Perineural or neurogenic tumors, which might be confounded with lateral herniation in native MR images, are identified by their high uptake of contrast medium, which may be homogeneous, heterogeneous, or annular (Fig. 42-32) (100–102).

Synovial cysts and ganglia can be recognized easily by their high homogeneous signal intensity in T2-weighted images and various signal intensities on T1-weighted images. The signal intensity depends on the fluid composition ranging from serous to proteinaceous to hemorrhagic (Fig. 42-33). In most cases, the synovial tissue is enhanced after i.v. application of Gd-contrast media (42,103,104).

Hematomas may be confounded with herniation in T1- and T2-weighted images (34,76,105). Better differentiation is possible with T1-weighted GE out-of-phase sequences where hematomas appear very bright because of susceptibility effects.

**FIG. 42-30.** **A:** Five days after surgical intervention, the patient presented with acute low back pain. A bend-shaped retrodiscal structure can be seen with nearly disclike signal intensity (sagittal image, GRE 500/7 out of phase). **B:** The throughout enhanced mass after i.v. application of Gd-contrast media exclude a disc herniation (transverse image, GRE 500/7 out of phase after intravenous [i.v.] administration of gadolinium [Gd] contrast medium). **C:** At reoperation, the mass reveals to be infectious tissue with pus accumulation (coronal image, GRE 500/7 out of phase after intravenous administration of Gd contrast medium).

**FIG. 42-31.** **A:** The unenhanced T1-weighted opposed phased image shows a mass of uncertain origin (transverse image, GRE 500/7 out of phase). **B:** After intravenous (i.v.) application of gadolinium (Gd) contrast medium, an enhancing rim appears. The center has slightly lower signal intensity than disc material. At operation, the mass is revealed to be an abscess (transverse image, GRE 500/7 out of phase after i.v. administration of Gd contrast medium).

**FIG. 42-32.** **A:** The foramen is obstructed by a mass of high-signal intensity equal to the intensity of the disc (sagittal image, GRE 500/7 out of phase). **B:** The homogenous high uptake of contrast media is characteristic for neurinomas (transverse image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium).

**FIG. 42-33. A:** Well delineated space occupying lesion with high signal intensity (sagittal image, STIR 2000/150/20). **B:** After intravenous (i.v.) application of gadolinium (Gd) contrast medium, there is a strong enhancement of the hypertrophic synovial membrane of the apophyseal joint. The synovial cyst compresses the thecal sac (transverse image, GRE 500/7 out of phase after i.v. administration of Gd contrast medium).

### CLINICAL RELEVANCE

As shown, there are different imaging techniques to elucidate the pathomorphologic origin of low back pain and sciatica. The evaluation of methods regarding accuracy and predictive value highly depends on the technical performance (106) and the expertise of the persons interpreting the data.

A plain radiograph may show a narrowing of the disc space, osteophytes, and calcification. Therefore, it is not the method of choice when there are strong clinical hints for discal herniation, and no suspicion of consuming diseases is given.

Myelography demonstrates filling defects of the thecal sac and dural recess that may be caused by any stenosing process (discal, spondylotic, osteoarthritic, or tumorous). Therefore, this imaging procedure is only indicated today when patients have metal implants.

Discography describes the internal derangement of the discs, and rupture and herniation of the outer annulus. Major disadvantages of discography are: invasiveness, selectivity of examination, and no differentiation between subligamentous and transligamentous extrusion. It can be combined with the pain reproduction test to locate the painful segment. The reliability is controversial (19,21, 101,107–114). When discography is followed by CT examination, it is possible to precisely locate the herniation and determine the form and volume of herniated material (62,112). Because of invasiveness and inherent risks, discography and CT discography are image procedures that are secondary to CT and MRI.

Computed tomography delineates the outer contour of the disc as well as gas and calcification. It does not supply any information about the disc matrix. Sagittal and coronal views are only available by reconstruction. This demands thin contiguous axial section. Exposure to radiographs should not be neglected. Apart from MRI, this technique is the imaging modality of choice to demon-

strate disc herniation and osseous stenosing processes, even when subligamentous and transligamentous extensions cannot be evaluated.

Magnetic resonance images correlate well with macroscopic anatomic sections (112). However, in 13% of the cases, discs that appear normal on MRI may show tears on discography (71). The high-intensity zone (HIZ) (115) does not seem to be a relevant feature for an aching disc (116). Annulus and nucleus can be distinguished. The location of herniation inside and outside the canal as well as its correlation with the neurovascular structures can be exactly identified. Subligamentous and transligamentous extrusions are hardly ever indistinguishable. Views of the whole lumbar spine can be taken from all angles without any risk for the patient. To sum up, it can be said that MRI has some advantages in comparison with CT regarding the diagnosis of disc herniation.

One has to review the ways that image information can explain patients' symptoms and therefore form the basis for treatment.

There is a high incidence of disc abnormalities, as described by CT and MR examinations in asymptomatic individuals (21,117–122).

Studies have shown that spontaneous regression of the hernia can occur with regression of radicular pain (76,77, 90,123–129). It seems that sequestered disc material has a greater potential for regression than extruded and protruded disc material (50). The contact of herniated material with the vascular system in the epidural space is probably responsible for this natural course of herniation (130–133). Therefore, conservative treatment should be considered for at least 2 months after onset of radicular pain (125,134–137).

The morphometric measurements and their ratios (volume or size of the herniation, diameters of the dural sac and spinal canal), and different types of herniation are considered for their predictive value for the outcome of conservative or surgical treatment (137–145).

A connection can be assumed of nerve root compression and swelling of the root and ganglia with location and severity of leg pain (78,117,120,146–148).

For the welfare of the patient, the collaboration between radiologists and clinicians is a *sine qua non*. For this purpose, the following demands have to be accomplished:

1. The technical performance has to be optimal.
2. Disc herniation has to be exactly characterized for morphology, location, and its relation to the neurovascular system.
3. A generally accepted nomenclature is necessary.
4. In the absence of disc abnormalities the imaging should be able to detect other reasons to explain the pain of the patient.
5. The results of imaging have to correlate with the patient's symptoms.

## CHAPTER 43

# Disc Herniation: Nonoperative Treatment

Kevin P. Singer and Peter J. Fazey

---

“... surgical treatment of spinal disorders produces the best results when clinical symptoms and signs are congruous and confirmed by carefully selected imaging studies, and when they have resulted in an unequivocal diagnosis amenable to surgical management. An additional and important caveat is that the surgical result ought to be better than the ‘natural history’ of the disease being treated.”

—J.W. Frymoyer, 1997

Herniations of the intervertebral disc (IVD) have probably afflicted man since earliest times, with the associated backache entrenched within folklore. The depiction by Luschka in 1885 of a central nuclear herniation of a lumbar IVD (1) (Fig. 43-1) is perhaps the first illustration of a specific spinal pathology that continues to command the attention of modern societies. The fact that, for tens of thousands of years, humans have been reliant upon nature underscores the challenge from John Frymoyer (2) to not disadvantage the individual if the natural history of spinal disease may be better in the long term than surgical interventions. The early clinical reports by Lindblom and Hultquist (3), and Hakelius (4), which identified progressive recovery following sciatica, have been quantified by others using cross-sectional computed tomography (CT) and magnetic resonance imaging (MRI) (5,6). These observations of the spontaneous regression of disc herniations have since prompted investigation into the physiology of this process.

The natural history of disc herniation describes a process of resolution both of symptoms and often a diminution of the herniation itself; which may be aided pharmacologically through epidural steroids and nerve root sleeve blocks or through rest and other conservative interventions. The purpose of this chapter is to review the natural history of lumbar disc herniation and principles of nonoperative management of this clinical problem. A case study report of the sequence to spontaneous regression of a large central disc herniation at L4-5 in a 32-year-old woman is provided to illustrate the natural course of this condition.

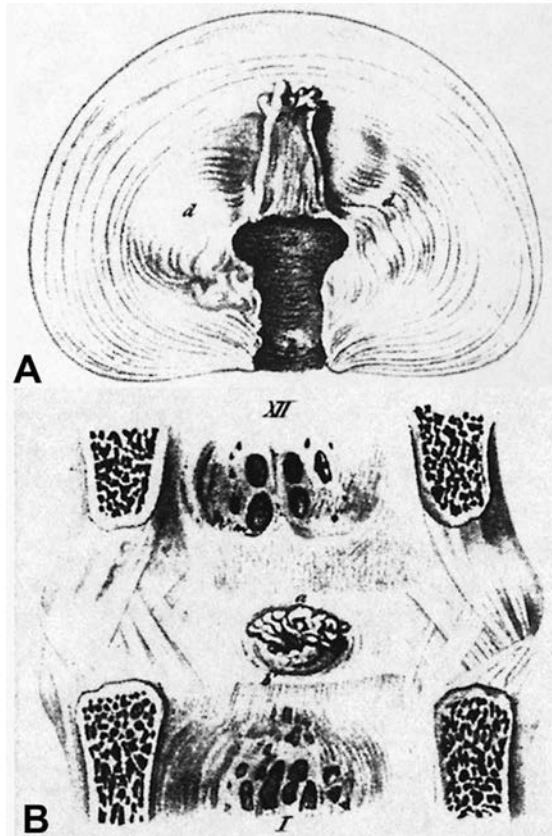

In the case of established herniated nucleus pulposus (HNP) there is an abundance of literature that confers advantage to conservative management (7). The efficacy of nonoperative management, observed through spontaneous regression of disc herniation, has been reported not only for the lumbar (8–10), but also thoracic (11–13) and cervical disc herniations (14,15). Further reinforcement for the principle of management by “watching and waiting” stems from the numerous reports of disc herniation and related disease in a large proportion of asymptomatic individuals.

In the 10-year controlled follow-up study reported by Weber (16), similar patterns of neurologic recovery in groups treated surgically and conservatively were demonstrated. In contrast, the 5-year follow-up study by Atlas et al. (17) determined that patients with moderate or severe sciatica, who had lower functional status at baseline, reported better outcomes following surgery compared with nonoperated patients. Irrespective of the extent of the initial neurologic deficit, a trend favoring nonoperative treatment was reported by Saal and Saal (18) who confirmed the capacity of HNP to resolve clinically without surgery or chemonucleolysis. The trend for larger herniations and sequestered fragments to show an enhanced capacity for regression was supported by subsequent reports (9,19–21). Importantly, a 10-year review by Fraser et al. (22) clearly indicated that long-term improvement of a patient’s symptoms of HNP could occur with or without regression of the herniation.

### EVALUATION OF DISC HERNIATION

Early postmortem studies of the thoracic and lumbar spine by Andrae (23) and Schmorl (24) indicated that HNP was a frequent occurrence (Fig. 43-2). Since the advent of plain radiography, a high prevalence of spinal disease has been identified within asymptomatic individuals (25). Similarly, CT and MRI have highlighted the extent to which advanced pathology of the IVD, includ-

**FIG. 43-1.** Depiction of posterior disc herniation, as represented by Luschka (1) showing a nuclear fissure (reflected) passing through the posterior annulus (A) and protruding into the vertebral canal (B).

ing disc herniations, are present in asymptomatic study cohorts (26–30). These observations make more difficult the interpretation of results from diagnostic procedures used to investigate individual patients presenting with low back pain. According to Beauvais et al. (31), CT imaging did not predict the outcome of lumbar IVD herniation. Although a larger herniation or free fragment was found in the group with the best clinical outcome, the differences at 3 months were not significant in conferring any prognostic value. In contrast, a review by Henmi et al. (32), which followed the conservative management of 10 individuals with HNP, found signal intensity ratios derived from T2-weighted MRI sequences in the acute and late follow-up phases that predicted the pattern of HNP reduction. These authors reported that those HNPs with lower signals did not show size reductions.

#### MODEL OF DISC RESORPTION

Although the mechanisms of disc resorption remain unclear, it has been proposed that, following HNP and its immediate postinflammatory sequence, intrinsic hydrophilic capacity is impaired which leads to progressive

**FIG. 43-2.** Axial views of the thoracic (A) and lumbar (B) cadaveric discs, depicting a midline radial fissure through the posterior annulus with degeneration and dissection in the nuclear region of the disc. Apart from a localized osteophyte to the right side of the vertebral body in B, and the radial annular defect, the annulus appears relatively normal.

desiccation. End stages of the inflammatory cascade are phagocytosis and eventual resorption (33). Larger isolated disc fragments may regress more readily given their tendency to migrate and regress due to the inflammatory mediated response (34,35). Fibroblast growth factor, inducing neovascularization, appears to be one potent source for this functional change in morphology of the fragment (36). In a study by Bozzao et al. (37), reductions of more than 70% were recorded for large and medium herniations, averaged across an 11-month follow-up period. Similar observations have been noted by Ito (7). In an interesting study by Boos et al. (38), 22 symptomatic and asymptomatic disc herniations, matched according to age, gender, disc level, and the extent of disc herniation, were compared using MRI (T1 and T2 relaxation times). In the symptomatic disc herniations, significantly reduced T1 and T2 relaxation times were recorded compared with the matched asymptomatic herniations. In addition, the symptomatic disc herniations were associated with more advanced levels of disc degeneration. These results suggest that symptomatic and morphologi-

cally matched asymptomatic disc herniations differ with regard to the matrix composition of the whole disc.

An early consideration during the acute phase of HNP is the role of epidural steroid injection, either local to the site of the HNP, or nerve root sleeve injections (39). Epidural steroids introduced specifically into the epidural space adjacent to the HNP can aid the inhibition of inflammatory mediators, moderate pain, and facilitate the resorption process (40). Although there has been considerable debate over the years, recent reviews provide support for spinal epidurals and nerve root sleeve blocs, respectively, as adjuncts to the conservative management of disc herniation and radiculopathies (40,41).

## DISC HERNIATION AND SURGERY

The lifetime prevalence for lumbar radicular syndrome has been estimated at approximately 5% (42). However, there are marked regional and international differences in rates for surgery and conservative management of this problem that reflect a wide range of issues (2). Candidates for surgery following lumbar disc herniation account for a relatively small proportion of all spinal cases. Classic indications include: cauda equina syndrome, functional weakness of the lower extremity, and severe pain (2). In selecting surgical cases, many factors have been found to be predictive of outcome including unequivocal radicular symptoms and associated sensory changes, motor weakness, and straight-leg raising (SLR) test reduced to less than 30°, with positive tension signs from contralateral SLR, all of which must be confirmed by concordant positive imaging studies (43). An increasingly important consideration of presurgical screening is the determination of psychosocial factors that can moderate the outcome (44).

While the study by Weber (16) provided evidence that discectomy produced better clinical outcomes at 1 year, delaying surgery in cases where indications were uncertain to monitor the natural recovery did not produce long-

term harm. The reviews by Hoffman et al. (45) and Stevens et al. (46) reiterate the importance of careful patient selection and confirm clinical empiricism that the principal benefit of surgery for HNP is the rapid relief of sciatica in those individuals who have failed to improve under conservative care. Consideration of the state of the involved disc as a whole may be important given the observations by Boos et al. that symptomatic HNP cases tended to be associated with more advanced disc degeneration (38). It is valuable to determine, during the physical examination, whether peripheral (radicular) symptoms can change to a more central location following repeated movements (47). If symptoms can be changed with mechanical maneuvers, such a finding should encourage a “wait and watch” approach.

The astute clinician is able to identify salient indications for surgery based principally upon symptomology, while recognizing that patient preference and psychosocial indicators also play a role in determining outcomes (48,49).

## PRINCIPLES OF CONSERVATIVE MANAGEMENT

As a consequence of the burden of back pain on health care systems, a diverse range of nonoperative management options exist. At present, not all interventions have an established scientific basis, however this deficiency is progressively changing through the impetus of systematic reviews of published literature and randomized controlled studies into specific therapies (50). The Cochrane Back Review Group maintains a comprehensive resource of contemporary systematic reviews of many of these therapeutic strategies (51), which is updated and expanded according to the cyclic review process (46, 52–57) (Table 43-1). In addition, other published nonsystematic reviews are available from this resource (58).

The goals associated with many conservative interventions are: reduction of disability, symptomatic management of pain and gradual restoration of pre-morbid levels

of spinal motion, cardiovascular fitness, muscle strength, motor coordination, and function. Conservative therapeutic options for the management of disc herniation are many and mirror, in part, the strategies that are employed for mechanical back pain, namely (a) limited bed rest, physical therapy including exercise prescription, manual therapy, and forms of electric stimulation for pain management; (b) local and systemic analgesic and anti-inflammatory medications; and (c) holistic groupings of rehabilitation strategies which include cognitive behavioral approaches (53).

The need to guide patients to an informed decision, based upon careful monitoring of the severity of the clinical presentation and their tolerance of symptoms over the first 2 months, is crucial to successful conservative outcome (Table 43-2). Understanding the physiologic sequelae of the natural history (7), and imparting this information objectively and positively to the patient is essential to optimize outcomes. The issue of psychological support to this patient group is particularly important (50,53,56,59). This process has been likened to that of a coach motivating a patient throughout the rehabilitation program (60). In addition to describing the expected natural history of recovery as it relates specifically to the individual, there is the need to provide accurate information regarding the various progressions that the rehabilitation program will involve (60). Such programs need to be modified according to the extent and location of the HNP. If the chosen approach is one of a conservative rehabilitation strategy, the patient can be encouraged to progressively avoid prolonged bed rest and to increase activity levels within pain limits. The role of pain and anti-inflammatory medications should be explained, along with promoting an expectation that recovery will occur, and that surgery may not be required. Careful selection of a combination of interventions such as manual therapy, including mobilization, manipulation and traction of spinal segments in the involved area; active exercises for range of motion and trunk stabilization; in addition to education concerning back care and short-term rest during exacerbations will be necessary, along with ongoing reassurance. According to some investigations, specific supervised retraining of trunk stabilizing muscles appears superior to general exercise programs in restoring spinal function and preventing recurrence of symptoms (61,62). However, general exercise in the form of supervised gym cir-

cuits may combine elements of many of these interventions and contribute positively in terms of social interactions with others who are well.

As disc herniation is a relative contraindication to manipulation, such forms of manual treatment are not usually recommended, particularly at the affected intervertebral level or in the presence of protective muscle spasm (63). However, in carefully selected individuals screened for contraindications to manipulation, symptomatic relief can be achieved and sustained over the medium term from such therapy (64). For example, manual traction or specific mobilization may be effective in relieving symptoms by decreasing mechanical stress on sensitized structures and encouraging local physiologic responses to assist in reduction of edema and inflammatory reaction (65). Some forms of lateral flexion mobilization of the lumbar spine, popularized by McKenzie (66), may be helpful in correcting a scoliotic list, producing improvement which may be short-lived but beneficial. Of interest are the reports that find certain types of spinal manipulation can achieve marked symptomatic relief in patients with HNP (64,67,68). Even short-term reduction in symptoms may reassure patients that their pain is able to be managed and, importantly, increase their expectation of a favorable prognosis. Symptom control will also expedite return to functional activity.

Although focusing on back pain of mechanical origin, *The Back Book* (69) conveys essential conservative back care information (48,70), which can benefit individuals with disc herniation, particularly if additional cautions are emphasized during the acute period according to the severity of symptoms. The principles of such advice for patients regarding conservative management of herniated disc are summarized in Table 43-3.

The effect of HNP on the spinal musculature is an important consideration of rehabilitation following injury. In parallel with pain arising from HNP marked muscle atrophy can occur, particularly in multifidus and adjoining paraspinal muscles. This atrophy can be unilateral, associated with a specific segmental level (71), and persist well beyond the time of injury and symptom resolution (72,73) (Fig. 43-2). Although this observation was confirmed by Kader et al. (74) in a retrospective analysis of 78 patients with mixed spinal symptoms, the associations between muscle atrophy, radicular symptoms, root compression, HNP, and degenerated discs were not

**TABLE 43-2.** Assessment criteria for conservative versus surgical management for herniated lumbar disc, according to SINS

<b>Severity:</b>	Self-reported severity of symptoms, using a visual analog scale; confirmed by responses during examination of active and passive spinal motion, and nerve tension testing.
<b>Irritability:</b>	The ease with which symptoms are aggravated and their duration, which determines physical capacity and treatment options. Key indicators: intractable pain, limited range of pain-free motion and functional activity, poor quality sleep.
<b>Nature:</b>	Characteristics of symptoms in relation to local and referred pain, and symptomatic response to compression or traction, or positioning which may caution against activity.
<b>Stage</b>	Is the presentation improving, stable, or progressively worsening?

**TABLE 43-3.** Principles of patient advice regarding conservative management of disc herniation

Be aware of the “red flags” and report them if they arise. These include: bladder and bowel problems, progressive increase in pain, loss of sensation, progressive peripheral muscle weakness.
Take it easy initially. When pain is acute, rest is necessary but avoid prolonged bed rest.
Believe that you will get better, but be aware that it may take several months.
Pain management is important: epidural and nerve root sleeve injections may help.
Maintain general spinal movements, avoiding positions or directions that increase symptoms. This will assist recovery and not worsen the problem.
Traction or gentle passive treatment may help during exacerbations but may offer only short-term relief. Active movement and general exercise are important for the long term.
Keep mobile without aggravating pain levels. Initial light activity can be gradually extended to include exercises to restore spinal muscle strength and endurance, and cardiovascular fitness. Hydrotherapy may be helpful in the early stages of recovery.
Minimize prolonged static weight-bearing postures.
Avoid unnecessary lifting.
Surgery may not produce better outcomes than conservative care in the longer term. Unless “red flags” are evident, watchful waiting may be better than early surgery.
After 2 months of conservative management, surgery is much less likely to be required.

Adapted from Buchbinder R, Jolley D, Wyatt M. Population based intervention to change back pain beliefs and disability: three part evaluation. *BMJ* 2001;322:1516–1520; Nachemson A. Back pain: delimiting the problem in the next millennium. *Int J Law Psychiatry* 1999;22:473–490; and Weinstein SM, Herring SA. Lumbar epidural steroid injections. *Spine J* 2003;3:37S–44S, with permission.

strong. The morphologic effects of spinal muscle damage and atrophy following surgery and arising from other forms of back pain have been examined in a series of investigations (75–77). Similarly, profound effects of deconditioning on paraspinal muscles have been docu-

mented after disc injury (78). Minimization of muscle atrophy must be balanced with the need for adequate initial bed rest. Following the acute phase, a graduated active exercise program, which may include hydrotherapy, should be encouraged and reinforced with education. Restoration of muscle strength and endurance through specific back exercises appears to be achieved initially through neuromuscular adaptations rather than overt changes in muscle morphology (77), which have a longer time course for recovery. Abdominal stabilizing exercises have been demonstrated to play a key role in recruitment of muscles that sustain lumbar mechanical function (61,79,80). Aerobic exercise is a recommended component of the rehabilitation in most cases as an aide to restoration of trunk, spinal, and lower extremity musculature (60).

Effective management of pain is a very important consideration during the acute phase (Fig. 43-3), given its profound inhibitory effect upon function and muscle morphology (81,82). The model of structural pathology imposing pain inhibition on joint movement, and contributing to local muscle atrophy, subsequently creating a vicious cycle of ongoing mechanical pain and dysfunction is a well-recognized sequence for many musculoskeletal systems (83) (Fig. 43-4). Some gentle forms of passive movement during the acute stage may also be helpful but must be guided by the symptomatic response of the individual with consideration of the key elements of the severity of the clinical presentation, presented in Table 43-2. Graduated mobilization and some forms of manipulation for pain-induced limitation of spinal movement may be indicated in the postacute stage of rehabilitation (64,65).

The natural history of HNP is presented in the following clinical case which highlights the process of symptom reduction and functional improvement and concomitant changes in MR images. The rehabilitation approach in this case included initial rest and analgesia followed by a graduated exercise program, including hydrotherapy, which was moderated according to symptom changes.

**FIG. 43-3.** Schematic representation of the interrelationship between pain, muscle function, and cardiovascular fitness following disc herniation. Initial chemical pain and related inhibition can result in early and profound spinal muscle disuse (atrophy), which may contribute to decreased stability of the involved segment(s). General deconditioning resulting from reduced functional activity must be addressed if the rehabilitation program is to be successful. An early focus on pain management is important in the acute phase followed by progressive cardiovascular maintenance exercise and muscle endurance/strength. Unless specific muscle stabilization and strengthening protocols are implemented (A) there is the potential for chronically inhibited and atrophic spinal musculature (B) following herniated nucleus pulposus. Exercise can also contribute to pain control through improved functional capacity and endurance.

**FIG. 43-4.** A “vicious cycle” of pain-mediated inhibition on the musculoskeletal system is depicted. Initial chemical pain from the herniated nucleus pulposus produces profound suppression of motor function that may directly contribute to dramatic muscle atrophy and disturbed mechanics of the motor segment. This compromise can induce further mechanical disruption and pain that perpetuates the cycle. (Adapted from Young A, Stokes M, Iles JF. Effects of joint pathology on muscle. *Clin Orthop* 1987;18:21–27.)

**Case Study**

A 32-year-old woman presented with severe back pain, radiating to her left buttock, posterior thigh, and lateral leg as far as the left ankle. This followed an incident involving shifting of frozen food products from a low refrigerated container into storage with a time imperative to avoid deterioration of the frozen goods. This work required repetitive lifting in a sustained stooped posture. Over the next 24 hours, progressive worsening of back pain and leg symptoms forced her to stop work and seek urgent medical attention. At no time were bladder or bowel symptoms reported.

On physical examination, at 3 weeks following the onset of sciatic symptoms, sitting was not tolerated and the patient preferred to stand and move around during interview. She reported that sleep was frequently disturbed. Static standing posture showed a list to the right.

**FIG. 43-5.** Sagittal T1- (A) and T2- (B) weighted magnetic resonance images depicting the extent of the central disc protrusion at L4-5 in a 32-year-old woman. The initial imaging was performed 4 weeks after the incident (left), with subsequent investigations at 6 months (middle) and 4 years (right), respectively. Degenerative changes of the L5-S1 disc are also noted.

All spinal movements were markedly restricted. Forward flexion was arrested by pain with fingertips reaching above the knees. Extension was limited to less than 50%. Sensation was impaired over the L5 distribution into the region of the posterolateral leg. In supine lying, there was marked restriction of SLR ( $45^\circ$ ) bilaterally, with crossover sign from the right causing left buttock pain. Reflexes were diminished at the knees and could not be elicited at either ankle. Lower limb perfusion was normal.

Plain films demonstrated long-standing degenerative changes at L4-5 with some anterior osteophytes and loss of disc height. A large posterior central disc protrusion at L4-5 was demonstrated on initial CT. The bony canal dimensions were good and adjacent disc levels were satisfactory. At 4 weeks post-onset, lumbar MRI sequences confirmed the extent of the central disc herniation with migration of disc material inferior to the L5 superior end plate, causing compression of the ventral aspect of the thecal sac (Figs. 43-5, 43-6). At this time the patient had epidural steroid injection under radiologic guidance at the left L4-5 level which resulted in marked improvement in local and referred pain.

On review at 8 weeks post-onset, SLR was still reduced to  $45^\circ$  on the left and  $60^\circ$  on the right. Standing posture was normal and only a mild limp was noticeable.

Although surgery was discussed with the patient she refused this option preferring to continue with conservative physical therapy, including hydrotherapy and antiinflammatory medications as required. Due to persisting radicular symptoms and sleep disturbance, a second L4-5 epidural was given at 9 weeks achieving further good effect. At this time forward flexion was still limited by pain to fingertips reaching the knees. While spinal extension was reduced to approximately 75% of the expected range for her age, SLR had increased to  $60^\circ$  on the left.

A repeat MRI examination at 6 months demonstrated more than 70% reduction in the size of the central disc prolapse (Figs. 43-5, 43-6). On review at 12 months following the injury near normal lumbar extension was achieved and on forward flexion, fingertips reached to mid-shins. SLR was now approximately  $75^\circ$  bilaterally with negative nerve root tension signs. Subtle reduction in sensation persisted over the lateral aspect of the left leg.

Repeated MRI at 4.5 years demonstrated further reduction in the extent of the L4-5 disc prolapse since the 6-month assessment (Figs. 43-5, 43-6). Mild reduced sensation persisted along the L5 distribution. Spinal mobility was slightly limited although movements were pain-free. Symptoms had reduced to a significant extent, apart from

**FIG. 43-6.** Axial T1- (A) and T2- (B) weighted magnetic resonance (MR) images depicting the extent of the large paracentral disc protrusion at L4-5 resulting in marked displacement of the thecal sac. Comparison with the initial MR images clearly shows the substantial reduction in size of the disc extrusion, particularly in the anteroposterior dimension. Note the serial changes in muscle cross-sectional area with marked increase in the relative fatty infiltration and coincident bilateral muscle atrophy.

occasional activity related low back pain, in parallel with restoration of normal activity levels.

It is interesting to note that profound muscle atrophy persists almost 5 years after this acute disc herniation at L4-5 (Figs. 43-5, 43-6). This may in part result from modification of the patient's occupation and functional activities to accommodate the requirement for more conservative spinal loading during the postinjury period.

## SUMMARY

Epidemiologic and clinical studies show the potential for the majority of IVD prolapses to regress naturally over time with conservative management alone. In carefully selected patients with sciatica due to lumbar HNP that fail to resolve with conservative care, there is good evidence that surgical discectomy achieves effective clinical relief of symptoms; although the scientific evidence on the optimal timing for surgery is limited. Even less clear is the balance of risks associated with delayed intervention, of relative complication rates over the intermediate years following disc injury, and of the longer term clinical outcomes due to the natural history of nonoperated disc herniation.

The immediate challenge is to improve the planning and execution of controlled trials of nonoperative management, with particular attention to areas such as blinded assessment, randomization, follow-up period, and the use of discriminating clinical outcome measures. Perhaps the single major need is to support longer-term reviews into the lifetime natural history of disc disease, including HNP, which can then be referenced to specific diagnostic groups. In this regard, the work of Boos et al. (38) in differentiating the characteristics of symptomatic HNP appears helpful.

Nonoperative management of disc herniation can result in successful resolution of symptoms in a large proportion of individuals although the time course to initial recovery may be variable and longer than that achieved with early surgery. While the late results appear similar, the operated cohort may be more disposed to subsequent mechanical back pain (43). The initial evaluation for serious pathology and monitoring for the onset of significant complications, such as neurologic defects, progressive cauda equina syndrome, or refractory pain, are critical in the optimal management of disc herniation. The recommendation for a conservative strategy should persist because a large number of operations performed currently are unnecessary when the late outcomes and morbidity following surgical intervention are considered (43,50).

In the absence of clear indications for surgery, conservative management, at least for the first 2 months, is recommended to determine the initial progression of the problem.

In this regard, careful education of each patient is mandatory as is the patient's involvement in the decision-making process (84–86). Further, clinical education models employing decision leaders can positively influence surgical intervention patterns (87). Throughout the often prolonged rehabilitation following HNP, biopsychosocial issues need to be considered. Acknowledgment that perseverance is necessary is important when counseling patients to consider a conservative rather than an operative strategy.

# Operative Treatment of Disc Herniation: Natural History and Indications for Surgery

Charles G. Greenough

---

In 1985, Frymoyer and Donaghy (1) reported the 50-year follow-up of a case of surgical treatment of lumbar disc herniation. This was a 25-year-old man with a 2-year history of left leg pain, commencing after a skiing accident. On examination the straight leg raise was 25 degrees and the ankle jerk was absent. A myelogram (Lipiodol) was negative, the cerebrospinal fluid protein was 108 mg with a pressure of 145 mm HG and there was a slow rise with jugular compression. Operation was undertaken with osteotomy of the spinous processes and left hemilaminectomies from L2-S1. The dural sac was opened and no abnormalities were seen. Beneath the sheath of the L5 root, a 1-cm nodule was found arising from disc L5-1, which was excised. The patient required transfusion. He was discharged in a brace 19 days following surgery. Fourteen years later he presented with recurrent leg pain that responded to conservative treatment. A further episode of leg pain occurred 19 years later; at 50 years he was symptom free. The excised specimen was originally reported as a chondroma, but the pathologist then remarked on the lack of cellular material and was able to make the correct diagnosis after comparison with sections of normal disc material.

“K.N. is of particular interest as he is the first patient in whom a ruptured intervertebral disc was recognized as such and as a cause of sciatica. Therefore, he is the man who started all the damn trouble” (2).

Excision of lumbar disc herniation is the most common spinal operation undertaken and, with precisely defined indications, one of the most successful.

Prolapsed intervertebral disc is rare in adolescents and most common in the third, fourth, and fifth decade. Usually occurring at L5-S1 or L4-5, the prolapse most often consists of nuclear material and is frequently unilateral within the central canal. Commonly the root exiting immediately below the affected level is involved, the

direct pressure leading to root dysfunction (loss of sensation or motor power), and the inflammation leading to radicular pain. Urgent referral is indicated for bowel or bladder disturbance

### ASYMPTOMATIC DISC PROLAPSE

The correlation of radiologic findings to clinical symptoms and examination findings is vital. The incidence of asymptomatic disc prolapse in the lumbar spine is significant and without careful clinical correlation, the surgeon may make the mistake of operating on purely archeological findings.

Boden et al. (3) noted the presence of asymptomatic lumbar disc prolapse on magnetic resonance imaging (MRI) in 20% of subjects under 60 and in 36% of subjects over 60. These findings were confirmed by Jensen et al. (4), who noted protrusion in 27% of 98 volunteers and one patient with extruded disc. Boos et al. (5) examined a cohort of subjects matched by age, sex, and work intensity to a group of patients who presented with symptomatic disc prolapse. These asymptomatic matched subjects were found to have abnormalities in 76% of the 46 volunteers, 27 volunteers had a protrusion and three an extrusion. Therefore, it is clear that radiologic disc prolapse is common, particularly in subjects whose work environment is associated with an increased incidence of prolapsed intervertebral disc.

Follow-up of patients with asymptomatic disc prolapse has been undertaken. Boos et al. (6) followed 41 of their original 46 matched volunteers for a period of 5 years. At follow-up the subjects underwent MRI scanning and completed a questionnaire. There was almost no change in the radiologic classification of the disc prolapse (Table 44-1). Magnetic resonance images also were assessed for severity and at follow-up 31 out of 41 subjects were rated

**TABLE 44-1.** Asymptomatic disc prolapse, progression over 5 years

	Baseline	Follow-up
No prolapse	11	11
Protrusion	27	26
Extrusion	3	4
Neural compromise	29	29

Source: Adapted from Boos N, Semmer N, Elfering A, et al. Natural history of individuals with asymptomatic disc abnormalities in magnetic resonance imaging: predictors of low back pain-related medical consultation and work incapacity. *Spine* 2002;21:1484–1492, with permission.

the same and 10 rated radiologically worse. However, multiple regression analysis of these subjects indicated that presence or absence of asymptomatic disc prolapse or its type and extent had no predictive value for duration of low back episodes during the follow-up period, for consultations with health care professionals for low back pain or time off work. These findings were corroborated by Borenstein (7), who performed a 7-year follow-up of 50 subjects with a symptomatic disc prolapse. During the follow-up period, 20 reported low back pain; in seven patients this was a duration of more than 7 weeks. However, no correlation was found with the MRI appearances.

Thus, it appears that asymptomatic disc prolapse is not only relatively common, but when present does not appear to progress significantly over time in the majority of subjects. Therefore, it is not clear why some disc prolapses are symptomatic and others are not. Recently an intriguing hypothesis has been suggested by a research group in Birmingham, England. Stirling et al. (8) made use of an enzyme-linked immunosorbent assay (ELISA) incorporated with lipid S antigen, an antigen that is present in the cell wall or membrane of gram-positive cocci. This assay has already been established in gram-positive bacterial endocarditis and other deep-seated staphylococcal infections. The assay was being investigated for suitability in diagnosing and monitoring spinal infection. However, an unexpectedly high incidence of positive results was found in a group of disc prolapse patients who had been used as controls. In a formal trial, 108 patients undergoing surgery for prolapsed intervertebral disc were studied. Forty-seven positive cultures were obtained from excised disc material taken under the strictest of aseptic precautions. Nineteen patients were found to have a positive immunologic assay (Table 44-2). There was a significant association between positive culture and positive assay ( $p < 0.01$ ). The bacteriologic species cultured are given in Table 44-3. Although these findings need to be replicated in other centers, it remains possible that at least some cases of symptomatic disc prolapse are related to subclinical bacteriologic infection.

Turning to the natural history of symptomatic disc prolapse some information is available. In 1992, Gogan and

**TABLE 44-2.** Immunological assay

Fraser (9) perform a randomized control of Chymopapain against placebo (saline injection) for prolapsed intervertebral disc. Thirty subjects were injected with saline. Twenty-six of these subjects were reviewed at 10 years; approximately half subsequently underwent surgery (10). Of the remaining 12, six were symptom free at review, four were significantly improved, and two were not improved.

In his seminal paper, Weber (11) found that in patients with radiologically proved disc prolapse, 70% reported decreased pain and 60% returned to work within 4 weeks during initial conservative management. Further, on long-term (10-year) follow-up, they were able to show that patients with good long-term results with conservative therapy had demonstrated significant improvement within 3 months of onset. This study remains the only controlled trial of surgical intervention against conservative therapy. A group of 126 patients with proved disc prolapse and “uncertain indications” for surgery was defined. Of these 66 were allocated to conservative treatment and 60 were treated surgically. Of the randomized subjects at 1 year, those allocated to surgical treatment were significantly better. At 4 years, improvement was still noted but less marked and statistically nonsignificant. At 10 years, the results were identical. This trial may be criticized on a number of grounds, particularly because there was no blinding and a crossover of some 26% of the conservative group to surgery in the first year. However, it did provide evidence that surgery may improve the outcome in the short term. Subsequently it

was estimated by Malter et al. (10) that operative treatment for lumbar disc prolapse provided 5 months of healthy life as compared with conservative treatment.

Hakelius (12) retrospectively examined 583 patients with sciatica. He noted that surgically treated patients had a better result initially but this advantage over conservatively treated cases was not demonstrable at 6 months. However, at 7 years the conservatively treated group had more back pain, recurrences, and time lost from work.

Radiologic appearances also can change with time, but not consistently (13,14). Delauche-Cavallier et al. (13) performed repeat scans at 12 months and found that in 21 patients with disc prolapse, five had completely disappeared, five had undergone major reduction, four minor reduction, and no significant change was observed in seven. At 1 year, Matsubara found the size of the herniation decreased by more than 20% in 11 patients (34%), by 10% to 20% in eight (28%), and was unchanged in 12 (38%). Even after treatment, in some cases the radiologic appearance remains unchanged. Fraser et al. (15) rescanned 39 patients 10 years after therapy. Twelve had been treated by saline injection alone, 14 by chemonucleolysis alone, and 13 had subsequently required laminectomy for a failed intradiscal injection. The signal of the treated disc was absent in all cases in each group. Thirty-seven percent of patients were found to have a persistent herniated disc and the incidence was similar in all three treatment groups. The presence or absence of radiologic herniation at 10 years had no significant bearing on a successful outcome.

Not all patients who recover spontaneously go onto have permanent improvement. Following the first attack of sciatica, some 5% of subjects experience a recurrent attack. Following the second attack, the incidence of recurrence rises to 20% or 30%, and following the third or subsequent attack, recurrence occurs in 70% of patients (G. Findlay, personal communication).

**DIFFERENTIAL DIAGNOSIS**

Differential diagnosis in the spine includes conus and cauda equina lesions, infection at the vertebral body or disc, arachnoiditis, and intracanal neoplasia. Extrapinal differential diagnosis includes peripheral vascular disease, gynecologic conditions, orthopedic conditions (e.g., osteoarthritis of the hip or sacroiliac disease), neoplasia involving the lumbosacral plexus, mononeuropathy, conditions involving the sciatic nerve itself, and shingles.

**INVESTIGATION**

Magnetic resonance imaging is the tool of choice today. Computed tomography scanning may be used but lesions outside the area actually scanned cannot be visualized (e.g., cauda equina lesions). With exact concordance of CT findings with clinical findings, CT remains

a satisfactory method of investigation. It is important that scanning is undertaken from pedicle to pedicle rather than simply at disc space level to ensure sequestered fragments are visualized. There is no place for myelography, radiculography, or discography in the diagnosis of prolapsed lumbar intervertebral disc.

**CLINICAL INDICATIONS FOR SURGERY**

**Increasing Neurologic Deficit**

If neurologic deficit is progressive, then intervention is indicated.

General indications for surgical intervention in herniated lumbar discs are well understood. Disc excision surgery is far most successful in relieving leg pain than back pain. It has been outlined in the preceding that the natural history in this condition is favorable; 70% report decreased pain and 60% have returned to work within 4 weeks of the onset of symptoms. This is not dependent on the size or location of the prolapse radiologically. Long-term success with conservative management is indicated by substantial improvement within 3 months. Except in the case of profound motor deficit, there is little indication for operative intervention within 6 weeks of the onset of symptoms. Further, little improvement may be expected in patients with neurologic deficit that is pain free, because neurologic recovery is unusual.

The criteria of Macnab or “the Rule of Five” (16) have withstood the test of time and still remain the gold standard for indications for disc excision surgery (Table 44-4).

Careful examination is required to confirm the presence of neurologic deficit and sciatic tension signs according to Macnab’s criteria. Muscle spasm and spinal tilt do not add independent prognostic significance.

**TECHNICAL INDICATIONS**

Technical factors had been thought to influence the results of surgical procedure for prolapsed lumbar intervertebral disc, and thus had been relative indications for surgery. The size of the prolapse and presence of spinal

stenosis were felt to have an important influence; the larger the prolapse or the smaller canal, the worse the results (17,18). More recent studies in large patient groups, however, have failed to confirm these findings. Van Leeuwen et al. (19) could not find any predictive value in the size of the herniation or dimensions of the spinal canal in patients treated by chemonucleolysis. In a large study of 148 patients, Garreau (20) made a careful analysis of type and size of herniation and the shape and size of the spinal canal. The overall dimensions of the canal were examined together with the shape and size of the lateral recess. They were unable to demonstrate any relationship of canal size or hernia size with the results of chemonucleolysis. Thus, the radiologic size of the prolapse does not appear to constitute an indication for surgery.

Jensen et al. (21) reported no association of postoperative results with epidural fibrosis or appearance of residual or recurrent disc prolapse. However, they were able to demonstrate an association of overall result with facet joint degenerative disease (Table 44-5).

### PATIENT-RELATED INDICATIONS

Patient-related factors also provide important modifiers to the indications for surgery, because they appear to have significant influence on the outcome of surgery. In a well-conducted study, Spengler et al. (22) examined the influence of neurologic signs, sciatica tension signs, personality factors, and imaging studies on the outcome of surgical discectomy. Careful evaluation of the history, examination, and investigation findings was performed and points were awarded in each category according to a strictly defined protocol. Personality factors were evaluated using the Minnesota Multiphasic Personality Inventory. Overall, the preoperative assessment scores were highly predictive of the surgical outcome. Forty-seven patients with good results had a mean preoperative score of 86, whereas four patients with fair results had a preoperative score of 73 and 10 patients with poor results scored only 62. However, more detailed analysis revealed different contributions of the four factors to the overall outcome. The best predictor of the operative findings was the imaging studies. Thirty-nine

percent of the variance was explained of which imaging studies contributed to 26%. Neurologic signs and sciatic tension signs were much less predictive at 8% and 5% respectively. However, the clinical result was overwhelmingly predicted by the personality factors. Total variance explained all four factors were 40%, of which personality factors contributed 26%. Imaging studies contributed 10%, but neurologic signs and sciatic tension signs contributed only 3% and 1%, respectively.

Another large study by Junge et al. (23) examined a large number of possible predictive factors. The factors that in his analysis were of prognostic significance, however, did not include specific examination findings or investigations. Eighty percent of good and poor results in this study were predicted by physical mobility, pain intensity, other pain locations, compensation, and socioeconomic group. They found no prognostic significance in age or sex, sciatic tension signs or imaging appearances.

In 1991 Tregonning et al. (24) found the presence of a compensation claim had a significant impact on the overall results (Table 44-6).

### ADMISSION AND POST OPERATIVE CARE

The management of patients during the operative treatment has also been studied. A number of reports have examined the performance of micro-discectomy under day case conditions (25-28). One case series has also been reported examining fenestration and discectomy without a microscope undertaken as a day case (29). Recently a prospective randomized controlled trial has further examined the use of day case management in conventional fenestration and discectomy surgery (30). Patients were randomized to day case surgery or to overnight admission. All patients were admitted on the day of surgery. Significant advantages in mobility on the day of surgery, daytime hours spent in bed on the first post-operative day and walking distance at two weeks were demonstrated. Patient's opinion of the length of stay was good. No increase in complications was noted. Thus, there is evidence that conventional fenestration and discectomy surgery for prolapsed lumbar intervertebral disc may be safely and with benefit undertaken as a day case.

Postoperative management of patients undergoing surgical treatment for prolapsed intervertebral disc is also controversial. Fear of recurrence, re-injury, or instability has led to the suggestion of several post operative protocols to restrict activity. However, a study by Carragee et al, (31) has indicated that these may not be necessary. In this study, patients were allowed to determine their own levels of activity post operatively and no postoperative restrictions were imposed. All were urged to return to full activity as soon as possible. The mean time from surgery to return to work was 1.7 weeks and 25 percent of patients returned to work the following day. 97 percent of those working at the time of surgery returned to full duty by eight weeks. At two years, no patient had changed employment because of back or leg pain. Recurrent disc prolapse occurred in six percent (three patients) of whom one required surgical intervention. Thus when freed from restrictions imposed by health care professionals, patients returned to activities and work much more rapidly and in apparent safety. Magnusson et al (32) have found no rational basis for lifting restrictions after lumbar spine surgery.

In a recent review of rehabilitation after lumbar disc surgery (33) the authors found strong evidence that intensive exercise programs commencing 4 to 6 weeks following surgery were more effective in improving functional status and produced a faster return to work as compared to mild exercise programs (34, 35). However, there was also strong evidence that this influence was not maintained into the long-term. No evidence was found of the effectiveness of supervised training as compared with home exercises. There was also no strong evidence of the effectiveness of multi-disciplinary rehabilitation over the usual care. Limited evidence indicated that exercises were more effective in improving low back function status than physical agents, joint manipulations, or no treatment.

## CONCLUSIONS

Surgery for prolapsed intervertebral disc is principally indicated on clinical grounds. The radiologic appearances do not appear to add significant independent predictive value but patient-related factors are important.

# Operative Treatment of Disc Herniation: Laminotomy

Charles G. Greenough

---

The first operation undertaken to remove a lumbar disc herniation involved osteotomy of the spinous processes and hemilaminectomies from L2 to S1. A transdural approach was employed (1). Significant refinements of surgical technique took place in the following 70 years. Open discectomy now requires only excision of or raising of a flap of ligamentum flavum and minimal resection of the adjacent borders of the laminae. In contrast to the 19-day hospitalization of the first surgery, patients now may be subjected to open discectomy on an outpatient basis (2).

### TECHNIQUE

Open discectomy is undertaken under endotracheal general or spinal anesthesia. The patient is generally positioned prone, although a small number of surgeons prefer to perform the surgery in the lateral position. However, in the latter case, it can prove awkward if intraoperative extension or exploration on the opposite side is required. Relevant scans and other investigations must be available, and the surgeons should use them to confirm level and side of the prolapse. Careful assessment should be made for the presence of segmentation abnormality. Note should be taken of the relative position of the iliac crests and involved disc space. The direction and extent of the prolapse must be identified, together with any possible sequestered fragments.

Controversy has existed over whether or not the use of the microscope improves outcome. Proponents of the microscope point to the improved illumination, provision of binocular vision, and magnification. Others express concerns about the difficulty of seeing pathology outside the field of view and the possible increased risk of infection. Three randomized controlled trials have failed to show any significant differences between the two techniques (3–5).

The positioning of the patient should allow some reduction of the normal lumbar lordosis to increase the interlaminar space and should also allow decompression of the abdomen to reduce epidural bleeding. A number of positioning techniques are available, each of which has advantages and disadvantages. The surgeon employs the one with which he or she is most familiar and is most convenient in the operative working environment. The knee/chest position provides excellent abdominal decompression but can place the thoraco-lumbar fascia under tension. In addition, considerable manual handling of the patient is required; with heavy patients this can present a risk both to the patient and staff. A modification of this technique is to use a Salford seat where the patient's weight is taken on the buttocks and the table is tilted foot down to produce a more sitting posture. Both of these positions require increased positioning time. A Wilson frame is convenient, but in obese patients it does not provide abdominal decompression as satisfactorily as other devices. A four-post support system with supports under the antero-superior iliac spines and shoulders provides good abdominal decompression but less reduction in lumbar lordosis. In addition, pressure complications have been reported with this frame. The Montreal mattress is convenient and easy to employ and elimination of lordosis can be achieved by breaking the operating table. However, in obese patients insufficient room may be available for the abdomen to hang freely to produce good decompression. Shorter patients on a thick mattress can develop pressure-related complications across the upper anterior thigh.

Once the patient is properly positioned, the skin is prepared and consideration given to identification of level. Some surgeons rely on identification of the sacrum at the time of surgery when undertaking L5-S1 or L4-5 surgery. This is not possible to do with confidence at L3-4 unless one makes a large excision and employs radiologic iden-

tification of level. X-rays may be taken with a percutaneous needle, leaving the needle *in situ* or injecting methylene blue to mark the tissues. Even this method is not foolproof; exploration of the wrong level can occur despite placing a needle in the right interspace and using it as a dissection guide.

It should be borne in mind that two of the most common errors in disc surgery are operating on the wrong side and operating at the wrong level. Experience has shown that when the wrong level is operated on it is usually above the intended level. The surgeon must remain alert to this possibility throughout the approach; if the intraoperative findings do not agree with the preoperative imaging, then a careful review of the level is mandatory. This may include further radiologic confirmation or exposure to the sacrum to count and confirm the level.

If no radiologic confirmation is being used, then the position for the incision may be estimated relative to the position of the iliac crests. The incision is carried down to the thoraco-lumbar fascia once hemostasis is obtained. A self-retaining retractor is placed in the fat layer.

Using cutting diathermy, an incision made vertically in the thoraco-lumbar fascia, immediately adjacent to the supraspinous ligament and the side of the spinous process. To allow tension-free retraction of the musculature, the length of this excision should be adequate, usually 4 or 5 cm. This fascial incision may be longer than the skin incision. Muscle then is carefully dissected from the spinous processes and interspinous ligament using cutting diathermy under direct vision. Dissection is carried out on the superior and inferior laminae, taking care to divide the muscular attachments as close to the bone as possible. Stripping of the muscle using a Cobb or flat periosteal elevator results in avulsion of tendonous attachments from the muscle because the instrument cannot conform to the complex shape of the laminae. Avulsion of these tendonous slips may cause bleeding, which may result in postoperative stiffness and discomfort.

If radiographic confirmation has not been done, the level is then confirmed by identification of the sacrum. The sacrum produces a different sound under percussion than L5, and usually presents a continuous bony surface. The inferior margin of the L5 lamina often is sharp, whereas those laminae above are blunt. Identification may be made of the lowest mobile segment by use of a large Cobb or other instrument. None of these indicators is pathognomic; confirmatory radiographs should be obtained if the operating surgeon has any doubt. Having identified the correct level, the ligamentum flavum and adjacent laminae are cleared of all soft tissue with a large pituitary rongeur or curette.

The attachment of the ligamentum flavum to the adjacent laminae is significantly different at each end of the lamina. Caudally it is attached to the superior edge of the lamina; cranially it is attached to the superior edge and the deep surface of the lamina. Therefore, access to the

canal can be obtained by careful use of a small Cobb or similar instrument to detach the fibers of the ligamentum flavum from the superior border of the caudal lamina. A smooth instrument (e.g., a McDonald dissector) can be introduced immediately beneath the lamina to ensure that no adhesions are present. The ligamentum flavum then can be excised with a Kerrison rongeur, taking care to ensure that no adhesions are present as removal proceeds. Some surgeons prefer to raise the ligamentum flavum as a medially based flap.

The most important landmark is then the medial border of the caudal pedicle. The superior border of the lamina and, if necessary, part of the medial portion of the base of the superior facet may be carefully excised with a Kerrison rongeur until the pedicle can be positively identified. To preserve stability, it is important not to allow bony dissection to stray lateral to the medial border of the pedicle at any point. The nerve root is identifiable adjacent to the medial border of the pedicle. Care should be taken to ensure that there is no conjoined root, because the superior portion of this often exits in contact with the superior border of the pedicle. The nerve root then can be traced proximally and carefully mobilized medially off the disc prolapse. It is safer to identify the root at the point where it approaches the pedicle because, with a large prolapse, the root can be thinned and stretched to such an extent that the edge can become difficult to identify at the level of the disc.

Once the root is safely mobilized medially, the disc space may be opened and all loose disc material removed. Careful examination is then made anterior to the root and for any sequestered fragments identified on the scan. Curettage of the end plates is not necessary.

It must always be borne in mind that the great vessel is immediately in front of the anterior annulus. Particular care should be taken that a rongeur is not introduced deeper than the anterior annulus. On occasion a preexisting defect may be present in the anterior annulus; this represents a significant hazard.

At the end of the procedure the surgeon should examine the excised material and compare with this with the amount and location of the disc prolapse visible on the preoperative scan as a final assessment of completeness of disc removal. An assessment also should be made of the dimensions of the lateral recess. It may be necessary to perform an undercutting facetectomy to decompress the lateral recess. This facetectomy should not be carried lateral to the medial border of the pedicle. Before closure, careful review of the operative field is necessary to ensure that the nerve root is freely mobile and free from compression. A probe is passed down the intervertebral canal and superiorly and inferiorly in the spinal canal. Gentle elevation of the root is performed to allow examination anterior to the root itself. Careful and gentle palpation through the dura is undertaken to detect any subligamentous residual fragment or the rare intradural fragment.

Hemostasis of epidural bleeding is obtained with bipolar diathermy. Recently, interest has been expressed in the use of materials to reduce the fibrosis following disc surgery. However, although there is good evidence that such substances do reduce postoperative fibrosis, the evidence that this results in any clinical improvement is conflicting. BenDebba et al. (6) studied 298 patients who underwent surgery for lumbar disc herniation in a randomized, controlled, double-blind multicenter clinical trial using the scar-inhibiting substance ADCON-L. Those patients receiving ADCON-L at surgery developed significantly less scar ( $p = 0.01$ ) and experienced less activity-related pain than the control group ( $p = 0.05$ ). Logistic regression analysis demonstrated a significant association ( $p = 0.02$ , odds ratio = .7) showing that the odds of extensive scar decreased by 30% for every 31% decrease in activity-related pain score. Similar results were noted by Geisler (7), but no such effects were found by Richter (8). Hieb (9) noted an increased risk of cerebrospinal fluid (CSF) leakage with ADCON-L.

The thoraco-lumbar fascia is repaired and the superficial fascia within the fat layer is sutured. The skin wound is closed and the wound may be infiltrated with local anesthetic.

Postoperatively, patients are mobilized on the day of surgery and can be discharged the same day (2). Carragee (10) has demonstrated that when encouraged to return early to normal activities, patients return to work very early. Twenty-five percent of his cases returned to work the day following surgery, and the average time to return to work was 1.7 weeks. No increase in complications or recurrent disc herniation was observed. Magnusson et al. (11) have found no rational basis for lifting restrictions after lumbar spine surgery.

