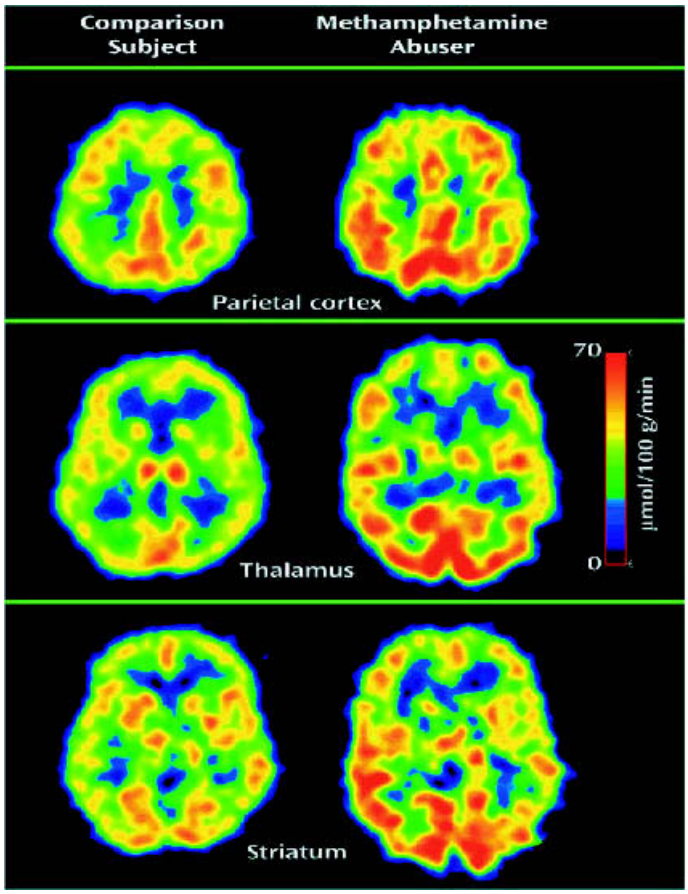

Figure XVI-8.5 Representative comparison of brain metabolism in a normal control and a methamphetamine abuser. Note the increased metabolism in the parietal cortex but decreased metabolism in the thalamus and striatum. Reproduced from Volkow *et al.* (2001b)

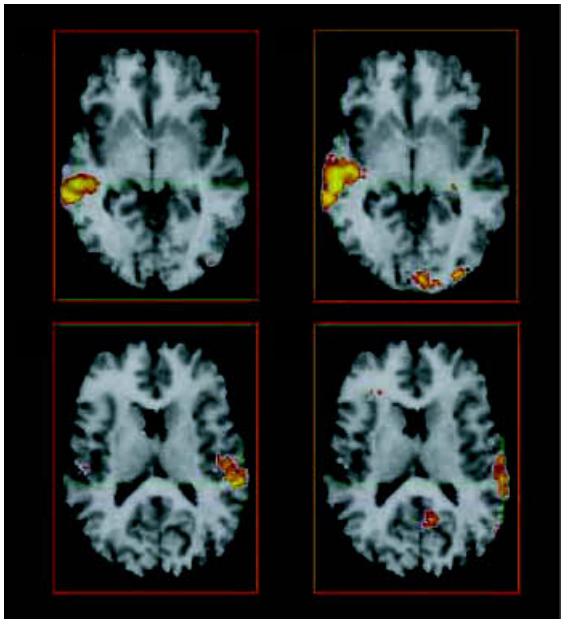

Figure XVII-8.4 Difference in rCBF between schizophrenic patients with a strong predisposition to auditory verbal hallucinations (hallucinators), schizophrenic patients with no history of hallucinations (non-hallucinators), and normal controls during tasks that engaged inner speech and auditory verbal imagery. When imagining sentences spoken in another person's voice, which entails both the generation and monitoring of inner speech, hallucinators showed reduced activation of the left middle temporal gyrus and the rostral supplementary motor area, regions activated by both normal subjects and non-hallucinators. Adapted from McGuire *et al.* (1996)