In a recent Cochrane review (12) intensive exercise programs commencing 4 and 6 weeks postoperatively also were found to be more effective for improved functional status and more rapid return to work than mild exercise programs.

## RESULTS OF SURGERY AND FUNCTIONAL OUTCOME

The results of modern minimally invasive open discectomy are the gold standard against which other treatments are measured. Sciatica from disc herniation is more amenable to discectomy than is low back pain and results are maintained over 24 months. Weber (13) performed the only randomized study of discectomy against conservative care. At 1 year, surgically treated patients were statistically significantly better than patients randomized to conservative treatment, but at 4 years the difference was not statistically significant.

The results of surgery are influenced by many factors. Howe and Frymoyer (14) used 14 different outcome measures to assess the 10-year follow-up results of 244

patients who had undergone lumbar disc surgery. They found that the percentage of "satisfactory outcomes" ranged from 60% to 97%, depending on the outcome measure employed. In general, measures examining patient satisfaction provided a higher success rate than measures using more objective criteria, such as return to previous occupation. This range of satisfactory results is substantially greater than the difference among many techniques used in the surgical management of lumbar disc herniation. Therefore, it is essential that only direct comparisons using validated instruments be used to compare outcomes.

Loupasis et al. (15) analyzed 109 patients with surgically documented herniated lumbar disc over 12 years. The late results were satisfactory in 64% of patients, but 28% still complained of significant back or leg pain. Ninety-four percent of patients were very satisfied or satisfied with their results. The reoperation rate was 7.3%, about one third of which resulted from recurrent disc herniation. Sociodemographic factors predisposing to unsatisfactory outcome included female gender, low vocational education, and jobs requiring significant physical strength.

Atlas et al. (16) retrospectively examined 507 patients with sciatica, 275 surgically treated and 232 non-surgically treated. On average, surgically treated patients had more severe symptoms, signs, and imaging findings than non-surgically treated patients. At 1 year, surgically treated patients reported significantly greater improvement in symptoms, functional status, and disability. Seventy-one percent of surgically treated and 43% of non-surgically treated patients reported definite improvement ( $p < .001$ ), an effect increased after adjustment for differences between treatment groups at entry (relative odds of definite improvement, 4.3;  $p < .001$ ). However, little difference in the employment or workers' compensation status of patients treated surgically versus non-surgically was observed at 1 year (5% versus 7% unemployed, 46% versus 55% receiving workers' compensation, respectively).

Davis (17) was able to examine 98% of 984 patients operated on for a herniated lumbar disc with a mean follow-up period of 10.8 years. L4-5 and L5-S1 discs were involved with equal frequency (47%). The recurrence rate was 6%, one third of which developed during the first year after operation. The complication rate was 4%, with no intraoperative vascular or intestinal injuries. The outcome was good in 89% of patients, defined as a Prolo score of 8 in 10%, 9 in 19%, and 10 in 60% of patients. Patients who did sedentary work and homemakers had a statistically higher total and economic Prolo scores ( $p < .01$ ) than those who did strenuous work. Risk factors for a poor result were pending legal or workers' compensation claims and psychological distress.

Two large reviews (18,19) have indicated consistent surgical success rates of 65% to 90% in clinical series, but have emphasized that careful selection of patients is of great importance.

**TABLE 45-1.** Incidence of complications in open discectomy

Complication	Incidence (percentage)
Cauda equina syndrome	0.2
Thrombophlebitis	1
Pulmonary embolism	0.4
Wound infection	2.2
Pyogenic spondylitis	0.07
Postoperative discitis	2
Dural tears	1.6
Nerve root injury	0.5

Modified from Spangfort.

Adapted from Spangfort EV. The lumbar disc herniation: a computer aided analysis of 2,504 operations. *Acta Orthop Scand* 1972;142(suppl):1, with permission.

## COMPLICATIONS

In 1972, Spangfort (20) analyzed 2,504 operations and recorded the incidence of complications (Table 45-1).

Cauda equina syndrome may result from excessive compression of the dural contents during surgery. In the presence of a very large disc fragment, the exposure should be widened to allow the fragment to be removed without excessive traction on the dura. It should be remembered that diabetic patients are more vulnerable to this complication, and extra care is required for such patients.

Wound infection and postoperative discitis may be reduced by use of prophylactic antibiotics. Rohde (21) studied 1,642 patients in whom 1,712 discectomies were performed. In 508 patients, no prophylactic antibiotics were given; in 1,134 patients, a collagenous sponge containing gentamicin was placed in the cleared disc space. A postoperative spondylodiscitis developed in 19 of the 508 patients who were not treated with antibiotic prophylaxis (3.7%), whereas none of the 1,134 patients who received antibiotic prophylaxis developed infection ( $p < .00001$ ). A single dose of intravenous antibiotics at induction of anesthesia may be as effective as other regimens.

Dural tear occurs in a small percentage of surgeries. Pseudomeningocele and fistula formation following dural tears should be repaired. It is essential that the exposure be widened to provide a good view of, and access to, the whole length of the tear. With loss of CSF the cauda equina is much more sensitive to pressure, and extreme caution should be exercised. Suction should be avoided inside the dural cavity and over the area of any prolapsed nerve roots. Suction through a patty is permissible. Dural tears should be repaired with continuous monofilament, nonabsorbable suture, taking care not to narrow the dural sac. Large defects can be repaired with dural replacement material and fibrin glue. Postoperative patients with dural repairs should be maintained on bed rest for 48 to 72 hours.

Penetration of the anterior annulus is a rare complication that can be associated with vascular or visceral damage (22). Constant monitoring of the depth of the rongeur is mandatory. If penetration of the anterior annulus is suspected, careful postoperative monitoring of blood pressure, pulse, and abdominal signs is indicated. Laparotomy should be undertaken without hesitation in the presence of adverse physical signs.

## CHAPTER 46

# Chymopapain and Chemonucleolysis

Jeremy Fairbank

---

Chemonucleolysis is one of the best investigated interventions for the treatment of spinal disorders. There is good evidence of efficacy, and yet its use has declined sharply in North America in recent years. It is still used in Europe. Recently, manufacture was discontinued although it is likely to resume shortly.

Chemonucleolysis dates back to the early 1960s when Lyman Smith first injected a purified extract of the papaya fruit into the intervertebral disc to treat intervertebral disc prolapse (1,2). Chymopapain was first extracted in 1941. In 1959 Hirsch was the first to propose the use of a proteolytic enzyme to dissolve the intervertebral disc. Chemonucleolysis has been the subject of a series of randomized controlled trials. Its use has been fashionable in various countries at various times. Its reputation was damaged because of complications that generally turned out to be either due to poor technique of needle placement or to unrecognized comorbidity. Intrathecal injection of the enzyme with serious neurologic sequelae has occurred, but experienced radiologic technique should make this complication extremely unlikely. There was also anxiety in the United States because of anaphylaxis. This is unusual in Europe, perhaps because meat tenderizer (based on the same enzyme) is not widely used (3,4). A lower dosage was also used in Europe. In the United States some surgeons have been reluctant to use chemonucleolysis because of reimbursement issues.

The most serious complication of chemonucleolysis is transverse myelitis. This occurs in 1:18,000 to 1:25,000 cases (note that this is less than the risk of cauda equina damage in surgically treated cases). Litigation in California is four times more common following discectomy than following chemonucleolysis.

Figure 46-1 shows needle placement and pre-injection discography in a 23-year-old woman with a 1-year history of back and leg pain. The symptoms and signs in this patient were consistent with a disc prolapse at L5-S1. She was frightened of surgery and eventually chose chemonucleolysis. This gave her good relief of leg pain, but her

back pain persisted. A 3-month postintervention magnetic resonance (MR) scan showed that the disc prolapse had largely dissolved. A 9-month scan showed complete resolution. The back pain was managed conservatively.

### BIOCHEMISTRY

Chymopapain is a sulfhydryl protease found in papaya latex. It closely resembles papain in its ability to hydrolyze a wide variety of substrates but at slower rates. Chymopapain was so named because it was thought to have a higher ratio of milk clotting to proteolytic activity when compared to papain. The clotting capacities of the two enzymes are in fact equal. It is supplied as a partially purified, lyophilized powder. Its activity is measured in units, where 1 unit hydrolyzes 1  $\mu\text{mol}$  of benzoyl-L-arginine ethyl ester per minute at 25°C and pH 6.2 after activation in a solution containing 1.1  $\mu\text{M}$  EDTA, 0.067  $\mu\text{M}$  mercaptoethanol, and 5.5  $\mu\text{M}$  cysteine-HCl for 30 minutes (5).

In humans there are measurable rises in keratin sulfate levels for 5 days following chymopapain injection (6).

### INDICATIONS

The indications for chemonucleolysis parallel those for the surgical treatment of disc prolapse. The McCulloch criteria are widely used (7). McCulloch's series of 480 patients showed 70% success in those patients fulfilling his criteria. He suggested that candidates for chemonucleolysis should meet three or more of the following:

1. Unilateral leg pain in a typical sciatic root-type distribution, including discomfort below the knee. The leg pain has to be more severe than, or at least equal to, the severity of the associated back pain. If the roots of the femoral nerve are involved, pain in the front of the thigh is produced.

**FIG. 46-1. A:** A lateral radiograph of the L5-S1 disc to show needle placement and a pre-chymopapain injection of contrast (discogram) in a 23-year-old woman with a 1-year history of back and right leg pain. **B:** An anteroposterior radiograph of the same patient.

2. Specific neurologic symptoms incriminating a single nerve (e.g., numbness over the dorsum of the foot or over the great toe region or flopping of the foot on walking, signifying the involvement of the fifth lumbar nerve).
3. Limitation of straight-leg raising, due to pain in the leg, by at least 50% of normal; crossover pain from the unaffected leg to the symptomatic leg; or radiating thigh or back discomfort or calf and foot numbness on bowstring pressure over the medial or lateral popliteal nerve.
4. At least two of four possible neurologic changes: muscle wasting, muscle weakness, sensory alteration, and reflex changes.
5. A positive myelogram showing a disc herniation at the level suspected clinically.

These criteria continue to hold up today. Number 5 can be reasonably substituted by findings on an MR scan confirming disc herniation. Lateral recess compression and exit foraminal stenosis have become contraindications. Even though these were not detected on the myelogram of the 1970s, McCulloch's report emphasized the clinical importance of spinal stenosis and lateral recess stenosis as a cause of failure. Other contraindications were nonorganic back pain and disc degeneration. Chymopapain should only be injected at an additional level in the unusual situation where the same criteria apply.

### CONTRAINDICATIONS

This intervention depends on the chymopapain reaching the proteoglycan element of the herniated nucleus

pulposus. This cannot occur if there is a sequestered fragment surrounded by fibrosis or a posterior ligament defect closed by fibrosis. If the offending herniation consists of annulus, its predominantly collagenous content will not be reduced by chymopapain. Spinal stenosis, whether central or lateral, may be exacerbated by chemonucleolysis rather than helped. This is because the disc space always narrows following chemonucleolysis and may produce neural compression from foraminal narrowing. It tends to regain some of its height after a year (8,9). The disc may be dose-dependent (10).

Allergy to chymopapain occurs. In the past chymopapain has been used as a meat tenderizer, and this may have led to undetected exposure to the antigen. Skin testing using subcutaneous chymopapain has been described by Grammer et al. (1988) (11). They used 10 mg per mL chymopapain on 540 chemonucleolysis candidates, of whom 6

**TABLE 46-1. Absolute or relative contraindications to chemonucleolysis**

Sequestered discs
"Hard" discs
Lateral recess stenosis
Foraminal stenosis
Fibrosis due to prior surgery
Arachnoiditis
Neurologic disease
Polyneuritis of diabetic origin
Tumors
Cauda equina syndrome
Severe spondylolisthesis
Known chymopapain or papaya allergy

were positive. These individuals were excluded. None of the negative patients developed unequivocal anaphylaxis to chymopapain. If anaphylaxis occurs it should respond to normal treatment including the use of adrenalin.

The full list of contraindications is listed in Table 46-1.

## COMPLICATIONS

In the United States, between 1982 and 1991, 121 adverse events were reported in approximately 135,000 patients having chemonucleolysis (12). This included seven cases of fatal anaphylaxis, 24 patients with infection, 32 patients with hemorrhage, 32 neurologic events, and 15 miscellaneous occurrences with an overall mortality rate of 0.019%. Of the 121 events, 105 reported to the U.S. Food and Drug Administration (FDA) occurred before the end of 1984. Among these, were six cases reported as acute transverse myelitis. It is likely that two of these were due to previously unrecognized multiple sclerosis. There were one each of cauda equina syndrome, diabetic neuropathy, intrathecal injection, and postviral myelitis. Three of the six patients recovered.

Overall it was found that 47 instances of the complications (out of the 135,000 patients exposed) were probably related to chymopapain, 38 were probably not related, and in the remaining instances, there was insufficient information to decide.

In all of the categories investigated, there was a lesser incidence of complications with chemonucleolysis than that seen following laminectomy. This report was important and was an accurate record of complications because of the supervision of the FDA. This meant that the data for chemonucleolysis were far more accurate than the available data on laminectomy and discectomy. The early neurologic complications and anaphylaxis cases dealt the reputation of the procedure a serious blow. This was only overcome by showing that the neurologic problems were associated with poor technique and that anaphylaxis could be avoided by careful history taking and sensitivity testing. In fact, anaphylaxis has been reduced from an early 0.5% to 0.25%, and there have been no reported deaths or major neurologic complications between 1987 and 1996 (13).

In a series from Austria, Deutman reported one case in 2,000 of anaphylaxis and seven "sensitivity" reactions. All survived with appropriate treatment (14).

## DISCITIS

When discitis was first described, it was thought to be a "chemical" discitis. Fraser demonstrated conclusively that this discitis was due to bacterial contamination (15,16). The use of a double-needle technique and prophylactic antibiotics has virtually eliminated this com-

plication. It is not always easy to grow bacteria from disc space biopsies, so some surgeons still believe in chemical discitis when there is a negative culture (17). Poynton et al. reported discitis in 6 of 105 patients (5.7%) (18). Only two had a positive culture (*Escherichia coli*). None had long-term sequelae. End-plate changes can be detected on MR after chemonucleolysis (19).

## TECHNIQUE

McCulloch advocated a posterolateral approach under local anesthesia (7). Anaphylaxis should be treated if it arises. Other authors have preferred a general anesthetic and watchful waiting for complications. In our institution, we use local anesthesia and sedation with an anesthesiologist in attendance. A transdural approach to the disc is strongly contraindicated. Some authors use discography to check needle position. Others believe that this has an adverse effect on the enzyme, although this has not been substantiated.

In the past back spasm was common after chemonucleolysis. The incidence of inflammatory changes can be reduced with smaller dosages (20). Dosage has been reduced from 3,000 to 4,000 U per disc down to 2,000 U per disc, or even to 500 U per disc by some (21). Pain and spasm may be reduced by injecting bupivacaine (8 to 10 mL, 0.25%) during needle withdrawal or by using intravenous corticosteroids just before the chymopapain injection. Antibiotic prophylaxis is essential (15).

The disc height decreases following injection by chymopapain by about one-fourth of the pre-injection height (22). It may recover some or all of the lost height over the course of a year.

Walking remains the best exercise post-chemonucleolysis. Swimming is encouraged. Most can return to a light or sedentary type of work within 2 to 4 weeks, and heavier work in 6 to 12 weeks.

## LONG-TERM RESULTS: CLINICAL TRIALS/REVIEWS

The most compelling evidence that chemonucleolysis is a safe and effective treatment for herniation of the nucleus pulposus is found in well-designed and conducted prospective, randomized, double-blind studies in the United States and Australia. One of these double-blind studies has been carried out for 10 years without code break or loss of follow-up (23,24).

In Australia, Fraser (24) randomized 60 patients to chemonucleolysis or intradisc saline. In the chemonucleolysis group 80% regarded treatment as successful compared with 34% in the saline group. In the chemonucleolysis group, 20% were operated on compared with 47% in the saline group. These patients were also assessed by an independent observer who concluded that 77% of the

chemonucleolysis group and 38% of the saline group had “moderate” improvement. One patient in each group developed discitis.

Success prevailed in 77% of patients receiving chemonucleolysis compared with only 38% for the placebo group ( $p < .004$ ). Only 6 of the patients receiving chemonucleolysis had required laminectomy compared with 14 in the placebo group ( $p < .028$ ) (24).

A European study (25) reported the success rate at 1 year for chemonucleolysis at 88% and for laminectomy at 76%. Chemonucleolysis continued to be superior to surgery after an additional year. In a 9- to 11-year prospective, randomized study comparing patients with these two methods, surgically treated patients who had done well initially deteriorated with time, whereas those who did well following chemonucleolysis maintained a successful outcome in the long term ( $p < .041$ ).

The long-term results of surgery after failed chemonucleolysis are similar to those obtained after primary disc excision, indicating that failure to respond to chemonucleolysis does not compromise surgical discectomy, should it be necessary. In comparing long-term follow-up of patients who have undergone postchymopapain laminectomy versus patients who have undergone repeat laminectomy, better results were obtained in postchemonucleolysis laminectomy which were statistically significant (26).

In trials versus placebo, there is a clear advantage for chymopapain (27,28). Trials against surgery (observational and randomized controlled trials) show slightly less efficacy of chemotherapy over surgery in the short term, fewer complications, and fewer long-term recurrences. In the longer term the results are comparable (23,29–33).

Nordby and Wright reviewed 45 studies (observational and randomized controlled trials) made between 1985 and 1993 (27). There were 7,335 patients. On average 76% reported a benefit with chymopapain compared with 88% in patients having open surgery.

Javid reported a prospective cohort design of 200 selected patients, 100 having chemonucleolysis and 100 undergoing surgery (26). Of chemonucleolysis patients 82% saw immediate benefit; 92% surgical patients saw immediate benefit. By 1 year 88% chemonucleolysis patients and 85% of surgical patients had benefited from the respective procedures. In this study chemonucleolysis was more cost-effective than surgery.

Observational studies are helpful for investigating efficacy and complications. Bouillet reviewed 43,662 cases from 316 centers. The overall complication rate was 3.7%, with 0.45% serious complications (34). Other observational data are reported by various authors (35–37).

### JUVENILE DISC PROLAPSE

Bradbury et al. reported a long-term observational study of 60 adolescents (13 to 19 years) with disc pro-

lapses (38). All were treated with chemonucleolysis initially. There were 18 failures (30%) treated by open discectomy. Follow-up in all cases was more than 5 years (mean follow-up: chemonucleolysis 8.5 years, surgery 7.2 years). Pain relief was successful in all the chemonucleolysis patients and 16 of 18 of the surgical patients. Failures are due to large prolapse, sequestered disc, lateral recess stenosis, facet arthropathy, and osteophytes (7,31,39,40).

The authors concluded that chymopapain injection was an effective first-line treatment for this group of patients. Surgery can then be confined to failures of this treatment with, in most cases, a good clinical outcome. Both this study and that of Javid (26) suggest that more chemonucleolysis patients are employed than those who have surgery. This may represent some selection bias.

### DISC PROLAPSE IN OLDER ADULTS

Evidence shows that chymopapain is effective in older adults with disc prolapse (14,41). Associated pathology, such as lateral stenosis or root canal stenosis, is more likely than in younger patients. This can preclude a good outcome.

### HEALTH ECONOMICS

It is likely that chemonucleolysis is less expensive than surgery, especially when done as outpatient procedure; it also may be more cost-effective (42). Short-term efficacy is slightly less than surgery, but in the long-term, it is as effective. It is likely that there are fewer recurrences with chemonucleolysis. The health economics of this issue have been investigated in various studies. None have been designed to investigate the current practice of low dose outpatient day care chemonucleolysis or have looked at the question of long-term recurrence. Malter et al. concluded that surgical treatment was cost-effective and that there was a cost-utility benefit (43). The cost-utility of surgery was just under \$30,000 per quality adjusted life year gained compared with nonoperative treatment. This compares favorably with coronary artery bypass grafting. These authors had insufficient data to make a conclusion on chemonucleolysis, but they thought that it would have comparable findings.

This view is contested by a study by Muralikuttan et al. (29). This study involved 92 patients randomized to surgery or chemonucleolysis. Nine of 46 chemonucleolysis patients came to surgery (19%) and only 1 surgery of the 46 was a failure. By 1 year there was no detectable difference between the groups. In this study the chemonucleolysis patients were kept in the hospital for a mean of 7 days and the surgical patients for a mean of 8 days. There was a demonstrated cost-benefit and cost-utility benefit for surgery and no advantage for chemonucleolysis. The prolonged inpatient stays make this study of lit-

tle relevance today. This matter is also reviewed by Javid (26) and Norton (44).

In a European study, Launois et al. (45). reported the success rate at 1 year for chemonucleolysis at 88% and for laminectomy at 76%. Chemonucleolysis continued to be superior to surgery after an additional year.

## ALTERNATIVES

Alternatives to chymopapain have been sought. There is some evidence to support the use of collagenase: in a 5-year randomized study of 100 patients comparing collagenase to chymopapain, collagenase was effective in relieving pain in 52% patients compared with 72% of patients treated with chymopapain. Surgery rates were 24% and 18%, respectively (46). Other agents, such as chondroitinase ABC have not shown efficacy. Chemonucleolysis is superior to automated percutaneous discectomy (47,48).

## CONCLUSIONS

I have used both chemonucleolysis and surgery in managing patients with disc prolapses when other interventions have failed. This requires waiting a minimum of 6 weeks from the onset of symptoms. Chemonucleolysis is safer than surgery, but its success rate is less. I prefer to use chemonucleolysis in my younger patients (under 25 years of age), but there is evidence of efficacy in older patients as well (41). Sequestered discs will not respond to chemonucleolysis. Chemonucleolysis does generate significant back pain in the first 6 weeks (so does surgery, but patients find postsurgical back pain easier to accept, and it is expected that strong opiate analgesia will be used). This means there is not much to choose between the interventions in recovery time. This risk of recurrence is probably less with chemonucleolysis compared with surgery (which is about 10% in 10 years). The size of the disc prolapse is irrelevant to outcome.

The complete rejection of chymopapain in the United States is difficult to comprehend when the results of treatment are carefully reviewed. Low-dose day treatment for a symptomatic disc prolapse should be offered as a treatment option to all eligible patients with sciatica from a contained disc prolapse that has not responded to non-operative treatment.

# Microscopic Lumbar Discectomy

Robert Kraemer, Alexander Wild, Holger Haak, Joerg Herdmann,  
and Juergen Kraemer

---

### **MICRODISCECTOMY OR MACRODISCECTOMY**

Open lumbar discectomy is still the most frequent and most important intervention in spine. The question is how to perform open disc surgery—with a small or wide exposure: microdiscectomy or macrodiscectomy? The choice of procedure depends on the expected pathology:

- Is it multisegmental?
- Is there a concomitant spinal stenosis?
- Is there a tumor or postoperative fibrosis?

A monosegmental disc prolapse is the most frequent cause for lumbar disc surgery. The surgical approach should be as small as possible and wide as necessary. Besides less trauma, less postoperative pain, and more rapid mobilization, a small approach reduces the amount of scarring which is important to prevent perineural fibrosis which is a cause of the failed back surgery syndrome. The interlaminar approach is similar for both microdiscectomy and macrodiscectomy, but the wound and scar formation might be more extensive in a wide approach. Using a microscope provides better illumination and better three-dimensional visualization, and is a better teaching tool. Several studies report good outcome with shorter hospital stay and earlier return to work rates compared to conventional disc surgery (1–3). On the other hand, there are reports of comparable outcome with both procedures, as well as concerns about specific complications (4,5).

There are potential pitfalls and errors with microdiscectomy. The limited exposure makes it easier to operate at the wrong level, to overlook free fragments, and to decompress inadequately. Technical difficulties and inexperience with the microscope can result in inadvertent injury to neural structures and vessels in the spinal canal. Because of these issues, many surgeons prefer a wide exposure for open disc surgery that permits better intra-

operative orientation and visualization. It is a challenge for a spine surgeon to abandon a wide exposure for microdiscectomy without a loss of quality. Optimal intraoperative orientation with a small exposure can be achieved by precise preoperative planning of the incision and X-ray localization with a needle. A small incision provides a better illumination of the operative field than can be achieved by a headlamp. Surgery through a small approach can be facilitated by special bayonet-shaped instruments.

Microscopic lumbar discectomy is a four-step procedure starting from the skin to the anterior epidural space that provides clear visualization of each layer and segment. The overlapping of the lamina over the disc space varies by level and must be recognized. The disc space at L5-S1 is interlaminar in location; at L4-5 the disc is partially covered by the lamina of L4; and at L3-4 and higher the disc space is completely covered by the superior lamina. The skin must therefore be appropriate: for an infradiscal L4-5 herniation the disc prolapse is below the spinal process, for supradiscal L5-S1 herniation the disc prolapse is at the level of the spinal process. For microdiscectomy, it is extremely important to visualize the pathology in the center of the wound. In microdiscectomy the surgeon must be oriented as to the precise location of the foramen, nerve roots, and pedicles.

For foraminal and lateral disc herniation the skin incision is placed 3 cm lateral to the midline and the approach is between the transverse process.

In conclusion, the surgical incision and approach should be as small as possible and as wide as necessary. One way to progress to microdiscectomy is to start with a headlamp and to use microinstruments. The surgeon should use the procedure with which he or she is most comfortable. It is better for a patient to be operated upon by an experienced macrosurgeon than by an inexperienced microsurgeon.

## CLASSIFICATION OF LUMBAR MOTION SEGMENTS FOR MICRODISCECTOMY

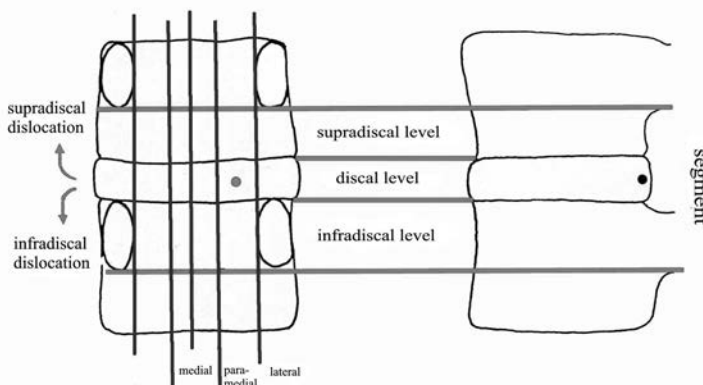

For a better correlation between preoperative and intraoperative findings in microscopic discectomy it is helpful to have anatomic landmarks that can be easily identified both on radiographic images as well as intraoperatively. In most classifications, posterior elements such as facet joints, laminae, and pedicles are key structures for the surgical approach to the lumbar spine (7–11). McCulloch (9) related his classification to the pedicles and compared the lumbar segments to the stories of a house. The disc level was the first story, the infrapedicle level the second story, and the pedicle level the third story of the house. Wiltse (11) added a suprapedicle level, which could be considered the upper part of McCulloch's third story, and laterally (horizontally), a subarticular zone. For orientation during interlaminar lumbar disc microsurgery, the surgeon has only a few anatomic landmarks. Exposure of the facet joint should be avoided in order to maintain the vascularization and innervation of its capsule and to avoid damage to the joint itself.

For the routine interlaminar approach to the lower lumbar spine, disc-related orientation is more useful, especially for less experienced surgeons. After identifying the inferior border of the lamina and the disc space by its relation to an intraoperative localizing needle on an X-ray film, it is easy to find the pedicles, foramen, and nerve roots.

The main difference from the classifications of McCulloch (9) and Wiltse (11) is that the intraoperative orientation is related only to the disc, not the foramen, pedicles and facet joints, which cannot be seen in most microsurgical approaches.

## DISC-RELATED CLASSIFICATION

A disc and the adjacent vertebrae form a segment (the Junghans motion segment) that is divided vertically into levels and horizontally into zones (Fig. 47-1).

At the center of a segment is the disc level, with the supradiscal level above and the infradiscal level below. Supradiscal and infradiscal levels border on the middle of the vertebra, which is identical with a line between the inferior borders of the pedicles. Protruded disc material can stay at the disc level or dislocate in a supradiscal or infradiscal direction.

From the midline of the segment in a lateral direction, there are three zones: medial, paramedial, and lateral. The medial zone has a right and a left part. The middle of the paramedial zone is identical with the center of the interlaminar approach at L5-S1 and, after removing parts of the upper lamina, also at L4-5 and higher segments. Most contained or noncontained disc herniations are in this area. They lie under or close to the traversing nerve root at the disc level or the supradiscal or infradiscal level. If pathology medial to the traversing root is closer to the segment midline, it lies in the medial zone.

The lateral zone begins at the medial border of the pedicle and includes the foraminal area and the extraforaminal (far out) area. Disc herniations that lie lateral to the traversing root usually have contact with the exiting root in the foramen, causing a double-root syndrome. All levels have the same zones except the infradiscal level, which does not really have a lateral zone due to presence of the pedicles.

Myelogram and anteroposterior reconstructions on magnetic resonance imaging (MRI) show the dural sac and nerve roots with bony structures.

In the lower lumbar segments, the nerve roots traverse the disc and infradiscal area before they exit the spinal canal through the intervertebral foramen of the segment below. The vertical part of the nerve root that passes the paramedial zone is called the traversing root until it enters the lateral zone at the medial border of the pedicle. From there on it is the exiting root.

The interlaminar approach to the lumbar spine always exposes the traversing root centrally and the exiting root cranially and laterally within the intervertebral foramen. The pedicle is caudally and laterally located. The travers-

**FIG. 47-1.** Disc-related classification of the segment. Above the disc level is the supradiscal level, and below it is the infradiscal level; these border on the middle portion of the vertebra. In the lateral direction are the medial, paramedial, and lateral zones.

ing roots are intrathecal until they leave the dural sac and enter the nerve root sheath at the axilla of the root. The main part of the lumbar traversing root lies intrathecaly. The lumbar traversing roots course past the disc and supradiscal levels intrathecaly. The sheath-surrounded part of the L3-4 and L5 traversing roots is very short. The entrance point into the nerve root sheath (axilla point) for the L5 root is infradiscal medial to the L5 pedicle, and for the L3 and L4 roots it is caudal to the pedicle. For the S1 root, it is just below the L5-S1 disc. This means that in microscopic lumbar discectomy an approach to the discal and supradiscal level in L3-4 and L4-5 segments and to the supradiscal level at L5-S1 exposes only the lateral part of the dural sac with the traversing root inside, not surrounded by a nerve root sheath. A medial part of traversing root does not exist at these levels of the spinal canal and separation should therefore not be attempted. Only an interlaminar approach to the disc and infradiscal levels of L5-S1 and sometimes the intradiscal levels of L4-5 show sheath-surrounded traversing nerve roots. Traversing nerve roots are most sensitive to mechanical strain in their sheath-surrounded part, especially at the entrance point, because they can be manipulated as easily as in their intrathecal part.

Exiting roots have a nerve root sheath that naturally adheres to the posterior surface of the vertebra and the pedicle. They are also sensitive to any kind of mechanical strain because they cannot move. Exiting roots are located cranio-laterally to the interlaminar approach and the disc. They pass around the pedicle into the superior (upper) part of the intervertebral foramen. The exiting nerve root and the pedicle adjacent to it have the same name: the L5 root passes beneath the L5 pedicle, the L4 root around the L4 pedicle, and so forth.

Fragment dislocation in the supradiscal direction often causes double-root involvement, with simultaneous compression of the traversing and the exiting root. This involves the intrathecal traversing root and the exiting root from the segment above.

### APPROACH TO THE LAMINA

After incision of the skin and fascia, contact with the spinous process with a bone rasp leads to the upper corner of the interlaminar window. The bone rasp passes along the inferior part of the spinous process to the inferior part of the lamina and then to the upper interlaminar corner. With the 30° oblique view the surgeon looks at the lower part of the spinous process and the medial part of the inferior lamina which form the upper interlaminar corner (Fig. 47-2). The highest point of this corner has specific relation to the disc space of the segment. At L5-S1 this point lies above the disc, at L4-5 it lies at the disc level, and at L3-4 and higher it lies below the disc space.

The inferior part of the lamina in the upper interlaminar corner is not covered by the ligamentum flavum. The

**FIG. 47-2.** A surgeon's 30° oblique view of the upper areas of a left-sided interlaminar window. Bony contact with the inferior part of the spinous process leads directly to the upper interlaminar corner.

superior part of the lamina in the lower interlaminar corner is much thinner and is partially covered by the ligamentum flavum. Before entering the spinal canal by flavectomy it is useful to take another X-ray with a dissector in the upper interlaminar corner, which is much closer to the disc than the needle used to radiographically localize the proper level for skin incision.

### SURGICAL VIEW THROUGH INTERLAMINAR WINDOW AND DISTRIBUTION OF FRAGMENT LOCATION

After removal of the ligamentum flavum from the lateral interlaminar area, epidural fat and the lateral portion of the dura and the traversing root appear. It is not necessary to remove the ligamentum flavum in the medial interlaminar area in order to expose nerve roots. The L5-S1 disc lies in the middle of the interlaminar approach to L5-S1, directly under the traversing S1 root. In the middle of the interlaminar approach to L4-5, directly under the traversing L5 root, lies the infradiscal area of the L5 vertebral bone surface.

Exiting roots cannot be seen from this approach, they can only be estimated. On a left-sided approach, the foramen and exiting root are on the surgeon's left, and on a right-sided approach they are on the surgeon's right. The segmental pedicle is on the opposite side (Fig. 47-3A,B).

In addition to the four main directions—cranial, caudal, medial, and lateral—there are intermediary planes (cranio-medial, cranio-lateral (foraminal), and caudomedial) for describing fragment migration. Caudolateral position of a fragment is not possible because of the presence of the pedicles. Even if a fragment lies lateral to the traversing root in the infradiscal area, it is still in the paramedial zone because the lateral border to this zone is the pedicle. Infradiscal caudal herniations are the most frequent indication for open surgery (59%). The disc fragment lies between bone and the traversing root, which is immobile because of the presence of the pedicle laterally. Hernia-

**FIG. 47-3. A, B:** Left-sided microscopic interlaminar approach to the lumbar spine. In front of the approach is the dural sac with the traversing root inside. Only at the disc and infradiscal levels of L5-S1, and sometimes at the infradiscal level of L4-5, is there a traversing nerve root surrounded by a nerve root sheath.

tions in other directions less frequently come to surgery. The distribution of fragment migration in patients who have been treated conservatively is completely different from that in surgically treated patients (12).

#### FOUR STEPS TO THE DISC

##### First Step: Skin

Needle localization with X-ray is generally more accurate than localization by palpation. The needle should be placed at a 90°-angle to the skin, approximately 2 to 3 cm paramedically on the contralateral side (Fig. 47-4).

Palpation of iliac crest and spinous processes is often misleading because of anatomic variations and difficulty in palpating bony landmarks in obese patients. The 3 cm skin incision is placed centrally at the appropriate level. For supradiscal and discal herniations of L3-4, L4-5, or L5-S1 the incision is placed at the level of the spinous process. For infradiscal herniations, the incision should be slightly below the spinous process.

##### Second Step: Ligamentum Flavum

After incision of the fascia and stripping aside the back muscles, palpation along the inferior part of the spinous process leads to the upper interlaminar corner (Fig. 47-2). The highest point in this upper interlaminar corner is the best place to enter the spinal canal. When the skin incision is correctly centered over the L5-S1 disc, the upper interlaminar corner is the cranial part of the approach; for the L4-5 disc it is in the middle of the approach. For L3-4 discs and higher the upper interlaminar corner is in the caudal part of the approach (Fig. 47-5). A modified Casper retractor is inserted to maintain exposure.

Before opening the spinal canal the upper interlaminar corner of the inferior part of the lamina has to be identi-

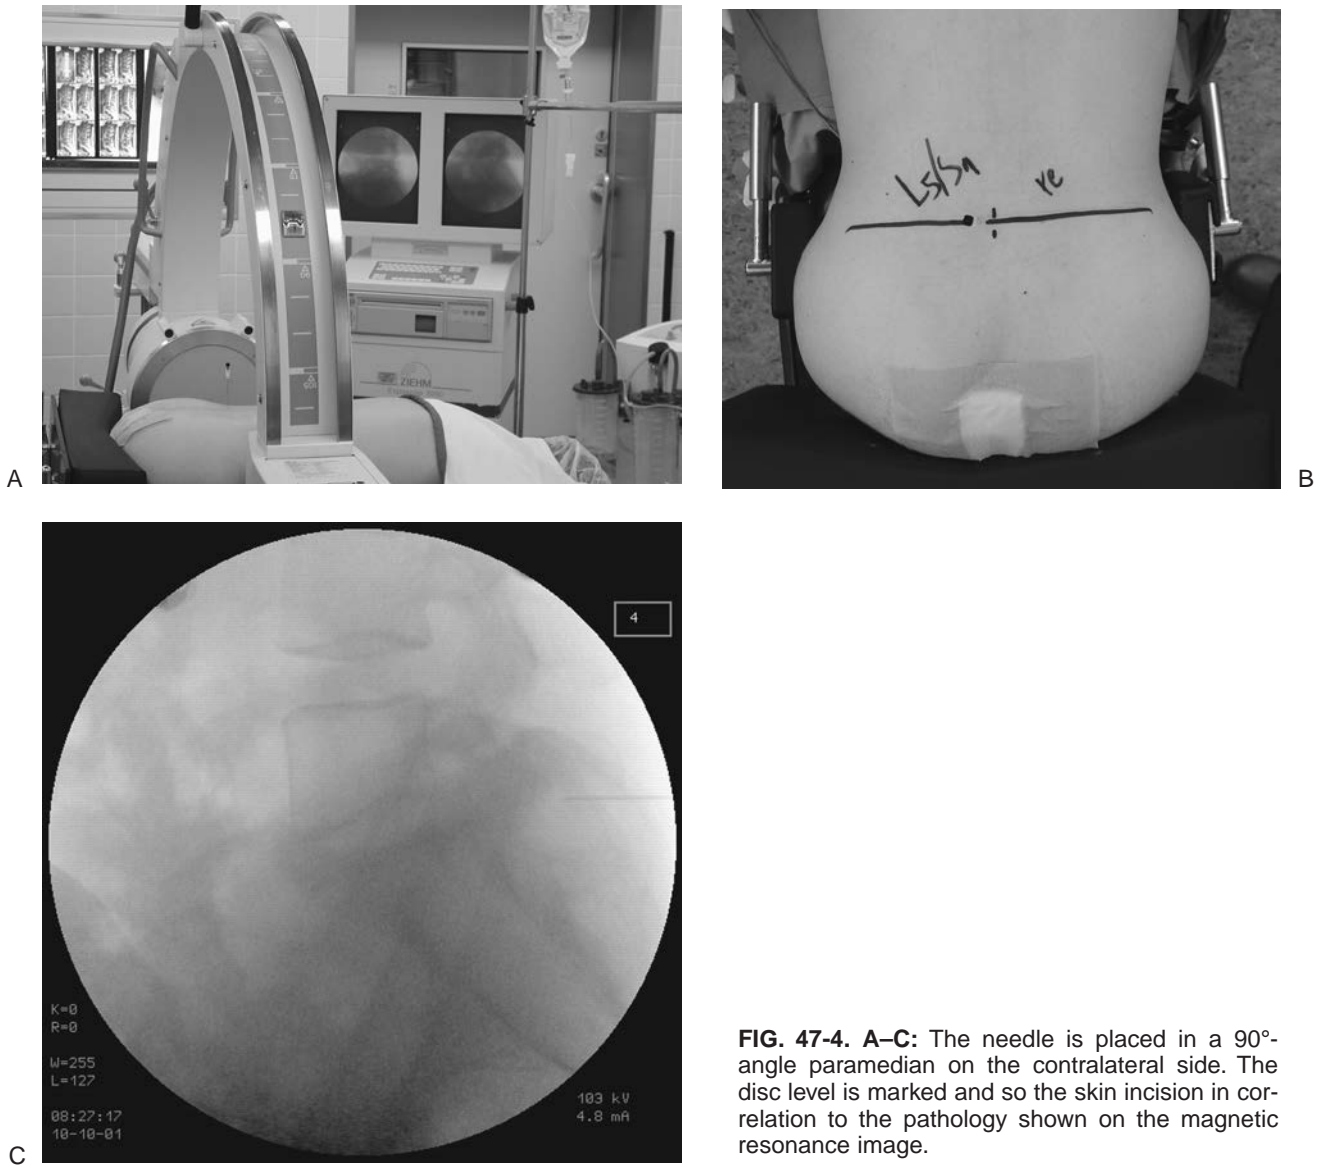

fied in relationship to the needle landmark in order to know where to find roots pedicle and discs in microscopic discectomy without further exposure.

##### Third Step: Posterior Epidural Space

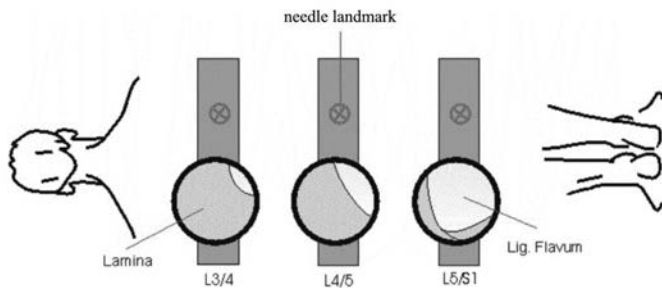

The spinal canal should be opened to reach the parent disc even if fragments have migrated. After removal of ligamentum flavum and parts of the lamina the posterior epidural space can be visualized. In the lateral part of the interlaminar window at L5-S1 the surgeon has a direct view on the transversing S1 root that is sometimes covered or surrounded by epidural fat. At L4-5, and in higher segments, the interlaminar window is more medial and the dural sac wider so that the transversing root is covered by the lateral dural sac.

##### Fourth Step: Anterior Epidural Space

Medialization of the transversing root with a lone nerve root retractor allows a direct view of the disc level at L5-S1 after flavectomy and of the L4-5 and more proximal levels after additional bone removal of the lamina in the upper interlaminar corner. At L4-5 and higher levels a flavectomy without laminotomy exposes the anterior epidural space on the vertebral bony surface of the infradiscal zone. This area has many epidural veins and should not be exposed if the pathology is at the disc or supradiscal level. Medialization of the dura and nerve root, extraction of the disc prolapse, and wound closure are the same as with conventional discectomy. A specialized disc extractor with a depth block is recommended in order to avoid anterior perforation of the annulus fibrosus with possible injury to the abdominal vessels (Fig. 47-6).

**FIG. 47-4. A–C:** The needle is placed in a 90°-angle paramedian on the contralateral side. The disc level is marked and so the skin incision in correlation to the pathology shown on the magnetic resonance image.

**FIG. 47-5.** Second step: lamina flavum at the disc level. When the skin incision is centered over the disc at L5-S1 the approach exposes the ligamentum flavum with the upper interlaminar corner cranially located. At L4-5 the upper interlaminar corner is in the middle and at L3-4 it is caudal and medial.

**FIG. 47-6. A, B:** Rongeur with a depth guard for intradiscal maneuvers to avoid anterior vessel injury (Aesculap).

**LIGHT SOURCES**

Good lighting is mandatory for a microsurgical approach. If there is no microscope available, a headlamp can be useful, although only the surgeon will have an adequate view. The use of a microscope is excellent for teaching conditions—the assistant has the same view as the surgeon—and it also provides optimal illumination and magnification of the operating field. Performing surgery with an operating microscope (Fig. 47-7) demands a certain level of training and the learning curve may vary between surgeons. The adapting time can be individually different. Nevertheless, a surgeon who uses a microscope should be able to switch over to the head lamp if technical problems with the microscope occur.

**FIG. 47-7.** Operating microscope. Surgeon and assistant have the same view.

**INSTRUMENTS**

The standard instruments used for the microsurgical approach to the lumbar disc are designed for manipulation in the spinal canal and are thin with a special angular shape.

**RESULTS**

The reported results of microscopic lumbar discectomy vary. These variations are the result of different indications for surgery and different outcome measures. Results after microsurgical procedures are reported by Caspar (13), Kahanovitz (14), Krämer (15,16), McCulloch (6), Silvers (2), Williams (17), Wilson (18), and Zahrawi (19).

Two trials were conducted comparing microdiscectomy with standard discectomy, both included clinical outcomes that were similar (20,21). Because of different outcome measures, metaanalysis is generally not possible (22).

**EARLY COMPLICATIONS IN MICROSCOPIC LUMBAR DISCECTOMY**

The complications of open disc surgery and microscopic discectomy are discussed mainly in books of experienced spine surgeons (6,23).

In the European Spine Society questionnaire (24) to evaluate a risk and value score for different diagnostic and therapeutic procedures in the spine, open discectomy had the highest effectiveness for pain relief, but a negative overall risk value score because of complications and poor results. Our recent studies evaluated different factors that influenced the outcome of open lumbar disc surgery (24,25).

## Classification

Complications of open lumbar disc surgery may be classified as intraoperative, immediate postoperative, and late postoperative according to when they are apparent rather than when they occur. Complications of lumbar spine surgery can either be general, and therefore common to any type of surgery, such as thrombosis, embolism, and anesthetic problems, or they may be specific for spine surgery.

Intraoperative complications are recognized immediately by the surgeon and should be recorded. Operative reports are not always complete so their true frequency remains uncertain. Many of these problems can be avoided by meticulous preoperative planning. Some intraoperative complications are common, such as epidural bleeding and durotomy, and can be managed quite easily. Other complications, such as anterior vessel and visceral injury, are severe, but fortunately extremely rare.

Immediate postoperative general complications such as vomiting, thrombosis, and circulatory problems can occur after any kind of surgery. Some of the specific spine complications occurring during the operation may be initially unrecognized by the surgeon and become symptomatic and obvious in the days following surgery. These include complications secondary to patient positioning, abdominal symptoms, and bladder disturbances.

Late postoperative complications after lumbar disc surgery may become obvious after the patient leaves the hospital. These include general complications like thromboembolism as well as specific complications such as recurrent disc herniation, spondylodiscitis, and the failed back surgery syndrome due to peridural fibrosis and instability. Late complications can only be evaluated by questionnaires or follow-up studies with patient examination since not all patients consult their surgeon when these complications arise.

## Intraoperative Complications

### *Missed Preoperative Checklist*

The surgeon performing a lumbar disc operation should examine the patient just prior to the surgical procedure to verify any recent change in symptoms or new findings. Symptoms can change in a short time because of fragment migration or resorption. A difference in visualization between MRI and intraoperative X-ray findings must be recognized. Sometimes a lumbosacral segment can be seen on MRI but not on X-ray. General anesthesia should commence only when all preoperative imaging is complete including an X-ray with the needle localization.

### *Wrong Level Exploration*

Precise preoperative planning is one of the main prerequisites for successful microsurgery and avoiding

wrong level exploration. For McCulloch (6) it is the most important prerequisite. In our comparative study (25), wrong level exploration occurred 1.2% of the time in a group of very experienced surgeons and 3.3% of the time in a group of less experienced surgeons.

Wrong level exploration is more likely to occur at L4-5 and higher segments than at L5-S1. In all cases the correct segment was ultimately identified intraoperatively by X-ray. As described previously it is useful to take a second X-ray with a dissector in the upper interlaminar corner before flavectomy.

### *Missed Pathology*

Missed pathology means that the compressive pathology causing the clinical symptoms was not adequately addressed. This can happen when wrong level exploration is not recognized and other nonsignificant pathology is removed. Under such circumstances the patient awakes with the same pain or worse than before surgery.

If the suspected intraoperative pathology is not found, an intraoperative myelogram can be considered.

### *Other Pathology*

Other pathology means the surgeon finds a different pathologic entity than what was expected but which could have caused the clinical symptoms. This could be an undiagnosed neurinoma or a synovial cyst from the facet joint. In these cases a closer look at the imaging pictures should be undertaken. In some cases it might be necessary to perform an intraoperative X-ray or myelogram to identify missed pathology.

### *Bleeding or Epidural Hematoma*

Epidural hematoma causing symptomatic neurologic compression or cauda equina syndrome is one of the most feared complications of spine surgery. During a posterior approach, lumbar spinal canal arterial bleeding from the back muscles and epidural venous bleeding are the most important causes for such bleeding. Intraoperative bleeding can be minimized by positioning the patient prone with the abdomen hanging freely.

Arterial bleedings from the back muscles should be identified and coagulated carefully.

At the end of the surgical procedure, after the muscle retractor is removed, the muscle walls should be checked for bleeders because prolonged muscle retraction may temporarily occlude potentially significant muscle bleeders, which could begin bleeding after muscle layer closure. When an epidural hematoma is identified, surgical intervention must be performed as soon as possible to evacuate the hematoma.

Epidural vein bleedings do not cause compression of the dural sac, but do cause cauda equina syndrome. Some

experienced spine surgeons (26–28) believe that epidural vein bleeding often stops when the disc fragment is removed and after wound closure. We prefer to tamponade as long as possible before using bipolar cautery. Excessive cautery of epidural veins may inhibit the nutrition of the nerve roots and may be the cause of epidural fibrosis and postdiscectomy syndrome (failed back syndrome).

An epidural hematoma, even if it does not compress the dural sac, can also cause epidural fibrosis. The main reason to prevent and stop bleeding from epidural veins is that they obscure the visual field. Because of the limited approach in microdiscectomy, even a small amount of bleeding may appear as a major hemorrhage under the microscope and make it difficult to perform a safe and adequate discectomy. Therefore the following precautions should be followed to prevent intraoperative bleeding:

- positioning of the patient with abdomen hanging freely
- avoid exploring the posterior surface of the vertebra if it is not necessary
- retract epidural veins with the retractor before entering the disc space
- cauterize veins if they are in the way.

If epidural vein bleeding occurs it may be better to remove as much of the protruded disc material as possible before taking care of the bleeding. The bleeding during this maneuver could be managed by continuous suction and the use of cotton tamponades. After removal of the disc prolapse, it is easier to expose the bleeding vein and cauterize it if necessary.

For continuous bleeding from cancellous bone we use a small amount of bone wax.

In our series excessive bleeding occurred in 7.1% of patients treated by the group of experienced surgeons and in 3.5% of the patients treated by the group of very experienced surgeons. In all cases, excessive epidural vein bleeding did not cause intraoperative or immediate postoperative complications (25).

### **Durotomy**

Injuries to the dura with loss of cerebrospinal fluid (CSF) occur in many types of spine surgery. Clear fluid in the wound should not automatically mean dural tear. It could also arise from a puncture hole from previous myelography, from a spinal anesthetic, or from inadvertent dural puncture from an epidural injection days before surgery. Other causes of intraoperative fluid include synovial fluid from facet joints (6) or from a wet cotton patty.

Unfortunately presence of clear fluid usually means CSF from inadvertent durotomy by surgical instruments. Most commonly this occurs during opening of the dura by incision of the ligamentum flavum. This can happen when the ligamentum flavum is very thin, which

occurs with lumbosacral anomalies (6), or when a big disc herniation displaces the dural sac posteriorly under the ligamentum flavum. This is why we prefer a two-step flavotomy with a special semi-sharp dissector. Under special conditions, intentional durotomy is necessary to deal with intradural pathology, which is rare in lumbar disc surgery (6).

When a CSF leak is recognized, localization and assessment of the injury must be determined: Is it medial or lateral, caused by incision or punch, are nerve roots involved? When the durotomy is localized, it is better to avoid it in order not to inadvertently enlarge the hole. After the disc herniation is removed, there is more space and less tension on the dura and suture repair is easier. A head down/back up position reduces dural tension and empties the dural sac. Tears of more than 3 mm in length should be closed with 6-0 sutures. Usually, the microsurgical exposure must be extended. Small punctures can be left alone. We prefer to put a small free fat graft from the subcutaneous fat to the dural repair. The patient should have intravenous antibiotics and be kept in bed for 3 days.

Complications of dural tears include headache due to CSF loss, CSF fistula, and postoperative pseudomeningocele, which can be seen by MRI. Our own experience with a follow-up study comparing patients who had intraoperative dural tears with a control group showed better results in the control group (25). With a two-step blunt perforation of the ligamentum flavum, appropriate instrumentation, and good visualization of the lateral dura and nerve root border it should be possible to reduce the number and extent of dural tears in lumbar microdiscectomy to a minimum. In conclusion, durotomies are a matter of experience. They occurred in the group of less experienced surgeons 7.2% of the time and among the very experienced surgeons 0.8% ( $p < .001$ ) of the time (25).

### **Nerve Root Lesion**

The incidence of nerve root lesions after lumbar spine surgery has been estimated at 0.2% (29). Such injury may be suspected postoperatively by the presence of a new or increased neurologic deficit. Iatrogenic intraoperative nerve root injuries are classified by the site where they occur, proximal to the foramen or extraforaminal, and by the way in which the injury occurs: open by sharp instrumentation or closed by excessive traction, compression, or heat from electrocautery. Poor visibility, perineural adhesions, and congenital neural anomalies such as conjoined nerve roots are the most common causes of damage to the nerve roots. Therefore, it is absolutely necessary to define the lateral border of the root and dural sac before removing any material from the spinal canal. Even when the neural elements are safely retracted by a nerve root retractor, the tissue in the anterior epidural space should be identified by the 2 mm dissector. The bright

white of disc material should not be mistaken for epidural fat and vessels.

Rootlets may herniate through a durotomy. After reduction of the rootlets the dura must be repaired. Small defects may be covered by a free fat graft especially if a suture could strangle the nerve root. The most vulnerable area for an open nerve root lesion is the axilla of the exiting nerve root. Thus effects to remove intradiscal fragments should not take place medial to the nerve root in the axilla. One of the principles of microdiscectomy is to stay lateral to the nerve root in order to avoid axillary injury.

### *Anterior Vessel Injury, Visceral Injuries*

When a rongeur penetrates the anterior annulus fibrosus, it may contact a major vessel that lies immediately in front of the lower lumbar discs. Grasping maneuvers in order to clean out the disc material may rupture the vessels. The most frequent lesion is an isolated injury to the left common iliac artery (30) caused by surgery of the L4-5 disc. The overall complication rate for anterior vessel injury is 0.045% (31). Only 50% of such injuries are immediately apparent with a dramatic unexplained fall in blood pressure and excessive hemorrhage from the disc. In these cases disc surgery has to be stopped immediately, the wound closed, and the patient turned over for a laparotomy and repair of the injured vessel.

In 50% of the patients the symptoms of anterior vessel injury and other abdominal injuries are recognized later in the recovery room with extreme hypotension and painful abdominal swelling. In these cases, laparotomy must be performed immediately. Even with prompt action, the mortality of this complication is approximately 50% (6). Prevention of this major complication is possible if intradiscal maneuvers are performed only with rongeurs that cannot be inserted deeper than 25 mm. This leaves an adequate safety margin since the anteroposterior disc diameter is 35 to 40 mm on average (Fig. 47-6).

### **Immediate Postoperative Complications**

#### *Postoperative Leg Pain and Neurologic Deficits (Table 47-1)*

Although not usually considered a complication in most series, persistent or residual leg pain after nerve root decompression surgery of the lumbar spine can be considered a complication. If the correct level was operated upon, and if neurologic symptoms are not severe or progressive, one can wait.

It is important, however, to consider the possibility of a residual disc fragment or a recurrent herniation. Indications for a careful postoperative neurologic examination and a repeat computed tomography (CT) or MRI study are:

- severe leg pain lasting more than 2 to 3 days

- progressing neurologic deficit
- cauda equina syndrome.

When a nerve root has been compressed for a long time by a disc herniation or an osteophyte it may not become asymptomatic immediately after decompression. The reasons for residual symptoms are not completely understood, but include the duration of compression, the presence of comorbidities such as diabetes, intraoperative nerve injury, compression from a hematoma, inadequate postoperative pain medication, and individual pain sensitivity.

In addition to wrong level exposure, missed additional pathology at the current level is another cause of failed lumbar disc surgery. Additional disc fragments can be missed or concomitant bony stenosis may not be appreciated and thus decompressed. The patient may awake from surgery with the same pain or it might even be worse because of additional operative trauma and postoperative hematoma. Repeat CT or MRI should be performed to detect the missed fragment or other pathology.

Continued postoperative leg pain and neurologic symptoms of the same or increased intensity as before surgery can be caused by either missed pathology or by an early recurrent disc herniation. This could be caused by abdominal pressure such as by coughing during the immediate postoperative period.

Usually symptoms from a recurrent disc prolapse occur after a pain-free interval. It may occur when the patient begins to stand and axially load the spine with more frequency. In our series we had 0.2% rate of recurrent disc herniation in the first week after surgery. Once a new herniation is verified by repeat CT or MRI conservative management or revision surgery at the same level may be considered. The risk of recurrent disc herniation cannot be eliminated by extensive disc curettage (6,29,30). It is generally recommended that all disc material under the annulus perforation that could lead into a recurrent herniation be removed at the time of the initial surgery.

All variations of the kneeling position that are used in lumbar disc surgery can produce compression on the skin and neurologic structures. Brachial plexus stretch injuries and compression of the radial and ulnar nerve can develop by the hyperabduction of the arm. Bernsmann (32) observed two cases of slight brachial plexus dysfunction in our series, all of which disappeared in the first few days following surgery. Severe lesions from position-

Residual symptoms from original condition
Intraoperative nerve root injury
Residual fragment disc, foreign body retention
Early recurrent disc herniation
Nerve irritation secondary to intraoperative positioning

ing, such as cervical myelopathy from hyperextension of the neck, or visual disturbances (6,33,34) from failure to protect the eyes during surgery and in the prone position are very rare and should be avoided by proper head positioning.

There is a wide range of possible cauda equina symptoms, from slight bladder disturbances to the fully developed cauda equina syndrome with perineal anesthesia, urinary incontinence and decreased rectal tone, and bilateral progressive leg weakness.

The absence of any of these clinical features does not rule out a developing cauda equina syndrome.

Injury to the cauda equina can occur at surgery from direct damage to the nerves or postoperatively from hematoma. We have not seen a cauda equina syndrome from fat graft compression in our large prospective randomized study of free fat graft versus no fat graft for epidural scarring (9), although this condition has been reported by others.

Concern about a possible cauda equina syndrome mandates a thorough neurologic examination and immediate CT or MRI. If a compression lesion is found, immediate surgery to decompress the cauda equina is necessary, although a study showed that there is no statistically significant difference in outcome between patients who had decompressive surgery within the first 20 hours after the onset of cauda equina syndrome and those who had surgery 24 to 48 hours after onset (35).

The reported incidence of disc space infection ranges from 0.13% to 0.9% (6,30,36–38). Most studies recommend infection prophylaxis with antibiotics.

It has been claimed that microdiscectomy has a higher infection rate than standard disc surgery because of contamination by the microscope. However, publications on microdiscectomy surgery (30) and our own experience show that the deep wound infection rate in microdiscectomy surgery is not significantly higher than with traditional discectomy.

## CONCLUSIONS

It is impossible to avoid all complications in any surgery, including lumbar microdiscectomy. According to McCulloch (6), the two major criticisms of microdiscectomy are wrong level exploration and missed pathology. If wrong level exposure is not recognized, pathology will be missed. The risk of complications with lumbar microdisc surgery can be minimized if meticulous attention is given to preoperative, intraoperative, and postoperative details (24). It is helpful for spine surgeons to master the microsurgery learning curve by working with other experienced spine microsurgeons and to read the literature about how to avoid intraoperative complications and how to manage them if they occur.

The outcome of lumbar disc surgery depends heavily upon proper patient selection (Table 47-2). The right

Postoperative care

patient with the right indication for microscopic disc surgery will have a good result if a well-trained surgeon removes the disc fragment using a standard approach. The learning curve in micro-decompression surgery can be improved upon in special training courses that provide instruction for working with the microscope on cadaver spines. Infection can be decreased by careful draping of the microscope and by the use of prophylactic antibiotics. Recurrent disc herniation is an uncommon but important complication in lumbar disc surgery that may result in another operation with a greater risk for complications and scar formation. In many cases it is the beginning of a failed back surgery syndrome.

# Classification, Natural History, and Clinical Evaluation

Yong Hai

---

Lumbar spinal stenosis is defined as the reduction in the diameter of the spinal canal, lateral nerve canals, or neural foramina. The stenosis may occur as a part of a generalized disease process and involve multiple areas of the canal and multiple levels or, conversely, may be localized or segmental. The reduction in the diameter of the spinal canal or neural outlets may be attributable to bone hypertrophy, ligamentous hypertrophy, disc protrusion, spondylolisthesis, or any combination of these elements. This clinical entity is used to describe a complex set of symptoms, physical findings, and radiographic abnormalities caused by a narrowed spinal canal. Pain in the back and leg(s) and, in particular, claudication caused by compression and ischemia of nerve roots are the main symptoms. Although it is one of the most common spinal disorders in people older than 65 years, and frequently causes significant functional impairment (1), there is still some uncertainty in diagnosing and treating lumbar canal stenosis, including:

1. Though nearly all people in this age group have radiographic evidence of degenerative disc and joint disease, the incidence of clinically symptomatic lumbar canal stenosis is unknown.
2. The diagnosis is largely clinical. Although imaging studies can confirm the diagnosis, they often show abnormalities in people with no symptoms.
3. Treatment is mostly empiric. Although lumbar canal stenosis is the most common reason for spinal surgery in this older population group (2) and accounts for inpatient expenses approaching \$1 billion per year (3), no comparison of surgical versus nonsurgical treatment has ever been done.

Lumbar spinal stenosis has been known for more than 100 years, but for a long time it was simply not addressed. This occurred because the association between herniated vertebral discs and sciatica received most of the

attention after it was discovered by Mixter (4) in 1934. However, since the early 1950s, starting with the studies of Verbiest (5), this has changed, and lumbar spinal stenosis now is an accepted clinical entity and a well-recognized spinal disorder.

Stenosis is most frequently a sequela of the aging process, usually readily identifiable on imaging studies as evidenced by the high incidence of positive radiographic findings in asymptomatic patients (6–8). The presence of a narrow canal on radiographic imaging studies does not by itself define the syndrome. Rather, the syndrome is defined by a complex set of symptoms and clinical findings that must be supported by radiographic evidence. Patients with spinal stenosis often present with few objective physical findings. Up to 95% of patients treated surgically have only subjective symptoms, mainly pain (9,10). Accurate diagnosis and treatment decisions must be based on a thorough knowledge of the clinical syndrome and natural history (11–15). Vascular claudication in particular (16) must be considered in the differential diagnosis, in addition to lumbar spondylosis, peripheral vascular disease, and peripheral neuropathy.

### CLASSIFICATION

The classification of lumbar stenosis is important because of the implications of the underlying etiology of the condition and when forming a therapeutic strategy, specifically directing surgical approaches (17).

Spinal stenosis may be classified by either its etiology or location. The classification of spinal stenosis proposed by Arnoldi (18) in 1976 remains useful and is still the most widely used classification. He divided lumbar stenosis into two major groups: congenital or developmental stenosis, and acquired stenosis. Congenital stenosis (primary stenosis) is present at birth as part of a malformation and is divided into idiopathic and achon-

droplastic etiologies. In contrary, acquired stenosis (secondary stenosis) is present in patients with symptoms and signs of stenosis but with normal dimensions of the original vertebral canal and is further classified into degenerative, combined congenital and degenerative, spondylotic and spondylolisthetic, iatrogenic posttraumatic, and metabolic. Degenerative stenosis of the lumbar region is the most common type of spinal stenosis. Symptomatic lumbar stenosis typically occurs in patients in the fifth to seventh decades of life with a reported incidence from 1.7% to 10%, and as the population ages, a greater number of patients will need to be treated for this condition (19–23). Although there may be a structural predisposition to spinal stenosis (congenitally short pedicles), symptomatic narrowing of the spinal canal usually is seen in association with osteoarthritic changes of the lumbar spine. Men and women seem to be affected equally with spinal stenosis; however, women are afflicted with associated degenerative spondylolisthesis four times more often than men (24).

Anatomic classification refers to central canal stenosis, lateral recess stenosis, or neural foraminal stenosis.

Central stenosis refers to a narrowing of the spinal canal across the anteroposterior diameter, the transverse diameter, or both (17,25,26). The central canal is enclosed anteriorly by the posterior portion of the vertebral body and the vertebral disc and posteriorly by the lamina and the base of the spinous process. Central canal stenosis, commonly occurring at an intervertebral disc level, defines midline sagittal spinal canal diameter narrowing that may elicit neurogenic claudication or pain in the buttock, thigh, or leg. Such stenosis results from ligamentum flavum hypertrophy, inferior articulating process, facet hypertrophy of the cephalad vertebra, vertebral body osteophytosis, and herniated nucleus pulposus (27,28). Stenosis at multiple levels is more common than strictly segmental stenosis. In approximately 40% of cases, central stenosis is caused by soft tissue hypertrophy. On computed tomography (CT) scans, midsagittal lumbar canal diameters less than 10 mm represent absolute stenosis and midsagittal lumbar canal diameters less than 13 mm represent relative stenosis (29).

Entrapment and compression of the nerve root in its pathway through the spine, referred to as the nerve root canal, is termed *lateral stenosis* (17,25,26,30,31). The nerve root canal begins where the nerve root exits the dura and ends where the nerve root leaves the intervertebral foramen. The nerve root canal is bordered by the pedicle of the vertebra above and the pedicle of the vertebra below. The anterior side of the canal is formed by the vertebral body and vertebral disc. The posterior side of the canal is formed by the facet joint structures of the vertebrae above and below. Lateral stenosis occurs when the spinal nerve is compressed within the nerve root canal or the vertebral foramina (32). As the disc narrows, the pedicle may move in an inferior direction, narrowing the

lateral recess and pinching the spinal nerve (33,34). MacNab (35) originally described this entrapment and compression of the nerve root between a diffuse lateral bulge of the disc and the pedicle above as pedicular kinking. Narrowing of the lateral recess can also be the result of facet hypertrophy or enlargement and ossification of the ligamentum flavum. Radiculopathy, or decreased function of a nerve root, is commonly observed with lateral stenosis.

Lateral recess stenosis (i.e., lateral gutter stenosis, sub-articular stenosis, subpedicular stenosis, foraminal canal stenosis, intervertebral foramen stenosis) is defined as narrowing (less than 3 to 4 mm) between the facet superior articulating process and posterior vertebral margin. Such narrowing may impinge the nerve root and subsequently elicit radicular pain. This lateral region has been compartmentalized by several authors into entrance zone, mid-zone, exit zone, and far-out stenosis (30,31,36).

The *entrance zone* lies medial to the pedicle and superior articulating process, and, consequently, arises from facet joint superior articulating process hypertrophy. Other causes include developmentally short pedicle and facet joint morphology, as well as osteophytosis and herniated nucleus pulposus anterior to the nerve root. The lumbar nerve root compressed below superior articulating process retains the same segmental number as the involved vertebral level (e.g., L5 nerve root is impinged by L5 superior articulating process).

The *mid-zone* extends from the medial to the lateral pedicle edge. Mid-zone stenosis arises from osteophytosis under the pars interarticularis and bursal or fibrocartilaginous hypertrophy at a spondylolytic defect.

*Exit zone* stenosis involves an area surrounding the foramen and arises from facet joint hypertrophy and subluxation, as well as superior disc margin osteophytosis. Such stenosis may impinge the exiting spinal nerve.

*Far-out* (extraforaminal) stenosis entails compression lateral to the exit zone. Such compression occurs with far lateral vertebral body end-plate osteophytosis and when the sacral ala and L5 transverse process impinge on the L5 spinal nerve (8).

In order to correlate the classification of lumbar spinal stenosis with surgical planning, Hansraj et al. (37,38) introduced a classification of typical and complex lumbar spinal stenosis. Typical lumbar spinal stenosis was classified in those patients:

- who did not undergo previous lumbar spine operations
- who did not have radiographic evidence of instability
- who had degenerative spondylolisthesis at most grade 1, with no instability, if present
- who had degenerative scoliosis with a curve less than 20°, if present.

In their study, patients with typical lumbar spinal stenosis were treated with decompressive surgery. Complex lumbar spinal stenosis was classified in patients with

- lumbar spine operations with evidence of radiographic instability, if present
- radiographic evidence of postoperative junctional stenosis, if present
- degenerative spondylolisthesis greater than grade 1 with instability, if present
- degenerative scoliosis with a curve greater than 20°, if present.

These patients were treated with decompressive surgery and also underwent surgical stabilization.

## NATURAL HISTORY

The natural history of lumbar spinal stenosis is not well understood. A slow progression appears to occur in all affected individuals. Even with significant narrowing, such persons are very unlikely to develop an acute cauda equina syndrome in the absence of significant disc herniation. Anecdotally, the clinical course varies considerably. In most patients, the course is chronic and benign (32,39,40).

Only one study has been concentrated on the natural course of lumbar spinal stenosis. In 1992, Johnsson et al. (40) reported on 32 patients followed up for an average of 49 months (range, 10–103 months). Fifteen percent of the patients were improved, 70% were the same, and 15% were worse. The patients received no specific nonoperative therapy. Two of the patients were not operated on because of advanced cardiovascular disease, and the remainder of the patients refused surgical treatment. No proof of deterioration was found after 4 years, and the authors concluded that the condition of the majority of patients with lumbar stenosis who were treated conservatively remained unchanged over a period of 4 years. However, the patients did not improve either, so surgical decompression may be an option as decompression of the symptomatic level yields a high rate of improvement.

Numerous other nonoperative outcome studies for lumbar spinal stenosis have been published. In 1996, Atlas et al. (41) assessed the outcomes of 81 patients who were treated surgically and 67 patients who were treated conservatively after 12 months. Although the conditions of patients who underwent surgery were worse clinically and radiographically at the start of the study, their results were better after treatment than the results of the patients who were treated conservatively. For 28% of patients who were treated conservatively, pain was better to completely gone, and for 15%, the pain was much worse. In 2000, the same authors (42) reported their results of 4 years' follow-up in their perspective study of surgical or conservative treatment of lumbar spinal stenosis. Among 119 patients, 67 were treated surgically and 52 were treated conservatively. After 4 years, 70% of the surgically treated and 52% of the conservatively treated patients reported that their predominant symptom, either leg or

back pain, was better. Satisfaction of patients with their current state at 4 years was reported by 63% of the surgically treated and 42% of the conservatively treated patients. Surgical treatment remained a significant determinant of 4-year satisfaction. For the conservatively treated patients, there was no significant change in outcomes over 4 years, whereas the initial improvement seen in the surgically treated patients modestly decreased over the subsequent 4 years.

Swezey (43) reported on the outcomes of 47 patients who had been evaluated 5 years earlier for lumbar spinal stenosis. Patients had symptoms of neurogenic claudication, and CT or MRI findings of moderate to severe stenosis (43 patients) or severe spondylosis by plain radiographs (4 patients). Treatments included instruction of ergonomics and flexion exercise, analgesic medications, intermittent pelvic traction (11 patients), and epidural steroids (13 patients). Eleven patients required laminectomy. Of the patients who were treated conservatively, 43% were improved. Symptoms of neurogenic claudication were unchanged in 30%.

Simotas et al. (44) reported 49 patients with lumbar stenosis treated conservatively with an average follow-up of 3 years. At 3 years following treatment, 9 of the 49 patients had undergone surgical intervention. Of the remaining 40 unoperated patients, it is reported that two suffered significant motor deterioration, one of whom still reported overall symptoms as mild improvement, and the other as definite worsening. Five of the 40 unoperated patients reported feeling overall symptoms as probably or definitely worse, 12 reported no change, 11 reported only mild improvement, and 12 reported sustained improvement. Twelve of the 40 unoperated patients also had no pain or only mild pain. The authors concluded that aggressive nonoperative treatment for spinal stenosis remains a reasonable option.

In a randomized study by Amundsen et al. (39), 100 patients with symptomatic lumbar spinal stenosis were given surgical or conservative treatment and followed for 10 years. Nineteen patients with severe symptoms were selected for surgical treatment and 50 patients with moderate symptoms for were chosen for conservative treatment, whereas 31 patients were randomized between the conservative (18 patients) and surgical (13 patients) treatment groups. After a period of 3 months, relief of pain had occurred in most patients. Some had relief earlier, whereas for others it took 1 year. After a period of 4 years, excellent or fair results were found in half of the patients selected for conservative treatment, and in four-fifths of the patients selected for surgery. Patients with an unsatisfactory result from conservative treatment were offered delayed surgery after 3 to 27 months (median, 3.5 months). The treatment result of delayed surgery was essentially similar to that of the initial group. The treatment result for the patients randomized for surgical treatment was considerably better than for the patients ran-

domized for conservative treatment. Clinically significant deterioration of symptoms during the final 6 years of the follow-up period was not observed. Patients with multilevel afflictions that were either surgically treated or not did not have a poorer outcome than those with single-level afflictions. Clinical or radiologic predictors for the outcome were not found. The authors concluded that the outcome was most favorable for surgical treatment, but an initial conservative approach seems advisable for many patients because those with an unsatisfactory result can be treated surgically later, with a good outcome.

As the population becomes older, this condition is encountered more frequently. The diagnosis accuracy has improved and the number of cases detected is increasing. Because of the relative unpredictability of surgical treatment, good knowledge of natural evolution and of the predictive factors influencing the course of the disease is crucial. Unfortunately, and in contrast with numerous surgical series, few studies have dealt with natural evolution. Only one randomized study (39) has compared short- and long-term results of medical versus surgical treatment. Most of these studies are retrospective, with methodologic flaws and are difficult to compare. At the present time no scientifically based recommendations can be made to lumbar spinal stenosis patients at diagnosis. Similarly, predictors of success of medical and surgical treatment still need to be identified. However, results of the studies published suggest that a substantial proportion of patients do not automatically deteriorate and will remain unchanged or even improved by medical means. Randomized studies with the necessary ethical precautions are needed to obtain clear-cut conclusions.

## HISTORY AND CLINICAL EVALUATION

Recognition of spinal stenosis depends primarily on the description of the leg symptoms. The history and physical examination are an essential component in the assessment of patients with lumbar spinal stenosis. Physical examination occasionally demonstrates neurologic deficits or exacerbation of symptoms with spinal positioning. However, many patients with spinal stenosis have no abnormal findings on examination. Spinal imaging confirms the clinical impression. Because many people who have no symptoms are found to have radiographic abnormalities, clinical correlation is critical.

Patients with lumbar spinal stenosis usually undergo a “staged” diagnosis (Fig. 48-1). The first diagnostic stage is the physician visit, during which the patient receives a physical examination. Results of the physical are combined with information from the patient history in a preliminary diagnosis. Lumbar spinal stenosis is not definitively diagnosed at this stage, so the diagnostic results are described as “consistent with” spinal stenosis or not consistent with spinal stenosis.

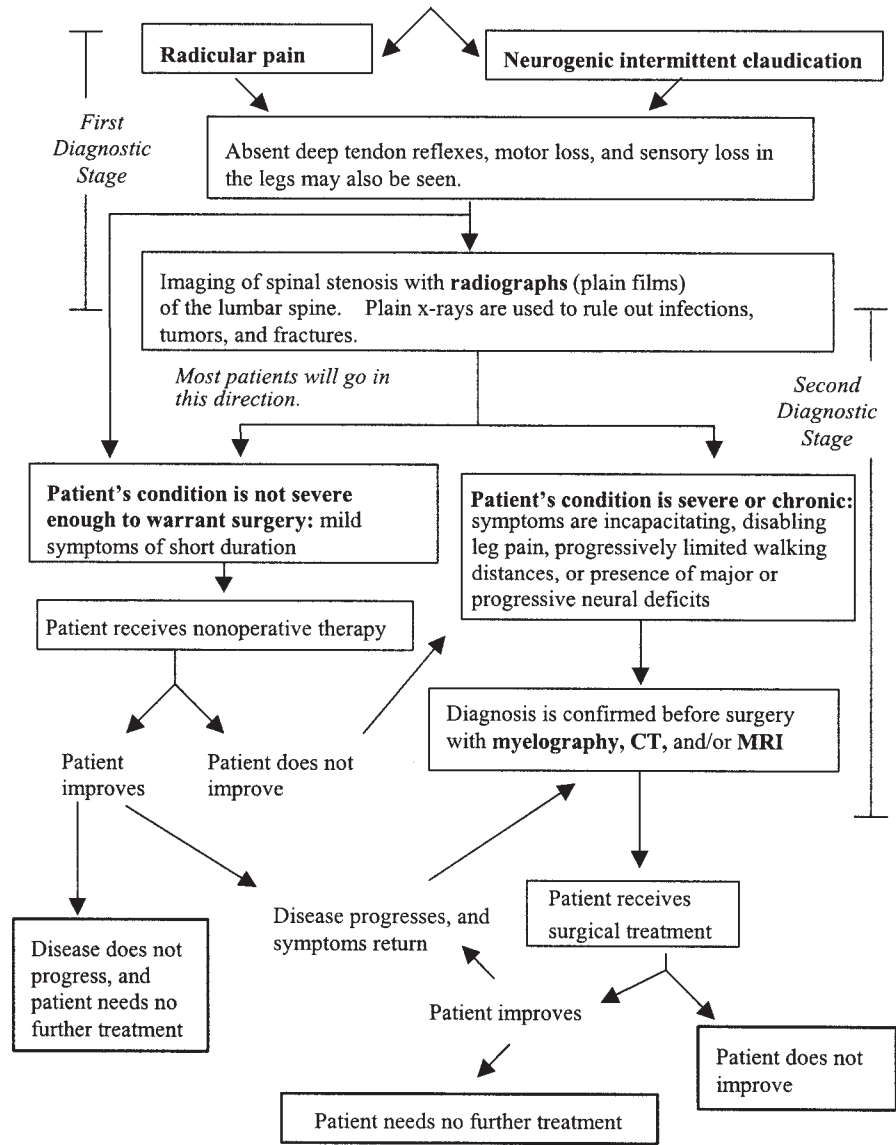

## History

Spinal stenosis typically affects persons over 50 years of age (45). It is uncommon in younger people unless they are anatomically predisposed by a congenitally narrowed canal, previous spine trauma or surgery, spondylolisthesis, or even scoliosis. The classic symptom of central canal stenosis is pseudoclaudication, also known as neurogenic claudication (1–3,45–47). Patients typically complain of pain, paresthesia, weakness, or heaviness in the buttocks radiating into the lower extremities with walking or prolonged standing, relieved with flexion or sitting. Though many patients have significant lumbar pain due to degenerative joint and disc changes, most have more lower extremity discomfort rather than spinal pain. The most important aspect of neurogenic claudication is the relationship of symptoms to posture. Symptoms occur with spinal extension and are relieved in flexion. Patients usually have no symptoms or have minimal discomfort when seated or supine. They can walk longer distances with less pain in a forward flexed position, such as when using a grocery cart while shopping (the “grocery cart sign”). They may be able to exercise using a stationary bicycle in the seated flexed position for a much longer time than when walking in the erect position on a treadmill. In a review of 68 patients with myelographically proven, surgically confirmed spinal stenosis (47), the most common symptoms were pseudoclaudication and standing discomfort (94%), followed by numbness (63%) and weakness (43%). Symptoms were bilateral in 68%. Discomfort was felt both above and below the knee in 78%, in the buttocks or thigh in 15%, and below the knee in 7%. Historic features correlating most strongly with a confirmed diagnosis of spinal stenosis (likelihood ratio 3:2) include age greater than 65 years, severe lower extremity pain, and absence of pain when seated (13).

## Physical Examination

The most important features of the physical examination are the motor, reflex, and the palpatory examinations. The physical examination in patients with lumbar canal stenosis is frequently normal or demonstrates only nonspecific findings. Many older people have reduced spinal mobility, with or without spinal canal stenosis. Extension is usually more limited than flexion (12,15). Patients with stenosis often have lumbar, paraspinal, or gluteal tenderness, probably related to underlying degenerative changes, muscle spasms, and poor posture. Some assume a characteristic “simian stance”, with their hips and knees slightly flexed and the trunk stooped forward (45). This semiflexed posture allows patients to stand or walk for longer distances. Hamstring tightness is often present and may produce a false-positive straight leg-raise test. The neurologic examination typically is normal or reveals only subtle abnormalities such as mild weakness, sensory changes, and reflex abnormalities. This is

**FIG. 48-1.** Diagnosis and treatment of lumbar spinal stenosis. Clinical symptoms at the time of presentation to the physician. Patient may have one or all of the symptoms.

particularly true if the patient has rested in the seated position before the physical examination begins. These subtle findings may be unmasked if the patient is examined after walking until developing leg and buttock symptoms similar to the presenting complaint (46).

Ankle reflexes are diminished in 43% to 65% of patients, while knee reflexes are abnormal in 18% to 42% (13,15). The straight leg-raising test and other nerve root tension signs are usually negative unless there is concomitant disc herniation. A careful motor examination should be done. Leg weakness is generally mild and overwhelmingly in the distribution of the L4, L5, or S1 nerve roots. Objective evidence of subtle weakness can usually be demonstrated in about 50% of persons with spinal stenosis (2). Weakness of the muscles innervated by the

L5 nerve root is the most common finding (46), and weakness of great toe extensors (extensor hallucis longus) and hip abductors should be sought, the latter by the Trendelenburg test (46).

The Trendelenburg test is performed by having the patient stand on one leg; if the gluteus medius is not functional or is denervated, the pelvis drops on the side opposite the damaged muscle. This is shown clinically by an abnormal, waddling gait called the “Trendelenburg gait”, caused by trying to compensate for a drooping pelvis. The gait should be carefully observed. Difficulty in walking on the toes suggests S1 root involvement. Difficulty with heel walking suggests L4 or L5 nerve dysfunction. Sensory abnormalities may be present in 46% to 51% of preoperative spinal stenosis patients (2,12).

Katz et al. (13) found a positive lumbar extension test to be strongly predictive of imaging confirmed spinal stenosis. This test is performed by asking the standing patient to hyperextend the lumbar spine for 30 to 60 seconds. A positive test is defined by reproduction of the buttock or leg pain. Katz et al. (13) examined the value of the history and physical examination in the diagnosis of degenerative lumbar spinal stenosis. In this study, 93 patients over 40 years of age with symptoms of low back pain were examined by attending physicians who were then asked the extent to which they were certain the patient had lumbar spinal stenosis. The diagnostic impressions of expert clinicians and imaging, when available, were used as a reference standard to evaluate the attending physician's diagnosis. Severe lower extremity pain, absence of pain when seated, a wide-based gait, thigh pain following 30 seconds of lumbar extension, and neuromuscular deficits were all strongly associated with patients with lumbar spinal stenosis. No pain when seated and wide-based gait had the highest specificity, 93% and 97%, respectively. The highest sensitivity came from age greater than 65 (77%), pain below buttocks (88%), and no pain with flexion (79%).

Fritz (48) has developed a treadmill test as a clinical diagnostic tool for the differentiation of neurogenic claudication due to lumbar spinal stenosis from other pathologies that may produce similar symptoms. Spinal extension and weight bearing that occur during walking narrow the spinal canal and exacerbate the symptoms of lumbar spinal stenosis. Spinal flexion or nonweight-bearing postures that occur while sitting increase the dimensions of the spinal canal and reduce symptoms. The treadmill test involves having the patient walk on a level surface and an inclined surface. The time until onset of symptoms, total walking time, and time until symptoms return to baseline are recorded for each surface. Walking on an inclined plane produces spinal flexion and may be better tolerated by patients with lumbar spinal stenosis. The treadmill test was evaluated using 45 subjects with low back pain of varying etiologies and self-reported limitations in walking. Diagnostic images with MRI or CT were used as the gold standard for diagnosis. Twenty-six of the subjects were diagnosed by imaging as being stenotic. Self-reported sitting to relieve symptoms was significantly related to diagnosis. The sensitivity of this self-reported measure was 88.5% [95% confidence interval (CI) of 76.2 to 100], but specificity was 38.9% (95% CI of 16.4 to 61.4). For the treadmill test, earlier onset of symptoms with level walking, greater total walking time during inclined walking, and prolonged recovery after level walking were significantly related to a diagnosis of lumbar spinal stenosis. The sensitivity and specificity for earlier onset of symptoms with level walking were 68.0% (95% CI of 49.7 to 86.3) and 83.3% (95% CI of 66.1 to 100), respectively; for larger total walking time during

inclined walking they were 50.0% (95% CI of 37.5 to 62.5) and 92.3% (95% CI of 77.8 to 100), respectively; and for prolonged recovery after level walking they were 81.8% (95% CI of 5.7 to 97.9) and 68.4% (95% CI of 47.5 to 89.3), respectively. The authors concluded that a two-stage treadmill test might be more useful in the differential diagnosis of lumbar spinal stenosis compared to patients' self-reports of posture.

Use of the treadmill-bicycle test for the differential diagnosis of neurogenic claudication was also examined by Tenhula et al. (49). In their study, 32 patients with documented lumbar spinal stenosis were evaluated before and after surgery. Patients were found to have a significant increase in their symptoms from the start to the end of the treadmill test but fewer patients were found to have significant symptoms on bicycle testing. Two years after surgery, patients had an improvement in their walking ability on treadmill testing, but showed no improvement in their ability to bicycle. The authors believe the treadmill-bicycle test may be a useful tool for the differential diagnosis of neurogenic claudication.

### CENTRAL CANAL STENOSIS VERSUS LATERAL STENOSIS

Symptoms of pseudoclaudication are associated primarily with central lumbar stenosis. In contrast, patients with purely lateral recess stenosis:

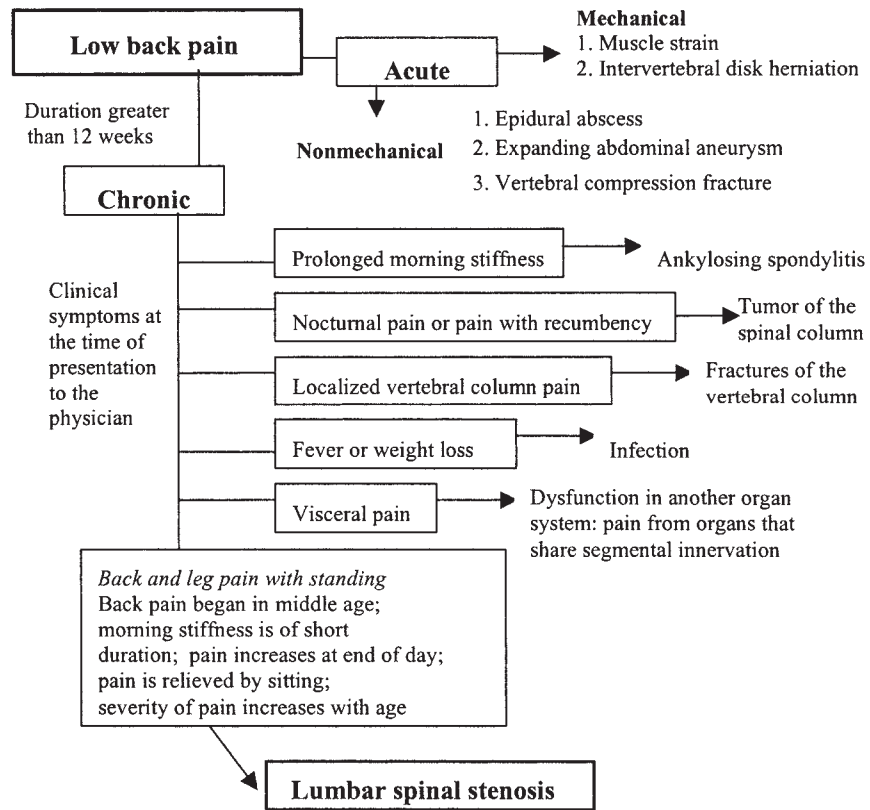

- usually do not develop symptoms of neurogenic claudication (15)
- typically have radicular symptoms in a specific dermatomal pattern (30)
- often have pain at rest, at night, and with the Valsalva maneuver (30)
- tend to be younger (mean age 41 years) than patients with central canal stenosis (mean age 65 years) (15).

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis is broad, and many conditions may be ruled out with a thorough evaluation (Fig. 48-2). Peripheral neuropathy, arteriovascular disease, and hip arthritis are common entities with similar symptoms. In older patients with back or leg pain, diagnostic possibilities differ from those in younger patients; nonmechanical causes of back pain such as malignancy, infection, or abdominal aortic aneurysm are more common in older patients than in younger patients (11,14).

#### Malignancy

Red flags that should raise the suspicion of underlying malignancy include significant weight loss, intractable night pain unrelieved by change in posture or pain medicine, or history of malignancy (50).

**FIG. 48-2.** Differential diagnosis of lumbar spinal stenosis. Arrows indicate the possible or most likely condition associated with the described symptoms. Many of these symptoms overlap, and an individual may need additional testing to determine the exact cause of low back pain.

**Infection**

Fever with localized back tenderness, recent systemic infection, or history of an invasive spinal procedure should raise the possibility of a spinal infection (11).

**Vascular Claudication**

When evaluating leg pain in older adults, neurogenic claudication must be distinguished from vascular claudication (Table 48-1).

**Peripheral Neuropathy**

Peripheral neuropathy may also superficially mimic features of spinal stenosis. However, patients with periph-

eral neuropathy usually have a stocking-glove distribution of pain or paresthesia. There may be a bilateral symmetric reflex loss. Vibratory sensation is frequently diminished (46). Numbness is typically constant with peripheral neuropathy.

**Hip Disease**

Hip disease may produce gait difficulty and leg symptoms. A careful examination of the hips and surrounding soft tissue should be done to exclude significant hip arthritis and gluteal or trochanteric bursitis.

Although clinicians consider a combination of results of the history and physical examination and imaging findings to be the most effective means of diagnosing lumbar spinal

**TABLE 48-1.** Findings in neurogenic claudication and vascular claudication

Finding	Neurogenic claudication	Vascular claudication
Symptoms with walking	Yes	Yes
Symptoms with standing	Yes	No
Variable walking distance before symptoms	Yes	No
Relief with flexion	Yes	No
Relief with sitting	Yes	Yes
Peripheral pulses diminished	No	Yes

stenosis, no objective criteria for using the history and physical examination have been reported. In addition, there are no reported clinical trials of the effectiveness of such a composite diagnosis. The only quantitative evidence correlating diagnostic information with outcomes is for the imaging findings. Clinical decision making should be based on a collection of data, including the history and physical findings, functional status, imaging and electrodiagnostic studies, and other adjunctive studies.

## CHAPTER 49

# Imaging of Spinal Stenosis and Degenerative Lumbar Spondylolisthesis with Stenosis

Donald L. Renfrew and Kenneth B. Heithoff

---

There is no universally accepted definition of the term spinal stenosis. Gunzburg et al. (1), in an article correlating computed tomography (CT) findings with decompression surgery, state, “Lumbar spinal stenosis is . . . a clinical condition and not a radiologic finding or diagnosis.” Nonetheless, the same authors also affirm, “CT or MRI [magnetic resonance imaging] combined with myelography has become the standard tool for iconographic evaluation of (spinal stenosis).” In an article on conservative treatment of spinal stenosis published in 2000, Simotas et al. (2) state, “No validated system for radiographic rating of stenosis exists.” Although we recognize that this controversy exists, we offer this chapter to explain and illustrate our approach to the imaging of spinal stenosis.

Many authors (3–5) use the term stenosis to signify *any* reduction of size of the spinal canal or neural foramina, whether from chronic bone, cartilage, or degenerative changes or from acute disc herniation, tumor, or epidural abscess. Others (6,7) reserve use of the term stenosis for bony reductions in canal size. Most clinical cases of spinal stenosis follow from degenerative changes of the intervertebral discs and facet joints. Although osteophytes along the disc and facet joints contribute to narrowing, degenerative soft-tissue abnormalities usually account for more of the narrowing than do bony abnormalities (5). Degenerative soft-tissue abnormalities include thickening of the ligamentum flavum (8), bulging of the disc, and capsular swelling of the facet joints. Therefore, we use the term stenosis for fixed bony or relatively fixed soft-tissue reductions in canal size. Used in this manner, the term is descriptive and does not name a disease process. Most cases of stenosis defined in this way result from degenerative disc bulging, osteophytic spurring, and facet arthropathy (Fig. 49-1), but stenosis may be caused by any of several other processes. Exam-

ples include foraminal stenosis from scoliosis (Fig. 49-2) or lytic spondylolisthesis (Fig. 49-3), and spinal canal stenosis from closed arch spondylolisthesis (Fig. 49-4) or after surgery (Fig. 49-5).

### CLASSIFICATION AND NOMENCLATURE

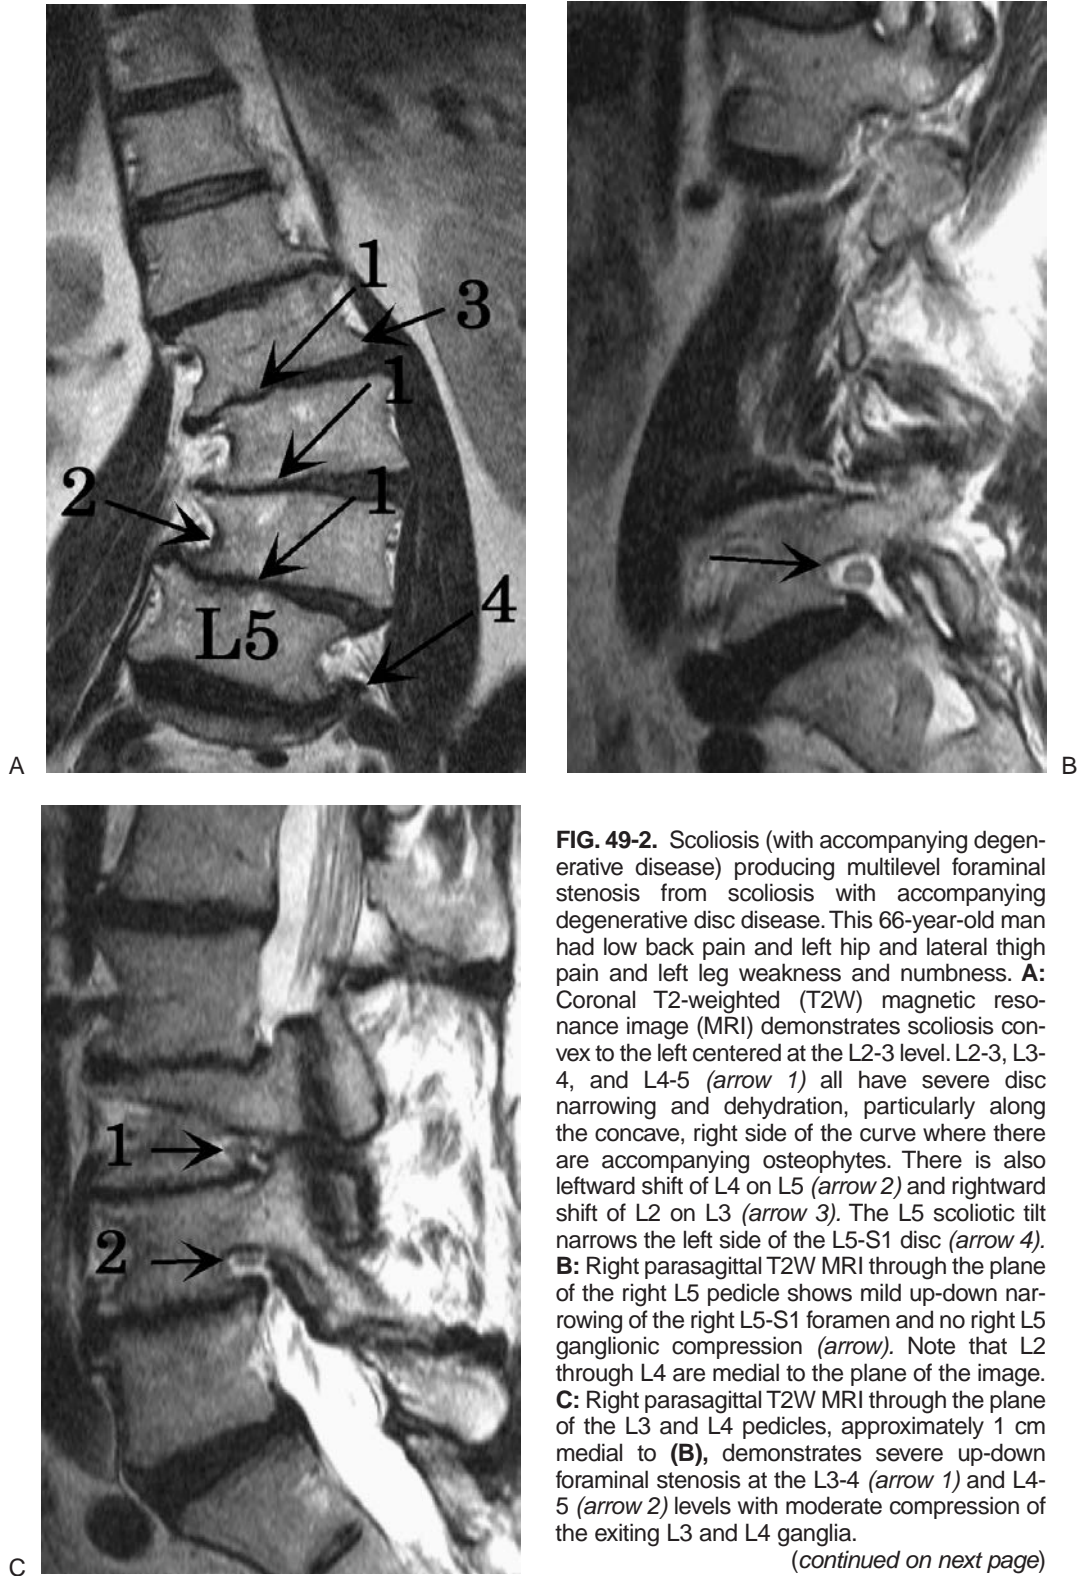

Classification systems of stenosis may use cause (e.g., congenital, degenerative, or combined) or location (e.g., spinal canal, subarticular recess, and foramen) (Fig. 49-6). Another method of classification is by severity (mild, moderate, or severe). When reporting an imaging study, we grade spinal canal, subarticular, and foraminal stenosis not only relative to other levels in the same patient (and, when necessary because of an inherently small canal, an idealized norm from other patients), but also taking into account the degree of neural compression (Table 49-1; Figs. 49-1 to 49-5, 49-7) (9). Reliance solely on percentages of narrowing overrates the severity of stenosis in patients with inherently large spaces (canals, subarticular recesses, and foramina) while underrating the severity of stenosis in patients with small spaces (Tables 49-2 to 49-4). In addition to grading the degree of stenosis, note may be made in appropriate cases that the spinal canal has a trefoil configuration, a characteristic of congenital or developmental (short pedicle) spinal stenosis (Fig. 49-8).

Grading spinal canal stenosis and lumbar foraminal stenosis and neural compression may be done relatively easily on most scans. Grading lumbar subarticular recess stenosis is more difficult because of either scan quality (for technical or patient related reasons) or crowding of neural structures. As an alternative to grading subarticular stenosis using a mild–moderate–severe scale, it may be preferable to note simply that narrowing is present, and estimate whether compression of the associated neural structure is likely or not.

(Text continued on page 479)

**FIG. 49-1.** Degenerative spinal canal and subarticular recess stenosis demonstrated on a myelogram-computed tomography (myelo-CT). This 45-year-old man had low back and bilateral leg pain. **A:** Axial 3-mm CT at the L5-S1 level following injection of intrathecal contrast demonstrates moderate facet arthropathy (*arrow 1*) but no spinal canal or subarticular recess stenosis. The degenerative abnormalities do not distort the S1 nerve root sleeves (*arrow 2*) or thecal sac (*arrow 3*). **B:** Axial 3-mm CT at the L4-5 level following intrathecal contrast demonstrates degenerative disc bulging with a vacuum phenomenon (*arrow 1*) and bilateral severe facet arthropathy (*arrow 2*). There is resultant severe (>50% antero-posterior diameter reduction) spinal canal stenosis (*arrow 3*) and severe left (*arrow 4*) and moderate right (*arrow 5*) subarticular recess stenosis. A focal abnormality of the facet joint capsule on the right (*arrow 6*) further narrows the subarticular recess; this may represent a small synovial cyst. **C:** Axial 3-mm CT at the L3-4 level following intrathecal contrast demonstrates findings similar (but less severe) to those seen at the L4-5 level, with degenerative disc bulging and facet arthropathy combining to cause severe spinal canal and subarticular recess stenosis (*arrow*). **D:** Axial 3-mm CT at the L2-3 level following intrathecal contrast demonstrates that the spinal canal and subarticular recesses (*arrows*) have normal caliber at this level. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-2.** Scoliosis (with accompanying degenerative disease) producing multilevel foraminal stenosis from scoliosis with accompanying degenerative disc disease. This 66-year-old man had low back pain and left hip and lateral thigh pain and left leg weakness and numbness. **A:** Coronal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates scoliosis convex to the left centered at the L2-3 level. L2-3, L3-4, and L4-5 (*arrow 1*) all have severe disc narrowing and dehydration, particularly along the concave, right side of the curve where there are accompanying osteophytes. There is also leftward shift of L4 on L5 (*arrow 2*) and rightward shift of L2 on L3 (*arrow 3*). The L5 scoliotic tilt narrows the left side of the L5-S1 disc (*arrow 4*). **B:** Right parasagittal T2W MRI through the plane of the right L5 pedicle shows mild up-down narrowing of the right L5-S1 foramen and no right L5 ganglionic compression (*arrow*). Note that L2 through L4 are medial to the plane of the image. **C:** Right parasagittal T2W MRI through the plane of the L3 and L4 pedicles, approximately 1 cm medial to **(B)**, demonstrates severe up-down foraminal stenosis at the L3-4 (*arrow 1*) and L4-5 (*arrow 2*) levels with moderate compression of the exiting L3 and L4 ganglia.

*(continued on next page)*

D

**FIG. 49-2.** (continued). **D:** Left parasagittal T2W MRI through the plane of the left L4 and L5 pedicles, on the convex side of the curve, demonstrates little narrowing of the L3-4 (arrow 1) and L4-5 (arrow 2) neural foramina. However, the L5-S1 neural foramen is severely stenotic (arrow 3), with abutment of the L5 pedicle and sacral ala and resulting severe compression of the L5 ganglion. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-3.** Lytic spondylolisthesis with severe up-down foraminal stenosis. This 71-year-old man had right back pain and right leg tingling. This patient had 20% lytic spondylolisthesis and severe loss of disc height and hydration at L4-5. Right parasagittal T2-weighted (T2W) magnetic resonance image (MRI) at the level of the neural foramina shows normal up-down dimension of the L3-4 (arrow 1) and L5-S1 (arrow 2) foramina with severe up-down narrowing of L4-5 (arrow 3) foramen with associated moderate compression of the exiting L4 ganglion. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

A

B

**FIG. 49-4.** Spinal canal stenosis from closed arch spondylolisthesis. This 25-year-old man had low back and bilateral leg pain. **A:** Sagittal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates 40% spondylolisthesis of L5 on S1. The posterior elements of L5 are directly adjacent to the dorsal L5-S1 disc margin and dorsal superior aspect of the S1 vertebra, causing severe spinal canal stenosis (arrow). **B:** Parasagittal T2W MRI demonstrates a dysplastic (but otherwise intact) L5 pars (arrow). Usually, spondylolisthesis in young people is associated with pars defects that allow the posterior elements to remain in place while the remainder of the vertebra subluxes anteriorly, resulting in no spinal canal stenosis. In this case, the intact pars resulted in forward movement of the posterior elements as well, causing severe spinal canal stenosis.

**FIG. 49-5.** Spinal canal stenosis following surgery, with additional adjacent segment degenerative stenosis. This 43-year-old man had undergone remote posterior fusion with instrumentation at the L5-S1 level. The patient returned with low back pain with lower extremity pain on ambulation. **A:** A lateral scout digital radiograph from myelo-CT (myelography-computed tomography) study demonstrates posterior hardware with two sets of paired laminar hooks. The lower set is over the S1 laminae (*arrow 1*) and the upper set beneath the L4 laminae (*arrow 2*). Also noted is L3-4 degenerative disc narrowing with a vacuum phenomenon (*arrow 3*) and 15% degenerative spondylolisthesis, and wedging of L1 (*arrow 4*). **B:** Axial 3-mm myelo-CT image at the L5-S1 intervertebral disc level demonstrates solid dorsal fusion, posterior instrumentation, and severe spinal canal stenosis at the level of the laminar hooks (*arrow*). **C:** Axial 3-mm myelo-CT image through the L3-4 (superior adjacent segment) demonstrates degenerative disc disease with a vacuum phenomenon (*arrow 1*) and disc bulging combining with severe facet arthropathy (*arrow 2*) and degenerative spondylolisthesis to produce severe spinal canal and subarticular recess stenosis (*arrow 3*). The patient tolerated the spinal canal stenosis at L5-S1 relatively well until development of adjacent segment degenerative stenosis at L3-4. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-6.** Illustration demonstrating anatomic nomenclature. Axial magnetic resonance imaging at the L5-S1 level illustrating anatomic terms. The spinal canal (also called the central zone) is bounded anteriorly by the posterior disc margin, posteriorly by the laminae, and laterally by a plane drawn through the medial margin of the facet (zygapophyseal) joint. The subarticular recess (also called the subarticular zone) is bounded anteriorly by the disc margin, posteriorly by the superior articular facet of the S1 level, medially by a plane drawn through the medial margin of the facet joint, and laterally by another plane drawn through the medial margin of the pedicle. The foramen (also called the foraminal zone) is bounded anteriorly by the disc margin, posteriorly by the S1 superior articular process, medially by a plane drawn through the medial margin of the pedicle, and laterally through another plane drawn through the lateral margin of the pedicle. Note that the foramen also has a superior margin (the inferior aspect of the L5 pedicle) and an inferior margin (the superior aspect of the S1 pedicle), but that the subarticular space and spinal canal have no superior and inferior margins, although discussion of these spaces is generally about their configuration at the level of the disc. Also note that the lateral recess is defined as the space medial to the pedicle, and thus does not exist at the level of the disc, spinal canal, subarticular recess, or foramen (where most stenosis occurs). (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**TABLE 49-1.** Neural compression definitions

Term	Definition
Mild	75%–99% of normal diameter of the structure is maintained
Moderate	50%–74% of the normal diameter of the structure is maintained
Severe	<50% of the normal diameter of the structure is maintained

**FIG. 49-7.** Foraminal stenosis. This 42-year-old man had low back and right hip pain numbness in left foot. Sequential right parasagittal T2 weighted images (T2WI) from the lateral aspect of the L5 pedicle past the medial aspect of the pedicle to the right side of the spinal canal. **A:** Right parasagittal T2-weighted (T2W) magnetic resonance image (MRI) shows greater than 50% reduction in the up-down dimension of the L5-S1 foramen (arrow); however, no associated ganglionic deformity is present, so the stenosis is graded as moderate (see text). **B:** Right parasagittal T2W MRI medial to **(A)** demonstrates moderate stenosis is again seen at L5-S1 (arrow 1). At L4-5, there is severe combined up-down and front-back foraminal stenosis (arrow 2) from a combination of degenerative disc narrowing, degenerative disc bulging (arrow 3), and facet arthropathy (arrow 4). These degenerative processes result in mild compression of the L4 ganglion. No L3-4 narrowing is identified (arrow 5). **C:** Sagittal T2W MRI at the level of the medial aspect of the neural foramina shows no L5-S1 narrowing but there continues to be severe L4-5 narrowing (arrow). **D:** Sagittal T2W MRI at the lateral aspect of the spinal canal shows subarticular recess stenosis at the L4-5 level (arrow 1). There is severe loss of disc height and disc dehydration at L4-5 (arrow 2) and L5-S1 (arrow 3), and subchondral Modic type II degenerative changes at L4-5. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**TABLE 49-2.** Spinal canal stenosis grading scheme

Term	Description
Mild	The spinal canal has >75% of the antero-posterior dimension of a normal level. The nerve roots are evenly distributed without crowding.
Moderate	The spinal canal has 50%–74% of the antero-posterior dimension of a normal level. <sup>a</sup> The nerve roots “crowded” or closer together than at a normal level.
Severe	The spinal canal has less than 50% of the antero-posterior dimension of a normal level. Typically, there is no visible cerebrospinal fluid (CSF) around the nerve roots at the level of severe stenosis. <sup>b</sup>

<sup>a</sup>If the patient has an inherently small spinal canal and this degree of narrowing produces a crowded appearance of the nerve roots with scant CSF around the nerve roots, the degree of stenosis should be upgraded to “severe.” If the patient has an inherently large spinal canal and there is abundant CSF around the nerve roots, the stenosis should be graded as “mild.”

<sup>b</sup>If the patient has an inherently large spinal canal so that there is still abundant CSF around the nerve roots with little crowding of these structures, the stenosis should be graded as “moderate.”

**TABLE 49-3.** Subarticular recess stenosis grading scheme

Term	Description
Mild	The subarticular recess has 75%–99% of the antero-posterior dimension of a normal level, and the traversing nerve root has ample surrounding cerebrospinal fluid (CSF), without displacement or compression of the nerve root.
Moderate	The subarticular recess has 50%–74% of the antero-posterior dimension of a normal level. <sup>a</sup>
Severe	The subarticular recess has less than 50% of the antero-posterior dimension of a normal level. There is no visible CSF around the nerve root at the level of severe stenosis. <sup>b</sup>

<sup>a</sup>If the patient has an inherently narrow subarticular recess and this degree of narrowing produces compression of the traversing of the nerve root, the degree of stenosis should be upgraded to “severe.” If the patient has an inherently generous subarticular recess and there is abundant CSF around the nerve root, the stenosis should be graded as “mild.”

<sup>b</sup>If the patient has an inherently generous subarticular recess so that there is still abundant CSF around the nerve root, the stenosis should be graded as “moderate.”

**TABLE 49-4.** Foraminal stenosis grading scheme

Term	Description
Mild	The neural foramen has 75%–99% of the antero-posterior <i>and</i> cephalocaudad dimension of a normal level, and the traversing nerve root has ample surrounding cerebrospinal fluid (CSF) or perineural fat, without displacement or compression of the nerve root.
Moderate	The neural foramen has 50%–74% of the antero-posterior <i>and</i> cephalocaudad dimension of a normal level. There may be up to mild (<25%) compression of the ganglion or nerve root. <sup>a</sup>
Severe	The neural foramen has less than 50% of the antero-posterior dimension of a normal level. There is no visible perineural fat around the nerve root at the level of maximal stenosis. <sup>b</sup>

<sup>a</sup>If the patient has an inherently small neural foramen and this degree of narrowing produces at least moderate (>25%) compression of the exiting nerve root or ganglion, the degree of stenosis should be upgraded to “severe.” If the patient has an inherently generous neural foramen and there is abundant perineural fat or CSF around the nerve root and ganglion, the stenosis should be graded as “mild.”