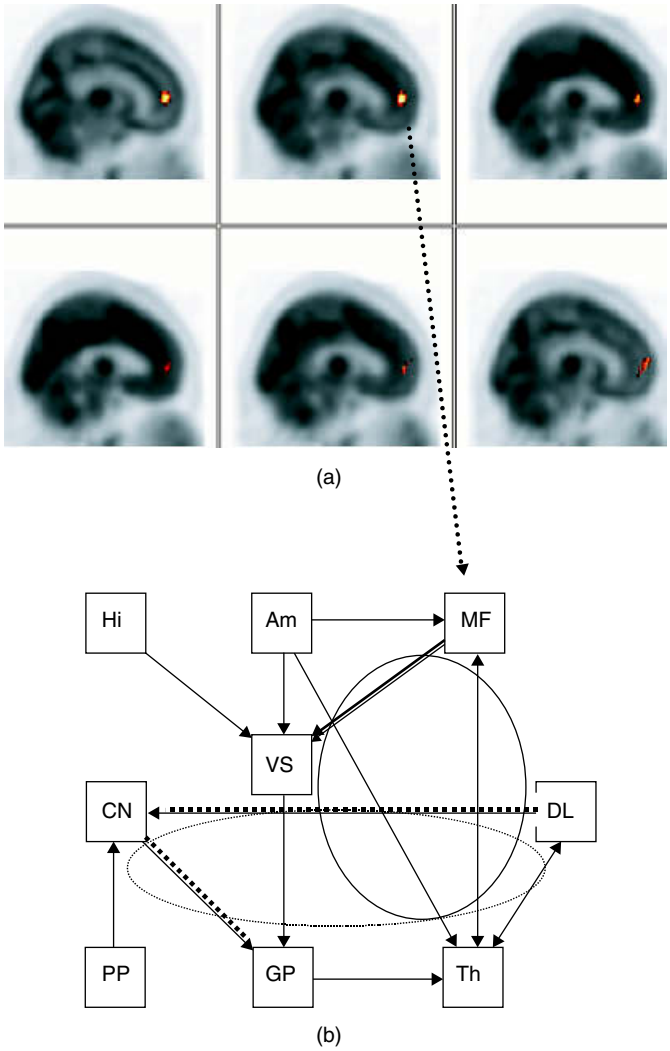

Figure XVIII-9.1 Effect of one session of TMS (5–20 Hz at 80% motor threshold over the left dorsolateral prefrontal cortex) on rCBF during a word-generation task. (a) Statistical parametric map of areas with $P < 0.01$ for effect size (z) and contiguous area (k), using Statistical Parametric Mapping, version 1996. (b) Neuroanatomical projections. Am, amygdala; CN, caudate nucleus; DL, dorsolateral prefrontal cortex; GP, globus pallidus; Hi, hippocampus; MF, medial orbitofrontal cortex; PP, posterior parietal cortex; Th, thalamus; VS, ventral striatum; Dotted ellipse, dorsolateral prefrontal loop; continuous ellipse, limbic loop; dotted arrow DL to CN, increase in regression coefficient c with significance levels in left dorsolateral loop ($c = 2.45$, $P < 0.05$); dotted arrow CN to GP, increase in regression coefficient c with significance levels in left dorsolateral loop ($c = 2.15$, $P = 0.05$); continuous arrow MF to VS, bilateral limbic loop (left: $c = 2.51$, $P < 0.05$; right: $c = 2.89$, $P < 0.05$)