<sup>b</sup>If the patient has an inherently large neural foramen so that there is still abundant fat or CSF around the nerve root and ganglion and there is no neural compression, the stenosis should be graded as “moderate.”

The direction as well as the degree of lumbar foraminal stenosis may be noted. Loss of disc height or disc margin osteophytic spurring and degenerative disc bulging causes the overwhelming majority (>90%) of cases of lumbar foraminal stenosis (10). Disc disease produces loss of the cephalocaudal dimension (craniocaudal or up-down) stenosis (Figs. 49-3, 49-7). On the other hand, facet arthropathy causes antero-posterior (AP) narrowing, and the stenosis may be termed either AP or front-back. A combination of both is called, logically enough, combined stenosis.

Although almost all causes of bony neural compression occur within the confines of the spinal canal or within the subarticular recesses or foramina, occasionally such compressions occur lateral to the foramen. Causes of this phenomenon include: (a) bony stenosis between the transverse process of L5 and the sacral ala (11); (b) a pseudoarthrosis between a transitional transverse process or sacral ala and the vertebral body of the next higher segment (Fig. 49-9); or (c) a lateral osteophyte formation off of the L5-S1 disc with narrowing of the space between the disc margin and ipsilateral sacral ala (Fig. 49-10).

In addition to the imaging findings of reduction of size of the normal spinal canal, subarticular recess, foramen; or extraspinous space and narrowing of neural structures,

**FIG. 49-8.** Trefoil spinal canal with severe stenosis. This 76-year-old man with long-standing low back and bilateral leg pain and weakness. Axial T2-weighted magnetic resonance image at the L4-5 disc level demonstrates severe spinal canal and subarticular recess stenosis. Complete effacement of cerebrospinal fluid makes it difficult to identify the small, trefoil spinal canal (arrow 1). Note degenerative disc bulging (arrow 2) and bilateral facet arthropathy (arrow 3).

Hacker et al. (12) have described an additional sign in spinal stenosis consisting of redundant nerve roots in the thecal sac (Fig. 49-11). They posited that such redundancy follows repeated stretching of the nerve roots above a level of stenosis, with failure of passage of the nerve roots back past the level of stenosis once pulled through.

## DEGENERATIVE SPONDYLOLISTHESIS

Degenerative spondylolisthesis is a common cause of spinal stenosis. In this condition, degeneration of the facet joints and intervertebral disc may cause spondylolisthesis, or forward displacement of one vertebra relative to the next lower level. Degenerative spondylolisthesis occurs most frequently at the L4-5 level in middle-aged to elderly women (13–19). Overly sagittal (20) or axial (13,18) alignment of the facet joints may produce degenerative spondylolisthesis. Whether abnormally aligned or not, the facets almost invariably demonstrate moderate or severe degenerative changes in degenerative spondylolisthesis. A combination of spondylolisthesis, facet arthropathy, and associated degenerative disc disease produces associated stenosis, particularly of the subarticular recesses and spinal canal and usually somewhat less dramatically of the neural foramina (Figs. 49-12 to 49-14). Sequential images may

**FIG. 49-9.** Stenosis between a pseudoarthrosis and the next higher vertebral body. This 50-year-old man had low back and right leg pain. Plain films (not shown) demonstrated transitional anatomy with sacralization of the right side of the L5 segment. **A:** Axial 3-mm computed tomography (CT) examination at the level of the upper sacrum demonstrates asymmetry of the sacral ala. The right L5 ventral ramus (*arrow*) is located in a notch along the medial aspect of the right sacral ala. **B:** Axial 3-mm CT examination superior to (**A**), demonstrating the sacralized right side of the L5 vertebra (*arrow 1*) and a narrow channel for passage of the right L5 ventral ramus (*arrow 2*). Note that the contralateral left L5 ventral ramus (*arrow 3*) sits along the anterior aspect of the sacrum. The right L5 ventral ramus is in a position where it could be compressed between the L5 vertebral body and disc and the anomalous lateral mass. **C:** Axial 3-mm CT examination superior to (**B**). Note the anomalous articulation between the right L5 lateral mass and S1 sacral ala (*arrow 1*). There are reactive or degenerative changes along the lateral margin at this level (*arrow 2*). At this level, the space between the lateral mass and L5 vertebra (*arrow 3*) is much larger than in (**B**).

**FIG. 49-10.** Stenosis between lateral osteophyte formation and the sacral ala with radicular pain. This 67-year-old man had low back and left leg pain in the hip, lateral thigh, and lateral calf. **A:** Right parasagittal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates a widely patent neural foramen (*arrow*) without L5 ganglionic compression. **B:** Left T2W MRI shows severe up-down foraminal stenosis (*arrow 1*) secondary to loss of disc height and osteophyte formation (*arrow 2*), with associated mild flattening of the exiting right L5 ganglion. **C:** Axial T2WI through the L5-S1 intervertebral disc demonstrates moderate facet arthropathy (*arrow 1*) and degenerative disc bulging. Furthermore, there is extensive left-sided osteophyte formation (*arrow 2*), which projects along the left lateral aspect of the L5 vertebral body and narrows the space between the vertebral body and the left sacral ala (*arrow 3*), with displacement and compression of the L5 ventral ramus (*arrow 4*). (Compare to the position of the left L5 ventral ramus [*arrow 5*].) The stenosis is lateral to the plane in (**B**), and lateral to the parasagittal images obtained in routine lumbar MRI. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-11.** Redundant nerve roots above a level of stenosis in the lumbar spine. This 68-year-old man had low back and bilateral leg pain. Sagittal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates severe L3-4 spinal canal narrow/stenosis (*arrow 1*) secondary to a combination of degenerative disc disease and facet arthropathy with a superimposed caudally dissecting disc extrusion. Superior to the level of the stenosis, there is redundancy of the nerve roots within the thecal sac (*arrow 2*). This redundancy is thought to be secondary to a lack of free movement through the level of stenosis (see text).

demonstrate progression of degenerative spondylolisthesis through time (Fig. 49-15). Table 49-5 lists imaging features differentiating degenerative and lytic spondylolisthesis, but note that the two processes may coexist at different levels in the same patient (Fig. 49-16).

The development of synovial cysts sprouting off of degenerated facet joints in patients with degenerative spondylolisthesis frequently contributes to symptoms (10); this complication should be suspected when a patient develops superimposed radicular pain on long-standing

(Text continued on page 487)

A

**FIG. 49-12.** Magnetic resonance image (MRI) of mild degenerative spondylolisthesis. This 59-year-old woman had central low back pain radiating into both legs. **A:** Sagittal T2-weighted (T2W) MRI minimal (<5%) degenerative spondylolisthesis: Note the forward shift of L4 on L5 (*arrow*). The examination also demonstrates multilevel degenerative disc disease with disc dehydration and Schmorl node formation.

(continued on next page)

B

C

**FIG. 49-12.** (continued) **B:** Right parasagittal T2W MRI through the level of the foramina show no foraminal stenosis (arrow). **C:** Axial T2W MRI at the level of the L4-5 disc shows moderate facet arthropathy (arrow 1), mild spinal canal (arrow 2), and mild subarticular recess (arrow 3) stenosis. No neural compression is present. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

A

**FIG. 49-13.** Magnetic resonance image (MRI) of moderate degenerative spondylolisthesis. This 74-year-old woman had a constant backache with radiation of pain into both hips and legs, and superimposed sharp pain with walking. **A:** Sagittal T2WI shows multilevel degenerative disc disease, 15% degenerative spondylolisthesis at L4-5 (arrow 1), and 3 mm of retrolisthesis at L5-S1 (arrow 2).

(continued on next page)

**FIG. 49-13.** (continued) **B:** Parasagittal right T2-weighted (T2W) MRI shows mild L4-5 up-down narrowing (*arrow 1*) from a foraminal disc protrusion (*arrow 2*) and a patent L5-S1 foramen (*arrow 3*). **C:** Axial T2W MRI at the superior margin of the L4-5 disc shows a pseudodisc appearance because of spondylolisthesis (*arrow 1*), moderate facet arthropathy (*arrows 2*), and mild spinal canal and subarticular recess stenosis. The pseudodisc appearance is secondary to volume averaging through two adjacent segments on axial images. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-14.** Computed tomography-myelogram (Myelo-CT) of severe degenerative spondylolisthesis. This 62-year-old woman with low back pain had bilateral leg pain and right leg weakness. **A:** Sagittal reconstruction CT examination shows moderate L4-5 and severe L5-S1 disc narrowing. There is 20% degenerative spondylolisthesis of L4 on L5 and complete block to flow of myelographic contrast material at the L4-5 level (*arrow*). **B:** Axial 3-mm CT cut at the level of the L4-5 intervertebral disc shows severe facet arthropathy (*arrow 1*). Note the volume averaging through the L4 and L5 levels and severe spinal canal stenosis, with no myelographic contrast within the spinal canal (*arrow 2*). (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

**FIG. 49-15.** Progression of degenerative spondylolisthesis through time. **A:** Sagittal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates multilevel degenerative disc disease. Minimal degenerative spondylolisthesis of L4 on L5 is seen (*arrow*). **B:** Sagittal T2W MRI done 5 years later demonstrates 15% degenerative spondylolisthesis (*arrow*). Note ongoing degenerative disc disease and improved image quality with technologic advancements in the interval since the prior study. The patient originally had exclusively back pain, but developed leg symptoms by the time of the second scan.

**TABLE 49-5.** Differentiation of degenerative and lytic spondylolisthesis

	Degenerative spondylolisthesis	Lytic spondylolisthesis
Usual location	L4-5	L5-S1
Facet arthropathy	Moderate or severe	Usually none; the joints beneath the level of lysis tend to be atrophic
Spinal canal diameter	Decreased	Increased
Pars interarticularis	Intact	Interrupted

**FIG. 49-16.** Coexistent lytic and degenerative spondylolisthesis. This 73-year-old woman had low back pain with right leg pain and tingling. **A:** Sagittal T2-weighted (T2W) magnetic resonance image (MRI) shows multilevel degenerative changes with lumbar disc dehydration and L4-5 and L5-S1 disc narrowing. There is 20% spondylolisthesis of L4 on L5 and L5 on S1. Note spinal canal stenosis at L4-5 (*arrow 1*) at a level of degenerative spondylolisthesis and lack of spinal canal stenosis at L5-S1 (*arrow 2*) at a level of lytic spondylolisthesis.

(continued on next page)

B

**FIG. 49-16. (continued) B:** Right parasagittal T2W MRI demonstrates L4-5 facet arthropathy (*arrow 1*) and a pars defect at L5 (*arrow 2*). Note that the L4-5 foramen demonstrates severe stenosis (*arrow 3*), whereas there is less stenosis at L5-S1. **C:** Axial T2W MRI through the level of the L5 pars demonstrates fibroproliferative changes along the pars margins (*arrow 1*) and asymmetric and dysplastic posterior elements (*arrow 2*). **D:** Axial T2W MRI through the level of the L4-5 intervertebral disc demonstrates severe facet arthropathy (*arrow 1*) with a pseudodisc anteriorly and moderate spinal canal and subarticular recess stenosis (*arrow 2*).

C

D

A

**FIG. 49-17.** Degenerative spondylolisthesis with radicular pain secondary to synovial cyst formation. This 52-year-old woman had new onset of low back and right leg pain. **A:** Sagittal T2-weighted (T2W) magnetic resonance image (MRI) shows 5% degenerative spondylolisthesis of L4 on L5 and L5-S1 mild disc degeneration and bulging. In addition, there is a dorsal soft-tissue mass within the spinal canal at the L4-5 level (*arrow*).

(continued on next page)

**FIG. 49-17.** (continued) **B:** Axial T2W MRI demonstrates bilateral L4-5 facet joint arthropathy (arrow 1). In addition, a synovial cyst (arrow 2) projects off the anteromedial aspect of the right joint. **C:** Oblique fluoroscopic image from an L4-5 facet joint injection. A 22-gauge needle is at the inferior aspect of the L4-5 facet joint and contrast flows through the joint (arrow). With injection of a small volume of local anesthetic and steroid, the patient had a brief recurrence of her typical pain followed by long-standing, complete pain relief, consistent with synovial cyst rupture.

low back pain (Fig. 49-17). Of course, an acute disc herniation may be seen in the same clinical scenario, and imaging is required to make the differentiation (Fig. 49-18).

### IMAGING MODALITIES AND CONTROVERSIES

The classification system proposed here applies regardless of the imaging modality used. Myelography, CT, MRI, and myelography with CT (myelo-CT) have all been used for evaluation of spinal stenosis. We typically use MRI to evaluate stenosis, supplemented by myelo-CT in some cases. Bartynski et al. (21) recently published a study suggesting that both MR imaging and myelo-CT significantly underestimated spinal stenosis 28% to 38% of the time, and that standard myelography performed much better, underestimating spinal stenosis in only about 6% of cases. This finding runs counter to the trend of using MR imaging for diagnosis of stenosis. In addition, the outperformance of myelo-CT by plain film myelography suggests that myelography may always or nearly always have an appearance of spinal stenosis. We could determine whether myelography was in fact often a false-positive test if we had a reliable reference standard; however, we do not. Measurements typically are not obtained at the time of surgery as to the AP diameter of the spinal canal, subarticular recess, or foramen, and it is questionable whether such measurements would be considered reliable. We can use surgical outcome as the reference standard of whether someone has spinal stenosis, and assume that those who fare well following surgery are “disease-positive” for stenosis and those who do not are “disease-negative.” In Bartynski et al.’s study, all patients were relieved of symptoms following surgery. Differentiating which of the three imaging methods evaluated in Bartynski’s study (MRI,

myelo-CT, and myelography) probably would be best evaluated using receiver operating characteristic curve analysis, but this topic is beyond the scope of this chapter. Note that at least three problems arise if we use such surgical outcome as the reference standard: (a) Patients achieving symptom relief might be getting it through a placebo mechanism. (b) Patients who fail to achieve symptom relief may still have stenosis but also have or develop other conditions producing similar symptoms (including failed back surgery). (c) Other studies have shown no relationship between relief of symptoms and improvement of stenosis as depicted by imaging. Attempts to find a specific fixed numerical value for a given measurement (either AP diameter or cross-sectional area) predictive of symptom production or surgical outcome have not been successful (5,7,22–24). Use of only bony measurements makes little sense in light of the contributions of soft tissue to spinal canal narrowing (5,22). Use of dural sac dimensions makes more sense, but is still not predictive of surgical results (1,25). In fact, some studies have shown poorer outcomes when operating on more severe degrees of narrowing, perhaps because of the permanent damage of the nerve roots before operation. Thus, although absolute measurements of a linear dimension or (with markedly greater difficulty) cross-sectional area of the spinal canal, subarticular recess, or neural foramen may be reported, their significance in a given case is questionable. Factors contributing to the lack of correlation between measurements of narrowing and symptoms or surgical outcomes include the necessity of a second location of stenosis for symptom production (26,27), the rapidity of onset of stenosis (slowly progressive stenosis is better tolerated than rapidly progressive stenosis), superimposed minor trauma (10), positional narrowing of the structure in question (28,29), and

**FIG. 49-18.** Degenerative spondylolisthesis with superimposed disc herniation. This 66-year-old woman with chronic low back pain had new onset left leg pain. **A:** Sagittal T2-weighted (T2W) magnetic resonance image (MRI) demonstrates multilevel degenerative disc disease with 5% degenerative spondylolisthesis at L4-5. There is a superimposed cranially dissecting 6-mm disc extrusion (*arrow*). **B:** Axial T2W MRI at the level of the L4-5 disc demonstrates severe facet arthropathy (*arrow 1*) and moderate spinal canal and subarticular recess stenosis (*arrow 2*) with a trefoil appearance of the spinal canal. **C:** Axial T2W MRI just above the level of the L4-5 disc demonstrates the cranially dissecting disc extrusion (*arrow 1*) with severe spinal canal and bilateral subarticular recess narrowing (*arrow 2*) with compression of the traversing L5 nerve roots, left greater than right. (From Renfrew DL. Atlas of spine imaging. Philadelphia: Elsevier, 2003, with permission.)

poor interobserver and intraobserver agreement among interpreters of imaging studies (30–32). Our terminology and the illustrations offered in this chapter are our attempt to address the last concern.

**TREATMENT**

Treatment of spinal stenosis varies greatly. Many publications have supported conservative treatment (2,33) with a combination of exercise, nonsteroidal antiinflammatory

drugs, or epidural steroid injection (2,4,34–35). Because symptom production follows from not only single level narrowing, but also from any additional areas of narrowing (26,36), the rapidity of onset of the narrowing of such superimposed soft-tissue abnormalities as disc herniations, synovial cysts, minimal trauma (10), and additional as yet unidentified factors, addressing only the stenosis at a single level does not invariably lead to a favorable outcome. However, in a meta-analysis of 74 articles on spinal stenosis, Turner et al. (37) found favorable outcomes reported in

an average of 64% of cases. In a more recent publication, Atlas et al. (38) compared 4-year outcomes in a matched prospective observational study and found that surgical treatment was associated with a greater improvement in patient-reported outcomes than nonsurgical treatment. The decision to perform surgery usually hinges more on clinical symptoms (particularly on neurogenic claudication interfering with activities of daily living or progressive neurologic dysfunction) (39), than it does on imaging appearance. Controversy continues regarding whether fusion should accompany decompression (40,41).

In the special case of degenerative spondylolisthesis, Vogt et al. (17) in a population study found no relationship between anterolisthesis and back pain. Kauppila et al. (42) found it problematic to ascribe back pain to degenerative spondylolisthesis, and Matsunaga et al. (16) felt autostabilization prevented progression of disease and that the natural history of the disease was thus benign. Iguchi et al. (43) found most patients did well even without surgery. On the other hand, Moller et al. (19) found that surgery provided better pain relief and functional outcome than an exercise program.

## CHAPTER 50

# Spinal Stenosis Without Deformity: Nonoperative Treatment

Arto Herno

---

The nonoperative treatment of lumbar spinal stenosis (LSS) is a very current and practical topic because the aging of the general population is increasing the number of patients with this degenerative spinal disorder. Even now degenerative LSS is a major cause of low back and lower extremity pain as well as functional limitation in elderly persons (1–3). Research on the nonoperative treatment of LSS patients has been very modest compared with the large number of studies on the operative treatment of LSS (2,4,5). In fact, surgery has been the treatment of choice since the 1950s, when Verbiest (6) published his first report; however, at present it seems unreasonable that this increasing number of LSS patients could be left to surgical management alone. The basic problem with the nonoperative treatment of LSS is that little is known about the efficacy of nonoperative therapy modalities and the factors that are associated with a better outcome (2). Until now, LSS patients with mild to moderate symptoms have been treated conservatively, and patients with severe symptoms have been treated surgically (7). Recently, more reports concerning nonoperatively treated LSS patients have been published. In these comparative cohort studies between nonoperative and operative treatment, the results were more favorable to operative than to conservative treatment. However, regardless of treatment, unsatisfactory outcomes were common: 20% to 40% of patients treated operatively, and 50% to 70% of patients treated nonoperatively had unsatisfactory outcomes after 4 years (4,5,8,9).

### THE PATHOANATOMY AND PATHOPHYSIOLOGY OF LUMBAR SPINAL STENOSIS

Lumbar spinal stenosis is a posture-dependent functional and structural disorder caused by the progressive degenerative and reparative stenotic process of the lum-

bar spine resulting in continuous reduction of the central and lateral canal spaces. This process is slow and gradual, taking many years to occur and deteriorate. These degenerative changes dominate at the level of the mobile portion of the lumbar segment (i.e., at the level of the three-joint complex) (10), and mostly at the three lower lumbar levels (11). In patients with initially diminished size of the spinal canal (i.e., preexisting developmental relative stenosis) (12), symptomatic LSS generally occurs before the age of 50 because these patients have limited reserve space to accommodate the degenerative encroachment. Although various radiologic measurements of the lumbar spinal canal and the dural sac are useful as guidelines, the degree of impingement on the neural elements by the bone and soft tissues is more important. The cross-sectional area of the caudal fibers varies from 62 mm<sup>2</sup> at L1 to 30 mm<sup>2</sup> at L5 in men, and 50 mm<sup>2</sup> and 32 mm<sup>2</sup> in women, respectively (13).

The physiology of the lumbar spine is characterized by space changes in the spinal canal during various lumbar positions. The available space within the spinal canal decreases in extension and axial loading (minimum size of the canal), and increases in flexion and axial distraction of spine (maximum size of the canal) (14). In healthy subjects, the relative narrowing of the antero-posterior diameter of the dural sac from lumbar flexion to extension decreases about 10% but in patients with mild, moderate, or severe LSS this diameter decreases 32%, 45%, and 67%, respectively. Thereby, the more the canal is structurally narrowed by the stenosing process, the more it will be functionally narrowed by additional lumbar extension. Penning (13) called this phenomenon “the rule of progressive narrowing.”

The decisive turning point for symptomatic LSS is when the available reserve space of the spinal canals for the nerve roots has been used up. Schönström (14) called this point to the critical size of the spinal canal. In prac-

tice, this means that the ability of the nerve roots to receive their needed nutrition and blood supply is reducing when the spinal canal dimensions are decreasing to this point. For instance, if the patient has moderate stenosis, the spinal canal enters this critical size only in extension of the lumbar spine (i.e., walking and standing), but when the spinal canals are reduced, the patient has to bend her or his back in order avoid the canal to enter the critical point and escape symptoms (15). It is obvious that in most LSS patients this stenosing process is not continuously progressive but stabilizes at a certain individual level of stenosis.

The functional pathophysiology of LSS explains the posture-dependency of the LSS patient's symptoms: Pain is exacerbated in lumbar extension (i.e., on prolonged standing and walking), and pain is relieved in lumbar flexion (i.e., on standing or sitting with the trunk in flexion, or lying down with knees flexed) (7–18). These posture-dependent changes can be proved by various functional radiographies (i.e., functional myelography, dynamic computed tomography [CT], axially loaded CT-myelography, MRI, and positional MRI) (13,19–21). Takahashi et al. (17,18) demonstrated that this functional phenomenon is more sophisticated by measuring the changes of the local epidural pressure at the stenotic level in various body postures and during walking.

### **CLINICAL EVALUATION OF PATIENTS WITH LUMBAR SPINAL STENOSIS**

Symptomatic LSS is a dynamic and structural syndrome in which the symptoms are dependent on the patient's posture. Although the symptoms of LSS may be variable, bizarre, and vague, their typical feature is the relationship between symptoms and body posture. This "symptom-posture" analysis is a keystone when diagnosing LSS because radiographic findings are meaningful diagnostically only if they are accompanied by the clinical syndrome of neurogenic claudication or chronic nerve root compression (16). However, the basic clinical problem is that symptoms, signs, and radiologic findings of patients with LSS are not associated with each other (11). Further, if pain and other symptoms of LSS are solely related to compression of the cauda equina, nearly all elderly people would suffer from symptoms of stenosis because the pathoanatomic changes related to LSS are a function of the aging process (7). Hence, it is important that the physician listens closely to the patient's symptoms and pays attention to the relationship between symptoms and body postures. Furthermore, the extension test of the lumbar spine (16) and the treadmill test (22) with pain analysis may help to verify the clinical diagnosis of LSS.

Before the clinician is able to reliably diagnose LSS, she or he has to reconcile the patient's symptoms, signs, clinical tests, and imaging findings, to exclude other condition mimicking LSS symptoms and identify the etiol-

ogy and coexisting pain syndromes of LSS (16,23). Consequently, the most demanding task of the clinician is to estimate how much the aging patient's symptoms and lowered functional capacity is related to her or his radiologically confirmed stenotic findings, and how much is related to coexisting spinal, other musculoskeletal, and medical comorbidities (16,24). The conclusion of this thinking process is critical to appropriate selection of therapy for the patient. Optimal treatment begins with accurate identification of the condition.

### **NONOPERATIVE TREATMENT OF LUMBAR SPINAL STENOSIS**

The nonoperative treatment of LSS is not supported by controlled studies, but has to apply a practical and rational understanding of the pathoanatomic and pathophysiologic changes that are taking place in LSS patients during aging.

When a patient comes to the physician with pain in the back and lower extremities related to LSS, she or he is most likely requesting some form of treatment (7). At present, the primary treatment of LSS is mostly nonoperative because many patients respond well to this treatment (4,25,26). Although nonoperative treatment is less successful in patients who have more severe pain, functional limitation, and neurologic dysfunction, the nonoperative approach is recommended because a delay of surgery for some months does not worsen the prognosis of these patients (3,4). Also the rapid symptomatic or functional decline is unexpected in patients with LSS but a traumatic distortion of the lumbar spine or a lumbar disc herniation may temporarily exacerbate the LSS patient's symptoms. Further, although an attack of cauda equina syndrome is very rare in LSS patients, the physician has to keep this possibility in mind because these patients have to be operated on as soon as possible.

The nonoperative option is the only chance for an LSS patient who refuses surgical treatment or in whom surgical treatment is contraindicated because of the patient's medical condition. Currently, we have more and more elderly LSS patients who have many other diseases (i.e., heart disease, asthma, other lung diseases, aortoiliac occlusive disease, osteoarthritis of hip and knee joints, diabetes, severe obesity, peripheral neuropathy, rheumatoid arthritis, osteoporosis, etc.). Thus, the physician has to have a good overall picture of the LSS patient and her or his other diseases when considering appropriate therapy for alleviation of LSS symptoms.

### **NONOPERATIVE TREATMENT OPTIONS OF LUMBAR SPINAL STENOSIS**

Nonoperative treatment is based on the rational application of the pathoanatomic and pathophysiologic findings for the nonoperative therapy plan. The treatment is aimed at acting on these biomechanical and muscu-

loskeletal alterations and on inflammatory processes to alleviate the patient's pain and discomfort and improve functional capacity. Simotas (27) proposed that nonoperative treatment is divided into three independent but overlapping phases: pain control, stabilization, and a conditioning phase. Thus, it is often necessary to combine many treatment options and time them properly so that therapy can be effective on various etiologic factors.

Little is known about the efficacy of nonoperative therapy of LSS and which factors are associated with better outcome (2). Nonetheless, there is a rational reason to suppose that the current nonoperative treatment can have an effect on those pathoanatomic and pathophysiologic mechanisms that cause symptoms in patients with LSS. It is reasonable to suppose that we attain better results by using concurrent or overlapping treatment options.

## Medical Treatment

### *Nonsteroidal Antiinflammatory Drugs*

The use of nonsteroidal antiinflammatory drugs (NSAIDs) is based on the presumption that mechanical and structural alteration combined with local inflammatory changes lead to pain in LSS patients (28). Thus, NSAIDs are aimed at relieving the LSS patient's pain and inflammation to relax the muscle tension, and in this way to improve the functional cooperation of the lumbar spine, pelvis, and lower extremities. These drugs are effective for acute low back pain, but sufficient evidence on chronic low back pain and on LSS is still lacking (29,30).

We have several NSAIDs, as well as cox-2 specific drugs, in clinical use at the present time. However, the efficacy of various NSAIDs is roughly equivalent (28,30). The most common side effects of NSAIDs are gastrointestinal irritation and bleeding, which one has to pay attention to in older patients. These drugs can also deteriorate renal function because of the inhibition of renal prostaglandin synthesis.

### *Analgesic Drugs*

Most LSS patients have chronic low back pain caused by degenerative changes of the lumbar spine (11). There are various pathogenetic mechanisms for this chronic pain (e.g., vascular damage, neuromodulation, and the extensive nerves innervating degenerative discs). Degenerative discs have more extensive innervation than normal discs; these additional nerves may have nociceptive properties (31). It is rational to suppose that the same pain mechanisms play a role in LSS. Centrally acting analgesics should be effective for chronic low back pain and sciatica. Schnitzer et al. (31) showed that tramadol was very effective for the treatment of chronic low back patients. Tramadol also can be used in combination with NSAIDs for a double-active antiinflammatory and analgesic effect.

These centrally acting analgesics are valuable additions to our drug arsenal; however, because of the potential for addiction, sedation, constipation, and other adverse effects (e.g., nausea, dizziness, somnolence, and headache), their use among older patients is limited.

### *Muscle Relaxants*

Muscle relaxant drugs are a logical approach for muscle tension, which may be one of the important etiologic roles in the pathogenesis of chronic low back pain (28,31). However, there is limited evidence for the effectiveness of these drugs in the treatment of chronic low back pain. Further, it is debated whether muscle relaxants offer additive relief when combined with analgesics or NSAIDs (28).

### *Antidepressant Drugs*

Originally, the efficacy of antidepressant drugs was demonstrated in patients with painful diabetic neuropathy. Thus, their use in patients with LSS, including radiculopathy and neuropathic pain, seems to be reasonable, although there is no evidence for the use of antidepressants in LSS. Also, the evidence of their effect is conflicting in chronic low back pain patients. But two other reasons support the use of these drugs for chronic pain of LSS patients: antidepressive effect for subclinical depression and sedating effect for improving sleep. Newer antidepressant drugs (i.e., serotonin reuptake inhibitors) have not been well evaluated in the treatment of chronic pain syndromes (28).

### *Calcitonin*

The effect of salmon calcitonin on LSS pain is probably based on central analgesic effect, improvement of cauda equina blood flow, or antiinflammatory effect (32). Calcitonin has some beneficial analgesic effect on LSS patients with spinal claudication (33,34), but its use has not become standard for LSS nonoperative treatment. However, the use of calcitonin is reasonable in LSS patients with osteoporosis or Paget disease.

## Physical Therapy

All treatment options of physical therapy are based on a rational understanding of the degenerative process of the lumbar spine resulting in LSS. Thus, the goal of physical therapy is to counteract the mechanisms of the degenerative process causing symptomatic LSS.

In practice, the physiotherapist has to apply this knowledge to various treatment modalities because currently little is known about the efficacy of physical therapy options. Because LSS patients are often elderly people, the physiotherapist also should have an understanding of age-related changes in the musculoskeletal tissues and their relationship to musculoskeletal impairment (35).

### **Manual Traction**

The therapeutic goal of the manual lumbar traction is aimed at increasing space of the lumbar spinal canal in order to reduce the pressure on the cauda equina (15). It is obvious that traction causes axial movement on discs and facet joints to mobilize and stretch the stiff three-joint complex. If this traction therapy relieves pain, the patient can continue this therapy at home by hanging from the horizontal bar.

### **Therapeutic Exercise**

Therapeutic exercise includes stretching, strengthening, and conditioning, as well as postural education (36). The biomechanical goal of therapeutic exercises is aimed at decreasing the anterior pelvic tilt to decrease the extension the lumbar spine in order to increase space of the lumbar spinal canals (25). The prescription of proper therapeutic exercise should be based on the specific limitations detected during the physical examination and on the understanding of the age-related changes in the musculoskeletal tissues and their relationship to musculoskeletal impairment (35,37). Lindgren et al. (38) showed that therapeutic exercise does not influence segmental instability seen on functional radiography, whereas functional electromyographic (EMG) findings were significantly improved. Further, Arokoski et al. (39) showed by using the surface EMG measurement that simple therapeutic exercises were effective in activating both abdominal and paraspinal muscles.

### **Transcutaneous Electrical Nerve Stimulation**

Transcutaneous electrical nerve stimulation (TENS) is a noninvasive therapeutic option used for pain relief by electrically stimulating peripheral nerves via skin surface electrodes. The goal of TENS in LSS patients is to relieve pain, reduce muscle spasms, improve range of motion, and advance functional ability (40).

The evidence from randomized controlled trials does not support the use or nonuse of TENS alone in the treatment of the chronic pain. Transcutaneous electrical nerve stimulation is likely useful to employ concurrently with other physical therapy modalities because patients in the TENS groups consistently report less pain, better functional status, and greater satisfaction (40). Thus, it is reasonable to suppose that LSS patients benefit from these concurrent treatments.

### **Epidural Steroid Injection Therapy**

Favorable outcomes from some controlled and many uncontrolled studies suggest that epidural steroid injections reduce lumbar radicular pain caused by lumbar disc herniation and LSS. The therapeutic benefit of this therapy may be best attained with concurrent use of other nonoperative treatment (e.g., physical therapy) (41).

The mechanical compression of the nerve root may cause microvascular injury, resulting in formation of nerve root edema, which is likely to cause various neural changes and may be involved in the production of pain in nerve roots (42). The alleged rationale for using epidural steroids is that they reduce the edema and inflammation around nerve roots. However, there is weak evidence in the scientific literature supporting the use of epidural steroids in the management of LSS.

Lumbar spinal stenosis usually occurs in the elderly population in which the surgical risk may be considerable. Because of such risk factors the treating physician may consider alternative treatment options (42). In a descriptive, prospective study of 30 patients with a mean age of 76 years and 10-month follow-up, the caudal epidural injection offered significant pain relief for up to 10 months (43).

Epidural injections should be performed by experienced physicians, and fluoroscopically monitored injections are recommended. Further, no absolute orders can be made regarding the most effective type and dosage of steroid, timing or number of injections, or route of administration (41).

## **Other Nonoperative Treatment Options**

### **Lumbar Belts**

The use of lumbar belts in LSS patients has two goals: to maintain the lumbar spine in slight flexion in order to decrease the compression of the cauda equina and to mitigate irritation or inflammation of the nerve roots, and to improve the motion control in order to result in more stable motion patterns of the functional spinal unit.

Current definitions of spinal instability are based on a loss of stiffness (44). The degeneration of the three-joint complex considerably alters spinal dynamics (44), resulting in abnormal kinematics of the motion segment that may produce irritation or inflammation of the spinal nerves and cauda equina (3,7). Further, a gradual increase in lordosis of the lumbar spine is one sequela of degenerative disc disease. Thus, lumbar supports that decrease lumbar lordosis could be helpful (1).

### **Ultrasound Therapy and Trigger Point Injections**

Myofascial pain syndrome is very likely one of pain expression that arises from the irritated and inflamed source of the degenerative lumbar spine. Both ultrasound therapy and trigger point injections (1% lidocaine) with stretching were found to be effective in reducing pain intensity, increasing pain threshold of myofascial trigger points, and improving range of motion (45).

## **SUMMARY**

Lumbar spinal stenosis is a common and increasing clinical entity because of the growing number of elderly

people. The pathoanatomic verification of LSS is practical and easy by means of CT or MRI equipment, but the accurate reconciling the patient's complaints with radiologic changes is not verifiable by clinical means. Further, these elderly patients may have much concurrent pathology. However, the functional nature of LSS, the extension test, and the treadmill test help the physician to unite compatible symptoms and signs with radiologic findings for the clinical diagnosis of LSS.

The management of LSS is not established. The treatment is aimed at alleviating the severity of pain to guarantee the patient's functional capacity in everyday life. In practice, conservative treatment is often adequate in patients with mild or moderate pain, whereas in patients with severe pain surgical decompression is a noteworthy option after 3 months of conservative treatment. The increasing number of LSS patients should motivate us to carry out all-round functional studies on the conservative treatment of LSS.

# Indications for Surgery and Laminotomy Procedures

Franco Postacchini

---

Lumbar spinal stenosis has been defined as a “narrowing of the osteoligamentous vertebral canal and/or the intervertebral foramen causing compression of the thecal sac and/or the caudal nerve roots; at a single level, narrowing may affect the whole canal or part of it” (1–3). This definition implies a clear-cut distinction between a narrow spinal canal in which the neural structures are not compressed and a stenotic canal causing compression of the caudal nerve roots (Fig. 51-1A, B).

Spinal stenosis includes developmental, degenerative, and combined (developmental and degenerative) stenosis.

Developmental stenosis can be achondroplastic or constitutional. The former is the pathologic narrowing that can be found in achondroplastic dwarfs. The latter, which has also been called idiopathic developmental stenosis (4), is characterized by an abnormal narrowing of the bony vertebral canal that cannot be ascribed to any known etiologic factor. A narrow spinal canal may transform into stenosis in the presence of minor degenerative changes of the intervertebral disc or the articular processes and is unable to cause compression of the neural structures in a spinal canal that primarily is of normal size.

Degenerative stenosis is most often associated with deformities such as degenerative spondylolisthesis or scoliosis. The form not associated with deformities may be called simple degenerative stenosis. The latter is due to degenerative changes of the articular processes or osteophytosis of the vertebral end plates in the presence of a spinal canal originally of normal size.

Each condition includes spinal canal stenosis and isolated nerve root canal stenosis, which correspond, respectively, to the so-called central stenosis and lateral stenosis (Fig. 51-1B, Fig. 51-2). Stenosis of the intervertebral foramen, which should not be identified with lateral stenosis, is usually associated with one of the two other types of stenosis (5).

## INDICATIONS FOR SURGERY

### Natural History

Johnsson et al. (6) compared 19 untreated patients with 30 patients who underwent surgery. They were followed for a mean of 31 and 53 months, respectively; all patients in both groups had lumbar stenosis of moderate severity. One-third of the untreated patients were improved and two-thirds were unchanged or had worsened. Porter et al. (7) reviewed 169 patients with lateral stenosis, most of whom had no treatment. After a mean of 2 years, radicular symptoms persisted in 78% of cases, but had improved in 90%. In the vast majority of preoperative patients, however, there was no evidence of neurologic deficits, and in no instances was clinical diagnosis confirmed by imaging or neurophysiologic studies.

### Conservative Management

In a retrospective study (8) of 49 patients followed for a mean of 33 months, it was found at the latest follow-up that 9 patients had undergone surgery, 7 had worsened, 12 were unchanged, and 21 were slightly or significantly improved.

In a prospective study (9), 19 patients with severe symptoms were selected for surgery and 50 patients with moderate symptoms for conservative treatment, whereas 31 were randomized between the conservative and surgical treatment groups. At 3-month follow-up, relief of pain had occurred in most patients. After 4 years, satisfactory results were observed in half of the patients in the conservative group and in four-fifths of those treated surgically. After 10 years, the results showed no significant deterioration in both groups. The results in the patients randomized for surgery were considerably better than in those randomized for conservative management. In another prospective study (10), 67 patients treated surgi-

**FIG. 51-1. A:** T1-weighted magnetic resonance imaging (MRI) sagittal scan showing a narrow spinal canal. The thecal sac has small anteroposterior diameters, particularly at the lower three lumbar levels, but the neural structures show no osteoligamentous compression. **B:** T2-weighted sagittal MRI scan showing severe stenosis at L2-L3 level and less marked stenosis at L4-L5.

cally and 52 nonsurgically were followed for 4 years. At the latest follow-up, satisfactory results were reported by 63% of the patients in the surgery group and 42% of those treated conservatively.

In my experience, most patients with severe central stenosis do not improve or show temporary relief after

**FIG. 51-2.** Anteroposterior myelogram showing lateral stenosis at L4-L5 level. The L5 root is not filled with contrast medium bilaterally (arrows) and the thecal sac shows a mild indentation on both sides.

conservative management. Conversely, patients with central stenosis causing posterior or posterolateral compression of the thecal sac, but no significant nerve root compression in the radicular canal, often show a significant improvement, which is probably due to the natural course of the disease. The same is true for lateral stenosis: if narrowing of the radicular canal is severe and responsible for significant neurologic changes, conservative management does not usually lead to significant improvement, particularly in the long term.

### Candidates for Surgery

There is no indication for surgery in patients with only a narrow spinal canal. Similarly, surgery is usually not indicated in stenotic patients who complain only of back pain, in the absence of deformities, such as degenerative spondylolisthesis or scoliosis, or vertebral instability. In patients with an unstable motion segment who have only back pain it is usually sufficient to carry out a fusion alone if stenosis is mild, because it is very unlikely that neural compression will significantly increase and become symptomatic over time once the motion segment has been stabilized. Conversely, neural decompression should be performed if stenosis is severe, because the modifications of reciprocal position of the articular processes, as a result of fusion, can be responsible for postoperative onset of radicular symptoms.

In patients with radicular symptoms, surgery is indicated when conservative management protracted for at least 3 months has led to no significant improvement.

In the presence of motor deficits only, it can be difficult to decide whether there is an indication for decompression. Surgery is usually indicated when stenosis is severe and the deficits are severe and of less than a few months' duration. In the presence of paresis lasting more than 6 to 8 months, there can be no indication for decompression because there are few or no chances of improvement of muscle function.

The best candidates for surgery are those patients under the age of 70 years with no comorbid diseases, who have a severe or very severe stenosis, long-standing radicular symptoms associated with severe intermittent claudication, moderate, or no motor deficits, and mild or no back pain. On the opposite side of the spectrum are patients who have mild stenosis, mild or inconstant leg symptoms with no precise radicular distribution, a history of claudication after several hundred meters or longer, no motor deficit, and back pain of similar severity to, or more severe than, leg symptoms. In these cases, surgery usually involves high risk of a poor result and should be thus avoided or delayed as long as possible. Between the two extremes there are numerous situations in which the surgical indication should be evaluated individually, based on several factors, which may or may not influence the decision.

### ***Advanced Age***

Several studies have shown that surgical decompression also may offer significant relief of symptoms to patients older than 70 years (6,11–13). In my experience, there is no significant difference in the results of surgery between patients in early older adulthood (60 to 70 years) and those who are older (over 80 to 90 years), provided the stenosis is severe and the patient is in satisfactory general health.

### ***Comorbidity***

In one study (12), a high rate of comorbid illnesses was found to be inversely related to the rate of satisfactory results after surgery. Another study (14) compared the long-term results of surgery in 24 diabetic and 22 nondiabetic patients. In the diabetic group there was a 41% rate of satisfactory results, compared with 90% in the nondiabetic group. Different results, however, were observed in a similar study (15), in which the outcome was satisfactory in 72% of the diabetic and 80% of the nondiabetic patients. Neither the duration of the diabetes before surgery nor its type correlated with the outcome. A mistaken preoperative diagnosis was the main cause of failure in diabetic patients, in whom diabetic neuropathy or angiopathy may mimic the symptoms of stenosis.

### ***Previous Surgery***

Surgery for spinal stenosis tends to give less favorable results in patients who previously underwent decompressive procedures in the lumbar spine (11,16–18). This is particularly true when stenosis is at the same level or levels at which the previous surgery for disc herniation or stenosis had been performed (3). In these cases, decompressive surgery should usually be undertaken in the presence of severe compression of the neural structures and severe symptoms well correlated with the vertebral level or levels that appear stenotic on the imaging studies.

### ***Disc Herniation***

A concomitant disc herniation in the stenotic area does not influence the indications for surgery. However, the presence of multiple, markedly bulging discs associated with only mild posterolateral compression of the neural structures exposes the patient to the risk of persistent anterior compression of the nerve roots after a posterior decompression.

### ***Type of Stenosis***

There is no significant difference in terms of indications for surgery between the various types of central stenosis. However, patients with degenerative or combined stenosis at a single level appear to be the best can-

didates to surgery because they tend to have a better outcome compared to those with stenosis at multiple levels. In patients with constitutional stenosis, the intervertebral disc may play a significant role in the compression of the neural structures. When the disc bulges considerably in the spinal canal, but is not truly herniated, it may be impossible to eliminate the anterior compression of the neural structures and this may lead to less satisfactory results compared with the cases in which the neural compression is caused exclusively by the articular processes. Patients with lateral stenosis tend to have better results than those with central stenosis in terms of relief of both radicular symptoms and back pain, particularly when stenosis, as usually occurs, is at a single level.

### ***Certainty of the Diagnosis***

It is sometimes difficult, in patients with leg symptoms, to determine whether the symptoms are related to compression of a nerve root and which root is involved. This often occurs in patients with mild or moderate narrowing of the central or lateral spinal canal and no motor deficits or reflex changes. In these cases, in which magnetic resonance imaging (MRI) and computed tomography (CT) may be unhelpful, there is an indication for myelography. When myelography is inconclusive, nerve root injection with local anesthetic may be indicated. Even the latter, however, may leave the diagnosis uncertain. These patients are the worse candidates for surgery. Surgical management can be taken into consideration only when other diseases, particularly hip conditions and peripheral neuropathies, are excluded and the clinical symptoms and preoperative investigations indicate that there are enough possibilities that a given spinal root is the cause of symptoms.

### ***Spinal Fusion***

Fusion of motion segments decompressed bilaterally is unnecessary, unless (a) the motion segment, albeit in the absence of degenerative spondylolisthesis, is preoperatively unstable, as shown by flexion-extension X-rays; (b) at surgery, the articular processes have completely been removed, accidentally or purposely, on both sides; or (c) the articular processes have been excised on one side and discectomy has been performed bilaterally in a patient complaining of chronic back pain, particularly when the latter probably originated from the decompressed motion segment. These guidelines, previously indicated based of the clinical experience (3), were confirmed by a prospective randomized study (19).

## **SURGICAL TREATMENT**

### ***Definition of Terms***

Decompression of the lumbar spinal canal can be carried out by central laminectomy—also defined as bilat-

eral or complete laminectomy—or by laminotomy. The latter—also called keyhole laminotomy or hemilaminectomy or partial hemilaminectomy—consists in the removal of the caudal portion of the proximal lamina, the cranial portion of the distal lamina and a varying portion of the articular processes, together with a part of, or the entire, ligamentum flavum on the side of surgery.

The term *foraminotomy* indicates removal of a part of the posterior wall of the intervertebral foramen, while the term *foraminectomy* refers to complete excision of the wall of the foramen.

### Unilateral Laminotomy at a Single Level

#### Indications

The main indication is lateral stenosis at a single level on one side.

The preoperative planning may be difficult when lateral stenosis is severe and symptomatic on one side and mild and asymptomatic on the opposite side. In these cases, the advantage of performing a unilateral decompression is more to preserve the stability of the motion segment and to avoid the risk of onset of radicular symptoms on the asymptomatic side after surgery. There are patients who complain of radicular pain for several weeks or months after decompression on the asymptomatic side. A possible explanation is that the surgical trauma and the scarring tissue may irritate a nerve root which is not significantly compressed before surgery, while these factors have no detrimental effect on a compressed root.

Unilateral decompression may also be indicated in the presence of severe lateral stenosis on both sides in older patients with unilateral symptoms who are in poor general health or when there are high chances that bilateral decompression may lead to vertebral instability and spinal fusion is, for any reason, not indicated.

In patients with central stenosis at a single level or multiple levels, unilateral laminotomy may be indicated in the presence of monoradicular symptoms, particularly when nerve root injection with a local anesthetic has shown that a single root is symptomatic or when a more extensive decompression appears unnecessary or contraindicated.

#### Technique

The surgical technique is similar to that used to remove a herniated disc. When using the operating microscope, the skin incision is some 4 cm in length. I usually begin by removing the caudal half of the cranial lamina and the medial half of the inferior articular process of the vertebra above using an osteotome. There is no risk in using the osteotome for removal of the inferior articular process because the underlying superior articular process of the vertebra below protects the emerging nerve root. The lig-

**FIG. 51-3.** Postoperative radiograph of a patient with lateral stenosis at L4-L5 level on the left side who underwent laminotomy on that side (arrows). Note the wide decompression performed on the transverse plane.

amentum flavum can now be seen and detached from the border of the caudal lamina and the superior articular process with a curette. The osteotome can also be used to remove the proximal half of the caudal lamina and the superior articular process. When removing the latter, attention must be paid to place the blade of the osteotome in the most lateral part of the process and to orient the osteotome 15° to 20° obliquely in a medial-lateral direction to avoid damage to the underlying root (17). Alternatively, a Kerrison rongeur is used for piecemeal removal of the caudal lamina and the superior facet. Once the emerging root and the thecal sac are exposed, bone removal from the lateral part of the canal is continued using the osteotome obliquely until the neural structures are completely free of compression. Complete excision of the articular processes must be avoided. However, when laminotomy is performed on one side only, decompression can be generous because there is no risk to destabilize the motion segment, if this is stable preoperatively (Fig. 51-3). The disc is inspected and excised if it is soft and protrudes markedly. The final step is to use a probe to determine whether the emerging nerve root is compressed in the intervertebral foramen and to remove bone until it is completely free of compression, paying attention to not perform an unnecessary foraminectomy.

### Bilateral Laminotomy at a Single Level

#### Indications

The advantage of bilateral laminotomy at a single level, compared with central laminectomy, is that laminotomy preserves vertebral stability to a greater extent than laminectomy by preserving the supraspinous and interspinous ligaments and the central portion of the vertebral arch.

This procedure is the treatment of choice in patients with lateral stenosis at a single level in the presence of bilateral leg symptoms. In central stenosis, bilateral laminotomy is indicated when narrowing of the spinal canal is mild or moderate, particularly when discectomy on one side or both sides is performed due to concomitant disc herniation or marked disc bulging. This often occurs in constitutional stenosis, in which bilateral laminotomy should usually be preferred to central laminectomy. In degenerative central stenosis, there is an indication for laminotomy when narrowing of the spinal canal is not exceedingly severe. When stenosis is marked, bilateral laminotomy may lead to persistence of radicular symptoms due to inadequate decompression of the thecal sac in the central portion of the spinal canal.

### **Technique**

The technique is similar to that described for unilateral laminotomy. More attention must be taken to preserve the outer third of the articular processes because total or subtotal arthrectomy, particularly when bilateral, entails a high risk of postoperative instability.

### **Laminotomies at Multiple Levels**

#### **Indications**

Patients with constitutional central stenosis often have stenosis at multiple levels. Usually they are middle-aged or in early older adulthood and in many cases stenosis is of moderate severity and the intervertebral discs are normal in height. Furthermore, the discs often play an important role in the compression of the neural structures by protruding in the spinal canal. In these patients, central laminectomy exposes the patient to the risk of postoperative vertebral instability, particularly when discectomy is carried out or stenosis involves the high lumbar levels, where it is more difficult, with central laminectomy, to preserve the articular processes. In these cases, laminotomies at multiple levels allow vertebral stability to be preserved, thus avoiding fusion procedures at two or more levels.

The same considerations are valid for degenerative central stenosis. In this type of stenosis, however, it is less often necessary to make any effort to preserve vertebral stability and avoid spinal fusion because the presence of intervertebral osteophytes or a marked decrease in height of the discs exposes the patient less to the risk of postoperative instability. Furthermore, narrowing of the spinal canal may be much more severe than in constitutional stenosis and laminectomy thus ensures a more complete neural decompression. However, in patients with degenerative stenosis there is also often an indication for multiple laminotomies. This occurs when central laminectomy is a risk to destabilize the motion segments, or

stenosis, although involving the whole canal, is particularly severe in the nerve root canal. An advantage of laminotomy is that decompression is focused on the nerve root emerging from the thecal sac and it can therefore be more effective in terms of clinical results, because in stenotic patients the radiated symptoms are often caused by compression of the emerging root, rather than the thecal sac.

Occasionally, the two procedures can be combined, when stenosis is very severe at one or two levels and moderate and essentially lateral at one or two additional levels.

### **Technique**

The spine is exposed using the same technique employed for central laminectomy. The interlaminar spaces are cleaned of residual muscle tissue using a curette. Beginning on one side, laminotomy is performed, as described earlier, at the most stenotic level and then at the cranial or caudal levels needing decompression. The same procedure is successively carried out on the opposite side (Fig. 51-4). When performing laminotomy at two adjacent levels, care should be taken not to remove the entire lamina on one side and particularly on both sides at the same level, since in the latter case the spinous process becomes unstable and should be removed. If complete arthrectomy is inadvertently carried out on one side, at least the outer third of the articular processes on the opposite side should be preserved and discectomy should be avoided, particularly on both sides.

**FIG. 51-4.** Radiograph taken 2 years postoperatively in a patient with constitutional stenosis at L2-L3 to L4-L5. The arrows indicate the laminotomies performed at the stenotic levels.

### Results of Laminotomies

In a prospective randomized study comparing central laminectomy with multilevel laminotomy in central lumbar stenosis, Postacchini et al. (20) found laminotomy to give similar overall results to total laminectomy. Patients submitted to laminotomy had less back pain and none had vertebral instability postoperatively, but they also had less subjective improvement for radicular symptoms, although the difference was not significant. It was concluded that multiple laminotomy is the treatment of choice when narrowing of the spinal canal is mild or moderate.

In a prospective study of patients with central or lateral stenosis, 96% were satisfied with tier treatment at a mean of 4 years after surgery (21). Aryanpur and Ducker (22) obtained satisfactory results in the vast majority of their 32 patients with lateral stenosis. None of these individuals experienced surgical complications. However, Young et al. (23), using multiple laminotomy with an operating microscope in 32 patients with lateral or central stenosis reported a 9% incidence of dural tears. In the series of patients mentioned above, we found a higher incidence of postoperative neural deficits with laminotomy than with central laminectomy and in most cases neural complications occurred in patients with severe stenosis.

# Laminectomy for Spinal Stenosis

Brian J. C. Freeman

---

Spinal stenosis may be defined as a narrowing of the central spinal canal, the lateral recess, or the neural foramina. Normal canal size has been reported as a midsagittal diameter of greater than 11.5 mm and a cross-sectional area of greater than 1.45 cm<sup>2</sup> (1,2). *Absolute stenosis* is said to occur when the midsagittal diameter of the canal is less than 10 mm and *relative stenosis* is said to occur when the midsagittal diameter of the canal is between 10 and 13 mm (3).

Spinal stenosis may be primary or secondary. Primary spinal stenosis may be congenital or developmental (e.g., achondroplastic stenosis or constitutional spinal stenosis). Secondary stenosis occurs in a canal of normal dimension and is acquired as a result of conditions such as spondylosis. Degeneration in the three joint complexes typically starts this process. Synovitis commencing in the facet joints leads to the thinning of articular cartilage and loosening of the joint capsule (4). This leads to greater spinal motion accelerating degeneration in the disc. Disc height is lost leading to a reduction in the size of the neural foramina (so called up-down stenosis). The ligamentum flavum becomes redundant with infolding further contributing to a reduction in canal dimensions (5). Osteophytes on the superior articular facet narrow the lateral recess; osteophytes on the inferior articular facet narrow the central canal. Reduction in canal volume can compromise vascular supply to the neural elements leading to an ischemic neuritis (6), and direct compression of nerve roots may lead to demyelination causing unremitting pain. Spinal stenosis may be present in isolation or in combination with other conditions such as degenerative spondylolisthesis or degenerative scoliosis. The natural history of spinal stenosis remains unclear. There are few longitudinal prospective studies documenting the course in untreated patients (7). Existing literature suggests that symptoms progress in approximately 20% (8) to 33% (7) of nonoperated patients.

## INDICATIONS FOR SURGERY

Patients present with an insidious onset of back, buttock, thigh, and calf pain. Typically in neurogenic claudication, back, and leg pain are increased when standing and walking. Patients may sit or bend forward to relieve this pain. These postural changes result in an increase in the size of the canal. Walking is increasingly restricted and ultimately rest pain or a neurogenic bladder may develop. Vascular claudication may be confused with neurogenic claudication. The patient with vascular insufficiency has pain that is increased by walking and lying down but is often decreased by standing. The patient with spinal stenosis may be able to cycle a considerable distance because the lumbar spine is flexed during this activity. The patient with vascular insufficiency however is likely to provoke symptoms during such activity. A search for risk factors such as cigarette smoking and diabetes, plus a careful examination of peripheral pulses will usually help to distinguish the two conditions.