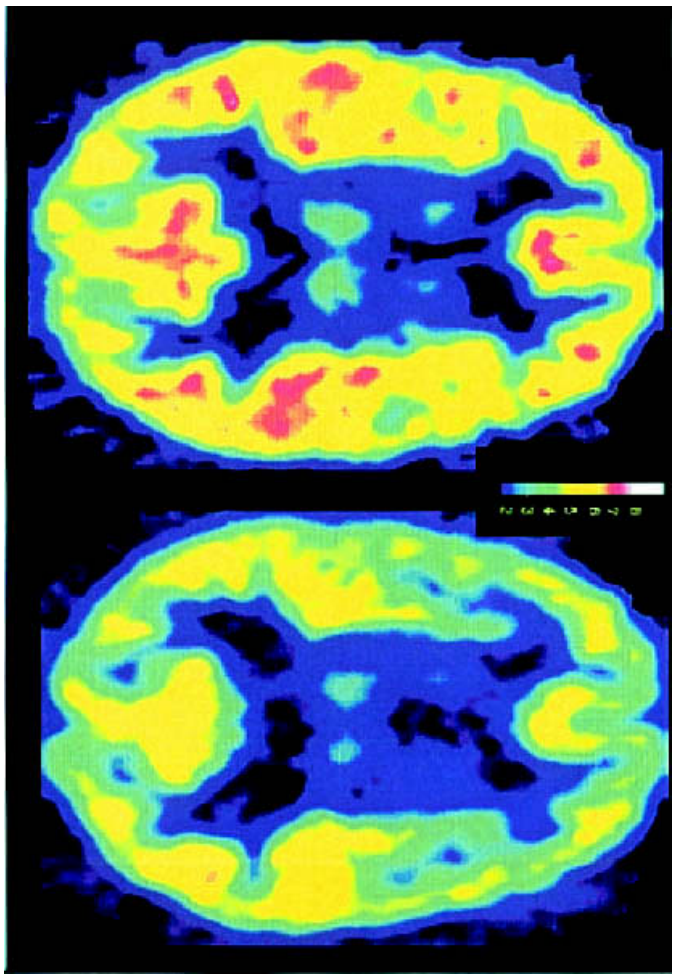

Figure XIX-10.2 A comparison of flumazenil binding between controls and panic disorder patients. The image shows a coloured scale of volume of distribution of flumazenil. The horizontal brain slice is through the middle of the brain showing occipital cortex (left) thalami amd basal ganglia (centre) temporal cortex (middle rim) and frontal cortex (right). A decrease in flumazenil binding is seen throughout the cortex and subcortical structures on the bottom which is the median map for panic disorder patients. The median map for controls is on the top

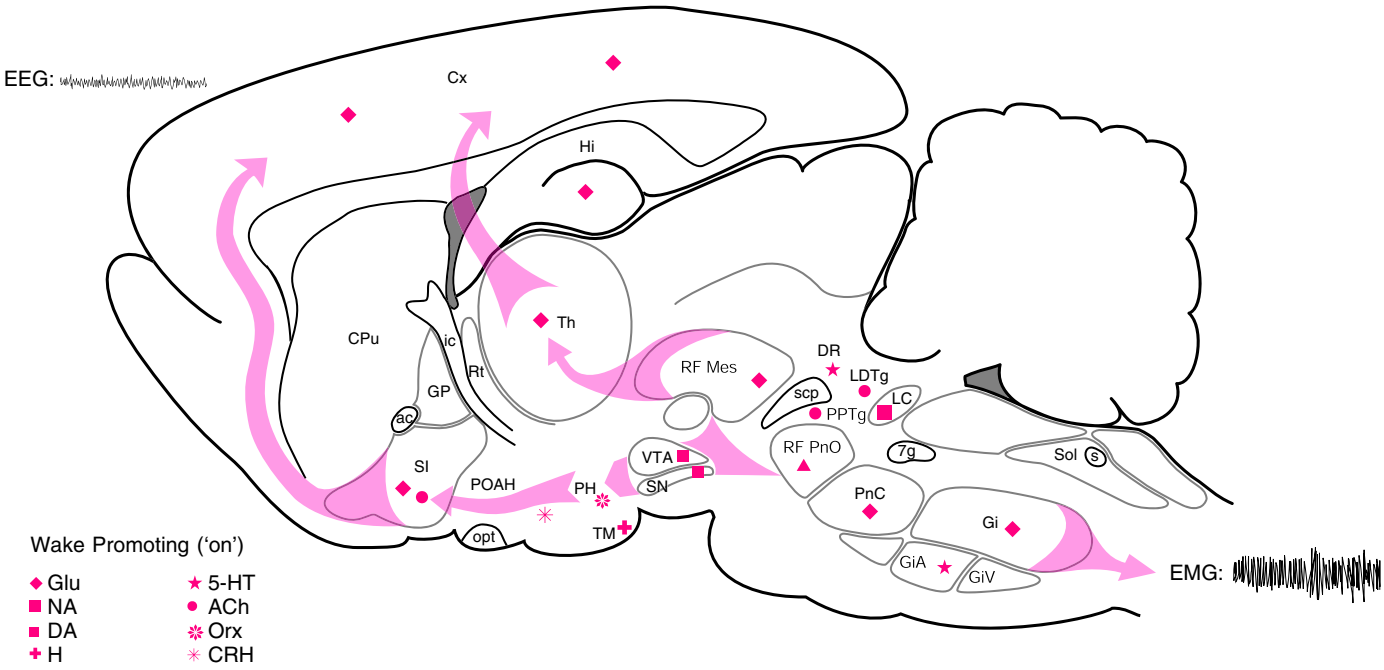

Figure XXIV-2.1 Wake-Promoting Systems. Schematic sagittal view of rat brain showing the major neuronal systems and their major excitatory pathways (arrows) involved in promoting the EEG fast activity (upper left) and EMG high muscle tone and activity (lower right) characteristic of the waking state. The major ascending pathways emerge from the brainstem reticular formation (RF, most densely from the mesencephalic, RF Mes, and oral pontine RF PnO, fields) to ascend along a) a dorsal trajectory into the thalamus (Th) where they terminate upon (midline, medial, and intralaminar) nuclei of the non-specific thalamo-cortical projection system, which projects in turn in a widespread manner to the cerebral cortex (Cx), and b) a ventral trajectory through the lateral hypothalamus up to the basal forebrain where they terminate upon neurons in the substantia innominata (SI) (and septum, not shown), which also project in turn in a widespread manner to the cerebral cortex (and hippocampus, Hi) (Jones, 1995). Descending projections collect from multiple levels of the reticular formation (though most densely from the caudal pontine, PnC, and medullary gigantocellular, Gi, fields) to form the reticulo-spinal pathways. The major transmitter systems that promote waking and discharge maximally ('on') during waking contribute to these ascending and descending systems and are represented by symbols where their cell bodies are located. Glutamatergic (Glu) neurons comprise the vast population of neurons of the reticular formation, the diffuse thalamo-cortical projection system and a contingent of the basalo-cortical projection system. Noradrenergic (NA) neurons of the locus coeruleus (LC) send axons along the major ascending and descending pathways to project in a diffuse manner to the cortex, the subcortical relay stations, brainstem and spinal cord. Dopaminergic (DA) neurons of the substantia nigra (SN) and ventral tegmental area (VTA) project along the ventral pathway in the nigro-striatal system and meso-limbo-cortical system, respectively. Histaminergic (H) neurons of the tuberomammillary nucleus (TM) project in a diffuse manner to the forebrain and cortex. Serotonergic neurons containing 5-hydroxytryptamine (5-HT) of the midbrain (including the dorsal raphe, DR) project to the forebrain, including the cerebral cortex (and hippocampus), as well as the subcortical relay stations, and those of the medulla (in raphe pallidus and obscurus, not shown, as well as pars alpha of the gigantocellular field [GiA]) project to the spinal cord. Cholinergic neurons, containing acetylcholine (ACh), are located in the laterodorsal and pedunculopontine tegmental (LDTg and PPTg) nuclei in the brainstem, from where they project along with other reticular neurons dorsally to the thalamus and ventrally to the posterior hypothalamus and basal forebrain, as well as to the brainstem reticular formation. They are also located in the substantia innominata (SI, and septum, not shown), from where they project to the cortex (and hippocampus). Orexinergic (Orx) neurons in the (perifornical and lateral) mid- and posterior hypothalamus (PH) project diffusely through the forebrain, brainstem and spinal cord to exert an excitatory influence at multiple levels. Corticotropin-releasing hormone (CRH) is contained in neurons within the paraventricular nucleus of the hypothalamus which project to the pituitary, as well as in other scattered neurons (not shown) projecting to other forebrain and brainstem areas that collectively stimulate the hypothalamo-pituitary-adrenal axis and central arousal systems. Some state-specific GABAergic neurons (triangle) may be on during waking to prevent activity of REM-promoting neurons in the oral pontine reticular formation (PnO) (Figure XXIV-2.3)