Physical examination in a patient with spinal stenosis typically reveals a loss of lumbar lordosis, increased pain on extension, and reduced pain on flexion. Specific neurologic signs are rare, but may be provoked by exercise. Passive straight leg raise is often negative. The shuttle walking test (9) and the exercise treadmill (10) have been used to measure baseline functional status and surgical outcome objectively. Patients with hip, groin, or knee pain may have osteoarthritis of the hip or knee. If doubt exists, plain radiographs of the lumbar spine, pelvis, and knee will help to confirm the pain source. Patients with diabetes commonly have symptoms of peripheral neuropathy. Electromyograms (EMGs) and nerve conduction studies may help with the diagnosis. Finally it should be remembered that there is an associated cervical stenosis in approximately 5% of patients with lumbar stenosis (11).

Conservative management should always be considered before surgery. Nonsteroidal antiinflammatory medication can reduce both back and leg pain. Physiotherapy working on trunk stabilization and flexion exercises may be beneficial. General fitness work including cycling, swimming, and walking in water may improve a patient's symptoms. The use of epidural steroids remains controversial. They may relieve acute pain, but long-term results have been disappointing. Others suggest epidural steroids should be considered as a nonsurgical alternative, especially in the older adult patient where surgery carries greater risk (12). There is circumstantial evidence that calcitonin is beneficial for approximately 40% of patients with neurogenic claudication, particularly in those with spinal Paget disease (13). Simotas et al. studied 49 patients with lumbar spinal stenosis who were treated with aggressive nonoperative treatment including exercise, analgesics, and epidural steroids (14). They reported 25% of patients were significantly better after a 3-year period, and that neurologic deterioration was rare.

Patients who fail conservative treatment and persist with moderate or severe intractable leg pain should be considered for surgery. Patients who are unable to stand upright, and have a significant reduction in walking distance, and who find this degree of disability unacceptable should also be considered for elective surgery. The patient should be medically fit and able to tolerate a general anesthetic, the prone position, and the estimated blood loss. Occasionally, among older adults multiple comorbidities may preclude surgery. A delay in surgery of months or even years does not appear to adversely affect the result of surgery (15). Patients with rest pain or acute onset of urinary retention or fecal incontinence should be considered for *urgent* surgery.

Imaging studies are of prime importance in defining the level and degree of stenosis. Plain radiographs may show a narrow interpedicular distance on the anteroposterior view and short pedicles on the lateral view in congenital stenosis. They may also reveal a degenerative spondylolisthesis or a degenerative scoliosis. Water-soluble myelography combined with computed tomography (CT) has until recently been regarded as the gold standard. However, this invasive technique has largely been replaced by fine-cut CT scan (Figs. 52-1, 52-2) and magnetic resonance imaging (MRI) (Figs. 52-3 through 52-7). The latest generation two-dimensional CT scanners allow soft tissue and bony windows of both axial and sagittal orientation. However, there is still the difficulty of surveying the whole spine with CT. MRI is noninvasive and allows surveillance of the whole spine. Its use is contraindicated in the presence of ferromagnetic implants. Bony detail and extent of foraminal stenosis is still best observed on a good CT scan. CT and MRI remain complementary investigations, with the majority of surgeons opting for MRI as the initial investigation.

**FIG. 52-1.** Case 1. An 81-year-old man with bilateral leg pain, maximum walking distance 100 yards. Computed tomography of the spine, axial section at L3-L4, showing moderate central and lateral recess stenosis. Circumferential disc bulge (*arrow*) and hypertrophic degenerative changes in the facet joints with associated flaval ligament thickening (*arrow*).

Before proceeding with surgery all imaging should demonstrate clear evidence of neural compression that is *congruent* with the patient signs and symptoms. If doubt exists regarding the extent of decompression, electrodiagnostic testing can help. EMGs show changes in approximately 80% of patients with spinal stenosis and may help

**FIG. 52-2.** Case 1. Computed tomography of the spine, axial section at L4-L5, showing further central canal and lateral recess stenosis.

**FIG. 52-3.** Case 2. An 80-year-old man with weakness in both legs when walking more than 3 yards. Midline sagittal T2-weighted magnetic resonance image scan showing critical central canal stenosis L3-L4, relative stenosis L2-L3, and L4-L5.

to localize surgery (16). Somatosensory evoked potentials have been used, but have a high false-positive rate. Motor evoked potentials may also play a role in the assessment of the complex patient. The response to lumbar epidural steroids can predict the outcome of decompressive surgery.

**FIG. 52-4.** Case 2. Right parasagittal T2-weighted magnetic resonance image showing foraminal stenosis, right L3-L4 (arrow).

**FIG. 52-5.** Case 2. Axial T2-weighted magnetic resonance image through L3-L4. Central and lateral canal stenosis. Note facet joint hypertrophy and thickening of ligamentum flavum.

In one series, patients who had pain for less than 12 months and in whom epidural steroids reduced leg pain by 50% for more than 1 week, a good result was observed in 95% 12 months after surgery (17). On the other hand if symptoms were present for more than 1 year, and the

**FIG. 52-6.** Case 3. A 76-year-old man unable to stand straight, intense bilateral leg pain. Walking distance 3 yards. Midline T2-weighted magnetic resonance image scan showing multilevel severe central stenosis due to degenerative discs and narrow central canal.

**FIG. 52-7.** Case 3. Right parasagittal T2-weighted magnetic resonance image scan showing multilevel foraminal stenosis, right L2-L3, L3-L4, L4-L5, L5-S1. Contrast with the foramina at L1-L2 and above. This patient underwent a five-level spinal decompression facilitated by a spinous process osteotomy. Estimated blood loss 800 to 900 mL. Patient was discharged from hospital on postoperative day 6.

improvement after epidural was less than 50% and only 5% were improved by surgery. Diagnostic nerve root blocks can be helpful in predicting the outcome of localized decompression. Preoperatively, if the patient can find relief by postural changes such as sitting or bending forward, a good outcome can be predicted (18). If postural changes do not produce relief, only 50% of patients can be expected to improve with surgical decompression.

## SURGICAL TECHNIQUE

Patients are fitted with thromboembolic deterrent (TED) stockings. A general anesthetic is administered and a urinary catheter is inserted. The patient is positioned in mild lordosis on well-padded rolls. The abdomen must be free to reduce venous distension and potential epidural venous bleeding. We routinely use hypotensive anesthesia and intraoperative cell salvage to minimize the need for homologous blood transfusion. I prefer to use Loupe magnification (2.5×) with a fiberoptic light source.

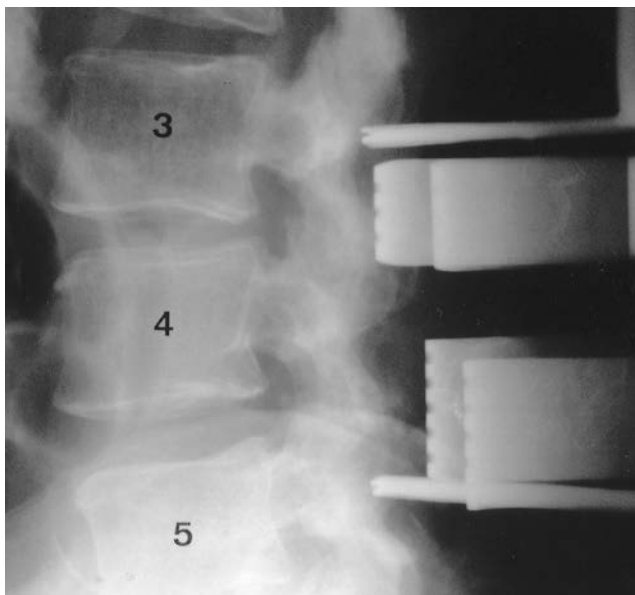

### The Approach

I commonly use a spinous process osteotomy (19) to facilitate lumbar decompressive surgery. The multifidus

is taken down unilaterally approaching on the most clinically symptomatic side. Care is taken not to extend the subperiosteal dissection beyond the medial aspect of the facet joint, thereby preserving the medial branch of the dorsal ramus. Using a broad curved osteotome, an osteotomy is made through the involved segments just superficial to their junction with the lamina. The spinous processes with the attached interspinous and supraspinous ligament are then retracted to reveal the lamina. The technique affords excellent visualization with a wide area available for Kerrison use while minimizing destruction to the tissues. Weiner et al. discuss the advantages of this approach including reduction in paraspinous denervation, preservation of the supraspinous/interspinous ligament complex, reduction of dead space, and preservation of the median furrow, which may be of cosmetic concern to the patient (20). I believe the procedure saves time when compared to a bilateral take down of multifidus and results in significantly lower blood loss. An average blood loss is 250 mL (range 125 mL to 1,100 mL) for two, three, four and five level decompressions, a figure similar to that reported by Weiner et al. (20).

### Laminectomy

Laminectomy addresses the global degenerative process by allowing decompression of the central canal, lateral canal, and neural foramina across multiple levels. The extent of the decompression will depend on the preoperative imaging. The most frequent error is to decompress too little (21). Most decompressions are carried out for degenerative changes. These changes will continue after surgery and it is easier to fully and adequately decompress on the first occasion. The laminectomy is most easily performed with a Leksell rongeur. This double-action rongeur is particularly good for hard bone. When the majority of the bony work has been done, checks should be made for any adhesions between the remaining lamina and the dural sac with a Watson-Cheyne dissector. The laminectomy is then completed with a Kerrison rongeur. The decompression should always begin away from the area of maximal stenosis. The lamina can safely be removed out to the most medial portion of the articular facets. Care is taken to preserve the pars interarticularis. When the central canal has been decompressed for the planned distance it is advisable to place a Kocher tissue forceps at the most cranial and at the most caudal extent of the decompression and take an X-ray (Fig. 52-8). This provides clear documentation of the limits of decompression and allows for any intraoperative adjustment to the length of decompression (Fig. 52-9). The decompression is now moved out laterally. A partial facetectomy is best achieved with a 1 to 2 cm osteotome angled away from the dura commencing cranially and moving to the most caudal limit of the decompression. The loose bone is then removed with a pituitary

**FIG. 52-8.** Case 1. Operative marker film showing Kocher tissue forceps on the cranial and caudal extent of the planned decompression.

rongeur. Up to 50% of the facet joint can be removed without significantly compromising stability. Finally, the nerve root canals are checked and further decompressed with a Kerrison rongeur. At this point it is helpful if the assistant retracts the dura protected by a pattie, with a fine-tipped sucker in one hand and a nontoothed forceps in the other. Epidural bleeding may be controlled by judicious use of bipolar diathermy. After decompression of the nerve root a 3 to 4 mm probe should easily pass out the nerve root foramen and it should be possible to

**FIG. 52-9.** Case 1. Operative picture showing the extent of decompression. Partial laminectomy L3, and total laminectomy L4 and L5 have been performed.

demonstrate a 1 cm medial displacement with a root retractor. One should check for concomitant disc herniation that may be contributing to the neural compression. Rarely is it necessary to perform a discectomy in addition to a laminectomy. However, if laminectomy and discectomy are performed simultaneously, then a spinal fusion should be considered to prevent the risk of postoperative instability. I prefer to avoid the placement of Gelfoam, Surgicel, Floseal, or other hemostatic sealant on the dura. There are reports of cauda equina and spinal cord compression caused by such agents (22,23).

### Hemilaminectomy

Hemilaminectomy involves the unilateral removal of bone and ligamentum flavum. It is appropriate for patients with unilateral symptoms from a unilateral stenosis. Hemilaminectomy allows the ipsilateral exiting and the traversing nerve root to be decompressed, while preserving the spinous process and the interspinous and the supraspinous ligaments. To improve visualization, the table can be tilted away from the surgeon. Foraminal stenosis may be decompressed with an upbiting Kerrison. Total facetectomy can decompress this region, but concern regarding postoperative stability will mean that stabilization and fusion will usually be necessary.

Extraforaminal stenosis is best dealt with by the paraspinous approach described by Wiltse (24). Decompression may require total facetectomy, removal of the transverse process, and partial removal of the pedicle.

### The Closure

When closing a spinous process osteotomy, the retractors are removed and the spinous process remnant checked for any sharp bone spikes. If present, these are removed with a rongeur. A deep drain is placed and the dorsolumbar fascia is resutured to the supraspinous ligament/fascial complex with the osteotomized spinous process resuming its native position, maintaining the posterior midline furrow.

### Postoperative Care

Patients are mobilized the next morning. The drains are removed at 24 to 48 hours. If concern exists about stability, a lumbosacral orthosis may be worn for the first 6 weeks. Patients are usually discharged within 3 to 5 days. Physiotherapy to increase range of motion and restore trunk stability is offered at 6 weeks. Patients may return to light work at 6 weeks and heavy manual work at 3 months.

### RESULTS

Johnsson et al. compared 44 patients with lumbar spinal stenosis treated surgically to 19 patients with lum-

bar spinal stenosis treated without surgery (7). The study was not prospective, nor randomized. They found 59% of operated patients to be clinically improved, compared to 32% of nonoperated patients. However, a greater percentage of the surgical group compared to the nonsurgical group (25% versus 10%) was worse at follow-up. Katz et al. reported retrospectively on 88 consecutive patients who underwent laminectomy for degenerative lumbar stenosis and were followed for 2.8 to 6.8 years (25). Repeat operations for instability or stenosis were required for 17% of patients and 30% had severe pain at the latest follow-up. Risk factors for poor outcome included preoperative comorbidity and limited single-level decompression. They concluded the long-term outcome of decompressive laminectomy was less favorable than had been previously reported.

Turner et al. reviewed 74 articles reporting on the outcome of surgery for spinal stenosis. Overall they found 64% of patients had a good or excellent result (26). The results in those with degenerative spondylolisthesis were good or excellent in 83% to 85% of patients. Atlas et al. reported the 1-year outcome of surgical and nonsurgical management of lumbar spinal stenosis in a prospective, nonrandomized cohort study (27). They concluded that patients with severe lumbar spinal stenosis treated surgically had greater improvement than patients treated nonsurgically. They subsequently reported the 4-year outcome (28). Of 119 patients with 4-year follow-up, 67 were treated surgically (the vast majority with laminectomy) and 52 were treated nonsurgically. The surgical group had more severe symptoms and worse function at baseline. Even after control for baseline differences, surgically treated patients reported better outcome at 4 years compared to nonsurgically treated patients: 70% of the surgical group compared to 52% of the nonsurgical group reported that their predominant symptom (either leg or back pain) was better. Satisfaction was greater in the surgical group: 63% compared to 42% in the nonsurgical group. The relative benefit of surgery declined over time with differences in outcome narrowing between the two groups over the four years. Nevertheless, the relative benefit of surgery remained superior to nonsurgical treatment.

In comparing the technique of multiple laminotomies versus total laminectomy, Postacchini et al. reported a longer operating time for bilateral laminotomy at two or three levels compared to total laminectomy at an equal number of levels (29). They reported a higher incidence of neural complications in the laminotomy group and a higher incidence of instability in the laminectomy group. At present Postacchini reports that 70% to 80% of patients have a satisfactory result from surgery, but the outcome tends to deteriorate in the long term (30). Iguchi et al. reported a minimum 10-year outcome following decompressive laminectomy for degenerative lumbar spinal stenosis (31). Over 50% of patients in this series were evaluated as good or excellent.

Comorbidities including osteoarthritis, cardiac disease, rheumatoid disease, and chronic pulmonary disease have a detrimental effect on outcome following surgery according to Katz et al. (25). Ragab et al. reported on 118 patients over the age of 70 years who had surgery on the lumbar spine for spinal stenosis (32). In this study advanced age and the presence of comorbidity did *not* affect the overall outcome of pain relief and resumption of daily activities, with 91% of patients experiencing good or excellent results. Similarly, Sanderson and Wood reported good or excellent results in 81% of patients 65 years of age or older undergoing decompression for degenerative lumbar stenosis (33). Diabetes mellitus was associated with poor results in one series (34), however Cinotti et al. showed similarly successful outcomes following spinal decompression in diabetic and nondiabetic patients (35). There is a strong association between self-rated health and surgical outcome reported by Katz et al. (36).

Gibson et al., in the Cochrane Review, concluded there was no acceptable evidence of the efficacy of any form of decompression for degenerative lumbar spondylosis or spinal stenosis (37). There is an urgent need for properly conducted prospective randomized controlled trials with subjective and objective outcome measures to assess the efficacy of decompressive surgery for spinal stenosis.

## COMPLICATIONS

### Dural Tears

Dural tears occur in approximately 5% of primary decompressions for spinal stenosis. This rate may increase in revision decompression procedures to 13.2% (38). Tears should be repaired with a 4-0 to 6-0 running suture (I prefer 5-0 Vicryl) and the repair should be tested with a Valsalva maneuver (positive pressure inspiration for several seconds). Fibrin glue may be used to supplement the repair, or indeed if the tear is small, fibrin glue alone may be sufficient. A deep drain is placed and allowed to drain under the effects of gravity. A careful watertight closure of the dorsolumbar fascia, subcuticular tissues, and skin is strongly recommended. Patients are kept lying flat for 48 hours, at which point the drain is usually removed. Dural tears that are recognized and treated appropriately do not lead to long-term sequelae (39).

### Neural Injury

Primary neural injury is extremely rare with primary lumbar decompressions but less so with revision procedures. The surgeon must suspect a nerve injury when a cerebrospinal fluid leak is observed and a close inspection should be made. Patients on aspirin may develop a postoperative hematoma that can compress the thecal sac leading to a delayed cauda equina syndrome. Particularly,

if the case was associated with a dural tear, the cauda equina seem less resilient to compression by an expanding hematoma. The operating surgeon should, as a matter of routine, perform a complete neurologic assessment of postoperative patients in the recovery area and document this in the medical records. Repeated neurologic assessment should be performed over the following 24 to 48 hours. Any significant deterioration in lower extremity power, loss of sensation in the perineal area, inability to void, or fecal incontinence must be investigated *urgently* with MRI and the appropriate action taken immediately.

### Infection

The risk of infection in primary lumbar decompressions is about 1% to 2%, however this figure may rise to 5% in revision procedures. Suspected cases should be taken to the operating theatre and have both the superficial and deep tissues explored and cultured. A thorough débridement should be performed and deep drains left *in situ*. A low threshold for repeated débridement should be operated. For deep infections, it is common to require 3 weeks of the intravenous antibiotics, dependent on the organism and the measured response of the patient's inflammatory markers.

### Iatrogenic Instability

Instability following laminectomy is uncommon. White and Wiltse reported a 2% incidence of postoperative iatrogenic spondylolisthesis (40). Johnsson et al. however reported 10 out of 31 patients (32%) in their series developing a slip following radical decompression (41). Postoperative slips greater than 2 mm were associated with poorer results and slips appeared to be more common in females. Robertson et al. stressed the importance of facet joint orientation and dimensions rather than the absolute amount of the joint removed (42). More sagittally aligned facets were more likely to result in slippage when compared to the more coronally aligned facets. Extensive decompressions over multiple levels with subtotal or near total facetectomies and discectomies are much more likely to slip. These cases should be considered for preoperative fusion. However, it is generally accepted that fusion is not required following decompressive surgery provided there is no evidence of segmental instability. This is confirmed by Grob et al. who prospectively evaluated 45 patients undergoing decompression of the spine with and without arthrodesis for the treatment of lumbar spinal stenosis without instability (43). They concluded that in the absence of segmental instability, arthrodesis was not necessary after decompression of the lumbar spine, provided the stabilizing posterior elements of the spine are preserved during the operation. This is possible with a spinous process osteotomy as previously described. Those patients with

preoperative spondylolisthesis and degenerative scoliosis are special cases and ones in which spinal fusion should more readily be contemplated.

### Epidural Fibrosis

This may be associated with heavy epidural bleeding and the excessive use of the bipolar diathermy. It is diagnosed as a worsening of leg pain and may be diagnosed by MRI with the administration of a contrast agent such as gadolinium. Treatment options include drugs such as amitriptyline, carbamazepine, or gabapentin, X-ray-targeted foraminal epidural steroid injections, or occasionally revision surgery and neurolysis.

### Arachnoiditis

This is characterized by intrathecal fibrosis and responds poorly to treatment. It may be minimized by careful handling of neural tissue and frequent release of retracted nerve roots during surgery. The risk of arachnoiditis is thought to increase with epidural bleeding. Larger epidural vessels should be controlled with bipolar diathermy, smaller vessels with temporary placement of patties, or absorbable hemostats (e.g., Surgicel).

### Failure to Relieve Pain

This may occur with long-standing ischemic neuritis, inadequate decompression, bony regrowth (44), postoperative instability, pseudarthrosis, flat back syndrome, and neural injury. Some of these problems are correctable. Many, however, are not and these patients should be referred appropriately to pain management programs.

### SUMMARY

Decompression without arthrodesis is the preferred treatment for spinal stenosis without instability. The spinous process osteotomy does much to facilitate decompressive surgery, while preserving the stabilizing posterior elements. Laminectomy allows a global decompression of the central canal, lateral canal, and neural foramen. Laminotomy is not suitable for congenital stenosis or constitutionally narrow canals. If more than one facet joint is sacrificed or the disc is removed then prophylactic fusion should be considered. Advances in anesthetic and surgical techniques mean the procedure may safely be offered to patients well over 80 years of age, provided multiple comorbidities have been taken into account. There is an urgent need for properly conducted randomized controlled trials to assess the efficacy of decompressive surgery versus conservative treatment of spinal stenosis.

## CHAPTER 53

# Laminoplasty

Yoshiharu Kawaguchi and Masahiko Kanamori

---

Extensive laminectomy has been used widely for the treatment of lumbar spinal stenosis. However, results of laminectomy were not consistent because of postoperative instability of the lumbar spine and laminectomy membrane into the spinal canal. To resolve these problems, the technique of lumbar expansive laminoplasty was developed in 1981 (1). This operation enlarges the spinal canal and preserves the posterior spinal structure for the adequate decompression of spinal nerve and reinforcement of spinal stability (2). This procedure has been used in patients who are active physically with combined lumbar stenosis, including developmental or degenerative stenosis, spinal stenosis with multiple ossification of intraspinal ligaments or herniated nucleus pulposus, and degenerative stenosis accompanied by segmental instability (3–5). In this chapter, we describe the indication, operative procedure, postoperative management, results, and complications of lumbar laminoplasty.

### INDICATIONS

Laminoplasty is usually carried out on active patients who have multilevel spinal stenosis. Recently, we have also used laminoplasty on older patients (over 70 years) who had spinal stenosis with segmental instability.

Other indications for laminoplasty include:

1. Multilevel degenerative spinal stenosis accompanied by developmental spinal stenosis in patients in whom heavy physical activity is required in daily living.
2. Multilevel combined spinal stenosis accompanied by herniated nucleus pulposus or intraspinal ossified masses (bony spur formation at the posterior vertebral edge, peridiscal ossification, ossification of the posterior longitudinal ligament, or ligamentum flavum) in active patients.
3. Cauda equina tumor in young or middle-aged patients (less than 60 years).

4. Multilevel degenerative spinal stenosis with instability of the segment in patients who require reinforcement of stability of the lumbar spinal segment.
5. Migrated lumbar disc herniation.

### OPERATIVE PROCEDURE

#### Groove Making in the Laminae

The spinous process is carefully removed at its base and used as a bone graft. The target laminae are cut by high-speed air drill. The outer edge of the bilateral grooves is made to reach the lateral one-third of the articular facet. The groove on the hinged side should be wider and more conical than the groove on the open side.

#### Tunnel Making for Wiring (Fig. 53-1A)

Just prior to mobilization of the laminae, small holes are made in each lamina on the open side, using a special awl, a pusher, and a perforator.

#### Rotating the Laminae

The laminae are completely cut off along the groove on the open side using a diamond burr and the ligamentum flavum is also dissected on the same side with a knife. Then, the laminae are turned up to an angle of at least 45°. In the hinged side, an incomplete separation of the laminae is recommended by means of an interrupted perforation of the internal cortex using a diamond burr.

#### Intraspinal Intervention

If there is a symptomatic herniated nucleus pulposus or cauda equina tumor, discectomy or tumor extirpation is performed through the open gap.

**FIG. 53-1. A–C:** Schematic representation of the procedure of expansive laminoplasty. [From Tsuji H. Expansive laminoplasty. In: Tsuji H, Dawson E, eds. Comprehensive atlas of lumbar spine surgery. St. Louis: Mosby-Year Book, 1991:116–119, with permission. (This edition published by arrangement with Nankodo Co, Ltd, Tokyo.)]

### Trimming of the Cut Surface

The edge of the groove facing the lateral recess of the spinal canal is trimmed with a rongeur and curette, and the remaining ligamentum flavum is removed as completely as possible.

### Wiring (Fig. 53-1B)

A 0.3-mm braided steel wire or 1.0 braided nylon is passed through each hole. Using a small-diameter steel burr, the orifice of each hole is sufficiently widened to facilitate each passage of the wire or the nylon. A curved blunt needle is used to pass the wire or nylon through the hole in the bone.

### Bone Grafting and Fat Tissue Grafting (Fig. 53-1C)

The spinous processes are reformed into cubes measuring 15 to 20 mm × 10 to 15 mm for bone grafts, and a transverse hole is made in each graft. One end of the steel wire or the nylon, first passed through the lamina, is also passed through the bone graft and the articular process. The wire or the nylon is tied after the bone graft is interposed into the gap on the open side. The laminae, including the articular processes are thoroughly decorticated with an air drill. The bone chips for the spinous process or posterior iliac bone are translated on both sides. Free fat tissue is also grafted onto the epidural areas of the open gap. After a suction drain is placed, the wound is closed.

## POSTOPERATIVE MANAGEMENT

The suction drain is removed 48 hours after surgery. Assisted turning of the patient and active exercise of the lower extremities are begun on the second postoperative day. The patient is permitted to walk 1 to 2 weeks after surgery wearing a body cast or hard corset. The cast or hard corset is worn for 4 weeks, followed by a soft corset for 8 weeks.

## RESULTS

### Neurologic Results

54 patients with lumbar spinal stenosis were operated on from 1981 to 1999. The average length of follow-up was 5.5 years with a range from 2 to 13 years. The local pathologic findings included 25 patients with degenerative stenosis, 12 with combined stenosis, and 6 with hyperostotic stenosis. Thirteen patients revealed spondylolisthesis and 12 had scoliosis (Cobb angle greater than 10°). The operation time and blood loss per one lamina were 60 minutes and 214 mL, respectively. Twenty-four patients (44%) received blood transfusion.

The Japanese Orthopaedic Association (JOA) proposed a scoring system for low back pain (Table 53-1).

Neurologic results were assessed by the system and evaluated based on the postoperative score and the recovery rate was calculated using the following formula:

The recovery rate (%) =

$$\frac{(\text{postoperative score} - \text{preoperative score}) \times 100}{29 (\text{full score} - \text{preoperative score})}$$

The preoperative and postoperative JOA scores and recovery rate are shown in Table 53-2. The average recovery rate at the last follow-up was 69.2%±21.1% in degenerative stenosis, 66.5%±44.5% in combined stenosis, and 65.2%±26.1% in hyperostotic stenosis. That was 54.7%±37.4% in the patients with spondylolisthesis and 63.7%±29.5% with scoliosis. The recovery tended to be poor in the patients with spondylolisthesis, but there was no statistical difference. As yet, long-term result has not been clarified, because this procedure developed in the early 1980s. In our follow-up series of more than 5 years, 6 patients showed spinal instability at the adjacent level of expansive laminoplasty.

### Roentgenographic Results

Using computed tomography, the shape of the spinal canal was enlarged with a rectangular shape (Fig. 53-2). The average cross-sectional area was expanded from 1.8 cm<sup>2</sup>±0.9 cm<sup>2</sup> to 3.0 cm<sup>2</sup>±0.9 cm<sup>2</sup> after surgery. None of the patients showed kyphotic change of the lumbar spine, but five patients revealed progression of degenerative spondylolisthesis. Laminar fusion was achieved in 21 patients (43%). In the patients without laminar fusion, the range of flexion-extension motion of the operated spinal area was reduced to 58% of preoperative range.

### Complications: How to Avoid/Treat

Surgical trauma in lumbar laminoplasty is not as limited as with laminectomy, however, there were no major general or neurologic complications experienced intraoperatively or postoperatively. Blood transfusion was required in 44% of the patients, but in the more recent cases, autologous blood transfusion was introduced and allogenic transfusion was avoided.

Expansive lumbar laminoplasty is most suitable for central canal stenosis. Decompression of the nerve root is usually difficult in patients with lateral stenosis in the ordinary procedure. Lateral recess decompression can be performed at the open side in the same manner as laminectomy. When decompression of the lateral recess at the hinge side is required, decompressive fenestration should be performed before lifting up the laminae. For decompression of the nerve root tunnel, unroofing of the tunnel can be performed.

In long-term follow-up of more than 5 years, spinal instability at the adjacent level of the laminoplasty was observed in 6 patients. This may be a disadvantage of

spinal fusion by laminoplasty. Thus, it is necessary to evaluate disc degeneration in the whole lumbar spine and the operative area should be determined according to the level of stenosis and the condition of the disc degeneration.

# Degenerative Lumbar Spondylolisthesis with Spinal Stenosis: Natural History, Diagnosis, Clinical Presentation, and Nonoperative Treatment

Mohamed Mostafa Mossaad

---

Forward displacement of a proximal vertebra in relation to its adjacent vertebra in association with an intact neural arch, and in the presence of degenerative changes is known as degenerative spondylolisthesis (1). The term is derived from the Greek word *spondylous*, meaning vertebra and *olisthesis*, meaning to slip or slide down a slippery incline.

Degenerative spondylolisthesis is usually a result of long-standing instability; it is most common at the junction of the fourth and fifth lumbar vertebrae. The instability is a result of a combination of disc degeneration and facet joint degeneration. The displacement results from a failure of the apophyseal joints to restrain shear (2,3). In 1950 MacNab showed that the displacement occurs in the sixth decade, and patients generally attend with symptoms around 60 years of age. He also postulated that the displacement is limited, and a slip ratio of more than 15% is unusual (4). The degenerative changes at the facet joints and disc degeneration add to subluxation of the facet joints, which allow forward or posterior movement of one vertebra over the other.

Degenerative spondylolisthesis narrows the spinal canal, and symptoms of spinal stenosis are most common. Hypertrophic facet arthrosis is a frequent cause of foraminal stenosis (1). The symptoms of lumbar spinal canal stenosis, particularly a complaint of neural claudication, serve as the most common operative indication (5).

Because the appearance of a significant deformity or neural claudication is often antedated by significant and recurring episodes of low back pain, sometimes the condition is considered a prototype for spinal segmental

instability. However, the radiographic abnormality may occur without current or prior symptoms (Fig. 54-1) (5).

### NATURAL HISTORY

Degenerative spondylolisthesis occurs when a vertebra is displaced in relation to that immediately below it, with no disruption of the neural arch, no congenital anomaly, and in the presence of degenerative changes in a spine not previously subjected to surgical or traumatic insult (6).

In 1997 Marchetti and Bartolozzi showed that there are two main types of degenerative spondylolisthesis: primary, in a spine without congenital or acquired pathologic conditions; and secondary, as a result of congenital or acquired pathologic conditions, both with degenerative changes at the facet joints and disc spaces (6).

They showed that primary degenerative spondylolisthesis occurs mainly in patients over or around the age of 60 years, most involving L4. The initial pathologic condition is usually degeneration of the posterior articular process, which is the cause of segmental instability and involves the disc space as well.

Most of these patients present a translational olisthesis that resembles lumbar spinal stenosis in clinical and radiographic assessment.

The disc may protrude posteriorly into the spinal canal. Symptoms start to appear gradually and develop slowly with severe back pain and radicular pain. Nonoperative treatment generally provides a satisfactory result, with indication for surgery when this fails.

Secondary degenerative spondylolisthesis occurs because of a congenital or acquired pathologic condition

**FIG. 54-1.** Lateral radiograph of a patient with degenerative spondylolisthesis at L4-5. The disc space is shown to be reduced with bony sclerosis and forward displacement of body of L4, with an intact neural arch. There is deformity of the superior articular facet of L5 and deformation of the central canal, root canal, and intervertebral foramen.

**FIG. 54-2.** Diagram to show shear through the lumbo-sacral disc, where  $W$  is the body weight above and disc, and  $\alpha$  is the lumbo-sacral angle. (From Porter RW. Management of back pain, 1st ed. Edinburgh: Churchill Livingstone, 1986:40, with permission.)

localized above or below the olisthetic vertebra, which is not clinically important. Marchetti and Bartolozzi reported that this condition is mild, presented with mild symptoms, and has little tendency to deteriorate. Nonoperative treatment is usually the treatment of choice and is appropriate. Surgery has never proved to be necessary in their or our experience (6).

In 1997 Bridwell reported that degenerative spondylolisthesis is variable as it is for all degenerative disc disease, but in 1990 Sakou et al. reported a gradual tendency toward loss of disc height and narrowing of spinal canal. They also mentioned that it is uncommon for an unoperated degenerative spondylolisthesis to slip more than 50% (7,8).

Forward displacement results from a failure of the apophyseal joints to restrain shear. They are orientated in the sagittal plane in the upper lumbar spine, and become progressively more coronally orientated toward the lower lumbar spine (Table 54-1; Fig. 54-2) (3).

**TABLE 54-1.** Forward displacement

	Mean facet angle (degrees)	
L1	66.5	$\pm 13.3$
L2	61.3	6.8
L3	54.4	10.0
L4	41.5	10.8
L5	38.8	7.4

The most frequent site for degenerative spondylolisthesis is at L4-5, where the shearing forces are not adequately restrained by the apophyseal joints. Microfractures and remodeling occur in the subchondral bone of the joints. The vertebra slowly displaces forward, with gradual bony deformity, loss of disc integrity, and stretching of the ligaments. The causative factors and their related importance are uncertain. Osteoporosis has been implicated in the sagittal orientation of the joints and disruption of the disc. There is no evidence that joint laxity is significant (9,10).

An intact neural arch is essential for the apophyseal joints to effectively restrain shear. The fact that spondylolysis can be present with no vertebral displacement suggests that spinal structures other than neural arch play a significant point in resisting shear forces (9,10).

The increasing shear forces in the lower lumbar lordotic spine are balanced by the progressively efficient restraint of the coronally orientated lumbar facet. L4-5 appears to be the level where the joints may fail to restrain shear. Several possible factors cause this failure:

1. Constitutional variation in the orientation of the apophyseal joints. Those individuals whose L4-5 facets are more sagittally orientated than the rest of the population are more prone to displacement (11).
2. Osteoporosis of the subchondral bone of the facet joints is vulnerable to microfractures, with deformity of the facet joints. It was suggested by Junghanns and

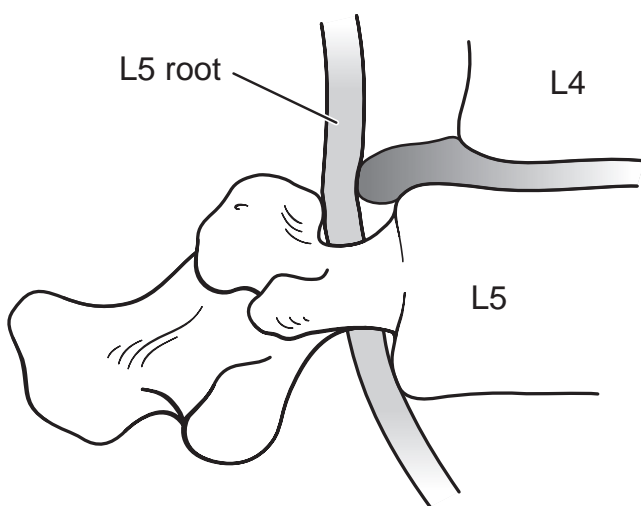

MacNab that an increased angle between the pedicle and inferior articular facet allows forward subluxation of the upper vertebra (2,4); however, Newman found no increase of this angle in the slipping vertebra. He suspected that progressive widening of the angle may accompany the progressive slip from remodeling in response to microfractures (3).

3. A degenerative disc less effectively restrains shear (12).
4. Increased lumbar lordosis increases the force of shear, but there is no evidence that these patients have an increased lumbosacral angle. Posture may be significant, especially in pregnant women, in whom the ligamentous restraint is less effective (11).
5. Newman believed that poor spinal and abdominal muscles place proportionally greater strain on the apophyseal joints, and the facets give way from an acquired instability of the soft tissues, especially the interspinous and supraspinous ligaments. He also thought the high incidence of spina bifida occulta is significant (3).
6. Obesity disproportionate to muscle strength increases the shear.
7. Diabetic patients (especially women) who have undergone oophorectomy are also at significantly higher risk (5).

Several of the mentioned causative factors in combination may explain the higher incidence of degenerative spondylolisthesis in women, especially obese women.

The proximal vertebra steadily displaces forward, deforming the vertebral canal, root canal, and intervertebral foramina (Fig. 54-3). If the central canal is already constitutionally narrow, then vertebral displacement with

**FIG. 54-3.** Diagram to show that the L5 nerve root can be affected in the central canal from a rim of L4-5 disc in degenerative spondylolisthesis. (From Porter RW. Management of back pain, 1st ed. Edinburgh: Churchill Livingstone, 1986: 147, with permission.)

an intact neural arch will deform the dura and its contents. The root canal can become critically narrow, especially at the exit of the foramina. If a dynamic element is superimposed on the reduction of the space for the neural contents, pathologic changes develop in the dura and nerve roots, producing symptoms (11).

Degenerative changes develop in the apophyseal joints and at the margins of the vertebral bodies until a degree of stability occurs. These osteophytic changes can encroach on the root canal. It is interesting that the vertebral body does not become wedge shaped as in the displaced body of an isthmic spondylolisthesis; the former displacing in adult life, the latter during growth (11).

The major instability is not flexion-extension instability (in other words, tilt), but axial rotational and antero-posterior (AP) transitional instability (13).

In 1994 Frymoyer mentioned that radiographic surveys showed that degenerative spondylolisthesis is more common in patients with hemisacralization. This finding is thought to be of etiologic significance because the immobility of the L5-S1 level shifts mechanical stress to the adjacent level of L4-5 (5).

An important requisite for degenerative spondylolisthesis is relative immobility of the lumbar segment below the lesion. The immobility is most commonly caused by hemisacralization, but can result from advanced disc degeneration at the level of L5-S1 (Fig. 54-4). Spinal fusion is an iatrogenic cause for immobility. The forward slip occurs many years after the original fusion. Surprisingly, many patients are asymptomatic despite the deformity (Fig. 54-5) (14).

Degenerative spondylolisthesis with a canal stenosis has been shown by Frymoyer to be more common in diabetic women who have undergone oophorectomy. These observations are clinically relevant because the orthopedist faced with a patient with degenerative spondylolisthesis, diabetes, and leg pain often has to determine whether diabetic neuropathy or spinal stenosis is the cause of the leg pain. The relationship to oophorectomy suggests that estrogen replacement might prevent or slow the onset of the deformity and symptoms. The higher prevalence in diabetic patients is thought to result from weakened collagen cross-linking. Other mechanical theories suggest that congenital or acquired abnormalities in the orientation of the facets predispose to forward displacement. Unfortunately, the various pathoanatomic theories have no utility for designing specific prevention strategies (5).

Degenerative spondylolisthesis is the result of long-standing intersegmental instability (15,16). As the slip progresses, the articular processes change direction and become more horizontal (17). Degenerative spondylolisthesis occurs six times more commonly in women than in men, six to nine times more frequently at the L4 interspace than at adjoining levels, and four times more frequently when the L5 is sacralized than when it is not.

**FIG. 54-4.** Lateral radiograph of a patient with degenerative spondylolisthesis at L4-5 with the L5-S1 space extremely narrowed. (From Frymoyer JW. Degenerative spondylolisthesis: diagnosis and treatment. J Am Acad Orthop Surg 1994;2:10, with permission.)

When the lesion is at L4, the L5 vertebra is more stable and exhibits less lordosis than is average (17,18).

Knutsson believed that flexion and extension views also reveal dynamic instability, a frequent precursor of degenerative spondylolisthesis, at even earlier ages (19).

Degenerative spondylolisthesis with an intact neural arch, which is a secondary form of lumbar stenosis, is more common at the L4-5 level, and followed in descending order of occurrence at the L3-4, the L2-3, and the L5-S1 interspaces (20–22).

**FIG. 54-5.** Lateral radiograph of a patient who had fusion from L5 to the sacrum, sometime previously. Displacement of L3 over L4 above the solid fusion is demonstrated (arrow). (From Frymoyer JW. Degenerative spondylolisthesis: diagnosis and treatment. J Am Acad Orthop Surg 1994;2:10, with permission.)

Interestingly, the slip in degenerative spondylolisthesis seldom exceeds 30% unless there has been surgical intervention (19).

Sakou et al. found that progression of slipping was observed in 30% of 40 patients followed for longer than 5 years, but the progression was not necessarily associated with deterioration of the patient's condition (8).

## DIAGNOSIS

As always, a careful history and physical examination are the first steps in the diagnosis of degenerative spondylolisthesis with lumbar canal stenosis. The description of the pain is helpful and important in the diagnosis. There may be sensory loss or leg weakness. Hamstring tightness is always a common finding. Patients with spondylolisthesis may exhibit a type of waddling gait.

As in most patients with lumbar spinal stenosis, the clinical examination findings often are nonspecific. The loss of lumbar lordosis can be detected by inspection if the patient is experiencing significant spine or neurologic symptoms (5). When stenotic symptoms are severe, a fixed forward-flexed posture, sometimes accompanied by hip-flexion contractures, can be observed. Except in very thin patients, the step deformity usually is not palpable (23).

Surprisingly, some patients with degenerative spondylolisthesis retain a normal spinal mobility or in some instances, hypermobility. It has been suggested that patients with this condition have generalized ligamentous laxity, which might be of etiologic significance (23).

The neurologic examination may be useful when the patient has an isolated unilateral radiculopathy. The knee jerk reflex may be reduced or absent when the L4 nerve root is involved. Unilateral dorsiflexion or quadriceps weakness and the pattern of sensory loss are important findings. However, a positive nerve root tension sign is uncommon, particularly in the older population. More commonly, the neurologic findings are nonspecific and

**FIG. 54-6.** Lateral radiograph of a patient with root pain. Degenerative spondylolisthesis at L4-5 (**A**), and L5-S1 (**B**), with reduction of disc spaces and root canals with intact neural arches.

may include bilaterally absent reflexes, spotty sensory losses, as well as muscle atrophy or weakness.

Plain roentgenogram (Fig. 54-6) include the essential finding of demonstrating the forward displacement of L4 on L5, the most common level at which this disorder occurs, or more rarely, L5 on S1 or L3 on L4 in the presence of an intact neural arch. Isthmic spondylolisthesis also may occur at this level, and plain X-ray should help to rule out this entity. Concomitant degenerative changes include disc space narrowing, end plate irregularities, sclerosis, osteophytes, and traction spurs (Fig. 54-7). Facet sclerosis and hypertrophy should all be noted on the plain X-ray film. Patients with isthmic spondylolisthesis are quite likely to be young and have neurologic symptoms. The AP radiograph often, but not always, demonstrates the accompanying hemisacralization of L5.

Dynamic flexion-extension views may be obtained but rarely demonstrate significant additional translational instability. Several authors have suggested recumbent supine or prone lateral flexion-extension radiographs for patients who are too uncomfortable to endure standing dynamic X-ray studies (24).

The alternative approach to demonstrate instability is the traction-compression radiographs, which has been described by Friberg (25). In this technique, a lateral lumbar radiograph is taken first after the application of a standard axial load and then after traction. The difference in displacement between these two views is correlated with back pain and instability, and is considered by Friberg to be of prognostic significance (25).

Further roentgenographic evaluation is not warranted for patients with predominantly mechanical back pain that responds to the usual conservative modalities. However, additional imaging studies may be warranted if sig-

nificant back pain persists that is unresponsive to nonoperative means or if significant radicular pain intervenes, with progressive neurologic claudication or radiculopathies and clinical suspicion that another condition (e.g., metastatic disease) may be causative. The presence of bladder or bowel complaints is an absolute indication.

The imaging alternatives include computed tomography (CT), myelography, contrast material-enhanced CT,

**FIG. 54-7.** Lateral radiograph of a patient with L4-5 isthmic spondylolisthesis with an advanced slip. Note the defect in the pars. (From Frymoyer JW. Degenerative spondylolisthesis: diagnosis and treatment. *J Am Acad Orthop Surg* 1994; 2;10, with permission.)

and magnetic resonance imaging (MRI). Typically, there is a diminished cross-sectional area at the level of the spondylolisthesis. There also may be hypertrophy of the superior facet with subarticular entrapment of the L5 nerve root. Soft-tissue abnormalities include thickening of the ligamentum flavum and posterior translation of a disc fragment.

Sagittal plane MRI is best for displaying the abnormal anatomy of spondylolisthesis, T2-weighted images for the canal and T1-weighted images for the pars interarticularis and neural foramina. The MRI sagittal view clearly shows the degree of subluxation and the relationship of the intervertebral disc to the adjacent vertebral bodies and spinal canal. Parasagittal images are excellent for showing encroachment of the nerve root in the foramina by disc or hypertrophic bone. Loss of the normal fat signal cushioning the nerve root is a sign for significant foraminal stenosis.

Ulmer et al. proposed the “wide canal sign” to distinguish between isthmic and degenerative spondylolisthesis (26). Using a midline sagittal section, they noted that the sagittal canal ratio (maximum anteroposterior diameter at any level divided by the diameter of the canal at L1) did not exceed 1:25 in normal controls and in subjects with degenerative spondylolisthesis. The measurement always exceeded 1:25 in patients with spondylolysis.

Technetium bone scanning was more commonly ordered before the advent of MRI scanning to rule out possible metastatic diseases. However, currently bone scanning is less commonly used in the initial evaluation of patients with degenerative spondylolisthesis.

Local anesthetic injections may be useful in specific cases. The best indication is concomitant degenerative spondylolisthesis and hip osteoarthritis. Relief of symptoms following an intra-articular hip injection suggests that the hip is the most probable origin for the symptoms.

## DIFFERENTIAL DIAGNOSIS

Epidemiologic studies have suggested that degenerative spondylolisthesis is often an asymptomatic roentgenographic finding. This fact is of enormous importance because there is a natural tendency for clinicians to ascribe symptoms to an obvious structural lesion. Numerous spinal entities can give rise to similar symptoms, including spinal stenosis, central disc herniation, and degenerative scoliosis. One study demonstrated that a high percentage of patients with degenerative scoliosis also had degenerative spondylolisthesis (27). In patients with coronal plane abnormalities, who are frequently elderly, neurologic symptoms may suggest multilevel involvement.

Disease of cervical spine commonly produces symptoms that radiate to the lower extremities in elderly people. In all patients who are being evaluated (especially for surgery) cervical abnormalities should be ruled out with flexion-extension plain radiographs and possibly an MRI

scan of the cervical spine if the physical examination raises any question of cervical problems.

Osteoarthritis of the hip joint occurs in 11% to 17% of patients with degenerative spondylolisthesis, and can mimic the anterior thigh pain of an L4 nerve root entrapment (16). Therefore, the hip needs to be carefully examined for an alternative cause for symptoms of leg pain. Also, medial knee pain from degenerative disease or a torn meniscus may stimulate an L4 radiculopathy and produce considerable confusion for the clinician.

Peripheral vascular disease is common in elderly persons, who are also candidates of degenerative spondylolisthesis. Pain with ambulation is a typical finding, but it is much more closely related to decreased oxygen-carrying capacity of circulation to the lower extremities than to activity. Patients with vascular disease typically have more problems walking uphill than do patients with degenerative spondylolisthesis or spinal stenosis. In addition, patients with peripheral vascular disease typically have increased pain when riding a stationary bicycle, whereas patients with spinal stenosis typically are able to ride a stationary bicycle for a prolonged period because they can flex the lumbar spine. Patients with peripheral vascular disease need only to stop walking to alleviate their symptoms; patients with degenerative spondylolisthesis often must sit down and flex the lumbar spine to relieve their symptoms.

Unfortunately, elderly patients often have both diseases. They should have Doppler studies if there is any question of diminished blood flow to the lower limbs. With equal degrees of vascular and neural involvement from spinal stenosis, the vascular problem is usually addressed first.

Diabetic neuropathy rarely produces a painful radiculopathy. Electromyographic and neural conduction studies should be performed in patients with diabetes mellitus. The surgical outcome for radiculopathy may not be as good in diabetic as in nondiabetic patients.

A less common coexistent condition is diffuse idiopathic skeletal hyperostosis. This condition is characterized by multilevel bridging osteophytes and commonly affects middle-aged and older men, who frequently are diabetic and uricemic. If surgery is required, these patients can be far more challenging than those with standard degenerative spondylolisthesis.

Other disorders that may resemble the symptoms of degenerative spondylolisthesis include metastatic disease of the spine or the presence of retroperitoneal tumor. Because of the age group affected and the substantial differential diagnosis, it is important to perform a current and complete medical evaluation before proceeding with definitive treatment of the spinal disorder (5).

## CLINICAL PRESENTATION

Back pain is the most common chief complaint in patients with degenerative spondylolisthesis. Often the

pain has been episodic and recurrent for many years. The course of the back pain in the patient's history may be highly variable and usually is unrelated to trauma. Few patients can recall a specific traumatic event. The back pain usually is mechanical and may be relieved with rest. Back pain usually is noted early as the superior vertebral body translates anteriorly with forward displacement of its inferior articular process (28). Radiation into the posterolateral thighs also is common and is independent of neurologic signs and symptoms. The second most common presenting symptom is neurogenic claudication. The advent of leg symptoms is the most common reason why patients and referring physicians become concerned and seek specialized medical attention. This results from further thecal compression by the posterior articular facets, as well as posterior displacement of the intervertebral disc level at the level ofolisthesis (29). The pain is usually diffuse in the lower limbs, involving dermatomes and muscles innervated by the L4-5 and S1 nerve roots. Another type of presentation is a monoradicular nerve pain pattern usually involving an L5 spinal nerve root. The leg pain is always accentuated by walking and relieved by rest. These symptoms of spinal stenosis are reported by 42% to 82% of patients who seek help from spine surgeons (23). Typically, the leg pain is also relieved by forward flexion of the spine. Additional complaints include cold feet, altered gait, and "drop episodes" wherein the patient unexpectedly falls while walking (23).

Genitourinary findings are uncommon, but patients with these complaints should undergo imaging studies.

Interference with bladder and bowel control can occur with extreme stenosis, as was reported by Kostuik et al. in 3% of their patients (30). Unlike the acute and often devastating bladder and bowel symptoms of cauda equina syndrome in lumbar disc herniation, spinal stenosis often

has an insidious and subtle presentation. The unwary examiner is at risk of attributing these symptoms to age-related conditions, such as cystocele in women and prostatism in men.

Stenotic symptoms are the result of mechanical and vascular factors. As the slip progresses, facet hypertrophy, buckling of the ligamentum flavum, and diffuse disc bulging contribute with forward displacement to compression of the cauda equina (Fig. 54-8). As in any stenotic condition, the relief of symptoms that follows forward spinal flexion is thought to be related to the increase in the AP diameters of the spinal canal that occurs in that posture. In extreme cases, patients may report the need to sleep in the fetal position to relieve leg symptoms.

The significant vascular component in complaints of leg pain may lead to restless legs syndrome sometimes called "vesper's curse" (31). In this condition, patients are awakened by aching pain in the calves, restlessness, an irresistible urge to move the legs, and fasciculations. This syndrome is reported to be exacerbated by congestive heart failure, which in turn may increase pressure in the arteriovenous anastomoses that characterizes the lumbar nerve-root microcirculation. Accordingly, if the patient reports increasing night cramps, it is worthwhile to obtain a thorough cardiovascular examination. Other associated neurologic symptoms (e.g., numbness and weakness) are present variably. The patients also may note a sudden episode of weakness, altered gait, or numbness. The pain may be progressive and incapacitating and may occur much more frequently with positional changes of the lumbar spine unrelated to significant exertion. For example, a patient may inadvertently extend the lumbar spine during sleep and produce such severe pain that significant sleep disturbance results (32,33). Progressive motion weakness and symptoms and signs of cauda equina syndrome are indications for emergent decompression surgery.

**FIG. 54-8.** Magnetic resonance imaging scan demonstrates the relationship of the caudal sac and nerve roots and facet degeneration. Note the marked narrowing of the lateral recesses.

The physical examinations findings in patients with degenerative spondylolisthesis (as in patients with spinal stenosis) may be nonspecific. In the standing position, the patient may decompensate anteriorly to allow a more flexed position of the lumbar spine. Inspection and palpation of the lumbar spine may reveal a palpable step off at the level of the olisthesis. The iliolumbar ligaments, sacral iliac joints, sciatic notches, other spinous processes, and trochanteric bursae should all be palpated and the presence of symptoms noted.

Range of motion of the lumbar spine usually is normal, and many patients can flex forward without difficulty. The examiner should attempt to extend the lumbar spine fully and, if possible, the patient should be asked whether the symptoms are being reproduced (33,34).

As noted, some patients present with degenerative spondylolisthesis above a spinal fusion (35). A long symptom-free interval is followed by the onset of nerve-root symptoms and stenosis emanating from the level above their previous fusion (35).

The neurologic examination may reveal a focal nerve deficit. The quadriceps tendon reflex may be reduced with an L4 radiculopathy. Less commonly, there is quadriceps weakness and possibly atrophy. Extensor hallucis longus weakness also may be encountered with an L5 spinal nerve root abnormality. However, most commonly, the results of neurologic examination are nonspecific, with symmetric motor findings and symmetrically depressed reflexes noted in the elderly population.

## NONOPERATIVE TREATMENT

Nonoperative management is the primary treatment for patients with low-grade adult degenerative spondylolisthesis who present with acute or chronic low back pain (36).

Nonoperative treatment should include reducing environmental pain generators, various physical therapy modalities, non-narcotic medications, immobilization, and occasionally multidisciplinary pain clinics (37). This nonoperative management regimen is similar for all populations with other types of mechanical low back symptoms and should be pursued diligently both by the patient and surgeon (38).

The initial recommendations include practicing healthy back care, including proper lifting and bending techniques, and avoiding periods of prolonged sitting or driving (39). Decreasing or eliminating tobacco use and pursuing an ideal body weight benefit the patient.

Nonoperative treatment of degenerative spondylolisthesis is similar to the nonoperative management of other mechanical disorders of the lumbar spine. No prospective randomized studies confirm a preferred method of nonoperative treatment. However, there is recent evidence that the natural history of degenerative spinal stenosis and degenerative spondylolisthesis may be more favorable than previously thought.

Johnsson et al. followed 32 patients with clinical symptoms and myelographically confirmed stenosis for an average of 49 months. No patient had significant deterioration, and surprisingly many patients improved (40). In patients who have predominantly back pain, the usual conservative modalities of appropriate rest, the use of anti-inflammatory nonsteroidal medication may have a significant beneficial impact.

## MEDICATION

### Anti-inflammatories

This group of medications, which specifically aims to decrease inflammation in tissues, can be quite effective in mild and moderate pain. Side effects (aside from allergic reactions) may include stomach upset, gastritis, ulcer problems, and kidney and liver problems.

### Analgesics

This group of medications aims to reducing the sensation of pain without any specific action at the source of the pain. In a sense, this covers or dampens the pain but does not treat the site of the problem.

### Muscle Relaxants

These medications aim to loosen the tension and irritability of muscle tissue. By relaxing a very tense muscle, the pain caused by spasm and cramping can be reduced. Some patients become very drowsy with these medications.

### Combination Drugs

These combine different types of medication to offer pain relief and anti-inflammatory effects.

### Narcotics

These pain medications are quite strong and act on the brain and spinal cord to decrease the sensation of pain. Because of addiction potential and risks of overdose, these medications should be restricted in use.

### Antidepressants

In some cases mild doses of antidepressant medication may offer added relief from chronic nerve related pain.

The second nonoperative measure that deals with pain in patients with degenerative spondylolisthesis is the encouragement of aerobic conditioning, on the premise that exercise may improve arterial circulation to the cauda equina because walking often aggravates symptoms. A stationary bicycle is a good alternative, particularly if the handle bars and seat are set up to allow the forward-flexed position.

## AEROBIC CONDITIONING

### Physical Therapy

Physical therapy for spinal conditions includes pain modality treatments such as transcutaneous electrical nerve stimulation (TENS), massage and ultrasound, acupuncture and traction, and structured guided strengthening programs for restoring good muscle function. There are many different types of exercise programs. Particular focus on isometric strengthening appears to be beneficial for many patients. Isometric exercises involve activities that stimulate contraction of a muscle (working the muscle) while maintaining the length of that muscle (i.e., no significant motion across the span of the muscle). Vigorous movements or extremes of motion are often avoided in physical therapy approaches to spinal care.

### Exercise

Most patients are advised to maintain some form of regular exercise on a long-term basis. Even patients with mild or intermittent back pain and no severe underlying problem may benefit from regular exercise. A number of studies have shown that regular aerobic activity reduces the change of developing repeated back injuries. Clear advantages of one type of sport over another have not been shown. Therefore, it may be more important to find an activity that is enjoyable and easy to maintain on a regular schedule, such as swimming, fast walking, and running.

### Weight Reduction

The third method of nonoperative therapy in managing back pain from degenerative spondylolisthesis is weight reduction. This strategy often minimally affects neurologic complaints. Careful management of osteoporosis may be helpful. Additional strategies include the judicious use of braces.

## ADDITIONAL STRATEGIES

There are a wide variety of binders, belts braces, and other devices designed to offer relief from back pain. Their effectiveness in most cases has not been clearly proven, and yet many patients do feel some relief from their pain with some of these applied devices. However, long-term wear of back braces may lead to gradual weakening of the supportive muscles owing to the effect of unloading the spine; therefore, this may not be desirable.

Epidural block and extended bed rest appear to be of little value and carry a significant risk of morbidity, especially in elderly patients. Likewise, there is no information to support the use of manipulative therapy, which may be contraindicated, particularly in osteoporotic patients.

Many studies suggest that radicular pain is much less amenable to the same nonoperative management strate-

gies that are applicable when radiculopathy is related to a herniated disc. In general, patients with predominantly leg pain require a longer trial of nonoperative care to evaluate the efficacy of treatment. For patients with significant leg pain, administration of epidural steroids is an appropriate temporizing measure (36–39).

Patients with low-grade degenerative spondylolisthesis may present with a multitude of physical, emotional, and psychological symptoms, and these patients often are best handled by a multidisciplinary pain center approach. This includes input from different services, including anesthesia, physiatry, psychiatry, physical therapy, occupational and behavioral therapy, and social work. It was found that this multidisciplinary approach is useful in both previously operated and nonoperated patients (41).

# Decompression

Bo Jönsson

---

Degenerative spondylolisthesis mostly occurs at the L4-L5 level and has a gender-related difference in prevalence, being four to five times more frequent in women. Radiographic cross-sectional studies of older adult women have demonstrated an incidence of anterior slip of 29% in the lumbar spine, but without correlation between pain and olisthesis (1). There was an increasing prevalence of L4-L5 olisthesis with increasing patient age.

The proportion of patients with degenerative spondylolisthesis in articles dealing with spinal stenosis shows a rather wide variation. Turner et al. (2) noted that 28 out of 74 articles on spinal stenosis included data on degenerative spondylolisthesis, with a mean proportion of 50% (range 0 to 100). Their compilation included, however, four articles containing only patients with degenerative spondylolisthesis and therefore 50% probably does not reflect the true prevalence. In a prospective, consecutive long-term study on spinal stenosis including 105 patients with radiographic reassessment of all patients (3), 32 out of 105 patients (30%) had degenerative spondylolisthesis. Katz et al. (4) have retrospectively analyzed a group of 88 patients with spinal stenosis regarding long-term result; of these 88 patients, 22 had a degenerative spondylolisthesis (25%). In a study on postoperative instability after lumbar decompression by Johnsson et al. (5), 20 out of 45 patients (44%) had a preoperative olisthesis. Katz et al. (6) presented another prospective, multicenter study including 272 patients with spinal stenosis, where 93 patients (34%) had a spondylolisthesis of 5 mm or more.

### ANATOMY

Patients with degenerative spondylolisthesis often have a specific laminar configuration predisposing for the vertebral slipping (7). The articular surface of the superior articular process is facing medially and the laminae are converging distally toward the inferior articular processes, which are medially located with their joint surfaces facing laterally. Due to this configuration of the

articular processes, the facet joints are more or less sagittally oriented. This configuration is more easily recognized in younger patients without degenerative changes (Fig. 55-1).

A number of radiographic studies have demonstrated a correlation between degenerative spondylolisthesis and sagittally angled facet joints (8–10). Grobler et al. (11) described the increased angles in patients with degenerative spondylolisthesis, but also the reduced coronal dimension after decompression, with increased risk for instability.

In a recent study (10) on orientation and osteoarthritis of the lumbar facet joints, the authors found a significant correlation between sagittally oriented joints and osteoarthritis, even in patients without olisthesis. The degenerative changes in patients with spondylolisthesis, however, were more severe.

Love et al. (12) confirmed the sagittal orientation of facet joints in patients with degenerative spondylolisthesis, but interpreted this joint configuration more as a consequence of arthritic remodeling.

### RADIOGRAPHIC FINDINGS

In a study of 105 patients with spinal stenosis by Jönsson et al. (3) the radiographic findings were assessed for all patients. There were 32 patients with degenerative spondylolisthesis, 4 at level L3-L4, 25 at L4-L5 and 3 at L5-S1 (Fig. 55-2). Patients with degenerative spondylolisthesis had a more pronounced narrowing of the spinal canal with an anteroposterior-diameter of 5.6 mm compared with 6.7 mm in patients with no spondylolisthesis. The site of the spondylolisthesis was the narrowest site in most (24 of 32) patients.

### DECOMPRESSION

The standard surgical procedure consists of a midline laminectomy extended laterally toward the edge of the

**FIG. 55-1.** **A:** Plain X-ray demonstrating laminar configuration in a patient with sagittally oriented facet joints. **B:** Magnetic resonance imaging, axial view demonstrating sagittal angles of facet joints.

dural sac. In order to decompress the single nerve roots, the decompression is extended laterally-distally including the medial part of the facet joints without violating the stability. In patients with facet joints orientated in the coronal plane (and no degenerative spondylolisthesis), nerve root impingement may occur in the lateral recess (i.e., below the superior articular process). Decompression is obtained by the undercutting technique. In patients with sagittally oriented facet joints and degenerative spondylolisthesis, root compression may be caused by the anteriorly displaced inferior articular process, necessitating resection of the medial/anterior part of this process (Fig. 55-3).

### Results of Decompression

In 1992, Turner et al. presented a survey of 74 articles on results after decompression for spinal stenosis (2). Good to excellent results were on average reported by 64% of the patients; there was, however a wide variation in outcome. The authors noted better outcome in studies including more patients with degenerative spondylolisthesis. There were four reports including only patients with degenerative spondylolisthesis and good to excellent result was noted by 83% to 85% in these articles. Some of these articles however included patients who underwent spinal arthrodesis.

A corresponding meta-analysis including only studies dealing with spinal stenosis and degenerative spondy-

lolisthesis was presented by Mardjetko et al. (13). Their analysis included 25 papers published between 1970 and 1993. Superior results were found in patients who underwent a concomitant spinal arthrodesis; satisfactory results were noted in 69% of patients who were treated with decompression only, while 86% to 90% of those who underwent fusion reported satisfactory results.

Herron and Trippi (14) evaluated 24 patients, all with degenerative spondylolisthesis treated with laminectomy

**FIG. 55-2.** Degenerative spondylolisthesis is most commonly seen at level L4-L5, but may occur at multiple levels.

**FIG. 55-3.** Magnetic resonance imaging, axial view at L4-L5 in a 70-year-old woman with degenerative spondylolisthesis and spinal stenosis. Note anterior displacement of inferior articular process.

alone. At follow-up (18 to 71 months after surgery) 20 out of 24 patients (83%) reported good result.

Epstein (15) has reported the results of decompression alone in 290 patients treated over a 25-year period. Excellent result was obtained in 69% and good result in 13%. Secondary spinal arthrodesis was performed in 8 (2.7%) of the patients.

In a prospective and consecutive study of 105 patients operated on due to spinal stenosis (16), 32 patients had a degenerative spondylolisthesis. Follow-up examinations were performed 4 months and 1, 2, and 5 years postoperatively. All radiographs were reassessed by a neuroradiologist, who had no information regarding surgical results. Predictors of good outcome were sought using logistic regression analysis. In this study design, the most important factors were, in this order: a low anteroposterior (AP) diameter of the spinal canal, absence of comorbid disease affecting walking, and less than 4 years of leg symptoms. Most patients with degenerative spondylolisthesis had a more pronounced narrowing of the spinal canal and reported good results at follow-up.

#### **POSTOPERATIVE PROGRESSIVE SLIP AFTER DECOMPRESSION ONLY**

Johnsson et al. studied postoperative slipping after lumbar decompression (5). In the patient group with degenerative spondylolisthesis, progressive slip occurred in 65% of the patients without influencing the surgical

results. During this period, many authors recommended a wide, radical decompression and total facetectomies were performed in more than 50% of the patients in this study.

Another study of postoperative stability after surgery using a facet-preserving undercutting technique (17) demonstrated better results with progressive slip in only 32% of patients with spondylolisthesis preoperatively. Also in this study, no correlation between surgical result and progressive slip was seen.

Recently, two studies using alternative decompressive procedures have reported good results and low risk of increased instability postoperatively. Kinoshita et al. (18) evaluated 51 patients who underwent decompression through a unilateral approach and found no increased slip postoperatively. Kleeman et al. (19) described their results in 54 patients who underwent decompression through the “port-hole” technique. Good to excellent result was noted in 88% and there was no statistical difference regarding result in patients with or without degenerative spondylolisthesis. Progressive slip was noted in 13% of the patients.

Matsanuga et al. (20) studied the natural course of slippage and described 30% progressive slippage in a study of 40 patients.

#### **DISCUSSION**

During the last decade, randomized, controlled studies have demonstrated superior surgical outcome in patients operated on with concomitant spinal arthrodesis. The results of these procedures are described in Chapters 56 and 58. Spinal stenosis, with or without degenerative spondylolisthesis afflicts an older adult patient group, and is the main indication for spinal procedures in the elderly. With increasing age, the incidence of concomitant cardiovascular and other degenerative diseases increase, with associated potential risks for anesthesiologic/surgical complications. The complication rate is higher in patients who are treated with a concomitant spinal fusion (21). In the clinical situation, the spinal surgeon has to include these considerations in the surgical decision making. In a study on patient selection, costs and outcomes, Katz et al. (6) noted that patients who underwent spinal fusion were significantly younger.

A national registry of lumbar spine surgery due to degenerative diseases has been evolved in Sweden (21). According to data from surgical procedures performed in the year 2000, 15% of patients with spinal stenosis underwent a concomitant spinal fusion, indicating that in common clinical practice, half or less than half of the patients with spinal stenosis and degenerative spondylolisthesis are selected for spinal arthrodesis in conjunction with decompression. Interestingly, Katz et al. (6) noted similar figures, with 50% of patients with spondylolisthesis greater than 5 mm or scoliosis greater than 15° being treated with laminectomy alone.

Studies on patients with spinal stenosis and degenerative spondylolisthesis have evaluated this patient group as a homogenous entity. The number of patients included in randomized studies, as in the Herkowitz study (22), has been too few to allow analysis of subgroups. In the clinical situation, however, the spinal surgeon encounters situations with a wide variation of symptoms within the same group of diagnosis. There are, for example, patients with minor or no back pain at all despite a radiologically verified olisthesis. Is there a need for fusion in these patients? Or consider the patient in whom physiologic stabilization has reduced the vertebral mobility at the slipped level. Does this patient need a fusion?

There is still no consensus regarding treatment of this patient group and there are different opinions between spinal researchers, exemplified by two recently published surveys (23,24). There is a need for further research with the aim to create more precise scientific guidelines regarding treatment of the different subgroups.

# Decompression with Posterolateral Fusion

Gianluca Cinotti

---

### INDICATIONS

As in any patients with spinal condition in whom the surgical option has been considered, a successful operation may be expected if a correct surgical indication has been made. A wrong surgical indication, in fact, is probably the most important factor responsible for poor surgical outcomes in patients with degenerative spinal conditions. This is particularly true in degenerative spondylolisthesis, since the condition may be asymptomatic, and thus not requiring any treatment, or cause a wide spectrum of symptoms including low back pain, radicular pain or both. As a result, in any patient with degenerative spondylolisthesis (DS) in whom surgery may be indicated, a careful clinical and radiologic evaluation should be carried out to confirm that patient's symptoms are due to the spondylolisthesis.

### Preoperative Planning

Historically, a degenerative spondylolisthesis can be treated with decompression alone, decompression plus fusion with or without internal fixation and, in a few patients, with fusion alone. Decompression plus fusion is thought to be the treatment of choice by most surgeons since it allows reaching better results compared to decompression alone (1–6). This is certainly true when an unselected population of patients with DS is randomly treated with the two procedures. However, if a selection of patients who need fusion or decompression is carried out preoperatively, the surgical outcomes may further improve and unnecessary fusion be avoided. An accurate clinical and radiologic assessment before surgery may be helpful to this aim.

Clinical evaluation should assess whether predominant symptoms are due to nerve root compression (radicular pain is the predominant symptom), to spinal instability (back pain is the predominant symptom), or both. Radiologic evaluation should assess the degree of vertebral instability and the severity of stenosis at the spondylolis-

thetic level. In particular, standard and flexion-extension radiographs should determine the degree of vertebral slipping and whether a hypermobility of the olisthetic vertebra is present. Magnetic resonance (MR) scans should assess whether a narrowing of the spinal canal or a true stenosis, including a compression of the nervous structures, is present and, in the latter event, if this involves the lateral or central portion of the spinal canal. On axial MR scans, the orientation of facet joints in the horizontal plane and the amount of facet joint resection necessary to free the nerve root in the lateral canal should be also evaluated (7,8). Disc herniation below the spondylolisthetic vertebra is uncommon; however, since a false impression of disc herniation may be seen on both sagittal and axial scans, the presence of a posterolateral or lateral disc herniation associated to the spondylolisthesis should be ruled out. Finally, MR scans should evaluate whether degenerated discs are present at the levels adjacent to the spondylolisthesis since this may influence the choice of vertebral levels which have to be included in the fused area.

On the basis of preoperative investigations, a decompression with fusion is indicated in patients with one, or more, of the following requisites: low back pain is predominant or equal to radicular pain; a grade II spondylolisthesis is present; a hypermobility of the spondylolisthetic vertebra is seen on flexion-extension radiographs; severe central stenosis is present, whereby central laminectomy is needed; facet joints show a marked sagittal orientation in the horizontal plane, so that a tendency to vertebral slipping may be expected after decompression (although this event is often asymptomatic). Conversely, decompression alone may be indicated in the minority of patients with the following requisites: radicular pain is the only, or predominant, symptom; a grade I spondylolisthesis is present; flexion-extension radiographs show no evidence of hypermobility of the slipped vertebra; a lateral stenosis is present, whereby a unilateral or bilateral laminotomy may be adequate to decompress

the nerve root; facet joints show a mild sagittal orientation in the horizontal plane, so that only a slight increase in vertebral slipping may be expected after decompression. Fusion alone is indicated in a few patients with DS in whom low back pain is the only symptom and no stenosis is present on MR scans.

### **Specific Indications to Decompression plus Posterolateral Fusion**

In any patients with DS in whom fusion is indicated, a posterolateral arthrodesis may be performed successfully. Spinal instrumentation may be associated to fusion; however, since most of the patients with DS do not show a marked vertebral instability, the indication to perform an instrumented or a noninstrumented fusion rests entirely on discretion of the surgeon. Many surgeons are used to associate pedicle screws to posterolateral fusion to reduce postoperative pain, avoid a rigid orthosis, shorten the hospitalization time and accelerate the functional recovery. Internal fixation was also found to increase the fusion rate (1,9–11), possibly by reducing vertebral motion and subsequent unfavorable mechanical stresses (axial rotation and tension stresses) on the graft material. However, no significant difference was found in the clinical outcomes of patients submitted to instrumented or noninstrumented fusion (9,12).

Posterolateral non-instrumented fusion may be advantageous in any patient with DS showing degenerative processes at the levels adjacent to the spondylolisthesis, since in these cases a less rigid fusion mass reduces mechanical stresses at the adjacent levels compared to an instrumented fusion. A noninstrumented posterolateral fusion may also be advantageous in severely osteoporotic patients in whom a poor fixation of pedicle screws may be expected.

Interbody devices may be associated to posterolateral fusion and pedicle screws to increase the fusion rate, reduce vertebral slipping, and restore the height of the disc space. However, there is no evidence that these factors may influence the surgical results in patients with DS. In particular, no prospective randomized study demonstrated better clinical outcomes after 360° fusion, nor that the reduction of olisthesis may improve the results in patients with DS. The restoration of the foraminal height subsequent to the insertion of interbody devices has little clinical effects on the nerve root (13), particularly in DS patients in whom the olisthesis may cause lateral or central stenosis whereas the foraminal dimensions are not affected by the condition. Patients with DS may be treated with interbody devices, along with pedicle screws, as alternative to posterolateral fusion, to eliminate the need for harvesting autogenous bone graft from the iliac crest. However, since the type of fixation (biological or mechanical) achieved with interbody cages has not well established yet, further studies

should assess whether this procedure can yield surgical outcome as good as those reported by patients submitted to posterolateral fusion at long- and very long-term follow-ups.

### **OPERATIVE TREATMENT**

Whatever support is used the patient should be positioned on the operative table so that the abdomen is maintained free during the operation in order to avoid compression on large abdominal vessels and reduce intraoperative bleeding.

The posterolateral approach described by Wiltse (14) or the posterior approach can be used. The former allows a better exposure of the fusion area and reduces intraoperative bleeding; the second is more frequently used when a decompression of the nervous structures has to be associated to fusion, that is, in the majority of cases. With the posterior approach the skin incision should be extended one or two levels proximally and distally to the fusion area so that an adequate muscular retraction to expose the transverse processes is achieved. If a decompression of the nervous structures has to be performed this is usually carried out before fusion to limit the blood loss.

### **Decompression**

In the most frequent situation (i.e., degenerative spondylolisthesis of L4), the vertebral slipping causes a compression of L5 nerve root in the lateral canal. If severe slipping is present, or if the sagittal dimension of the spinal canal is extremely narrow, the olisthesis may also cause central stenosis at the disc level due to the forward slipping of the posterior vertebral arch.

Nerve decompression can be performed with several techniques, but the most commonly used are central laminectomy and unilateral, or bilateral, laminotomy (15). Central laminectomy is indicated in patients with severe stenosis and in any patients in whom fusion has been planned. The procedure entails initially the excision of the spinous process of the slipped vertebra so that laminectomy can be started in the middle portion of the spinal canal and then extended laterally on both sides. This reduces the risk of damaging the nervous structures during decompression since the sagittal dimension of the spinal canal is larger, and stenosis less severe, in the central portion of the spinal canal than in the lateral portion. The ligamentum flavum, which can be normal or hypertrophic, is removed at this stage and the dural sac exposed. Partial facetectomy is then carried out to free the emerging nerve root that may be compressed by the superior or inferior facet joint. The extension of facetectomy varies depending on the severity of stenosis. Usually, in the presence of severe central stenosis both the inferior and superior facets should be extensively

resected (approximately the medial two-thirds of the facet joints) whereas a less extensive facetectomy may be performed in patients with moderate isolated lateral stenosis. The orientation of facet joints in the horizontal plane also affects the extension of facetectomy. When facet joints show a coronal, or slight sagittal, orientation, lateral stenosis is mainly due to a hypertrophic superior facet joint (Fig. 56-1A). In this case partial facetectomy may be accomplished by removing initially the medial one-half or two-third of the inferior facet with a small osteotome, and then the medial one-half or two-third of the superior facet with a pituitary rongeur. When facet joints show a marked sagittal orientation, stenosis is often caused by the forward slipping of the inferior facet (Fig. 56-1B). In this case, only the anterior portion of the inferior facet needs to be excised. Total facetectomy should be avoided, even if fusion has been planned, because it is usually unnecessary and it may cause marked postoperative instability that may increase the risk of pseudarthrosis, particularly in non-instrumented fusion. Laminectomy should be extended cranially, approximately 1 cm beyond the inferior endplate of the slipped vertebra, and caudally, until the emerging nerve root is entirely free in the lateral canal. Foraminotomy is usually not necessary in these patients. Nerve decompression is performed in a similar fashion when a unilateral or bilateral laminotomy is carried out. However, in these cases, the spinous process with the supraspinous and interspinous ligaments are preserved, whereby decompression consists in a unilateral or bilateral fenestration of the spinal canal including a small removal of the lamina along with partial facetectomy as described before. Laminotomy is the treatment of choice

in patients with DS in whom decompression alone has been planned or in those in whom posterolateral fusion has been planned but radicular symptoms involve only one leg, so that a unilateral opening of the spinal canal can be performed.

### Preparation of the Bed Graft

The bed graft for posterolateral fusion is prepared by dividing, with a diathermy blade, the insertions of the longissimus muscle from the lateral aspect of the articular apophyses. Two arteries may be found at this phase: one is located laterally to the pars interarticularis and one at the junction between the superior border of the transverse process and the pedicle. Both these arteries can be coagulated using bayonet forceps. The lateral portion of the articular apophysis is palpated with the index finger and the transverse process identified and exposed.

The bed graft should be carefully prepared and as large as possible to increase the amount of blood supply and osteoinductive factors available for the graft material. To achieve this goal the decortication should include, other than the transverse processes, the lateral portion of the superior facet joint and the pars interarticularis, so that a continuous bony bridge between the adjacent vertebrae will more likely occur (Fig. 56-2).

Decortication can be performed either manually or by using a high-speed burr. A manual decortication is preferred by some surgeons because the high-speed burr may cause thermal necrosis of the decorticated bone that could negatively affect the result of fusion. If a manual decortication is performed, a bone rongeur can be ini-

**FIG. 56-1. A:** In degenerative spondylolisthesis (DS) patients showing facet joints coronally oriented, hypertrophic changes of the superior facet are often responsible for lateral stenosis. In these cases, facetectomy includes the removal of the medial one-half of the inferior and superior facet joint. **B:** In DS patients showing facet joints sagittally oriented, the forward slipping of the inferior facet is often responsible for lateral or central stenosis. In these cases facetectomy may be limited to the removal of the ventral portion of the inferior facet providing no further compression is caused by the superior facet joint.

**FIG. 56-2.** Decortication of the bed graft in posterolateral fusion. The bed graft should include the transverse processes, the lateral portion of the superior facet joint and the pars interarticularis.

tially used to interrupt the thin cortical wall of the transverse processes, taking care to avoid its complete fracture. The decortication is then extended to the entire transverse process with a small curette. The pars interarticularis and the lateral aspect of the superior articular apophyses can be decorticated with a curved osteotome, a large curette or a bone rongeur. The preparation of the bed graft is completed when bleeding bone has been exposed throughout the fusion area and when soft tissues that might interpose between the bone graft and the decorticated bone have been carefully removed.

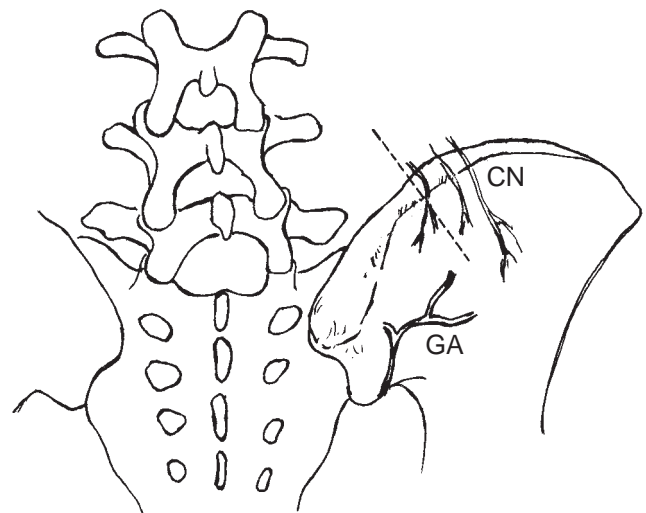

### Harvesting and Positioning of Graft Material

Autograft and allograft are currently used for posterolateral fusion. This author currently use autogenous bone graft from the iliac crest since, at the present, this seems to be the best graft material for spinal fusion. This is particularly true in degenerative spondylolisthesis in which a one level fusion is usually performed and unilateral harvesting of bone graft from the iliac crest is sufficient for the entire bed graft. Alternative graft materials, including osteoinductive and osteoconductive substances, are under investigations; however, further studies are needed to evaluate their effectiveness compared to autograft.

Autogenous bone graft is usually harvested from the iliac crest. Some surgeons are used to expose the iliac crest from the same skin incision of laminectomy. However, this implies that a wide subcutaneous dissection has to be performed to expose the iliac crest, with possible occurrence of subcutaneous seromas and delay in the healing of the surgical wound. It is preferable to perform a second skin incision, 3 to 4 cm lateral from the posterior iliac spine, with an oblique direction from cranial to caudal and from medial to lateral. This skin incision is perpendicular to the iliac crest, and thus limits the amount of bone graft which may be harvested, but is in the same direction of the cluneal nerves which lie subcutaneously in this region (Fig. 56-3). On the other hand, a skin incision parallel to the iliac crest allows harvesting a larger amount of bone graft but entails higher risks of transect-

ing the cluneal nerves, with possible occurrence of painful neuroma, compared to the previous skin incision.

Once the iliac crest is exposed, a subperiosteal dissection is carried out on the external portion of the iliac wing. Care must be taken to avoid a subperiosteal dissection, and elevator positioning, too close to the sciatic notch, since at this level the superior gluteal artery and vein may be damaged (Fig. 56-3). Although this complication is uncommon, the surgeon should be well aware of it because it can be difficult to control the bleeding, particularly if the transected vessel retracts within the pelvis. In this event treatments include: (a) a caudal enlargement of the surgical wound in order to elevate subperiosteally, and retract laterally, the gluteus maximus, to expose the piriformis muscle and, at its superior border, the superior gluteal artery which at this point can be ligated (16); (b) embolization of the superior gluteal artery (17); (c) direct ligation of the artery by turning the patient in supine position and reaching the arterial origin through an anterior retroperitoneal or transperitoneal approach.

**FIG. 56-3.** Anatomic structures which can be injured during harvesting autogenous bone graft from the iliac crest. CN, cluneal nerves; GA, gluteal artery.

Harvesting of bone graft consists in taking cortical bone and cancellous bone separately. Cortical bone is removed by performing vertical and horizontal cuts with a straight osteotome on the cortical wall of the iliac wing. A curved osteotome is then used to remove cortical chips while cancellous bone is usually taken with a gouge. Small bone chips are then prepared and placed in the bed graft, first positioning a layer of cancellous bone directly in contact with the decorticated bone and then positioning a layer of cortical bone over the cancellous bone. Paraspinal muscles are then replaced over the bone graft taking care to avoid a displacement of bone chips into the spinal canal. To prevent this from occurring, the dural sac should always be protected with hemostatic sponges before the positioning of the bone graft. Before skin closure, bone wax should be placed over the decorticated area of the iliac wing until bone bleeding is arrested and a drain is positioned in both surgical wounds.

### POSTOPERATIVE MANAGEMENT

Standing and walking is allowed from the first operative day as tolerated by the patient. We encourage six walks of 5 minutes from the second postoperative day and as long as possible from the fourth day after the operation. A plaster cast or corset is worn 24 hours before hospital discharge, that is, between the seventh and tenth day after surgery. This hospitalization time is substantially reduced (3 to 6 days) in patients submitted to instrumented fusion. The corset is usually removed 4 months after surgery but physical exercises are not allowed until 6 months from the operation.

### RESULTS

Although degenerative spondylolisthesis is probably the most frequent condition requiring spinal fusion in the adult population, few studies analyzed in detail the results of this procedure in DS patients.

Feffer et al. (2) analyzed the surgical outcome in 19 patients with DS treated in two different Hospitals. Eight patients underwent decompression and fusion, and 11 decompression alone. All patients had leg pain equal to or greater than their back pain and radiologic investigations showing a compression of the nervous structures. Length of follow-up ranged from 12 to 72 months. In the fused group, the clinical result was rated as good in 5 patients and fair in 3. In the decompressed group, the clinical result was rated as good in 5, fair in 3 and poor in 3 patients. Lombardi et al. (5) analyzed the surgical outcome in 47 patients with DS treated with wide decompression (bilateral total facetectomy) in 6 patients, standard decompression (partial facetectomy) in 20 patients, and decompression with partial facetectomy plus posterolateral fusion in 21 patients. The follow-up ranged from 24 months to 7 years. The surgical outcome was

rated as excellent or good in 30% of the patients who had wide decompression, 80% of those who had standard decompression, and in 90% of those who had decompression plus fusion. Postoperative increase in vertebral slipping did not correlate with the clinical result except when postoperative slip approached 50%.

We evaluated the clinical and radiologic results of 16 patients with DS (included in a larger group of patients with spinal stenosis) after a mean follow-up of 8.6 years (range 5 to 19 years) (18). The clinical outcome was rated as excellent or good in eight of the ten patients who had decompression and fusion and in two of the six who had decompression alone. A reconstitution of the posterior vertebral arch excised at surgery was found to occur more frequently in spondylolisthetic patients than in stenotic patients without spondylolisthesis and, in the spondylolisthetic group, in those who had decompression alone compared to those who had decompression and fusion.

Herkowitz and Kurz (4) analyzed prospectively the surgical outcome in patients with DS. Of the 50 patients included in the study, 25 were treated with decompression alone and 25 with decompression and fusion. The length of the follow-up ranged from 2.4 to 4 years. The clinical outcome was rated as excellent or good in 96% of the patients in the fused group and in 44% of those in the decompressed group. A pseudarthrosis was noted in 36% of the patients of the fused group; however, all these patients reported an excellent or good result.

A prospective randomized study analyzed the effectiveness of decompressive laminectomy and posterolateral fusion with or without spinal instrumentation in patients with degenerative spondylolisthesis (9). In the 67 patients available for a 2-year follow-up the clinical outcome was rated as excellent or good in 85% of patients who had a noninstrumented fusion and in 76% of those who had an instrumented fusion. However, a successful arthrodesis was found in 45% and 82% of the patients who had, respectively, a noninstrumented and an instrumented fusion. An excellent or good result was reported by 83% of patients with pseudarthrosis after noninstrumented fusion.

A meta-analysis of literature on DS patients treated with laminectomy alone or laminectomy and instrumented or noninstrumented fusion, revealed satisfactory results in 69% of those who had laminectomy alone, and 90% and 86% of those who had laminectomy with non-instrumented and instrumented fusion, respectively (6). The reported fusion rate was 86% in those who had a noninstrumented fusion and 93% in those who had an instrumented fusion.

McCulloch retrospectively reviewed 21 patients with degenerative spondylolisthesis who had a decompression and noninstrumented unilateral fusion (19). After an average follow-up of 38 months, the overall satisfactory outcome was 76%. Twenty of twenty-one patients had relief of their claudicant leg pain and the overall fusion rate was 86%.

Kuntz et al. analyzed the cost-effectiveness of fusion with and without instrumentation for patients with degenerative spondylolisthesis and spinal stenosis (20). The results showed that the cost-effectiveness of laminectomy with non-instrumented fusion compares favorably with decompressive alone and with decompressive plus instrumented fusion.

In conclusion, data on the surgical outcome in patients with DS are largely incomplete due to methodologic limitations of the studies. Most of the series are retrospective, did not analyze the functional outcome, did not address possible causes of failures, and are based on short-term follow-ups. Nevertheless, most of the studies show that DS is one of the spinal conditions in which the result of the surgical treatment is more predictable and that posterolateral fusion is one of the most effective procedures in the treatment of DS. A correct surgical indication, including an evaluation of the psychological profile of the patient, is one of the most important factors in determining the success of the operation. Preoperative assessment should also include a radiologic investigation at the levels adjacent to the spondylolisthesis, to avoid missing a concomitant spinal condition at another vertebral level.

## COMPLICATIONS

Decompression and posterolateral fusion is thought to be a safe procedure with a low complication rate. In keeping with this, no surgically related complications were reported in a meta-analysis of literature on DS patients treated with decompression and non-instrumented fusion (6).

Complications may be related to decompression or fusion. The former are similar to those reported by stenotic patients, including dural tear, motor deficits and infections. These complications are uncommon and their incidence is usually lower than in stenotic patients without spondylolisthesis, since in the latter decompression is more likely to be performed at multiple levels compared with patients with DS in whom stenosis is often present at a single level.

Complications related to posterolateral fusion are also rare. They are usually associated to the harvesting of iliac crest bone graft rather than to posterolateral fusion in itself. Their reported incidence was found to range between 0.7% and 25% for major complications and between 9.4% and 24% for minor complications (21,22). In a large retrospective study, none of the patients had major perioperative complications such as superior gluteal artery injury, sciatic nerve injury or deep infection, nor did patients report major late complications such as herniation at the donor site, meralgia paresthetica, pelvic instability or fractures (23). However, 18 patients (10%) had other major complications, including prolonged sterile drainage, subcutaneous seroma, unsightly

scar revision and chronic pain limiting physical activities. In the same series, 39% of the patients had minor complications, including temporary dysesthesia, wound drainage, and superficial infection (23). In a consecutive series of patients in whom autogenous bone graft was harvested through a skin incision perpendicular to the posterior iliac crest (study group) and, for comparison, through a skin incision parallel to the posterior iliac crest (controls), the patients in the study group reported significantly lower numbness, tenderness and pain at the donor site compared with the controls (24).

In conclusion, major complications, including superior gluteal artery injury, sciatic nerve injury, meralgia paresthetica etc. are uncommon and often published as case reports. Minor complications occur more frequently, particularly persistent donor site pain. This complication usually does not limit physical activities but may affect, in some way, the overall clinical outcome in approximately 10% to 30% of patients. The amount of bone graft harvested from the iliac crest with related soft tissue dissection, the accuracy in the surgical procedure and the type of skin incision used to expose the iliac crest seem to be the most important factors affecting donor site complications.

# Anterior Lumbar Interbody Fusion

Mamoru Kawakami and Tetsuya Tamaki

---

Degenerative spondylolisthesis is a clinical term characterized by the forward translation of a vertebra on the inferior vertebra in the presence of an intact neural arch. The pathoanatomic elements of degenerative facet arthropathy, anterolisthesis, narrowing of the disc space, and ligamentum flavum redundancy contribute to the development of spinal stenosis, including the central canal, lateral recess, and foraminal zones (1). It may be a source of low back pain with insidious onset of radicular or referred leg pain or intermittent claudication. Although there are many reports with regard to surgical results for patients with degenerative spondylolisthesis, evaluating the outcomes of surgical treatments requires knowledge of the natural history of the untreated condition. However, little is known of the natural history of, or the optimal surgical treatment for, degenerative lumbar spondylolisthesis.

When deciding on operative treatment for degenerative lumbar spondylolisthesis, it is essential to choose the appropriate surgical procedure based on the stage and pathogenesis (2). In the early stage of degenerative lumbar spondylolisthesis, the initial symptom is mainly low back pain, while pain of the lower extremities can also occur. These symptoms are thought to be related to either disc degeneration or degenerative arthritis of the facet joints. In the middle stage of degenerative lumbar spondylolisthesis, the dural sac is constricted, causing central canal stenosis because of the anterior shift of the inferior articular process of the slipping vertebra and posterior bulging of the intervertebral disc materials. During this stage, the patient suffers from low back pain associated with radicular pain of the lower extremities, and intermittent claudication. By late and end-stage degenerative lumbar spondylolisthesis, osteophytes have formed on the medial and ventral sides of the superior articular process of the lower spine, preventing the displacement from progressing further, and these osteophytes become one of the causes of lateral stenosis. Although low back pain occasionally abates because of the decrease in instability, this

is accompanied by the simultaneous development of numbness or paresis of the lower extremities at rest (2–4).

There does not appear to be a clear consensus for the optimal surgical treatment of degenerative lumbar spondylolisthesis. Most studies show that the clinical outcome is better when decompression is accompanied by fusion using the posterior approach (5). However, sufficient decompression and fusion may be obtained by the anterior lumbar interbody fusion in some condition or stage of degenerative lumbar spondylolisthesis. The mechanism of neural decompression is indirect, with restoration of disc space height, reduction of listhesis, and foraminal enlargement, which are achieved by intervertebral distraction and maintained by a structural anterior interbody fusion (1). An experimental study using cadaveric lumbar spines also demonstrated that interbody distraction using anteriorly inserted plugs, immediately improved the narrowed canal area and increased the spinal canal and the foraminal volume, in lumbar degenerative spondylolisthesis (6). An intervertebral fusion takes advantage of the large surface area for graft contact of both contiguous vertebral end plates, assists in maintaining or improving disc space height, and allows placement of the graft under compression, which biomechanically is a more suitable environment for graft maturation.

Using a meta-analysis of the literature from 1970 to 1993, Mardjetko et al. evaluated the results of anterior interbody fusion for patients with degenerative lumbar spondylolisthesis (7). They found that only three articles met the inclusion criteria and that pooling the data from these three studies yielded a 94% fusion rate, with an 86% rate of patient satisfaction (7). Two of these three papers are Japanese in origin and there are many reports in Japanese with regard to the anterior lumbar interbody fusion for degenerative lumbar spondylolisthesis. In this chapter, we review the indications and the clinical outcomes, including radiologic assessments and complications of anterior lumbar interbody fusion, for degenerative lumbar spondylolisthesis.

## INDICATIONS FOR ANTERIOR LUMBAR INTERBODY FUSION

Surgical treatment is indicated when appropriate conservative treatments fail to control clinical symptoms such as low back pain, leg pain, numbness, and intermittent claudication. Anterior interbody fusion involves an anterior retroperitoneal approach. Adhesion of the peritoneum is thus a factor of contraindication. It has been reported that patients can expect satisfactory results up to about 65 years of age (1,8,9). Anterior interbody fusion is indicated for younger patients (i.e., those under 50 years), but is not generally indicated for older patients (10–12). Patients with osteoporosis have a lower success rate for correction and are at risk of collapse of the bone grafts (12). Degeneration of the adjacent segment at the time of surgery may possibly cause enhanced degeneration after surgery (13). The indication is for patients without osteoporosis or degeneration of the adjacent segments (13,14). Anterior interbody fusion is not recommended for patients with an apparent multilevel involvement (1,9,10,14). A patient with a single-level lesion, symptoms and signs that usually appear or worsen after activities such as standing or walking, or who has neurologic symptoms and signs in the leg but no leg pain in the resting position, is a good candidate for this surgery (15). A patient whose clinical symptoms can be relieved by the application of a carefully molded body cast or corset in a flexed position is also a good candidate for this surgery (1,9). A poorer functional outcome may be found in patients who have responded poorly to a preoperative test brace.

An indication for this surgery, using data from dynamic X-rays, is lumbar instability of the affected segments but not severe stenosis, where posterior elements such as the facet joint are involved (10–12,15). A need for decompression can possibly occur in patients with stenosis of the lateral recess. The staging in degenerative spondylolisthesis proposed by Satomi et al., using computed tomography (CT) scanning after myelography, is very useful to evaluate the cause of dural sac compression (8,16,17). Stage 1 images exhibit posterior distension of the intervertebral disc with vertical inclination of the articular facets. In stage 2, the inferior articular process of the slipping vertebra shifts anterior to the superior articular process of the lower vertebra. In stage 3, osteophytes form anterior and posterior to the superior articular process of the lower vertebra. The anterior shift of the inferior articular process of the slipping vertebra can improve with reduction of slippage and restoration of the intervertebral disc height secondary to the anterior interbody fusion (stages 1 and 2). However, the anterior interbody fusion is not effective in those cases where the superior articular process of the lower vertebra is involved in the clinical symptoms (stage 3) (8).

## POSTOPERATIVE MANAGEMENT

Postoperative bed rest is recommended for 3 weeks after surgery (2,14). Supplementation with Arbeitsgemeinschaft für Osteosynthesefragen (AO) screwing and wiring (18) can reduce the time of bed rest after surgery (13,16) to 2 weeks. A body cast is applied for 4 to 6 weeks after bed rest (2,14,19), followed by a corset for about 6 months until bony fusion is obtained (14). Postoperative management should be very strict and is important because there is no optimal anterior instrumentation. An interbody cage, including threaded cylinders and monobloc devices from the anterior may give stabilization of the lumbar spine immediately after surgery and reduce the time of bed rest. Biomechanical studies reveal that the cage decreases intervertebral motion in flexion, axial rotation, and lateral bending compared with uninhibited motion (20). However, the cage does not stabilize the spine in extension (20). Supplementary posterior fixation including pedicle screw fixation and translaminar fixation substantially improves the stabilization (21,22). Therefore, supplementary posterior fixation can reduce the time of bed rest, and eliminates the need for a body cast. Supplementation with pedicle screw fixation to the anterior interbody fusion can reduce the period of bed rest to only 2 to 3 days in patients with degenerative lumbar spondylolisthesis (15).

## CLINICAL OUTCOMES

### Functional Results

Takahashi et al. have reported that long-term results have been achieved with anterior interbody fusion for the treatment of degenerative spondylolisthesis (1,9). They used the score rating system of the Japanese Orthopaedic Association (JOA) for clinical evaluation (23), a full score being 29 points. They classified patients with a score of 25 points or more as “satisfactory”, while those with a score of 24 points or less were classified as “unsatisfactory”. Using a Kaplan-Meier survivorship analysis at an average follow-up of 12 years and 7 months, Takahashi et al. reported a 76% rate of satisfactory results at 10 years, a 60% rate of satisfactory results at 20 years, and a 52% rate of satisfactory results at 30 years (1,9). All patients in their 30s (average age at surgery, 36.5 years) maintained satisfactory results at least until their final examination, with an average follow-up of 24 years, 11 months after surgery (range, 20 years to 29 years, 10 months). Results were also satisfactory in 80% of patients in their 40s (average age at surgery, 44.7 years) for up to 16 years, and 73% of patients in their 50s (average age at surgery, 54.8 years) for up to 10 years. However, results were satisfactory in only 4 of the 7 patients 60 years of age or older (average age at surgery, 65.2 years) immediately after surgery. The authors concluded that these results indicate that regardless of patient age at

surgery, patients can expect satisfactory results up to about 65 years of age, and that anterior interbody fusion is a treatment that can guarantee a good lifelong course for patients with degenerative spondylolisthesis.

Satomi et al. compared the results of anterior interbody fusion with or without AO screwing and wiring to patients who underwent posterior decompression with or without spinal fusion (8,16,17). They used the degree of recovery or recovery rates, which were calculated from preoperative and postoperative JOA scores. The mean follow-up period was 3 years, 2 months. Clinical improvement was seen in 77% of the group undergoing anterior interbody fusion compared with only 55.7% of patients in the group undergoing posterior decompression. Since their indications were different for patients with degenerative spondylolisthesis as described previously, it is questionable to compare these functional outcomes.

Nishizawa and Fujimura retrospectively reviewed 58 patients (13 men and 45 women) with degenerative spondylolisthesis treated with anterior lumbar interbody fusion. The follow-up period ranged from 28 to 128 months, averaging 63 months, and the mean recovery rate was 78%. They found that the recovery rate for low back pain and gait was better than for leg pain or tingling, clinical signs, and urinary bladder function (2).

Tanaka et al. reported surgical results for minimally invasive anterior lumbar interbody fusion (24) with a supplemental pedicle screw system for degenerative spondylolisthesis, compared with those of posterior lumbar interbody fusion (15). They found that the mean recovery rate was 76.8% in patients treated with minimally invasive anterior lumbar interbody fusion with a supplemental pedicle screw system, compared with 70.9%.

Nishizawa et al. reported on results following anterior interbody fusion for lumbar degenerative spondylolisthesis (19). The mean follow-up period was 11 years, 10 months. They found that the mean recovery rates were 76%, 80.9%, 81.6%, 73.1%, and 68.8%, in follow-ups at 1 year, 3 years, 5 years, and 10 years after treatment, and at the final follow-up, respectively. Long-term results showed some deterioration of functional outcomes in

patients treated with anterior interbody fusion (1,9,19). The deterioration of the JOA score is thought to be attributable to age-related general weakness (1,9).

Kim et al. reported six patients with degenerative spondylolisthesis treated with anterior interbody fusion (25). Their evaluation was a pain rating only: excellent, good, fair, and poor, where there was little or no pain, mild pain, moderate pain, and severe pain, respectively. One, three, and two patients had excellent, good, and fair results, respectively. Four patients were satisfied with the surgical results. Functional results using the recovery rates are summarized in Table 57-1. These results were obtained from retrospective studies.

The indications for anterior interbody fusion are different from those for posterior decompression with or without posterolateral fusion or posterior interbody fusion. Although reports from Japan have used the JOA score and recovery rates, the instrument for functional measures is also different from that reported in other countries. It is questionable whether these functional results of anterior interbody fusion are superior to those of the posterior approach for patients with degenerative lumbar spondylolisthesis.

### Radiologic Results

Inoue et al. performed anterior interbody fusion on 36 patients with degenerative lumbar spondylolisthesis to remove the diseased intervertebral disc (4). They reported a correction in sagittal malalignment with restoration of disc space height in the majority of patients. Fusion was successful in all single-level fusions and in 85% of double-level fusions (4). Takahashi et al. found 4 cases of nonunion in 10 patients treated with double-level fusions (1,9). Nishizawa et al. reported that bony union was achieved in 55 of 58 patients (95%), including fusion *in situ* for 39 patients (67%), collapsed fusion for 16 patients (28%) and nonunion for 3 patients (5%). They found that the recovery rate was 85% in patients with fusion *in situ*, 66% in those with collapsed union, and 46% in those with nonunion ( $p < .05$ ) (2).

**TABLE 57-1.** The periods of follow-up and recovery rates in anterior interbody fusion for degenerative lumbar spondylolisthesis

	Total	Mean follow-up period (mos)	Mean recovery rates (%)
Takahashi et al. (1)	19	151	71
Satomi et al. (17)	27	38	77
Nishizawa & Fujimura (2)	58	63	78
Tanaka et al. (15)	18 <sup>a</sup>	14	76.8
Nishizawa et al. (19)	27	142	68.8
Hirofuji et al. (11)	28	104	52.8
Total:	177	85	70.7

<sup>a</sup>Minimally invasive anterior lumbar interbody fusion with supplemental pedicle screw system.

Satomi et al. reported that the average percentage of vertebral slippage improved from 18.5% preoperatively to 7.4% postoperatively in the anterior interbody fusion group, and that the reduction rate of the slippage was 62.1% (16,17). Nishizawa et al. reported in their long-term follow-up study that the union rate was 92.6% (18). Nonunion was found in two patients treated with double-level fusion; both had poor outcomes. In their series, the average percentage of vertebral slippage improved from 19.1% preoperatively to 6.8% immediately after surgery, and to 9.2% at follow-up. The mean collapse rate was 22.4% and was not related to the recovery rate.

Rates of fusion reported in the literature are summarized in Table 57-2. According to the definition of fusion proposed by Fujimura (10), 16 patients (26%) were classified as collapsed fusion, where the collapse rate calculated from the disc heights immediately after surgery and at follow-up was more than 20%. Forty-two patients (69%) were classified as fusion *in situ*, where the collapse rate was less than 20%, and three patients (5%) had nonunion. The mean recovery rates were 86%, 67%, 47% in fusion *in situ*, collapsed union, and nonunion, respectively (10).

Collectively, these reports demonstrate that anterior interbody fusion for degenerative spondylolisthesis can improve and restore the percentage of anterior vertebral slippage and maintain the sagittal alignment at the fusion level. It has been reported that the facet angle and the spread ratio of the intervertebral disc space are factors influencing the collapse of bone grafts (26). In patients with osteoporosis, some countermeasures are required to prevent the collapse of bone grafts, due to a small facet angle and the need to spread the intervertebral disc space excessively. If there is a suspicion of incipient pseudoarthrosis, patients with spondylolisthesis should be treated by fusion with either intralaminar screw fixation or pedicle screw fixation, by posterior spondylodesis, or by posterolateral fusion. The combined use of bone graft substitutes, such as hydroxyapatite-based ceramic or an interbody cage, with autologous bone may prevent collapse of the grafting bone and

improve fusion rates and functional outcomes after anterior interbody fusion.

## COMPLICATIONS

Anterior interbody fusion involves an anterior retroperitoneal approach along with its attendant complications. The most serious complication has been death because of pulmonary embolism. Surgical injury to the presacral sympathetic nerves may result in either retrograde ejaculation or ejaculatory dysfunction. There is the possibility of vascular injury through the anterior approach, especially in older patients with fragile vessels. Usually, this is considered a temporary and very rare complication when the retroperitoneal approach is performed. No procedure-related complications were reported in two papers published by Takahashi et al. (9) and Satomi et al. (17). Nishizawa and Fujimura reported that 9 of 58 patients treated with anterior interbody fusion had complications including iliac donor-site pain (n = 3), wire breakage of AO screwing and wiring (n = 2), liver dysfunction (n = 2), deep vein thrombosis (n = 1), and pulmonary embolism (n = 1) (2). Anterior interbody fusion may be also complicated by injury to the lateral femoral nerve in connection with harvesting of the bone graft.

The iliac crest was used as the donor site. In 26 patients treated with anterior interbody fusion, Nakai and Abe found that 17 suffered complications: neurologic complication (n = 1); donor site complications (meralgia paresthetica (n = 7), fracture (n = 2); deep vein thrombosis (n = 2); and edema in left leg (n = 4) (12). Rates of complications are summarized in Table 57-2.

For anterior intervertebral fusion, bone graft substitutes such as allografts or hydroxyapatite instead of autologous bone or an interbody cage may be useful to prevent donor site complications. The rate of nonunion after anterior interbody fusion for patients with degenerative lumbar spondylolisthesis has been previously described. Anterior interbody fusion may result in enhanced degeneration in the adjacent segments of the fusion site. Long-term follow-up is needed to assess possible disc degener-

ation, including herniated disc and instability. Nishizawa et al. clearly demonstrated that the lesion of the adjacent segments did not result from anterior interbody fusion, because there were no significant differences in mobility of the intervertebral disc space and in disc height between the age-matched groups after the surgical and conservative treatments (19).

We have reported that lumbar sagittal alignment influences the clinical outcome after decompression and posterolateral spinal fusion for degenerative lumbar spondylolisthesis (27). Even in patients treated with anterior interbody fusion, imbalance of the sagittal alignment of the spine may result in enhanced disc degeneration in the adjacent segments. Further study is needed to evaluate whether the sagittal alignment of the spine influences the surgical result after anterior interbody fusion. Although there can be serious complications such as pulmonary embolism, the number of complication events is small. It is important to evaluate complication rates in large series and compare with the posterior approach to make clear the effectiveness and safety of anterior interbody fusion for patients with degenerative lumbar spondylolisthesis.

## CONCLUSION

The consensus throughout the literature about surgical approaches is that anterior interbody fusion in the surgical management of degenerative lumbar spondylolisthesis improves clinical outcomes and achieves solid fusion. However, surgical indications for this procedure should be limited because of the differing stages of degenerative spondylolisthesis. Although several comparative studies of anterior interbody fusion and posterior approaches have been undertaken, the indication was different and the results varied. Functional outcomes, fusion rates, and complications should be compared for both the anterior and posterior approaches. Prospective randomized studies addressing this issue have yet to be performed. The role of new bone graft substitutes and interbody cages should be made clear in anterior interbody fusion for degenerative lumbar spondylolisthesis.

# Decompression with Instrumented Fusion

Dilip K. Sengupta and Harry N. Herkowitz

---

A consensus has been formed that degenerative lumbar spondylolisthesis with stenosis benefits from decompression, with significant reduction of radicular pain and claudication, if nonsurgical treatment fails. But there is no general agreement about the indications for fusion. Indications for instrumentation are even more controversial. Generally speaking, the goals for decompression are to relieve radicular symptoms and neurogenic claudication. The goals for fusion are to relieve back pain from a degenerated disc and elimination of instability. The goals for instrumentation are to promote fusion and to correct listhesis or kyphotic deformity.

### INDICATIONS FOR INSTRUMENTATION

The factors leading to the decision for fusion and instrumentation may be based on (a) preoperative condition and (b) intraoperative assessment of stability of the motion segment.

There are four preoperative factors to consider:

1. Disc height
2. Degree of kyphosis
3. Degree of instability
4. Degree of listhesis.

There are four intraoperative factors to consider:

1. Extent of decompression procedure
2. Previous laminectomy
3. Adjacent segment disease
4. Available bone stock

### Disc Height

When the disc height is completely collapsed to only 1 or 2 mm, then progression of the spondylolisthesis after decompression is less likely (1). When the preoperative disc height is greater than 2 mm, an instrumented fusion is recommended to prevent progression of listhesis.

### Degree of Kyphosis

Normal sagittal Cobb angle at the L4-5 level varies between  $-8^{\circ}$  to  $-17^{\circ}$  (2). Degenerative spondylolisthesis results in a relative segmental hypolordosis. Presence of frank kyphosis is considered an indication of restoration of lordosis. Instrumentation is always indicated whenever a correction of deformity is intended at surgery.

### Degree of Instability

Presence of abnormal motion at the listhetic segment exceeding 5 mm is an indication for instrumentation to achieve fusion. The best way to demonstrate the pathologic motion is controversial. The instability may be assessed radiologically by flexion-extension films in either supine or sitting posture. An alternate method is to compare lateral radiographs in standing position versus in a supine hyperextended position on a pillow. However, even in absence of preoperative demonstrable motion, many observers noted as much as 20% to 40% reduction of listhesis, when the patient is positioned prone on table after general anesthesia (3,4).

### Degree of Listhesis

Degenerative listhesis rarely exceeds grade I or grade II. In occasional cases, listhesis may progress beyond 50%, even in absence of previous surgery.

Degenerative listhesis following previous laminectomy, or when involving an adjacent segment to previous fusion may exceed grade II. An instrumented fusion is indicated when listhesis exceeds 50%, whether or not a correction of deformity is indicated.

### Extent of Decompression

The stabilization structures in a motion segment include the disc anteriorly, the facet joints posteriorly, and the pars. The exact degree of instability engendered by a

given decompression is difficult to predict. However, previous reports in the literature show that removal of one-third to one-half of the facet joints on both sides or all of one facet joint at a given level is often tolerated, without progression of the listhesis (5,6). Abumi et al. (7) demonstrated in a biomechanical study in cadaver spine that removal of greater than 50% of each facet joint led to an unacceptable movement of the motion segment. Therefore, when facet excision in excess of 50% in each side is required for adequate decompression, an instrumented fusion is recommended. When adequate decompression warrants violation of the pars, or bilateral discectomy in addition to partial removal of the facet joints, progress of listhesis may be anticipated. An instrumented fusion is indicated in such cases as well.