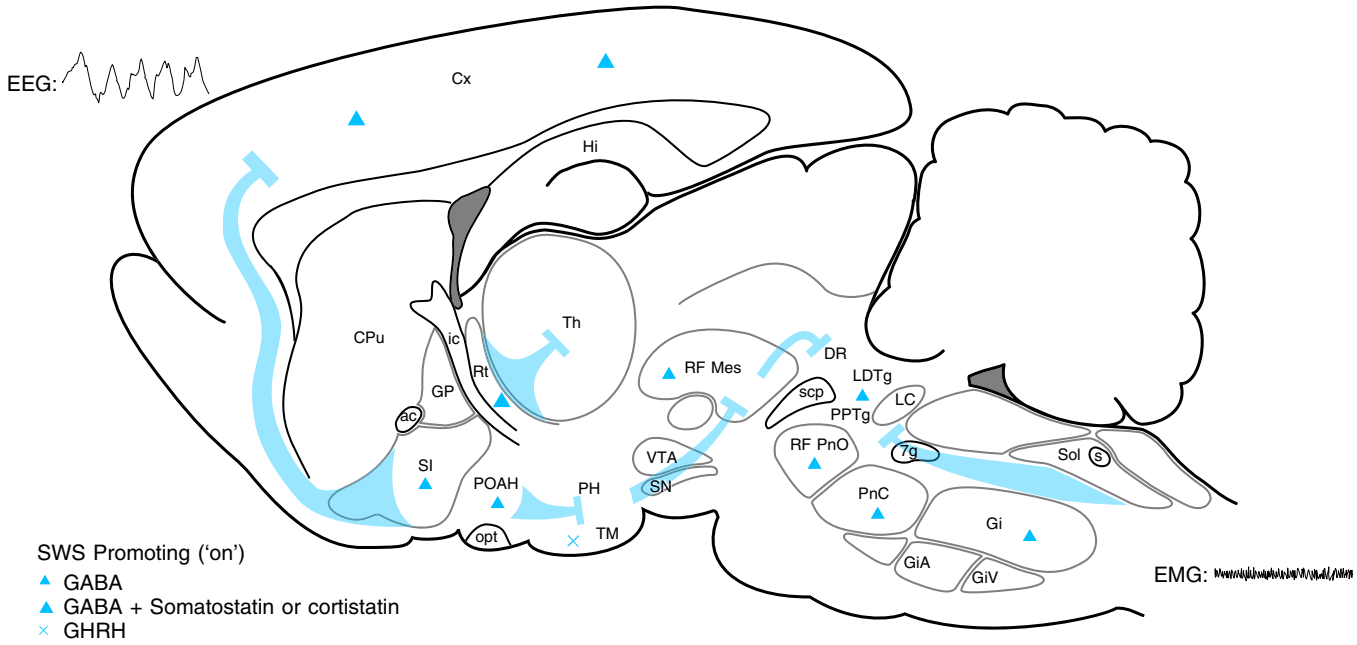

Figure XXIV-2.2 SWS-promoting systems. Schematic sagittal view of rat brain showing the major neuronal systems and their major inhibitory pathways (ending as blocks) involved in promoting the EEG slow-wave activity (upper left) and EMG reduced muscle tone (lower right) characteristic of the slow-wave sleep (SWS) state. Neurons in the region of the solitary tract nucleus (Sol) may exert an inhibitory influence on neurons in the ponto-mesencephalic tegmentum. A dampening influence on the brainstem activating system and the posterior hypothalamus (PH) also emerges from the basal forebrain and preoptic-anterior hypothalamic areas (POAH). From the basal forebrain (substantia innominata [SI]), an inhibitory influence is also exerted upon the cortex (Cx). The major transmitter systems that promote SWS and discharge maximally ('on') during SWS are represented by symbols where their cell bodies are located. These comprise largely GABAergic neurons that, by unit recording and/or c-Fos studies, have been shown to be active during SWS. Particular cortically projecting GABAergic neurons in the SI may have the capacity to dampen cortical activation directly during SWS. Locally projecting GABAergic neurons in the SI may inhibit the cholinergic and glutamatergic cortically projecting neurons. Other GABAergic neurons in the SI and POAH project caudally to the posterior hypothalamus (including the tuberomammillary nucleus [TM]) and brainstem (including RF Mes, DR, LDTg and LC), where they may inhibit multiple wake-active neurons of the activating systems. GABAergic neurons in the reticularis (Rt) nucleus, which surround and innervate the thalamic (Th) nuclei, discharge in bursts to generate spindles while inhibiting the thalamo-cortical projection neurons during SWS. These and local GABAergic neurons in the cortex (Cx) also contain somatostatin or the related peptide corticostatin, which may serve to prolong the inhibition in promoting the slow-wave activity of this state. GABAergic neurons in the brainstem may inhibit local neurons of the ascending reticular activating system as well as those of the descending reticulo-spinal system. Neurons containing growth hormone-releasing hormone (GHRH), primarily located in the arcuate nucleus and projecting to the median eminence, are actively involved in stimulating growth hormone and also promoting slow-wave activity during SWS