### Recurrent Stenosis after Previous Laminectomy

Degenerative listhesis may progress beyond 50% in the presence of previous laminectomy. Even if the listhesis has not progressed, a revision decompression at the same level often requires significant removal of the remaining facet joints, indicating an instrumented fusion. On the other hand, previous decompression surgery may achieve a spontaneous facet joint fusion that may add stability and may not need further fusion.

### Adjacent Segment Disease

Degenerative lumbar spondylolisthesis with stenosis at an adjacent level to a caudal fusion segment is subjected

to additional stress and is more likely to progress unless instrumented.

### Available Bone Stock

In order to achieve successful fusion without instrumentation, adequate bone graft needs to be applied on a sufficiently large bed. In patients with small transverse processes, meaningful transverse process fusion becomes unlikely. To accomplish facet fusion disruption of the facet joint capsule an articular cartilage is needed, which predisposes to further instability. Instrumentation is indicated in these situations to achieve fusion. Significant osteoporosis is a contraindication to instrumentation.

## TYPE AND EXTENT OF INSTRUMENTATION

### Posterior Pedicle Screw Fixation Alone

Only posterior pedicular instrumentation is adequate for most cases of degenerative lumbar spondylolisthesis with stenosis, where instrumentation is indicated. Although it is conventional to instrument both sides, there has been no difference in the fusion rate or clinical outcome after unilateral versus bilateral pedicle fixation (8). For multilevel fusion it is preferable to instrument both sides. End vertebrae should be instrumented, but it is not mandatory to insert pedicle screws in all the levels (Fig. 58-1). Many surgeons deliberately skip the middle vertebrae during pedicle fixation, if the bone quality is good and pedicle fixation appears firm at surgery. This

**FIG 58-1.** A: A 72-year-old female patient with degenerative spondylolisthesis at L3-4 and L4-5 segments presented with mechanical back pain and neurogenic claudication. B, C: Flexion-extension views show translation at both the levels. (continued)

**FIG 58-1.** (Continued) **D, E:** The patient was treated with decompression and posterior instrumentation fusion from L3 to L5 segments. Since L4-5 disc space was completely collapsed, no screw was inserted at this level. **F, G:** At 2-year follow-up, the instrumented segments maintained stability. Consolidation of bone graft is difficult to interpret from these plain radiographs. **H, I:** Flexion-extension lateral radiographs show no movement at the instrumented segment, indicating a possible fusion.

reduces the cost of instrumentation as well as avoids unnecessary complication associated with pedicle screw insertion.

### Selective Fusion

In the presence of multiple level spinal stenosis associated with degenerative spondylolisthesis it is not necessary to fuse all the segments. In a prospective randomized study in 45 patients with spinal stenosis without instability undergoing decompression alone, decompression with selective fusion or decompression with fusion of all the

segments, Grob et al. (9) found no difference in outcome between the different groups. They concluded that arthrodesis was not justified in the absence of radiographically proven instability. Herkowitz et al. also suggest decompression of all the symptomatic stenotic levels, but instrumented fusion of only the listhetic segment with instability (10) (Fig. 58-2).

### Interbody Fusion

When correction of listhetic segment is intended because of grade II slip or higher, or restoration of lordo-

**FIG. 58-2.** **A, B:** A 68-year-old male patient with mechanical back pain and neurogenic claudication. Anteroposterior and lateral radiographs show degenerative spondylolisthesis at L4-5 segment and stenosis at L3 to S1 segment. **C, D:** Flexion-extension lateral radiographs clearly demonstrate 5 mm translation at L4-5 segment. **E, F:** The patient was treated by decompression from L2 to S1 segment, but stabilization of the unstable L4-5 segment only. *(continued on next page)*

sis is intended due to presence of frank kyphosis, only posterior pedicle fixation may not be adequate. The pedicle screws are subjected to excessive stress in these situations, unless supported by an interbody fusion. This may be accomplished by either posterior lumbar interbody fusion or by an additional anterior interbody fusion.

An alternative to interbody fusion is to extend the fusion to an additional segment caudally. For example, correction of spondylolisthesis or slip angle at L4-5 level may be achieved by additional interbody fusion of L4-5

level alone or by extending posterior pedicle fixation from L4 to S1 levels.

#### Posterior Instrumentation without Fusion

A small but increasing group of surgeons prefer to use soft stabilization procedures after decompression with posterior instrumentation but without fusion. Gardner et al. (11,12) described the Graf ligamentoplasty (13) procedure with long-term follow-up (11) in degenerated disc

**FIG. 58-2.** (Continued) **G, H:** Anteroposterior and lateral radiographs at 3-year follow-up show the lumbar spine maintains stability, despite short segment fusion only.

diseases with or without spondylolisthesis. This procedure involves attachment of a Dacron ligament to the pedicle screws across the unstable segment. The disadvantage of this procedure is that it increases the lordosis by compressing the posterior segment of the disc, which may cause further narrowing of the foramen. The recently described Dynamic Neutralization System (Dynesys) implant (14), which involves insertion of a similar ligament, but with a plastic cylinder around it, may produce the distraction of the disc space. However, since the distraction is produced by an implant lying posterior to the axis of flexion-extension, this system may lead to loss of lordosis. Restoration of lordosis of the motion segment then depends on the muscle action by the spinal extensor muscles. Mochida et al. (15) reported an innovative method of posterior stabilization in which the Leeds-Keio artificial ligament was used as a nonrigid implant to stop movement in degenerative spondylolisthesis.

### POSTOPERATIVE MANAGEMENT

The average duration of surgery for decompression and instrumented posterolateral fusion is approximately 2 to 3 hours. Single-level fusion may be performed under spinal anesthesia. The patients are mobilized to a chair on the evening of surgery and ambulation begins the next day with the help of physical therapy. Deep vein thrombosis prophylaxis is done by sequential pumps and compression stockings around the legs and by early mobilization. Braces are typically not used. Drains are removed in the first or second postoperative day. The average hospital stay is 2 to 4 days. Most patients may be discharged

home. Some older adult patients may require inpatient rehabilitation. The patients are advised against bending, lifting, and twisting motion of the spine for 6 to 12 weeks. Return to work may vary between 6 to 12 weeks depending on the nature of job. Nonsteroidal antiinflammatory drugs should be avoided in all fusion patients.

### RESULTS

Traditionally, the surgical management of degenerative lumbar spondylolisthesis involves decompressive laminectomy alone. Superiority of fusion over decompression alone was being reported in the literature. A prospective randomized study comparing the role of arthrodesis versus decompression alone was lacking until 1991, when Herkowitz and Kurz published a prospective study in 50 cases, comparing decompressive laminectomy alone with additional intertransverse fusion for single level spinal stenosis with degenerative spondylolisthesis. The results of this study showed a significantly better outcome and a lesser chance of progression of the slip in the fusion group.

Several studies compared the role of instrumentation. The critical issues in adding instrumentation to a fusion are whether the fusion rate will increase and whether the clinical outcome will improve. This must be balanced against increased cost of the implants and potential complications of instrumentation.

In a prospective randomized study in 124 patients (including 56 with degenerative or isthmic spondylolisthesis) in 1993, Zdeblick (16) reported significantly better fusion rate in the instrumented group. However, no breakdown of the number of patients with degenerative

spondylolisthesis was made. Subsequently, Bridwell et al. (17) reported a study on 44 patients who underwent fusion after decompression for degenerative stenosis with spondylolisthesis. They compared a decompression group, decompression and uninstrumented fusion group, and fusion with instrumentation group. The instrumentation group showed a much higher fusion rate, better functional outcome, and improved restoration of sagittal alignment compared to the uninstrumented group, (87% and 30%, respectively).

In 1994 Mardjetko et al. (18), in a meta-analysis of literature between 1970 and 1993, reviewed 25 papers on degenerative spondylolisthesis, which met the inclusion criteria. This study compared fusion rate and clinical outcome between five groups, which were decompression alone, decompression and uninstrumented fusion, decompression, and fusion with control instrumentation (Harrington hook-rod construct, Luque segmental fixation with sublaminar wires), and decompression and fusion with pedicle screws. They found a 69% satisfactory outcome in the nonfusion group compared to a 90% satisfactory outcome in the fusion group, which was statistically significant. The fusion rate in the instrumented group varied from 93% to 96% and was significantly higher compared to uninstrumented group (86%). The clinical outcome (satisfaction rate) between instrumented groups (86% to 90%) and uninstrumented group (90%) was not significantly different. They concluded that spinal fusion rate is enhanced by adjunctive spinal instrumentation, with no significant difference between control devices and pedicle screws. Possibly, this reflected early results of pedicle fixation, and also a difference in the number of segments fused, with control devices versus pedicle screws.

Yuan et al. (19) published an historical cohort study of 2,684 patients with degenerative spondylolisthesis with 81% of patients being treated by pedicle screw fixation. They observed a significantly higher and faster fusion rate (89.1% versus 70.4%) in the instrumentation group, and in addition, a better maintenance of spinal alignment. The pedicle screw fixation group also demonstrated a higher rate of neurologic and functional improvement compared to the uninstrumented control group. Rehtine et al. (20) reported a prospective study with instrumented fusion for degenerative spondylolisthesis, and compared the results with a literature-based control group of degenerated spondylolisthesis with uninstrumented *in situ* fusion. They concluded that fusion was more than three times more likely to occur with instrumentation compared to the uninstrumented *in situ* fusion group.

Although these studies indicated a higher fusion and better clinical outcome rate with instrumentation over uninstrumented fusion, there was no conclusive evidence, in absence of a prospective randomized controlled study. Finally, Fischgrund et al. (21) presented a randomized controlled study, comparing decompressive laminectomy

and fusion with or without spinal instrumentation using pedicle screw in 67 patients with single-level degenerative spondylolisthesis with stenosis. Clinical outcome was excellent to good in 82% of the uninstrumented group, and 76% of the instrumented group. The difference was not significant ( $p < .45$ ). Successful fusion was observed in 45% of the uninstrumented group, and 82% of the instrumented group, and the difference was significant ( $p < .0015$ ). Overall, successful fusion did not influence patient outcome ( $p < .435$ ). They concluded that instrumentation certainly improves fusion rate but not necessarily improves clinical outcome. The long-term implications of pseudarthrosis and adjacent segment disease in this patient population remain to be studied.

## COMPLICATIONS

The potential complications of decompression and pedicle instrumentation include wound infection, dural tear, and complications related to malplacement of pedicle screws. Recurrent stenosis and junctional stenosis need further discussion.

Adjacent segment stenosis has been reported to be around 42% in a long-term follow-up study of lumbar fusion by Lehmann et al. (22). Whitecloud et al. (23) reported a study of 14 patients with adjacent-level stenosis, treated with decompression and fusion. They found an 80% pseudoarthrosis rate with uninstrumented fusion compared to only 17% with instrumentation.

Patel et al. (24) reviewed 42 cases in our institute that required surgery for adjacent-level stenosis and found that the symptom of adjacent-segment stenosis developed more frequently and at an earlier period when the initial surgery involved instrumentation compared to the uninstrumented fusion. Of the 42 cases reviewed, 12 had an uninstrumented fusion at the initial operation; they developed adjacent segment stenosis at an average of 143 months, compared to 30 cases with primary instrumented fusion that developed symptoms at an average of 62 months. Adjacent segment stenosis was found to be more frequent in the proximal segment. Some 24 cases had a floating fusion; 20 developed stenosis at the proximal level; 3 developed stenosis at the distal level; and one case developed stenosis at both the adjacent levels. While all these cases had decompression at the second operation, 33 of the 42 cases required extension of fusion to the adjacent level. The authors suggested, in absence of instability and when no significant facet excision is necessary, stenosis above a previous fusion may be treated with decompression alone; otherwise, instrumentation is recommended.

Recurrent stenosis may also be produced by laminar regrowth. Postacchini and Cinotti (25) reported some degree of bone regrowth in 88% of cases treated with laminectomy or laminotomy with or without fusion in 40 patients. They reported symptomatic restenosis in as

much as 40% of cases with moderate or severe degree of bony regrowth.

## CONCLUSION

Although there is some consensus for indications for fusion in the surgical treatment of degenerative spondylolisthesis with stenosis, indications for additional instrumentation remain controversial. Generally, presence of significant movement in the listhetic segment indicates instrumentation. Any intention for correction of listhesis or kyphosis of the listhetic segment warrants either interbody fusion or extension of fusion down to the sacrum, with instrumentation. Recurrent stenosis of a previous laminectomy level or adjacent segment disease often indicates instrumented fusion. Instrumentation certainly improves the successful fusion rate but there is no conclusive evidence that it improves clinical outcome.

# Degenerative Lumbar Spinal Stenosis with Scoliosis-Kyphosis: Surgical Techniques, Results, and Complications

Hirokazu Ishihara and Hisao Matsui

---

Degenerative lumbar spinal stenosis with scoliosis is a relatively new concept of the disease. In 1976, Arnoldi et al. (1) defined the international classification of lumbar spinal stenosis and nerve root entrapment syndromes. In their classification, lumbar spinal stenosis was defined as the following: congenital stenosis (idiopathic, achondroplastic) and acquired stenosis (degenerative, combined, spondylolisthetic/spondylolytic, iatrogenic, post-traumatic, Paget disease, fluorosis). The concept of degenerative lumbar spinal stenosis with scoliosis had not yet been described. Due to the longer life span and greater expectations during this life span, the number of patients being treated for this condition is increasing. It is important to differentiate degenerative scoliosis from other degenerative spinal stenosis syndromes because the pathogenesis of nerve root or cauda equina compression and treatment considerations are quite different. Despite the number of studies that have focused on degenerative lumbar spinal stenosis with scoliosis, considerable confusion continues to persist as to the optimal method of the treatment. This study defines the pathogenesis as well as the appropriate surgical techniques for degenerative scoliosis based on the current literature and our surgical experience.

### **PATHOGENESIS OF CAUDA EQUINA AND NERVE ROOT COMPRESSION**

Lumbar spinal stenosis refers to any narrowing of the spinal canal, resulting in highly variable signs and symptoms. In addition to the central canal containing cauda equina, there are three potential zones that may affect the nerve roots: the lateral recess zone, the foraminal zone, and the extraforaminal zone (2). Central canal and lateral

recess stenosis may occur with any one or a combination of disc prolapse, facet degeneration and hypertrophy, ligamentum flavum hypertrophy or degenerative spondylolisthesis, and may cause cauda equina and nerve root compression. In addition to these changes, loss of lumbar lordosis, an increase of apical rotation, lateral vertebral slip, as well as foraminal stenosis as a result of disc collapse, pedicle approximation and facet joint subluxation (the superior articular process of the inferior vertebra subluxates anteriorly and superiorly, diminishing the area of the foramen) can occur with the progression of degenerative scoliosis (2). Hasegawa et al. (3), in a cadaveric study, showed that significant foraminal stenosis is commonly associated with a foraminal height of 15 mm or less and a posterior disc height of 4 mm or less. Nerve root entrapments can also be caused by pedicular kinking (the root is kinked and over stretched by downward pedicle migration on the concave side concomitant with disc collapse) (Fig. 59-1). Foraminal or extraforaminal disc herniation can occur at the compression site (concave site) of the curve (4) (Fig. 59-2). Thus, it is very common for the nerve roots in the foraminal or extraforaminal zone to be compressed in patients with degenerative scoliosis. Many authors have stated that nerve root compression is almost always seen on the concave side of the scoliosis (5–7), and L4 and L5 nerve roots are the most often involved (8). We have analyzed the relationship between nerve root compression and the pattern of the scoliotic curve in 22 consecutive degenerative scoliosis patients. L3 root was affected in 23% of patients; L4 root in 68%, L5 root in 55%, and S1 root in 18%. Of these, both L3 and L4 roots and both L5 and S1 roots were affected in 23% and 18% of patients, respectively. L3 and L4 roots were more compressed by foraminal or extraforaminal

**FIG. 59-1.** A 54-year-old man complained of right leg pain. Neurologic examination indicated that the symptomatic nerve roots were L3 and L4. Lumbar spine radiographs show a left lumbar scoliosis from L1 to L4 of 23° with the apex at L3. **A:** On myelography, there is no remarkable compressive factor for L3 and L4 roots. **B, C:** Right L3 and L4 radiculographies reveal the compression and elongation of the nerve roots due to pedicular kinking.

**FIG. 59-2.** A 76-year-old woman presented with right L4 radiculopathy. L4-L5 discography (**A, B**) and computed tomography after discography (**C**) disclose L4-L5 foraminal intervertebral disc herniation with leakage of the contrast medium to the right L4 root sheath.

stenosis on the concave side of the curve, while L5 and S1 roots were commonly affected by lateral recess stenosis on the convex side. The Cobb angle of the curve and the lateral slip of the apex or next to the apex vertebrae of the cases in which L3 or L4 root was affected by foraminal or extraforaminal stenosis were significantly larger than those of the cases in which L5 or S1 root was compressed by lateral recess stenosis (8a).

### DIAGNOSTIC STRATEGY

It is necessary to determine the symptomatic nerve roots and their compressive factors. The symptomatic nerve roots can be determined by the pain distribution, neurologic findings, and nerve root infiltration using lidocaine. In plain radiographs, the pattern of scoliosis, such as the upper and lower end vertebrae, the apex vertebrae, Cobb angle of the curve, and the rotation and lateral slip of vertebrae are determined. Intervertebral disc space narrowing, osteophyte formation, shortening of the pedicles with pedicular thickening, and facet joint arthrosis are also important findings (6). Segmental instability is assessed by lateral flexion-extension and anteroposterior lateral bending radiographs (dynamic radiographs). The generally accepted standard criteria for instability are more than 4 mm of translation and more than 10° of angularity when compared with the adjacent proximal or distal levels (9).

The central canal and lateral recess stenosis are relatively easy to diagnose by magnetic resonance imaging

(MRI) or myelograms, however, in foraminal or extraforaminal herniation, discography, computed tomography after discography (CTD), and nerve root infiltration are necessary in addition to MRI and myelography (Fig. 59-2). The use of CT allows detection of bony encroachment on the foramen. Although the shape of the foramen is not well seen on axial images, parasagittally reconstructed images, including bony and soft tissue windows, allow better definition of the presence of bony spurs arising from the posterolateral vertebral body or facet joint and extending into the foramen (2). The parasagittal and coronal images of MRI may allow visualization of the foramina along the length of the lumbar spine. The most suggestive finding is a paucity of perineural fat surrounding the nerve root on T1-weighted images (10) (Fig. 59-3). However, scoliosis sometimes makes it difficult to read these images correctly. Radiculography may show a filling defect or deformity of the nerve root sleeves (Fig. 59-1). However, sometimes it may be difficult to demonstrate the foraminal stenosis from the neuroradiologic point of view. Foraminal stenosis is sometimes concluded based on the negative findings (e.g., radiculography demonstrated pain recurrence and disappearance after nerve root infiltration by lidocaine), but no obvious root compression was found in the lateral recess zone or extraforaminal zone. It is also necessary to consider the double crush syndrome (e.g., the same nerve root is compressed at both the lateral recess zone and the foraminal zone).

**FIG. 59-3.** Coronal and parasagittal T1-weighted magnetic resonance images of a 70-year-old patient with left L4 radiculopathy due to L4-5 foraminal stenosis. Note the presence of fat signal around the right L4 root in a coronal image (A) or L2 and L3 nerve roots in a parasagittal image (B), but the absence of fat signal around the left L4 root (arrow).

## INDICATIONS FOR SURGERY

Conservative treatment must be tried. Pitchett et al. (8) stated that nonsteroidal antiinflammatory drugs reduced symptoms in 54% of patients. Bracing, bed rest, exercise, traction, and application of heat were effective in relieving pain in 46% of patients. Indications for surgery include progressive neurologic deficit or severe pain that is refractory to conservative treatments.

## DECOMPRESSION ALONE

In 1974, Epstein et al. (11) first reported the surgical treatment of nerve root compression caused by degenerative lumbar scoliosis. Four patients between the ages of 58 to 80 years were followed for 6 to 18 months. Laminectomy or hemilaminectomy was performed with unroofing of the lateral recesses and foramina by medial facetectomy or total facetectomy, and lasting relief of pain was achieved. The authors concluded that because of associated spondyloarthrosis, advanced disc degeneration, and spontaneous interbody fusion in this age group, the spinal column is stable and can tolerate facet removal.

San Martino et al. (12) also performed hemilaminectomy, with foraminotomy and medial facetectomy in 12 patients and laminectomy with bilateral decompression of multiple nerve roots including facetectomy in 8 patients. The patients were followed up for 4 years and in 16 patients the results were considered excellent with return of function and no restriction regarding occupational activities. No patient suffered a recurrence of major symptoms and no one required additional surgery.

On the contrary, Benner and Ehni (5) also performed laminectomy, hemilaminectomy, and foraminotomy in 14 patients between the ages of 50 to 85 years. The results were generally quite good and relief of radiculopathy was obtained. However, occasionally low back pain and sacroiliac pain persisted and four patients in this group developed progression of scoliosis. These patients underwent additional Harrington instrumentation and fusion. Katoh et al. (13) compared the results of decompression alone (fenestration, laminectomy, or hemilaminectomy) and decompression with posterior fusion using Harrington instrumentation in degenerative lumbar scoliosis. Three patients were treated with laminectomy alone and seven were treated with laminectomy and posterior fusion. The mean age at surgery was 65 years (range, 54 to 75), and the curve measured between 15° and 50°. At follow-up (mean of 4.2 years), overall satisfactory clinical results with pain relief and improved walking distance were noted in the patients treated with laminectomy and posterior fusion. However, all patients treated with decompression alone needed reoperation because of recurrence of leg symptoms due to the progression of scoliosis.

Recently, many papers have stated that with decompression alone, without any form of stabilization as the treat-

ment of degenerative scoliosis, additional problems usually occur as does the progression of deformity. Such treatment does not yield a long-term satisfactory result (14).

## INDICATIONS FOR SPINAL FUSION

The selection criteria for which patients with degenerative scoliosis should be fused are not clear and are somewhat controversial. The average age of the patients is relatively high and a number of patients have some complications such as hypertension, diabetes mellitus, or heart problems. Thus, most surgeons prefer to avoid an operative procedure that causes prolonged and excessive bleeding.

Postacchini (15) stated that in a few older adult patients who present little or no back pain with mild scoliosis, there can be an indication for decompression alone; however, in patients who present with severe scoliosis and low back pain, there is an indication for wide decompression and spinal fusion using pedicle screw instrumentation. Because back pain is related to a loss of lumbar lordosis and trunk unbalance in severe degenerative scoliosis, a primary aim of the surgery is the correction of the curve and restoration of body balance. Hansraj et al. (16) stated that the spinal fusion and instrumentation is needed for degenerative scoliosis with a curve of greater than 20°. Gelalis and Kang (9) stated that each patient must be treated on an individual basis depending on the age of the patient, whether there has been documentation of progression of the scoliosis curve, the amount of low back pain versus the amount of radicular symptoms, and finally the experience of the spine surgeon. If the patient predominantly has stenosis symptoms with a minimal degree of scoliosis (less than 25° to 30°), in most instances a simple laminectomy along with foraminotomy without fusion is all that is necessary and a good outcome is achieved. If a patient has a more pronounced deformity (greater than 30°), with any degree of lateral translational listhesis, a fusion should be performed at the time of decompression. This becomes especially true if the main reason for the surgical treatment was to treat the spinal stenosis symptoms (17). The surgeons nevertheless must keep in mind the potential for destabilization of the spine during the decompression procedure, particularly if excessive amounts of facet joints are resected. However, it is difficult to predict which patients with subtle degenerative scoliosis will develop progression of the deformity after decompression surgery (9).

## EXPANSIVE LAMINOPLASTY WITH POSTERIOR SPINAL FUSION

Tsuiji et al. (18,19) have developed lumbar expansive laminoplasty. This technique provides reinforcement of the stability of the lumbar spine as well as decompression

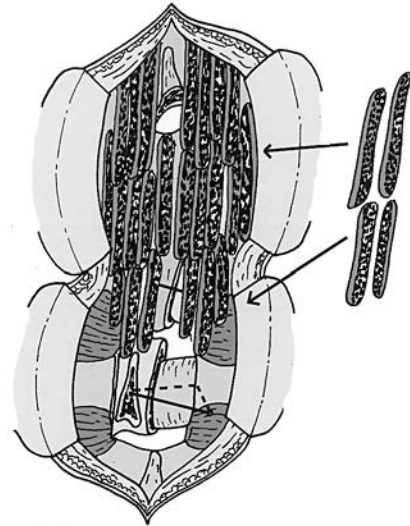

of the nerve roots by expanding the cross-sectional area of the spinal canal. The merits of this method are that it is minimally invasive, applicable for older patients who have other comorbid medical problems, and the use of instrumentation can be avoided. However, the method is limited to some extent in the decompression of the hinged side; thus, indications are limited. It is impossible to correct the deformity by this method. We have applied this procedure to treat lumbar spinal stenosis with scoliosis.

The spinous process is removed from its origin and used as a bone graft. The lamina is cut wider as the outer edge of the groove reaches the lateral one-third or one-half of the facets. The groove at the hinged side is outlined as a cone in the horizontal plane. Small holes are made in each lamina and in the articular processes on the open side using an awl, pusher, and perforator. The laminae are then detached completely at the open side in order to obtain sufficient rotation of the laminae. The lateral recess of the spinal canal is trimmed, and the remaining ligamentum flavum is removed completely. The medial facetectomy or partial pediclectomy are added in case of necessity. The bone grafts from the spinous processes are fitted into the gap of the open side and held in place by No.1 nylon threads. At least a 45° rotation angle of the lamina is necessary. The cross-sectional shape of the canal is altered from triangular to square. All of the open epidural space between the laminae is shielded by free fat grafting. The

**FIG. 59-4.** Lumbar expansive laminoplasty. Small holes are made in each lamina and the articular processes on the open side using an awl, pusher, and perforator. The bone grafts from the spinous processes are fitted into the gaps of the open side and held in place by nylon threads.

**FIG. 59-5.** In performing a posterior spinal fusion, the joint capsules are completely removed, and the laminae and the articular processes are decorticated bilaterally, including adjacent intact laminae, using a high-speed air drill. Corticocancellous bone sticks from the posterior ilium are carefully grafted.

joint capsules are completely removed, and the lamina and the articular processes are decorticated bilaterally, including adjacent intact laminae, using a high-speed air drill. Corticocancellous bone sticks from the posterior ilium are carefully grafted (Figs. 59-4, 59-5).

Matsui et al. (20) reviewed the clinical and radiologic results of 27 patients who underwent expansive laminoplasty with a mean follow-up of 5.6 years. There was marked recovery of clinical symptoms, and nearly 80% of patients obtained good or excellent results. Only one patient (4%) required additional surgery, which involved discectomy at the caudal level of the laminoplasty. Radiographic evaluation revealed that postoperative changes of scoliosis were slight both in the expanded area and at the L1-L5 levels (Fig. 59-6).

#### **DECOMPRESSION AND POSTEROLATERAL FUSION (PLF) OR POSTERIOR LUMBAR INTERBODY FUSION (PLIF) WITH PEDICLE SCREW INSTRUMENTATION**

Pedicle screw instrumentation is the best method to fuse and correct the deformity, because it has the best biomechanical advantage, acting through the three columns of the spine and also providing the best fixation in the bony substrate (14). Aebi (21) described the techniques of degenerative scoliosis correction using the Arbeitsgemeinschaft für Osteosynthesefragen (AO) internal spinal fixator system. The pedicle screws are inserted into the pedicles of both neutral vertebrae and the apex vertebra. The pedicles of the intermediate vertebrae are then supplemented by additional screws. Next, complete

**FIG. 59-6.** A 76-year-old woman complained of left leg pain and low back pain. Neurologic examination and root block revealed that her symptomatic nerve root was right L4. **A:** Lumbar spine radiographs show a right lumbar scoliosis from L2 to L4 of 24° with the apex at L3. There is a 10 mm lateral slip of L3 on L4 vertebra on the preoperative anteroposterior view. **B:** L3-5 laminoplasty with L4-5 medial facetectomy, L4 partial pediclectomy and posterior spinal fusion was performed. A 2-year follow-up anteroposterior radiograph indicates that the posterior fusion is accomplished. Postoperative computed tomography (CT) (**D**) shows that the spinal canal is enlarged into a rectangular shape, comparing with preoperative CT (**C**).

posterior soft tissue release over the involved spine is achieved to mobilize the curve. The distracter is then mounted on the concave side of the curve with attachment being made to the end vertebrae screws. Gentle distraction is performed with this device as the pedicle screws in the apex vertebra and the screws in the remaining intermediate vertebrae are used to mobilize the deformity manually, segment by segment, through repeated rotatory movements toward the midline. A long threaded rod is inserted on the pedicle screws on the convex side of the curve and fixed by a clamp. The apex vertebra is derotated as far as possible by this mechanism. The sagittal plane deformity, irrespective of the coronal plane curve, can then be corrected by pushing forward or pulling back on the pedicle screw.

The author pointed out sagittal curve correction and restoration of body balance are the most important factors influencing the incidence of low-back pain. The persistence of a flat back after surgery clearly correlates with continuous lumbar pain. Furthermore, the convexity of the curve can be reduced by compressing the pedicle screws of the neutral end vertebrae along the threaded rod toward the apex vertebrae. The screws in the intermediate vertebrae are tightened against the rod. The femoral distracter is removed and a second threaded rod with hinged clamps is inserted into the screws on the concave side. The screws in the remaining vertebrae are tightened in the same manner as on the convex side. A bilateral PLF using iliac crest autograft bone is then performed in a routine fashion. Nerve root exploration and decompres-

sion is performed after the spine is completely instrumented.

Aebi (21) has performed this operation for 8 patients who ranged in age from 44 to 74 years. The postoperative follow-up time was 1 to 3 years. The curves ranged from 22° to 48°. Seven of these eight patients subjectively rated the overall outcomes of their surgery as good or excellent and believed that surgery significantly improved the quality of their daily life. One patient was dissatisfied with the results and had expected greater relief from pain. The overall correction of curves was greater than 50%. There was no infection, no evidence of pseudoarthrosis, and no instrumentation-related complications.

Marchesi (22) reviewed the result of segmental pedicle screw instrumentation in degenerative lumbar scoliosis. The AO internal fixator was used for 9 patients and the Cotrel-Dubouset (CD) instrumentation was used for 18 cases. Mean age at surgery was 60 years (range, 40 to 88), and the curve measured between 22° and 82°. At follow-up (mean of 56 months for the AO Internal Fixator and 42 months for CD instrumentation), the average curve correction was better than 50%. Overall, satisfactory clinical results with pain relief and improved walking distance were noted in 86% of the patients. Using this technique, no postoperative deaths or neurologic deficits occurred. Only a few complications and a 4% pseudoarthrosis rate could be observed.

Liew and Simmons (7,14) described the two general techniques for correction of degenerative scoliosis. One is a technique used for patients with short degenerative collapsing curves with reasonably well-maintained lumbar lordosis or minimal loss of lordosis. This involves some distraction on the concave side with the rod carefully contoured to maintain lordosis and a neutralization rod on the convex side (Fig. 59-7). The other technique is a rod derotation maneuver as used for patients with idiopathic curves. This technique is useful for patients with longer degenerative curves and for patients with more significant loss of lumbar lordosis. In these patients, the derotation maneuver will convert the scoliotic curve in the coronal plane into a lordotic curve in the sagittal plane. The overriding principle for both of these techniques is to end up with a spine that is balanced above the sacrum with the areas that have been decompressed well stabilized within the instrumented segments. Another important principle is to avoid ending the instrumentation at an area of junctional kyphosis or at a level of a spondylolisthesis.

Simmons and Simmons have performed this operation for 40 patients with degenerative scoliosis. The average follow-up was 44 months. Satisfactory outcome was noted in 93%. The mean correction of the curve was 19°. No instrument-related failure or pseudoarthrosis occurred (23).

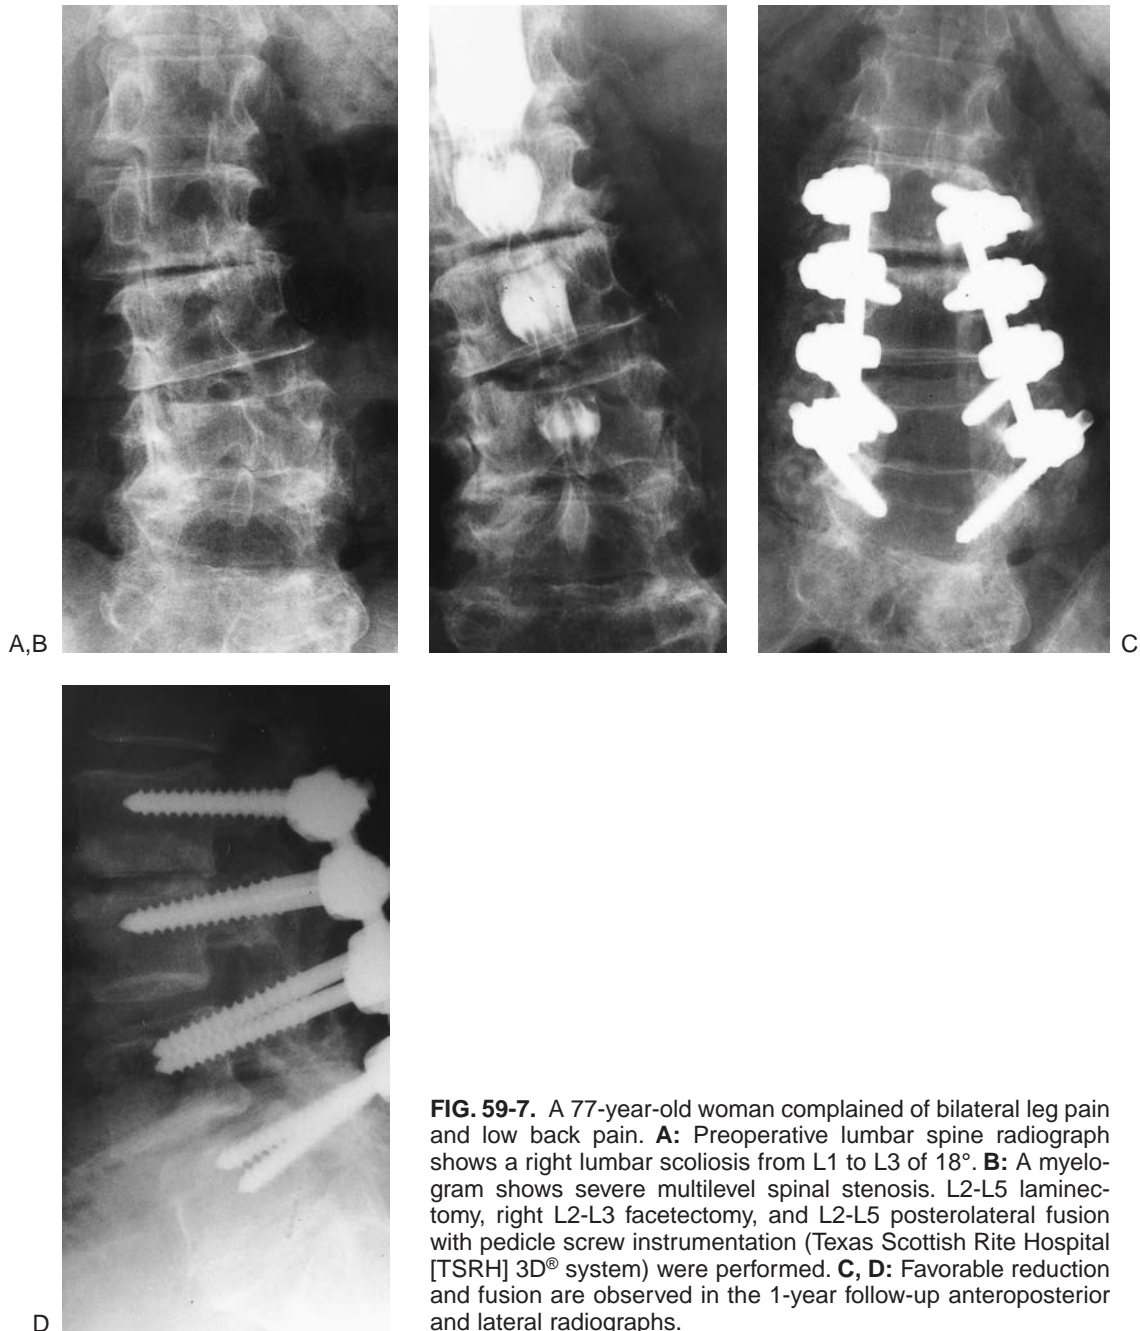

Zurbriggen et al. (24) also reported a surgically treated series of 40 patients with degenerative scoliosis. The surgical techniques applied consisted of decompression of neural elements by laminectomy and partial scoliosis correction with CD instrumentation and PLF with autologous bone graft. The series included 18 males and 22 females with a mean age of 62.8 years. Final evaluation was possible in 30 patients at a mean period of observation of 59.5 months. Following a very precise diagnostic and therapeutic protocol, excellent, good, and satisfactory results were obtained in 13 (43.3%), 16 (53.3%), and 1 (3.3%) patients, respectively. While scoliosis was converted from a mean preoperative Cobb angle of 18.7° to 7.6°, mean preoperative lumbar lordosis was slightly augmented from 37° to 41.5°. The results suggested that maintenance or correction of lumbar lordosis is more important than the correction of the scoliosis.

Oguma et al. (25) stated that PLIF using threaded titanium interbody fusion cage with pedicle screw instrumentation was better to correct and maintain lumbar lordosis. They compared the results of PLF with pedicle screw instrumentation (15 cases) and PLIF using threaded titanium fusion cage with pedicle screw instrumentation (35 cases) in degenerative scoliosis. The average follow-up period was 44 months, and successful fusion was observed in all cases. There was no significant difference about the correction and correction loss of scoliosis between PLF and PLIF cases. However, the mean correction loss of lumbar lordosis was 13.2° in PLF cases and 1.9° in PLIF cases.

The complications of these instrumentation surgeries include blood loss, infection, nerve root or cauda equina injury, and the pseudoarthrosis with or without instrumentation failure. The risk of adjacent segment degeneration is also higher when lengthy fusion with rigid instrumentation is performed. In a review of 125 patients, Etebar and Cahill (26) noted a 14% incidence of symptomatic adjacent-segment degeneration after lumbar fusion with pedicle screw instrumentation. A 78% incidence of adjacent segment degeneration occurred after fusion encompassing three or more segments.

## CONCLUSION

The appropriate surgical techniques for degenerative scoliosis remain one of the most controversial topics in spine surgery. It is important to determine the symptomatic nerve roots and their compressive factors. The nerve roots in the foraminal or extraforaminal zone are compressed frequently by pedicular kinking, foraminal stenosis because of disc collapse, pedicle approximation and facet joint subluxation, or foraminal and extraforaminal disc herniation. The decompression alone without some form of stabilization usually will have additional problems and progression of the deformity and will not yield a long-term satisfactory

**FIG. 59-7.** A 77-year-old woman complained of bilateral leg pain and low back pain. **A:** Preoperative lumbar spine radiograph shows a right lumbar scoliosis from L1 to L3 of 18°. **B:** A myelogram shows severe multilevel spinal stenosis. L2-L5 laminectomy, right L2-L3 facetectomy, and L2-L5 posterolateral fusion with pedicle screw instrumentation (Texas Scottish Rite Hospital [TSRH] 3D® system) were performed. **C, D:** Favorable reduction and fusion are observed in the 1-year follow-up anteroposterior and lateral radiographs.

result. Expansive laminoplasty with posterior spinal fusion or decompression and PLF or PLIF with pedicle screw instrumentation will result in a successful outcome.

## CHAPTER 60

# Nondegenerative Spondylolisthesis: Epidemiology and Natural History, Classification, History and Physical Examination, and Nonoperative Treatment of Adults

James Rainville

---

Spondylolisthesis is defined as a displacement of a vertebral body on the one below it. The term is derived from the Greek *spondylos* (vertebra) and *olisthesis* (a slippage or falling). The term was first used by Kilian in 1854 (1), though this spinal deformity was first described by Herbinaux in 1782 (2). Both descriptions were in obstetric literature as cases of severe anterior displacement of the fifth lumbar vertebra on the sacrum that were noted to compromise the pelvic inlet during labor and delivery.

The most common direction of spondylolisthesis, and the alignment abnormality that will be implied when the term is used in this chapter, is a forward or anterior displacement of the superior vertebral body, sometimes referred to as anterolisthesis. Posterior vertebral displacement termed *retrolisthesis*, and lateral displacement termed *laterolisthesis* are also commonly observed abnormalities of vertebral alignment.

The intact neural arches of the lumbar vertebrae add stability to the spinal motion segments, in part through the function of the inferior and superior articular processes of the facet joints. In the lumbar region, anterior displacement of the superior vertebra of each motion segment is resisted through overlapping of its inferior articular processes with the superior articular processes of the vertebra below (3). In 1855, Robert zu Koblenz first recognized that the presence of spondylolisthesis indicated failure of this essential function (4). When spondylolisthesis is noted, a systemic evaluation of the posterior aspect of the vertebra is required to determine the cause of that failure.

### CLASSIFICATION OF SPONDYLOLISTHESIS

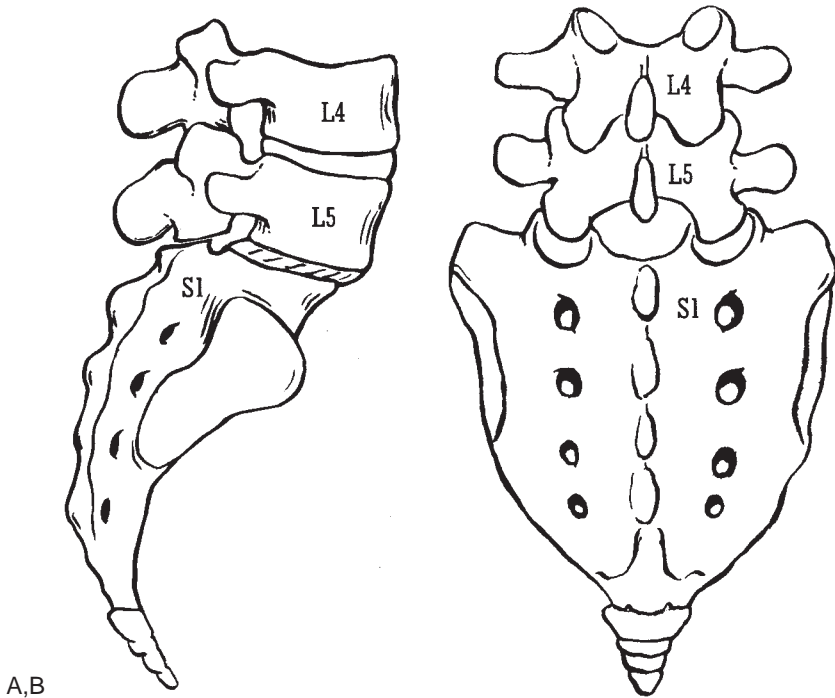

The causes of spondylolisthesis can be categorized into distinct categories. Classification of spondylolisthesis into five categories was derived from the collaborative work of Wiltse, Newman, and MacNab (5), and expanded into six by Wiltse and Rothman (6). The classification is based on anatomic characteristics of the neural arch for the first two types, and on acquired pathologic conditions for the last four types. Following presentation of this classification, this chapter will focus mainly on issues relevant to congenital and isthmic spondylolisthesis.

#### Type I: Congenital or Dysplastic Spondylolisthesis

Congenital abnormalities of the lumbosacral junction can permit slippage of L5 on the sacrum. These are divided into three subtypes.

##### *Subtype IA*

Here the articular processes of the facet joints are poorly developed and have a horizontal (axial) orientation, making them ineffective at preventing forward displacement of the lumbar vertebra above (Fig. 60-1) (5). It is often accompanied by spina bifida of L5 and S1. Although the pars may remain unchanged in this type, critical narrowing of the spinal canal could potentially occur if slip exceeds 25% as the posterior neural arch moves forward. However,

**FIG. 60-1.** Type IA congenital spondylolisthesis where the facet joints have a horizontal (axial) orientation, making them ineffective at preventing forward displacement of the lumbar vertebra above.

usually the pars articularis is also hypoplastic and often it either elongates or comes apart, thus preventing critical canal narrowing (6). When abnormalities of the pars interarticularis are combined with this congenital subtype, it is difficult to distinguish this type from the isthmic spondylolisthesis listed below (5).

**Subtype IB**

In this type the articular processes have a sagittal malorientation but the neural arch is usually intact (Fig. 60-2). The intact neural arch usually prevents high degrees of forward slippage in this type (6).

**FIG. 60-2.** Type IB congenital spondylolisthesis caused by the articular processes having a sagittal malorientation.

**Subtype IC**

This group includes all other congenital malformation of the lumbosacral junction, including congenital kyphosis due to congenital failure of vertebral body formation (6).

**Type II: Isthmic Spondylolisthesis**

In this type of spondylolisthesis, the location of structural failure is the pars interarticularis—the isthmus or bridge of bone between the superior and inferior articular processes of the neural arch. Two subtypes are recognized.

**Subtype IIA**

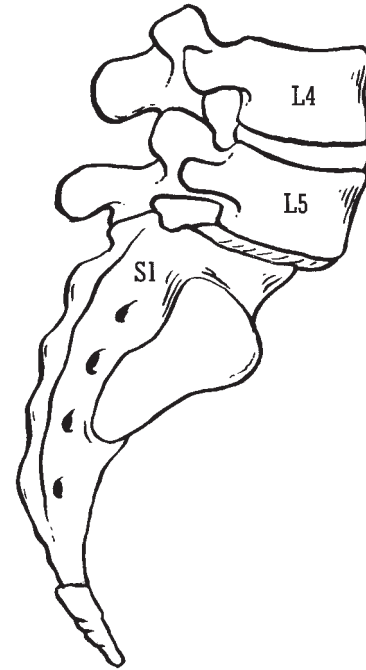

By far, the most common abnormality of the pars interarticularis is a bony defect that completely disrupts its integrity, termed *spondylolysis* [Greek: *spondylos* (vertebra) and *lysis* (loosening)] (Fig. 60-3). Spondylolysis can occur bilaterally or unilaterally. When bilateral spondylolysis is present, the inferior articular processes and the lamina are structurally dissociated from the remainder of the vertebra. This compromises the ability of the facet joints to control vertebral movement and alignment at that segment, thus allowing spondylolisthesis to occur (5).

**Subtype IIB**

Spondylolisthesis can also result from elongation of the pars interarticularis without separation (Fig. 60-4).

**FIG. 60-3.** Type IIA isthmic spondylolisthesis caused by bony defects of the pars interarticularis.

**FIG. 60-4.** Type IIB isthmic spondylolisthesis caused by elongation of the pars interarticularis.

The elongation is thought to develop from repeated fracturing and healing of the pars that occurs as the vertebral body slides forward (6).

**Type III: Degenerative Spondylolisthesis**

Long-standing degeneration of the lumbar motion segment can lead to failure of the ability of the facet joints to maintain normal sagittal vertebral alignment. This is discussed in Chapters 54 through 58.

**Type IV: Traumatic Spondylolisthesis**

This condition results from severe trauma, with acute fractures often involving multiple parts of the pedicles and neural arch. The resulting structural incompetence allows forward slippage to develop over a period of weeks or longer (6).

**Type V: Pathologic Spondylolisthesis**

In the presence of local or generalized bony disease, abnormalities can develop in the pedicles and neural arch leading to their failure to resist the forward thrust of the upright spine, resulting in spondylolisthesis (6). Basu et al. presented two cases of spondylolisthesis in patients with osteogenesis imperfecta caused by pathologic elongation of the pedicles (7).

### **Type VI: Postsurgical Spondylolisthesis**

During spinal surgery performed to decompress compromised neural elements, large amounts of the posterior supporting structures including the facet joints can be removed in order to obtain adequate decompression. In approximately 4% of cases, this can lead to incompetence of the neural arch and facet joints (and in some cases stress fractures of the weakened inferior articular process) and resulting spondylolisthesis (6,8).

### **EPIDEMIOLOGY AND NATURAL HISTORY OF SPONDYLOLYSIS**

Spondylolysis is an acquired condition, as it has never been documented in fetal dissections or at birth (9–12). Spondylolysis can occur soon after birth however and has been reported in infants less than 1 year of age (13,14). The majority of cases of spondylolysis are thought to occur in young children. Radiographic screenings of children entering first grade (ages 5 to 7) have identified defects in 4.4 % of that population (13,15). By 18 years of age, 6% of that same population was observed to have spondylolysis, suggesting that an additional 1% to 2% of people developed spondylolysis during later childhood and adolescents (13). Few additional cases are thought to occur throughout adult life, and the prevalence of 6% has been documented in radiographic screening of large numbers of adult spines (16). Spondylolysis is almost twice as common in males than females (7.7% versus 4.6%), (13,17), and is more frequently seen in white than black populations (12).

Higher prevalence of spondylolysis has been reported in some populations. Clinical studies of Alaskan Eskimo and archeologic studies of some Eskimo and Native American skeletons have noted a rate of spondylolysis of ranging from 17% to 53% (18–20). Children and adolescents aggressively participating in certain activities such as gymnastics (21–23), throwing sports (23), football (24), wrestling (25), dance (21), and swimming breast and butterfly strokes (26) are suspected to have a higher incidence of acute spondylolysis caused by the mechanical stresses of those sports on the pars interarticularis.

Spondylolysis occurs most frequently at the L5 vertebra, where about 90% of the cases are found, and then with decreasing frequency at higher lumbar levels (13,17,27).

Numerous factors have been implicated in the etiology of spondylolysis. Wiltse suggested that the basic lesion was a stress fracture of the pars interarticularis (28). His theory postulates that significant forces were transmitted through the pars interarticularis during vigorous activities and that either from repeated minor trauma, or occasionally after a single traumatic incident, a stress fracture develops. When this stress fracture fails to unite, spondylolysis results. Wiltse's theory implies that the pars inter-

articularis of some individuals is structurally susceptible to fracture under physiologic stresses that are common to active children and adolescents.

This theory has received some support by histologic studies of the lumbar vertebrae of human fetuses performed by Sagi et al. (29). They noted that after 12 to 13 weeks of gestation, ossific nuclei of the neural arch for the lower lumbar vertebrae were present in the region of the pars interarticularis and resulted in uneven distribution of trabeculation and cortication in these regions. This results in the development of a potential area of weakness, or a stress riser, that would be susceptible to failure under repeated stress or micro trauma. Of interest, in the upper lumbar spine, where spondylolysis is infrequently observed, the ossific nuclei were noted to be at the base of the pedicles and more uniform trabeculation of the pars was observed (29).

It seems likely that the upright posture and resulting lumbar lordosis are required to deliver sufficient stress to the pars interarticularis in order to induce spondylolysis. This is supported by the lack of spondylolysis in the lumbar spines of neurologically impaired individuals who have never walked (30), and the absence of neural arch defects in any species other than humans, the only species with lordosis in the lumbar spine (14).

A genetic predisposition to spondylolysis has long been suspected. Relatives of index cases of spondylolysis have been observed to have a greater incidence of this finding that ranges from 19% to 69% (5,13,31–33). Perhaps it is some morphologic feature of the pars interarticularis that is genetically transmitted which results in a predisposition to the formation of the pars defect (28,31,33).

### **EPIDEMIOLOGY AND PROGRESSION OF SPONDYLOLISTHESIS**

Radiographic evidence of spondylolisthesis is present in many children and adolescents at the time of diagnosis of spondylolysis. Fredrickson et al. noted spondylolisthesis in 68% of children with spondylolysis detected by radiographic screening at entry to first grade (13). For those who developed spondylolysis after first grade, Fredrickson et al. only noted spondylolisthesis in 35%. Higher prevalence of spondylolisthesis may occur in patients with spondylolysis who present for medical care. Wiltse et al. suggested that spondylolisthesis developed in about 50% of older children and adolescents who presented with symptoms of back pain suggestive of acute spondylolysis (28). Studies headed by both Danielson and Frennered noted spondylolisthesis in over 80% of children who were evaluated in a hospital clinic for spondylolysis (34,35). In contrast to these studies, Ishida et al. observed a much lower rate of spondylolisthesis of 40% in a review of 325 radiographs of patients with spondylolysis (36).

**FIG. 60-5.** The percent of slippage of spondylolisthesis is calculated by measuring the distance between the posterior borders of L5 and S1 at the level of the superior end plate of S1. This measurement is divided by the sagittal length of the inferior end plate of L5 and expressed as a percentage.

The degree of spondylolisthesis can be described in several ways. The slippage can be quantified by measuring the distance between the posterior borders of L5 and S1 at the level of the superior end plate of S1. This measurement is divided by the sagittal length of the inferior end plate of L5 and expressed as a percentage (Fig. 60-5) (34). At least 5% slippage must be present to confer a diagnosis of spondylolisthesis (36). In clinical practice, slippage is more commonly categorized into five grades:

**FIG. 60-6.** Meyerding classification of spondylolisthesis into grades is based on the amount of slippage of the superior vertebral body on the vertebrae below.

grade I indicates slippage from 5% to 25%; grade II, 26% to 50%; grade III, 51% to 75%; and grade IV over 75% (Fig. 60-6) (37). Grade V, termed *spondyloptosis*, refers to complete dislocation of L5 on S1.

The vast majority of cases of spondylolisthesis (60% to 75%) are classified as grade I, with 20% to 38% classified as grade II, and less than 2% of all cases grade III, IV, or V (17,36,38,39).

### Progression of Slippage

Following diagnosis, substantial concern about possible progression of spondylolisthesis is common. Fortunately, progression of slippage has received considerable study.

Evidence suggests that most progression of spondylolisthesis occurs in the immature skeleton. In a follow-up study of spondylolysis in children and adolescents that did not heal with conservative treatment, Sairyo et al. observed progression of slippage in 80% of children in the cartilaginous stage of skeletal development, and in 17% during the apophyseal stage of development. After skeletal maturity, no progression was noted (40). These findings that connect slip progression with skeletal maturity help explain the observation of others who have noted that most progression occurs during childhood and the early teenage years (13,41), and only minor progression occurs after skeletal maturity (42,43).

Prognostic factors are lacking to predict progression of spondylolisthesis (34,35). In a study of slip progression of 311 young patients (less than age 30) with mean observation time of 3.8 years, no radiographic or demographic predictor of progression could be found (34). When observed, only rarely was the slip progression greater than 20%. High initial slip correlated with a combination of high slip angle, convexity of the upper end plate of S1, low lumbar index and disc height reduction, but these factors did not predict further slippage. Instead these factors are suspected to be the consequences of high-degree spondylolisthesis (34). Participation in competitive sports does not influence progression of spondylolisthesis (44).