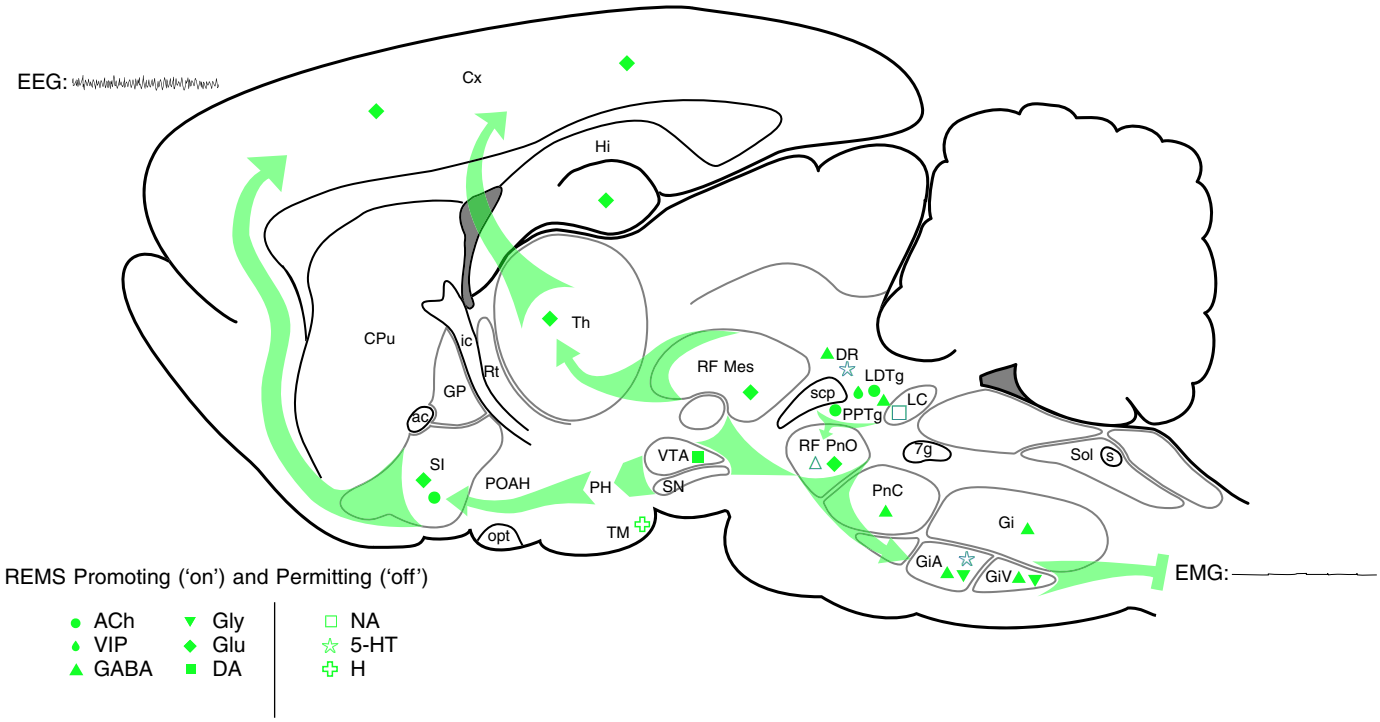

Figure XXIV-2.3 REMS-promoting and REMS-permitting systems. Schematic sagittal view of rat brain showing the major neuronal systems and their (excitatory, ending as arrows, and inhibitory, ending as blocks) pathways involved in promoting the EEG fast activity (upper left) and EMG muscle atonia (lower right) characteristic of rapid eye movement or paradoxical sleep (REMS or PS). Neurons essential for REM sleep are located in the pontine reticular formation, particularly the oral part (RF PnO). The major ascending pathways (indicated by arrows for excitation) promoting cortical activation are similar to those of the waking state; however, the extra-thalamic relay into the limbic system may be more important in REMS. The descending motor inhibition (indicated by a block) is triggered by neurons in the oral pontine reticular formation (RF PnO) and partly relayed through neurons in the alpha and ventral gigantocellular fields (GiA and GiV) of the medullary reticular formation en route to the spinal cord. The major transmitter systems that promote REMS and discharge ('on') during REMS are represented by filled symbols, whereas those that are permissive to REMS by stopping their discharge ('off') during the state are represented by empty symbols. Cholinergic neurons that release acetylcholine (ACh) and are located in the laterodorsal and pedunculopontine tegmental nuclei (LDTg and PPTg) are critically involved in promoting REMS through their projections locally into the brainstem reticular formation, and importantly to neurons in the PnO (where they excite glutamatergic neurons and could also inhibit local GABAergic neurons), as well as rostrally into the forebrain. These may be joined in promoting REMS by neurons with similar projections in the region containing vasoactive intestinal peptide (VIP). Noradrenergic (NA) locus coeruleus (LC) and serotonergic (5-HT) dorsal raphe (DR) neurons (as well as histaminergic, H, tuberomammillary neurons, TM) that directly inhibit the cholinergic neurons permit REMS to occur by ceasing their discharge. The arrest of their discharge is effected by local GABAergic neurons, which may be excited by ACh. GABAergic neurons through the caudal pontine (PnC) medullary reticular formation (Gi, GiA, and GiV) may also inhibit local reticulo-spinal and serotonergic raphe-spinal neurons to effect a disfacilitation of motor neurons. In addition, GABAergic and glycinergic neurons in the ventral medullary reticular formation (GiA and GiV) that project to the spinal cord may both directly inhibit motor neurons. One unique group of GABAergic neurons in the PnO ceases discharge during REMS to disinhibit PnO glutamatergic neurons that propagate the ascending and descending correlates of the state. In the ascending pathways, dopaminergic (DA) neurons of the ventral tegmental area (VTA), which are excited by the cholinergic neurons, may be important in activation of the limbic system. The cholinergic basal forebrain neurons (SI and septum) are particularly important in activation of the limbic cortex (hippocampus [Hi]) and neo-cortex (Cx) during REMS