Several recent studies have noted an anatomic finding that may influence spondylolisthesis. It has been observed that spondylolisthesis was rare in cases of spondylolysis in which there was an increased vertical thickness of the L5 transverse process (45,46). They found that this increased thickness of the transverse process was associated with increased size of the posterior band of the iliolumbar ligament, and postulated that this increased stability of the L5 vertebra, thus preventing anterior displacement (45). The same findings were noted to predict adjacent disc degeneration in older subjects with spondylolysis. Those with slender L5 transverse processes were found to have advanced degeneration at L5-S1, and those with thicker transverse processes had little degeneration at L5-S1 but advanced degeneration at L4-5 (36).

Progression of spondylolisthesis in adults has been noted in several studies. Spondylolisthesis may develop or progress with advancing age, though the amount of slippage is generally small (36,46). Fredrickson et al. noted a slip progression of 2%, 5%, and 1% during the third, fourth, and fifth decades, respectively (42). Floman reported on a series of 18 spondylolytic patients presenting with back pain. He demonstrated progression of a mean of 15% in vertebral slippage over an average of 7 years (47). In adults, disc degeneration at the level of the defect occurs with greater frequency in individuals with spondylolysis and spondylolisthesis (48,49), and when it occurs is associated with slip progression (39,42,47). Neither the degree of disc degeneration nor the amount of spondylolisthesis is associated with the prevalence of back pain (39) and no study has linked progression of slip with pain symptoms.

### Symptoms and Disability

It is apparent that the development of spondylolysis in toddlers and young children produces only minor symptoms, if any symptoms at all, for complaints of back pain are not acknowledged by the adults responsible for their care. Because of this, the development of spondylolysis is rarely detected in this age group (13,14,28).

For older children and adolescents, back pain occurring with the development of spondylolysis is a more common complaint, especially in those with acute stress reactions or acute stress fractures of the pars interarticularis. The intensity of pain can range from mild to severe (35), therefore, this diagnosis must be considered in all children and adolescents presenting with back pain, especially those participating in aggressive physical activities (28,35,50,51). Sciatica has been reported in a small percentage of adolescents with spondylolysis but neurologic deficits are rare (13,35,42).

In adults, an association between spondylolysis and spondylolisthesis with pain symptoms has been hard to establish (17). The soft tissue at the site of spondylolysis contains sensory nerve fibers and neuropeptides with potential to generate pain (52,53). Several epidemiologic studies (13,17,39,42), along with case series (38,47,49, 54–56) of subjects with spondylolysis and spondylolisthesis, confirm that some have back pain complaints. Saraste observed that low back pain symptoms were more frequently reported in the subpopulation of young adults with spondylolisthesis of greater than 25% (grade 2 or higher), with a high slip angle, with spondylolysis at the L4 level, or with early disc degeneration (48). In contrast, no relationship was noted between the grade of slippage and back pain in older adults (39). Abnormal motion or instability at the spondylolytic level has not been demonstrated to occur in adults with back pain (57,58). Clearly, most people with spondylolysis and spondylolisthesis are asymptomatic, and the incidence of back pain in adults

**FIG. 60-7.** Neuroforaminal stenosis caused by disc material entrapping the L3 nerve root under the pedicle above.

with these problems is similar to that in the population in general (13,17,31,33,39,56,59,60).

Some patients with spondylolisthesis develop progressive neuroforaminal encroachment, most commonly by disc material pushing upward toward the root from below and trapping it under the pedicle above, that can ultimately cause nerve root entrapment with resultant signs and symptoms (Fig. 60-7) (61–63). The most commonly involved roots are L5. The rate of occurrence of lumbar radiculopathies in spondylolisthesis is not reported, but is most likely quite low, but certainly not rare.

For women, spondylolysis and spondylolisthesis were not found to be risk factors for pregnancy complications, nor was pregnancy associated with slip progression or increased low back pain symptoms (64).

Disability because of back pain is not more prevalent in adults with spondylolysis and spondylolisthesis than in the general public (38,39,60). In studies of young athletes with spondylolysis and spondylolisthesis, frequent problems related to pain or disability were not observed, even in those participating in contact sports (44,65).

Regardless of the low frequency of symptoms with spondylolysis and spondylolisthesis, some patients do present with back pain or sciatica attributable to these structural problems. When patients do develop symptoms, spondylolysis and spondylolisthesis may be considered within the context of the patient's complex spinal situation, and viewed as concurrent factors but not necessarily the cause of symptoms.

### PHYSICAL EXAMINATION

The physical examination in spondylolysis and spondylolisthesis has few specific or sensitive findings.

Detection of spondylolisthesis on physical examination is difficult except in the rare cases of grade III or greater slips. Here a “step off” of the spinous processes can be seen or palpated at the level of the spondylolisthesis. In grade I and II spondylolisthesis, the “step off” is much more difficult to detect, and not a reliable finding in our experiences. Painful trunk range of motion is often noted with children and adolescents with symptoms from acute spondylolysis. This is especially noted for trunk extension, as this motion shifts load to the facet joints and neural arch and thus through the region of the pars (66). Limitation of range of motion for trunk extension has been observed (38,67), and palpation of the back may reveal local tenderness at the lumbosacral junction (38). Unfortunately, these findings are common to other spinal disorders, and are not specific for spondylolysis.

Neurologic deficits and positive straight leg-raising tests are rarely found in cases of spondylolisthesis, including cases with sciatica (38). When neurologic deficits are noted, they usually involve the L5 roots that can become irritated within their neuroforamina (38,61,62).

### **CONSERVATIVE TREATMENT OF ADULTS WITH SPONDYLOLYSIS AND SPONDYLOLISTHESIS**

Spondylolysis and spondylolisthesis are often first detected in adults when they present for evaluation and treatment of back or leg pain complaints. When discovered, these findings must be considered within the context of the complete clinical picture, and only with caution should the patient's symptoms be attributed to these bony abnormalities.

In general, evaluation and treatment of acute back pain in adults with spondylolysis and spondylolisthesis should follow recommendation for nonspecific low back pain, including avoidance of bed rest and rapid return to activities (68–71). No studies have addressed the use of commonly prescribed medication, modalities, and manual therapies for treatment of symptoms in this population. Some researchers have advocated extension bracing for adults with back pain including those with spondylolisthesis (72), but convincing evidence of efficacy is lacking.

#### **Exercise**

Exercise is commonly prescribed for the treatment of back pain. Several studies have evaluated exercise as a treatment for back pain with associated spondylolysis and spondylolisthesis.

Möller and Hedlund randomized a population of 111 adults with isthmic spondylolisthesis to one of three groups: an exercise program, posterolateral fusion, or posterolateral fusion with transpedicular fixation (38).

The exercise group underwent a program consisting of eight simple exercises that did not require equipment and four exercises that required a pulley and leg press machine. Exercises focusing on strengthening both the back and abdominal muscles and postural training were performed 3 times per week for 6 months, and then twice a week for the next 6 months under the guidance of a physical therapist. At 1- and 2-year follow-up, the exercise group demonstrated a small reduction in pain, and no change in disability. Both function and pain were significantly better in the two surgical groups. Return to work rates were similar for both groups at 2 years (54% versus 55%).

Another study compared flexion versus extension exercises in 48 adults with spondylolisthesis (73). The study reports randomly assigning patients to different physicians who prescribed (or perhaps preferred) either flexion or extension exercises. Flexion exercises consisted of pelvic tilts and the seated chest to thigh maneuvers, and extension exercises consisted of upper trunk extension and hip extension performed in the prone position. The study does not report on the type of instruction, the frequency and duration of the exercises, exercise compliance, or the methods used for conducting follow-up. Short- and long-term results strongly favored the flexion exercise group. Unfortunately, methodologic shortcomings make the findings interesting but in need of further study before full endorsement of flexion exercises can be given.

O'Sullivan et al. studied stabilization exercises in a group of patients with chronic back pain and spondylolysis or spondylolisthesis (74). They randomized 44 patients to a specific stabilization exercise treatment or uncontrolled care directed by their treating practitioner. The stabilization exercise group underwent 10 weekly sessions of physical therapy aimed at training the specific contraction of the deep abdominal muscles, namely the internal oblique and the transverse abdominus with coactivation of the lumbar multifidus muscles, presumably selectively proximal to the pars defect. After accurate patterns of co-contractions were achieved, these were incorporated into daily activities. The control group received variable exercises and passive treatment. Their results showed that the stabilization exercise group experienced significant reduction in pain intensity and disability scores compared to the control group. These results were maintained at 30-month follow-up.

Rainville and Mazzaferro reported on a group of 48 patients with spondylolysis and spondylolisthesis with chronic low back pain who were treated with exercise (75). This exercise program was based on the functional restoration model, where physiologically intensive exercises are prescribed to eliminate impairments in trunk flexibility, strength, and endurance. The exercise program was not altered because of the presence of spondylolysis and spondylolisthesis. Exercises were supervised by a

physical therapist, consisting of resistive training, stretching and endurance activities, and were done in both flexion and extension directions. Patients were encouraged to continue exercising in the presence of tolerable pain (76). Treatment time averaged 6 weeks. Outcomes included measurements of flexibility, strength, pain, and disability. Significant improvements in flexibility and strength were noted, and were similar to those observed in patients without these abnormalities. During treatment, pain score decreased by an average of 36%, and disability scores by 46%. Long-term outcomes were not reported.

## Injections

The use of spinal injection for the treatment of spondylolysis or spondylolisthesis has not been studied. Some clinicians do use injection with corticosteroid or local anesthetic agents into the facet joints adjacent to the pars defects, and others directly into the pars defects as potentially therapeutic interventions for back pain symptoms in these patients, but efficacy has not been validated. Some clinicians use selective injections as tools to diagnose the specific pain generator in spondylolysis. The lack of joint capsules at the pars defects, and the potential for uncontrolled spread of injected material may limit the conclusions that can be drawn regarding specific pain generators from these injection procedures (77,78).

In cases of radicular pain and foraminal stenosis, selective nerve root blocks with local anesthetic agents or corticosteroids may be used to try to confirm the source of pain generation or to treat the radicular symptoms. We are unaware of any studies that address this procedure in spondylolysis and spondylolisthesis.

## CONCLUSION

Conservative treatment options for adults with pain symptoms and spondylolysis and spondylolisthesis have received sparse study. In general, following the common treatment guidelines for back pain seems merited. Some evidence suggest that exercise may be useful, with programs using flexion exercises, spine stabilization, and aggressive stretching and strengthening all having some advocates. Diagnostic and therapeutic selective spinal injections may be of some use, but have not been studied in this population.

## CHAPTER 61

# Imaging in the Evaluation of Lumbar and Lumbosacral Spondylolysis and Spondylolisthesis

Stephen L. Gabriel Rothman and Leon L. Wiltse

---

Spondylolysis and spondylolisthesis continue to fascinate the medical community, with an ever-increasing mass of information being published each year (1). As imaging techniques become more sophisticated, more detailed information is available to the clinician. Thin section computed tomography (CT) with reformations (2,3) and magnetic resonance imaging (MRI) allow detailed analysis of the abnormal motion segment as never before. This chapter reviews the classification of spondylolisthesis and spondylolysis and illustrates how modern imaging studies have expanded our understanding of the group of disorders.

### ANATOMIC CLASSIFICATION

The classification adopted here is based primarily on the previous work of Wiltse et al., slightly modified from previous editions of the compendium. The classification is anatomic without regard to underlying etiology.

#### 1. Congenital

A. Juvenile dysplastic spondylolisthesis—This is type of spondylolisthesis occurs in young children. The articular processes of the affected motion segment are axially oriented. The anomalous articular processes are often associated with spina bifida of the upper sacral segment. This unstable anatomic situation may lead to forward slippage (4,5).

B. Adult facet misalignment—Congenital or developmental asymmetry of the articular processes occurs in two general forms. The articular processes may be sagittally oriented and therefore parallel to one another or they may be anomalous

in their orientation and asymmetric (Fig. 61-1). In both of these instances, the articular processes are free to glide forward one upon the other causing slippage in adult life as the joints begin to degenerate.

C. Other congenital anomalies of the lumbar spine allow spondylolisthesis to occur. Congenital kyphosis is the most common anomaly (6).

#### 2. Isthmic spondylolisthesis—The lesion is within the pars interarticularis. There are three variants.

A. Lytic spondylolisthesis—The most common type of spondylolisthesis is a stress fracture of the pars interarticularis that has not healed (7).

B. Healed lytic spondylolisthesis—Slippage is due to elongated pars interarticularis caused by healing of a previous stress fracture of the pars.

C. Acute fractures of the pars. These are very rare and are associated with other fractures of the neural arch or articular processes.

#### 3. Degenerative spondylolisthesis—This type is due to articular subluxation caused by 4. Postsurgical spondylolisthesis.

A. Slippage due to surgical removal of most or all of the articular processes.

B. Postoperative stress fractures of the base of the articular processes at the junction with the lamina. This occurs in patients with extensive partial facetectomy.

#### 5. Posttraumatic spondylolisthesis—This condition is always due to very severe trauma of the neural arch other than the pars.

#### 6. Pathologic spondylolisthesis—Slippage is due to deformity of the pars caused by a bone softening disease.

**FIG. 61-1.** Elongated but intact pars: **A:** Lateral radiograph showing elongation of the pars. There is no localized callus formation and no clear signs of pseudarthrosis. There is no open pars defect. **B:** Axial computed tomography scan shows dysplasia of the articular processes.

## TYPES OF SPONDYLOLISTHESIS

### Congenital Spondylolisthesis

#### Type A

Congenital spondylolisthesis of the lumbosacral area in young children is due to hypoplasia or dysplasia of the superior sacral segment. This most commonly manifests itself as a combination of spina bifida occulta of S1 and deformity of the sacral articular processes. The superior articular processes of the sacrum are axially oriented and very short. There is concomitant deformity of the inferior articular processes of L5 (Fig. 61-2). The inferior articular processes of L5 parallel the horizontally oriented sacral facets. This axial orientation produces a pair of joints, which allow forward slippage, because the articu-

**FIG. 61-2.** Congenital spondylolisthesis. Frontal radiographs on a patient with flat, axially oriented articular processes. Note the hypoplasia of the superior surface of the sacrum with spina bifida occulta.

lar processes cannot check the forward gliding of L5 on the sacrum. With flexion, the weight of the body bearing down upon the axial-oriented facets causes forward deformity and spondylolisthesis. The pars interarticularis remains intact in this disorder. Consequently, if the slippage significantly exceeds 35%, cauda equina compression is likely to occur. This manifests itself as tightness of the hamstrings.

On occasion there may be more pronounced anomalies of the first sacral segment and L5. The more the sacrum is hypoplastic the more likely there is to be slippage. Zembo et al. (8) reported a series in infants, two of who had the condition at birth. These lesions are different from congenital kyphosis, which usually occurs in the thoracolumbar area.

#### Type B

Adult congenital spondylolisthesis is a disorder of the articular processes. Slippage probably occurs because of an unstable orientation of the articular processes (Fig. 61-3). Typically, the articular processes are sagittally oriented. In most normal people, a line drawn along the plane of the joint surfaces of the lumbosacral facets will intersect within the spinal canal or vertebral body. Because of this orientation, the inferior articular processes prevent excessive forward gliding of the superior articular processes upon flexion. There is bone against bone contact throughout the range of motion. When the articular processes are sagittally oriented, there is no bone on bone contact in flexion. The soft tissues of the joint capsules bear the force of flexion and allow forward subluxation. In some patients, the articular processes are parallel to each other. This may also allow spondylolisthesis.

**FIG. 61-3.** Adult congenital spondylolisthesis. Axial computed tomography scan **(A)** and sagittal reformation **(B)** reveal abnormal orientation of the articular processes. The right articular processes is sagittally angulated and the left is hypoplastic.

### Type C

Other severe congenital anomalies may be associated with spondylolisthesis. Congenital kyphosis is the most common member of this group. Congenital failure of formation of a vertebral body, congenital failure of segmentation, and combinations of complex anomalies may all lead to spondylolisthesis (9).

### ISTHMIC SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis is one of the most common disorders of the lumbar spine. It is firmly established that lytic defects of the pars interarticularis are stress fractures of childhood. There are fewer than five reported cases of spondylolysis in very young children. There is a report on a child of 8 months with a defect in the pars interarticularis whose father had a similar lesion (10). Boukow and Kleiger (11) reported on a child whose defect was diagnosed at 4 months of age.

The fractures typically begin to make their appearance around the age of 5. There is an occurrence peak between the beginning of kindergarten and the end of the second grade. Baker and McHolick (12) and Frederickson et al. (13) reviewed radiographs on a large number of children at approximately 5 years of age and again 2 years later. Approximately 4.4% of children developed pars defects in this age group. The same authors reviewed films on the same group of patients and proved that approximately 2% more will develop spondylolysis by age 19, with a peak in the teenage years.

Spondylolysis is not caused by a single traumatic event. It is due to the repeated stresses of life. In teenagers, there is usually a history of sports-related back pain. The disorder is extraordinarily common in gymnasts, divers, and other participants in bending and twist-

ing activities. The etiology is unknown. There is a definite genetic propensity for developing pars fractures. Approximately 30% of Northern Slope Alaskan Eskimos have defects in the pars. There are numerous publications documenting the incidence in other populations.

### IMAGING ANALYSIS

In children, the diagnosis of spondylolysis can be made with regular X-rays or nuclear bone scan. The evolving fracture is obvious, especially on single photon emission computed tomography (SPECT) scans. It is not often that CT or MRI is necessary. It is possible to differentiate recent, evolving pars fractures from subacute and chronic lesions by CT. In the acute phase, the fracture line is sharp and jagged. As the lesion progresses the edges of the fracture become indistinct. Although pars fractures can be identified on almost any imaging study, CT is the procedure of choice for defining the subtleties of the bony abnormalities. It is usually possible to define nearly all the bony abnormalities on MRI but it requires more interpretive skill and high-quality images. Subtle signal changes can be seen in the pars on MRI during the acute phase similar to other fractures but they are hard to define. Bright signal is noted on the T2-weighted sequences in the pars and adjacent lamina and pedicle. Low signal is noted on the T1 scans. Abnormal signal within the pars and adjacent pedicle may be the earliest signs on MRI even before the fracture is obvious. There is occasionally abnormal signal noted within the adjacent pedicle in adults with spondylolysis. This is thought to represent increased fat in the marrow space (Fig. 61-4).

### L5 Spondylolysis

Having reviewed MR images and CT scans on more than 3,000 patients with spondylolysis and spondylolis-

**FIG. 61-4.** **A:** Axial T1-weighted magnetic resonance (MR) scan with abnormal bright signal with the pedicles adjacent to pars defects. **B:** Sagittal T2 MR scans show similar bright signal within the pedicle and adjacent bone.

thesis, a theory has evolved regarding the etiology of stress fractures of the neural arch. It has long been realized from routine radiographs, that anomalies of the superior sacral segment were very common in spondylolysis. Spina bifida occulta, for example, is extremely common. What was not obvious from regular X-rays is that another manifestation of superior sacral dysplasia is hypoplasia of the superior articular processes of the sacrum.

Children who develop pars fractures between the ages of 5 and 7 rarely have any clinical signs. The diagnosis was made based on imaging studies. Teenagers who develop pars fractures will usually have back pain. Nuclear bone scans in this painful period will be positive because of the body's attempt to heal the fractures. It is therefore reasonable to presume that there must be some difference in the cause or mechanism of fracture development.

A review of 250 consecutive reformatted CT scans of the lumbar spines in patients with L5 spondylolysis revealed two distinct anatomic patterns that suggest a unifying theory of the etiology of pars fractures and appears to explain the difference in clinical presentation.

Axial CT scans on patients with L5 spondylolysis reveal that approximately two-thirds will have hypoplastic superior articular processes of the first sacral segment (Fig. 61-5). Other minor and occasional major anomalies are also noted in this group of patients. Spina bifida occulta is the most common. One-third of patients with L5 spondylolysis have normal articular processes and neural arch (Fig. 61-6). This ratio of two-thirds with hypoplastic facets and one-third with normal facets is the same ratio Frederickson et al. (13) showed between the occurrence rate peaks in young children between the ages of 5 and 7 and the second teenage peak. We believe that this is not mere happenstance.

**FIG. 61-5.** Axial computed tomography scans showing marked symmetric hypoplasia of the sacral articular processes with forward slippage of L5 on the sacrum.

**FIG. 61-6.** **A:** Axial computed tomography scan demonstrates normal sacral articular processes and spondylolysis. **B:** Sagittal reformation shows the normal position of the superior articular process of the sacrum with respect to the pars.

In our series, the teenage patients with a known history of vigorous sports activity always had normal neural arches and normal sacral articular processes. None of the patients with an obvious sports-related clinical syndrome had hypoplastic articular processes. We were able to scan a number of children early in the course of a bout of severe back pain. In some of these children, recent fractures with sharp edges were visualized on the sagittal reformations. In several instances, fracture lines were visualized that had not gone completely through the pars. They always occurred in the same location. The fracture was always open on the inferior surface on the pars. The superior surface of the pars was intact. Several of these children had follow up CT scans. In some cases the partial fracture was seen to progress to complete fracture. In some cases, the fracture was noted to heal. Figure 61-7 depicts a CT scan on a child who presented with recent back pain. The nuclear scan was positive unilaterally. Note the unilateral partial fracture of the pars on the axial images and the sagittal reformations. Approximately one month later, the scan was repeated because of increasing back pain. The repeat scan demonstrated bilateral open pars fractures. Contrast this with the pair of scans in Figure 61-8. This child was also scanned because of recent onset of severe back pain and a unilaterally positive bone scan. On the initial scan, a fracture is noted extending superiorly from the undersurface of the pars extending upward toward the pedicle but completely through the bone. A follow-up scan approximately 6 weeks later showed that the fracture had healed. The pars was sclerotic and slightly deformed.

A small residual deformity was noted at the most inferior edge of the pars where the fracture began. This pattern of healing is quite common.

None of the patients with pars fractures, which were in a phase of active healing, had hypoplastic articular processes. According to Frederickson et al. (13), none of the children in their series who developed spondylolysis between the ages of 5 and 7 had any low back symptoms. We believe that the finding of hypoplastic articular processes on the CT or MRI scan indicates that the spondylolysis developed silently between the ages of 5 and 7. This would account for all the CT observations.

### Unilateral Spondylolysis

A series of CT scans was reviewed on adult patients with unilateral spondylolysis. There are two possible causes for unilateral spondylolysis in adults. Either the patients had a single stress fracture that failed to heal or had bilateral stress fractures that healed on only one side. It is certainly probable that both scenarios occur (as we have shown previously two patients, one of whom healed the fracture and one who went on to develop bilateral fractures). We suspect that most adult patients who are diagnosed with unilateral spondylolysis originally had bilateral fractures with healing on one side. The evidence for this is twofold. The most telling fact is that there is frequently sclerosis and deformity of the contralateral neural arch in patients with unilateral spondylolisthesis (Fig. 61-9). This may be so striking as to be confused

**FIG. 61-7.** Pars fracture in evolution **A:** Axial computed tomography (CT) taken near the onset of back pain. There is a unilateral right-sided pars fracture. The left pars is intact. **B:** Axial CT scan approximately 6 weeks later now shows bilateral pars fractures. **C:** Sagittal reformation of the first scan. The fracture line extends superiorly from the tip of the sacral articular process but does not extend completely through the pars. **D:** Sagittal reformation of the second scan. The fracture now extends completely through the pars and the defect has completely widened. The opposite pars looked identical.

**FIG. 61-8.** Pars fracture in evolution. **A:** Axial computed tomography (CT) scan shows a very subtle lucency within the right pars (*arrow*). This is the evolving pars fracture. **B:** Sagittal reformation. The fracture extends partially through the pars pointing superiorly from the tip of the normal size sacral articular process. **C:** Sagittal reformation performed on a second CT scan done several months later shows that the fracture line has shortened and the bone is more sclerotic indicating healing.

**FIG. 61-9.** Unilateral spondylolysis. Axial computed tomography scans demonstrate open pars defect on the right side and a dense, sclerotic lamina on the left. The lamina is diffusely thickened.

with osteoblastoma, the most common hyperostotic benign lesion of the neural arch. The explanation in the older literature was that the thickening of the neural arch and prominence of the trabeculae was due to the “stress effect” on the contralateral lamina. Based on CT observations on the many other neural arch stress fractures that will be discussed subsequently and on the numerous cases of proven healed spondylolysis, it seems obvious that this is not correct. Rather the sclerosis is due to a healed pars or laminar fracture.

The second interesting observation is that the majority of patients with unilateral spondylolysis have unilateral hypoplastic sacral articular processes. Occasionally the entire hemilamina is hypoplastic (Fig. 61-10). When we tabulated our data on this group of patients, we found the same two-thirds to one-third ratio of hypoplastic facets that was noted in the bilateral pars group. Remarkably, in the group with hypoplastic articular processes, the hypoplastic facet was always on the side of the open pars defect.

**FIG. 61-10.** Hypoplasia of the lamina and articular process on the side of an open pars defect. Axial computed tomography scans reveal a normal left articular process and lamina. The right lamina is hypoplastic and there is no recognizable joint.

### Healed Spondylolysis

We easily diagnose patients with open pars defects and spondylolisthesis, as their abnormality is obvious. Patients with healed spondylolysis may be very difficult to diagnose. These patients have sustained injury to the lumbosacral motion segment. This may very well lead to early disc degeneration. The deformity of healed pars defects is less well known and may only be seen on high-quality reformatted CT scans. There is usually residual deformity with bone sclerosis. There are numerous adult patients whose CT scans reveal sclerosis and subtle deformity of the pars. This has been termed “hockey stick” deformity and usually represents healing of the fracture with slight lengthening of the pars. The older literature describes many patients with a diagnosis of congenital spondylolysis with intact neural arch. While this probably occurs due to microfractures that do not actually separate, we believe that the great majority of these patients have healed bilateral spondylolysis. The subtle changes of healing are obvious on high-quality reformatted CT. The previous generations of researchers could not possibly see these minor abnormalities commonly on regular radiographs.

There are two common patterns of healing definable by CT. The healing fracture may unite *in situ* with little or no slippage. The bone will appear sclerotic as previously demonstrated in Figure 61-8. That scan showed a fracture in the process of healing. A hint of the residual fracture line was seen in that patient and may remain for a long time. In adults with old healed spondylolysis, the pars will be sclerotic and usually deformed in the shape of an inverted hockey stick. In those instances, the fracture heals across the entire width of the fracture line. The CT scan in Figure 61-11 demonstrates the characteristic changes of this type of fracture healing. In some patients, the entire length of the fracture may not heal. Ossification of the ligamentum flavum (which is also the joint capsule

**FIG. 61-11.** Healed pars fracture in adults. Axial computed tomography demonstrates thickening and deformity of the pars. A faint residual line is noted in the area of the previous fracture.

A

B

**FIG. 61-12. A:** Axial computed tomography scan on a patient with bilaterally healed pars fractures. The left pars and lamina are diffusely sclerotic, enlarged, and deformed. The entire length of the fracture has closed as in the previous figure. The right pars defect is still visible laterally but fused medially by a bridge of bone. **B:** Sagittal reformatted scan showing a portion of the residual open defect and the dense, downward projection of the bridge of bone which has formed in the ligamentum flavum.

of the zygapophyseal joint) may ossify and produce a medial projecting bridge of bone bridging the pars defect. This bar of bone may extend inferiorly into the neural foramen and compress the exiting L5 nerve (Fig. 61-12).

### ADULT SPONDYLOLYSIS AND SPONDYLOLISTHESIS

It is virtually unheard of to find a patient over the age of 20 with recent pars fractures without other major trauma to the motion segment. One must consider the adult pars defect a pseudarthrosis. CT will therefore demonstrate the findings typical of a pseudarthrosis. Adult pars defects have smooth edges, much as we would expect from any pseudarthrosis. Disorganized callus is commonly seen projecting into the spinal canal.

The overwhelming majority of patients with spondylolysis are diagnosed as adults. They present with back pain, leg pain, or both. Frequently, the spondylolysis is unrelated to the cause of the back or radicular pain, which may be coming from an acute process at a higher level. In adults with a diagnosis of spondylolysis made in childhood, spinal imaging is usually performed for the elucidation of the causes of neural compression or for planning operative intervention.

Imaging studies *are useless* for the evaluation of back pain. It is a common logical flaw to presume that the cause of back pain can be diagnosed on CT or MRI. Back pain cannot be seen on scans. A painless spondylolysis and one that is hurting look identical. The amount of slippage says nothing about the existence of back pain because the patient's spine undoubtedly looked the same the day before the onset of back pain as it did the day the scan was performed. Furthermore, nearly all L5 discs will be degenerated in patients with spondylolisthesis. Painful and painless discs look the same. Since approximately 25% of patients with L5 spondylolysis will have disc protrusions at L4 greater than 5 mm, one cannot

even know if the back pain is coming from the next rostral or any other disc space. Furthermore, even seeing hypermobility of the motion segment on flexion and extension films does not allow one to diagnose that as the cause of back pain. Hypermobility and even instability develops over a very long time, and was undoubtedly present on days when there was no back pain. Therefore, seeing hypermobility does not allow one to conclude that it is the cause of back pain. A patient may be having back pain from any of the anatomic areas just mentioned, but one can never conclude from the imaging study that any of these abnormalities is the pain generator.

### CAUSES OF RADICULOPATHY

The most common radicular syndrome is due to compression of the L5 nerve roots. This may occur anywhere from the nerve root origin near the L4/L5 disc, the lateral recess, along the course of the L5 neural foramen, and outward, beyond the foramen to the tip of the L5 transverse process. S1 radiculopathy is much less common. Forward slippage of the L5 body actually decompresses the S1 root because the neural arch remains behind with superior articular process of the sacrum. Consequently S1 radiculopathy is an unusual clinical finding. Disc herniation at the L5 level is also very rare.

The L5 root may be compressed at the L4/L5 disc space by a bulging or herniated disc. This is no different than the typical patient with L4/L5 disc herniation. The disc fragment compresses the origin of the L5 root as it exits from the thecal sac. At least one-fourth of patients with L5 spondylolisthesis will have up to 5 mm of disc protrusion at L4/L5. Compression of the L5 root also can occur in the subarticular gutter and the lateral recess due to buildup of fibrocartilaginous material at the pseudarthrosis. This bony callus can become very large. Figure 61-13 shows a patient in whom the callus is so large that the two masses nearly meet in the midline.

**FIG. 61-13.** Canal stenosis from fibrocartilaginous buildup at the pseudarthrosis. Axial computed tomography scans demonstrate amorphous lumps of bone projecting from the medial border of each of the pars defects. They nearly meet in the midline.

**FIG. 61-14.** The horizontal foramen of spondylolisthesis. Sagittal reformatted scan reveals normal orientation of the L4/L5 foramen. The L5/S1 foramen is flattened and horizontally oriented. Note the upward projecting spike of bone arising from the inferior end plate of L5.

The L5 root is most often compressed in the neural foramen. The foramen narrows and deforms in a characteristic way. As the L5 body slips forward, the pedicle descends relative to the sacrum and flattens the root against the bulging pseudo-disc and an osteophyte, which frequently projects upward from the superior edge of the sacrum. The shape of the neural foramen in spondylolisthesis is characteristic of vertebral slippage. This produces a horizontally oriented foramen rather than the typical keyhole-shaped foramen (Fig. 61-14). It is important to remember that the foramen is not simply a hole through which the nerve exits. It is a bony channel of at least 1 cm. The nerve root may be compressed throughout the length of the exit canal. Simply widening the entrance to the foramen does little to relieve compression of the L5 nerve. Furthermore, proper decompression of the foramen requires removal of the length of the S1 ridge projecting upward into the L5 nerve.

In patients with advanced slippage, the L5 root can be compressed beyond the exit zone of the neural foramen. This has been termed the “far-out syndrome”. It is critical to recognize far-out root compression because routine foraminotomy will fail to cure the radiculopathy. The nerve root is compressed between the transverse process of L5, which has slid forward, and the ala of the sacrum. Proper surgical therapy requires decompression of the nerve root within the foramen as well as removal of the L5 transverse process.

#### **AN ANATOMIC THEORY ON THE ETIOLOGY OF L5 SPONDYLOLYSIS**

We believe that the anatomic analysis of the CT scans in our series leads to unifying theory on the etiology of

spondylolysis. Since it is uniformly accepted that the basic lesion is a stress fracture, this theory must define a congenital anatomic variation, which should be the precursor of the fracture. We believe that hypoplasia of the sacral articular processes is anatomic malformation. The first premise is that the pars interarticularis is the weakest portion of the neural arch. The pars can be thought of as an inclined plane balanced on the tip of the superior articular process of the sacrum. The fulcrum of rotation is a point within the pars adjacent to the tip of the articular process (Fig. 61-15A, B). In children with normal articular processes, the rostral and caudal portions of the pars are of equal length and therefore balanced. In this balanced state, forces on the pars due to everyday motion are insufficient to fracture the pars.

In children with hypoplastic articular processes of S1, that portion of the pars in apposition to the tip of the articular processes is significantly displaced caudally. The fulcrum of rotation is therefore displaced caudally creating an asymmetric inclined plane with increased stress on the upper portion of the pars (Fig. 61-15C, D). The mobility of everyday life produces excess stress on the rostral end of the pars and causes silent stress fracture. This theory accounts for all of the previously described observations. Two-thirds of patients will develop silent stress fractures between the ages of 5 and 7 years. Two-thirds of patients with both unilateral and bilateral adult pars defects have hypoplastic facets. Finally, since none of the sports-related fractures occurred in patients with hypoplastic facets we can therefore conclude that in children with normal articular processes, the pars fractures are due to increased stress from vigorous sport, even in the face of normal anatomy.

#### **OTHER STRESS FRACTURES OF THE LUMBAR VERTEBRAE**

Although stress fractures most commonly occur in the pars interarticularis, any portion of the vertebral ring can fracture. These unusual fractures nearly always occur contralateral to a typical pars fracture and must be considered variants of the spondylolysis complex. The most common non-pars contralateral fracture occurs in the lamina. There are two types. The better-known lesion has been termed a “retro-isthmic cleft”. Originally, these lesions were thought to be congenital clefts in the neural arch posterior to a normal pars. They appear as fairly well circumscribed linear lucent defects, which run perpendicular to the long axis of the lamina. They generally have slightly shaggy edges consistent with a pseudoarthrosis and inconsistent with the smooth, corticated edges expected in congenital clefts (Fig. 61-16). These lesions are visible on MRI scans although they are much more difficult to diagnose on MRI than on CT. The signal in the bone adjacent to the cleft is generally low on T1 because of the sclerosis present in the area.

**FIG. 61-15.** Theory of the etiology of L5 spondylolysis. **A:** Diagrammatic representation of the forces on the pars in a patient with teenage spondylolysis with normal articular processes. Note that the forces on either end of the inclined plane will be balanced. The fulcrum is in apposition to the tip of the superior articular process. **B:** Sagittal computed tomography reformation on a patient with conforming anatomy. A line drawn through the L5/S1 disc passes well below the tip of the sacral articular process. **C, D:** Diagrammatic representation of the forces on the pars in a patient with hypoplastic sacral articular processes. The fulcrum descends along the length of the pars to a point just rostral to the tip of the articular process.

The second type of fracture is perhaps even more common but less well known. It is a spiral fracture through the lamina opposite a typical pars fracture. CT reveals the residual deformity of the fracture. The changes in the lamina are no different from those seen in healing fractures of other long bones (Fig. 61-17). It is probable that the thickened, sclerotic lamina in many patients with unilateral open pars defects are due to healed laminar fractures.

Much less commonly, defects occur within the pedicle on the contralateral side from a regular pars fracture. This is the least common neural arch fracture in our series, being seen in only two patients, one of who was a professional soccer

player. Stress fractures of the pedicle can also occur following laminectomy and facetectomy due to weakening of the neural arch by the decompression (Fig. 61-18).

The literature defines a lucent cleft in the vertebral body just anterior to the pedicle as a “retrosomatic cleft”. This was originally thought to be a congenital failure of fusion of the vertebral body ossification center to that of the pedicle. High-resolution CT has proven that incorrect. These are vertebral stress fractures. The typical retrosomatic cleft tends to be a well-defined lucent line between the pedicle and the posterior edge of the vertebral body (Fig. 61-19). The fusion plane of the

**FIG. 61-16.** Retro-isthmic cleft. Axial magnetic resonance imaging scan. There is a typical pars defect on the right and a retro-isthmic defect on the left. The edges of both fractures are irregular as seen in any pseudoarthrosis.

**FIG. 61-17.** Spiral fracture of the lamina. Axial computed tomography scans reveal an oblique fracture through the left lamina.

**FIG. 61-18.** Stress fracture of the pedicle. Axial computed tomography scan reveals sclerosis of the vertebra from degenerative disease. A stress fracture is seen in the right pedicle.

**FIG. 61-19.** Retrosomatic cleft. Axial (A) and (B) sagittal reformatted computed tomography scan. There is a typical pars defect on the left side and an irregular cleft on the right.

vertebral ossification center and the pedicular ossification center lies much farther anterior within the vertebral body. In many instances one can identify a faint, curvilinear, sclerotic line within the vertebral body representing the fusion plane of these ossification centers (Fig. 61-20). The retrosomatic fracture occurs posterior to this fusion plane.

Although not generally considered when one thinks of the neural ring, the posterior edge of the apophyseal ring of the vertebral body is the anterior margin of the neural canal. Separation of the posterior apophyseal ring is termed a *posterior limbus vertebra*.

**FIG. 61-20.** Failure of complete fusion of the ossification centers of the vertebral body with that of the right pedicle. Axial T1-weighted magnetic resonance scan reveals a lucent crescentic line well within the vertebra.

Posterior limbus vertebra occurs when a fragment of disc material herniates through the ununited posterior apophyseal ring, fracturing a segment of the ring and displacing it into the spinal canal. While technically this may not be a stress fracture, it is useful to include it as the last of the neural ring fractures to be associated with spondylolysis. The combination of spondylolysis and posterior limbus vertebra may be associated with heavy sports activity such as weight lifting (Fig. 61-21).

**FIG. 61-21.** Pars fractures and posterior limbus vertebra. Axial CT beside the typical bilateral pars defects, a crescentic bar of bone has displaced posteriorly from the vertebral body. This is a large segment of the apophyseal ring. This is due to herniation of disc material through the developing vertebral end plate prior to fusion of the apophyseal ossification center to the remainder of the vertebra.

**CONCLUSION**

Children between the ages of 5 and 7 years account for two-thirds of patients with spondylolysis. They likely fracture their pars because of increased forces on the pars due to the long lever caused by hypoplastic facets. There is usually no history of sports activity or unusual back activities. Teenagers account for one-third of patients. They fracture their pars through repeated vigorous activity and are often serious athletes. Although the pars is the most likely portion of the neural arch to fracture, any portion of the ring may be involved. Multiplanar CT is the procedure of choice for the evaluation of the bony anatomy in patients with spondylolysis, spondylolisthesis, and the stress fracture variants.

## CHAPTER 62

# Evaluation and Management of the Athlete with “Pars Fracture”

Robert Watkins III and Robert G. Watkins IV

---

A complaint of low back pain in a competitive athlete requires an in-depth investigation, specific diagnosis, and appropriate treatment. Lumbar pain in an athlete is a stress fracture until proven otherwise. While the incidence of stress fractures is higher in certain types of athletics compared to others, any athlete is potentially subjected to the repetitive twisting and extension motion that is identified with the etiology of spondylolysis. The typical spondylolytic lesion occurs in the pars interarticularis, but may be present in the pedicle or articular process.

While there have been references made to a congenital predisposition to spondylolysis, environmental factors have clearly been shown to be a significant source of pathology in the young athlete. The sports frequently associated with a significantly increased incidence are diving, gymnastics, wrestling, and weightlifting (1). The incidence of pars interarticularis defects in female gymnasts is four times that of the general female Caucasian population. The incidence of pars defects is approximately 4.5% during the first year of school and is more common in boys than girls (2). There are certain familial predispositions to pars defects in young children and there is an increased incidence of spina bifida occulta in young athletes who have spondylolysis (3). Spondylolysis rarely leads to progressive high-grade spondylolisthesis. Progressive slip has a higher incidence between the ages of 9 and 12 in girls and 10 and 14 in boys (4). Cahill's evaluation of the young athlete documented an incidence of 0.8% of children without evidence of fatigue fractures developing such a fracture between the ages of 10 and 20 (15). McCarroll documented an incidence of 2.4% of acquired spondylolysis during a 4-year college football career (6). In answer to the question, “Is spondylolysis a fatigue fracture?” Hutton, Stott, and Cryon demonstrated that cyclic loading can produce a fatigue fracture of the pars interarticularis (19). Because of the

increasing use of weightlifting as a training technique in all varieties of sports, many athletes suffer a fatigue fracture in the weight room as opposed to directly on the athletic field. There are still certain maneuvers in specific sports such as hyperextension in gymnasts, extension in anterior alignment in weightlifters, and extension with rotation in baseball pitchers that can lead to the repetitive loading that produces the fracture.

The pain source of acute spondylolysis is predominantly the fracture. Just as fractures hurt in other locations, the fracture of the pars interarticularis can produce pain. The location can be at any level of the spine. It is certainly more common at L5, because L5 is a transitional area between the fixed sacrum and the mobile lumbar spine. There is an abnormal distribution of forces at this level, and rotational forces may be inappropriately directed to the pars interarticularis at L5 (8). Shear forces at the lumbosacral junction have been shown to predispose the pars to fracture (7,9).

Athletes are often seen with asymptomatic spondylolysis. There is a high incidence of professional athletes with asymptomatic lesions not related to a specific complaint of low back pain. Bilateral defects with or without grade I spondylolisthesis can produce pain from the relative instability of the anterior column produced by the loss of inherent tensile and shear strength of the pars interarticularis. Symptomatic discogenic pain is a reality and certainly can be coupled with spondylolysis at the same level. The injured disc, innervated by the sinuvertebral nerve, undergoes annular tears and inflammation, which result in pain.

Often the patient arrives at the spinal specialist with a diagnosis, and is already improving after having stopped the sport activity. This patient needs the full history and physical examination afforded to every patient with back pain with testing for signs of nerve root impingement and a complete neurologic examination.

## HISTORY AND PHYSICAL EXAMINATION

The key to a proper history and physical examination is to have a standardized form that accomplishes the needed specific objectives:

1. Quantitate the morbidity. Use a value scale of pain, function, and occupation. Converse with the patient and listen to the inflections and manner of pain description. Detail the time of disability and the time of origin of the pain. We use the Oswestry Scale and Disability Rating. The severity of the morbidity often determines the aggressiveness of the diagnostic and therapeutic plan.

2. Delineate the psychosocial factors. Know what psychologic effect the pain has had on the patient. Know the social, economic, and legal results of the patient's disability. We use the pain drawing on the initial visit and a detailed psychologic report in certain instances. Understand what can be gained by the patient's being sick or well. Derive an understanding of what role these factors are playing in the patient's complaints.

3. Eliminate the possibility of tumors, infections, and neurologic crisis. These conditions have a certain urgency that requires immediate attention and a diagnostic therapeutic regimen that is very different from that required for disc disease. Constant, unrelenting pain that becomes worse at night is an indication of tumor or infection. Ask about bowel, bladder, and sexual dysfunction and do a thorough examination.

4. Diagnose the clinical syndrome:

- a. *Nonmechanical back or leg pain*—Inflammatory, constant pain; minimally affected by activity; usually worse at night or in early morning.
- b. *Mechanical back or leg pain*—Made worse by activity; relieved by rest.
- c. *Sciatica*—Predominantly radicular pain; positive stretch signs, with or without neurologic deficit.
- d. *Neurogenic claudication*—Radiating leg or calf pain; negative stretch signs; made worse with ambulation and spinal extension; relieved by flexion.

Pinpoint the pathophysiology causing the syndrome. Three important determinations are:

1. What nerve (especially in radiculopathy)?
2. What level? Which neuromotion segment?
3. What pathology? What is the exact structure or disease process in that neuromotion segment that is causing the pain?

Some key factors in the history and physical examination are:

1. What caused the injury?
2. The time of day when the pain is worse?
3. A comparison of pain levels during walking, sitting, and standing.
4. The effects of Valsalva maneuver, coughing, and sneezing on pain.

5. The type of injury and duration of the problem.
6. The percentage of back versus leg pain. (We insist on getting an accurate estimate of the relative amount of discomfort in the back versus that in the legs. These two numbers must add up to 100%.)

The physical examination should address:

1. Maneuvers during the examination that reproduce the pain.
2. The presence of sciatic stretch signs.
3. The neurologic deficit.
4. Back and lower extremity stiffness and loss of range of motion.
5. The exact location of tenderness and radiation of pain or paresthesias.

The presentation of an athlete or adolescent with mechanical low back pain requires a thorough examination. Most athletes can identify the mechanical activity in their sport that produces the pain. At times, players will only have pain while throwing or only have pain while batting. Of course, if the inflammation is significant enough the athlete may have constant unrelenting pain, even interfering with sleep. Some athletes present with a long history of pain with activity—a chronic lumbar pain that intermittently flares up. At other times, athletes can specifically remember the types of activities they were performing when the pain started. Many athletes with spondylolysis will have pain both in flexion and extension. Coughing, sneezing, and straining may also cause pain for patients with severe inflammation.

The examination begins with finding the location of pain and tenderness. The patient frequently points to a unilateral lumbosacral location in the area of the posterosuperior iliac spine.

Typically, patients with acute spondylolysis do not have leg pain, although it can be present. They often have paraspinous spasm and hamstring tightness. Patients typically have more pain with extension and with extension and rotation toward the painful side. The one-legged lumbar extension maneuver in which the patient stands on one leg and bends backward is a commonly used test to accentuate the pain from an acute spondylolysis.

## RADIOGRAPHS

X-ray evaluation is limited in the ability to pinpoint an area of acute spondylolysis. Areas of sclerosis may be an impending fracture or a more ominous osteoid osteoma or osteoblastoma (10). Oblique X-rays may demonstrate the presence of a spondylolysis. Because some defects are seen better at 30° and others at 60°, and because the presence or absence of an established spondylolysis has little correlation with the exact etiology of pain, we stopped the use of oblique X-rays on patients with lumbar pain (11).

The key to diagnosis in the athlete and adolescent with back pain is a lumbar single photon emission computed tomography (SPECT) scan (12). The tomography of the bone scan is a very accurate test for identifying an impending or established acute spondylolysis. The radionucleotide is picked up by bone-forming cells. These cells may be in response to a fracture or impending fracture. It can also be associated with arthritis in a lumbar facet joint (13). A chronic spondylolysis that is negative on the SPECT scan should not be the etiology of that patient's pain.

Our typical workup for the young athlete with back pain of more than 3 weeks' duration includes a lumbar SPECT scan. If it is positive for reaction, we order a lumbar CT scan to identify what area is positive. Is this an osteoid osteoma, osteoblastoma, injured facet joint, arthritic facet joint, or a stress fracture in the pedicle, pars, or articular facet? If the SPECT scan is negative, we order a magnetic resonance imaging (MRI) to rule out disc degeneration, infection, or tumor.

Use of the MRI to diagnose acute spondylolysis has been presented in a number of different forums. Proper technique with the MRI can identify acute bone edema. This certainly can be a method of identifying an acute spondylolysis. There is certainly less radiation exposure using the MRI. However, the combination of the bone scan and CT scan is a visual demonstration to parents and the patient of their exact back problem. The CT scan allows a clear-cut definition of what is positive on the bone scan and it allows one to determine how long the defect has been present. A very early defect is most likely to heal regardless of treatment. A well-established defect is less likely to heal. A CT scan offers a way of following this in the future that is much more specific than the MRI.

## TREATMENT

When the young athlete comes to you for care, it is the obligation of the clinician to properly demonstrate the lesion to the patient and the parents and devise an appropriate treatment program for the patient's complaints. Treatment begins with identification of the etiology of the problem. If the etiology of the problem is one specific maneuver in a sport, stop that maneuver. If it is participation in the sport, stop the participation in the sport. Stopping the motion that causes the problem is the first step in treatment.

For many years, conservative treatment has consisted of avoidance of physical activity and the use of orthoses to immobilize and support the back. Such treatment has been only minimally effective. For example, in looking at pars defects in 185 spondylolytic adolescent athletes, Morita et al. classified the defects into early, progressive, and terminal stages, depending on degree of severity, as revealed by CT (10). Patients wore a lumbosacral support

corset for periods as long as 6 months. The defect healed in 73% of the early cases, but only 38.5% of the progressive cases and none of the terminal cases. The subject of pain relief was not addressed in their report.

However, as early as 1976 physicians such as Magora in Israel advised that orthoses be used only to train the patient in building good postural habits, not for support in treating spondylolysis or asymptomatic spondylolisthesis (9). An orthosis may produce some relief from pain because of the limitation of movements and general feeling of support it provides. However, as Magora observed, as soon as the orthosis is removed the tenderness tends to increase, the back and abdominal muscles are weakened and atrophied, and some movements of the lumbosacral spine are limited, all of which result in a more prolonged and painful therapy. Only in the case of severe low back pain did Magora prescribe bed rest. When pain was mild to moderate, he recommended an immediate return to normal daily activities, albeit with some modifications to those activities, combined with an exercise program to strengthen back and abdominal musculature (15).

Others agree with this stance and, like Hensinger (18) and Johnson (26), maintain that when symptoms are related to activity, stabilization of the spine alone will achieve excellent long-term remission of symptoms and minor neurologic findings.

The trunk stabilization program offers an early return to sports without the use of a lumbosacral brace. It comprises a combination of activities that work to bring the spine back to a position of balance and power in injured athletes. By training muscles of the trunk to work in coordination, the program produces biomechanically sound spinal function. It uses special isometric strengthening exercises to develop specific trunk muscles that are molded in response to proprioceptive feedback. Muscle function based on balance and coordination, not strength alone, is the result. Initially, the athlete is taught to attain a very safe, neutral, pain-free, and controlled position. He or she then moves through a series of exercises that combine balance and coordination. Gradually, the athlete, while maintaining good trunk control, is moved in incremental steps through increasingly advanced exercises. In each succeeding exercise, the patient assumes a somewhat more precarious position than he or she had experienced in the one that preceded it. There are eight categories of exercises:

1. Dead bug
2. Partial sit-ups
3. Bridging
4. Prone
5. Quadripedal
6. Wall slides
7. Ball exercises
8. Aerobics.

Each of these categories consists of five levels, with each level of difficulty amplifying the intensity of perfor-

## TREATMENT

Certain spondylolytic defects will heal. Acute lesions have a higher chance of healing than chronic defects (18). Use of a Boston brace has never statistically been demonstrated to enhance healing of the spondylolytic defect (19,20). At our institution, follow up X-rays and CT scans are of no practical value in spondylolytic patients who are responding favorably to a back strengthening rehabilitation program and whose symptoms have subsided. Radiographically following spondylolisthesis is only important in young athletes. From the ages of 9 to 13, in the presence of occulta spinal bifida and with a doming of the sacrum, spinal optosis can occur. After the age of 16, this would be a rare occurrence. This can be followed with a simple lateral radiograph. General guidelines are that, with a slip of less than 50%, there are no restrictions necessary. With a slip of 50% or more, high-risk sports are not recommended until the growth stops. As a practical matter, those with high-grade slips are seldom able to participate in high-velocity sports.

Our experience in the use of bracing versus stabilization in adolescent athletes consists of an unpublished series of 31 athletes evaluated for return to full activity. The athletes were divided into two groups: group A, 19 patients treated only with the trunk stabilization and group B, 12 patients treated with a rigid lumbosacral orthosis, followed by a trunk stabilization program. The patients were selected randomly. Group A was treated purely with stabilization training. Group B wore the brace without physical therapy for 2 months before beginning physical therapy. Group A patients returned to full activity at 3 months, and group B patients at 4 months. The two groups reached the same excellent functional recovery rate. As a result, we have not used a lumbosacral orthosis in the last 15 years.

Return to sport after acute spondylolysis is based on the Watkins-Randle 1 through 5 rating scale of trunk stabilization exercises. An adolescent athlete should be able to do a full level 3 workout and college and professional athletes should be able to do level 4 or 5 workouts before practice. Steps in returning an athlete to play are as follows:

1. Complete the appropriate level of the stabilization program
2. Be in excellent aerobic condition compatible with the sport through aerobic conditioning while doing the stabilization program
3. Work with the coaching staff and training staff in a series of sport-specific exercises for the individual sport
4. Return slowly to the sport with playing time or position changes as needed and specific to the sport
5. Maintain the same level of stabilization training after return to the sport for a period of 6 months to a year.

## SURGICAL TREATMENT

There are very limited indications for the surgical treatment of spondylolysis. In 20 years of treating spondylolysis in adolescent, college, and professional athletes, we have resorted to surgery two times. One was in a minor league baseball pitcher with a unilateral defect who had already missed one season and was in danger of missing another. The other was for bilateral spondylolysis in a minor league pitcher. The incidence of symptomatic acute spondylolysis not responding to stabilization training and allowing a return to the sport is rare. Experiences with extremely demanding activities such as cricket bowlers may be different.

Direct repair of the spondylolytic defect has been shown to be effective (21–26). Many different techniques have been described such as hook screws (21,22,26), translaminal screws (21,26), wiring (26), and pedicle screws with a V-shaped rod (27). Our operation of choice is a lag screw across the spondylolytic defect and grafting of the defect with minimal exposure. A prerequisite for a spondylolysis repair is that the disc is normal (23). This can be determined with MRI or discography. Other operations such as the Hamby modification of the Cole and Scott technique for tension band wiring and bone grafting for bilateral defects (28) is certainly acceptable in treating the problem.

Patients with significant disc degeneration may need a one-level fusion. We have performed two fusions in professional athletes for spondylolisthesis with a 50% effectiveness rate. Lumbar spinal fusion in professional athletes is not a very successful operation because of the high demands placed on adjacent levels, the amount of time out from the sport for the fusion to heal, and the aggressive demands put on the spine in the early-healed phase. Artificial disc replacement for spondylolisthesis is an unknown factor at this time.

## CHAPTER 63

# Indications for Surgery in Spondylolysis and Spondylolisthesis in Adults and Surgery for Low-Grade Spondylolisthesis

Dahari D. Brooks and Bruce E. Fredrickson

---

The goal of this chapter is twofold: (a) present and discuss the indications for operative management of low-grade nondegenerative slips; and (b) present and discuss surgical options for the treatment of low-grade nondegenerative slips. For the purposes of this chapter, we will discuss the indications and procedures as they relate to low-grade, nondegenerative causes of spondylolisthesis only. Nonoperative treatment modalities, and the evaluation and management of high-grade (III through V) slips will not be addressed in this chapter.

The term *spondylolysis* is defined as the breaking down of a vertebral structure; and is derived from the Greek “spondylos” (vertebra) and “lysis” (dissolution). *Spondylolisthesis*, derived from the Greek “spondylos” (vertebra) and “oblisthesis” (a slipping), refers to any forward slipping of one vertebra onto the one below it. The underlying pathology that predisposes to this forward slippage includes spondylolysis, disc degeneration, elongated pars intra-articularis, or pedicles, and congenital arch defects. In 1963, Newman reviewed 319 cases of lumbar spondylolisthesis and described three categories (1):

1. Congenital (dysplastic)
2. Isthmic (spondylolytic)
3. Degenerative spondylolisthesis.

Since the publication of this classification scheme, Wiltse devised a classification scheme based on etiologic and anatomic factors (Fig. 63-1) (2):

1. Traumatic spondylolisthesis
2. Congenital or dysplastic
3. Isthmic
4. Pathologic spondylolisthesis
5. Iatrogenic (postsurgical) spondylolisthesis.

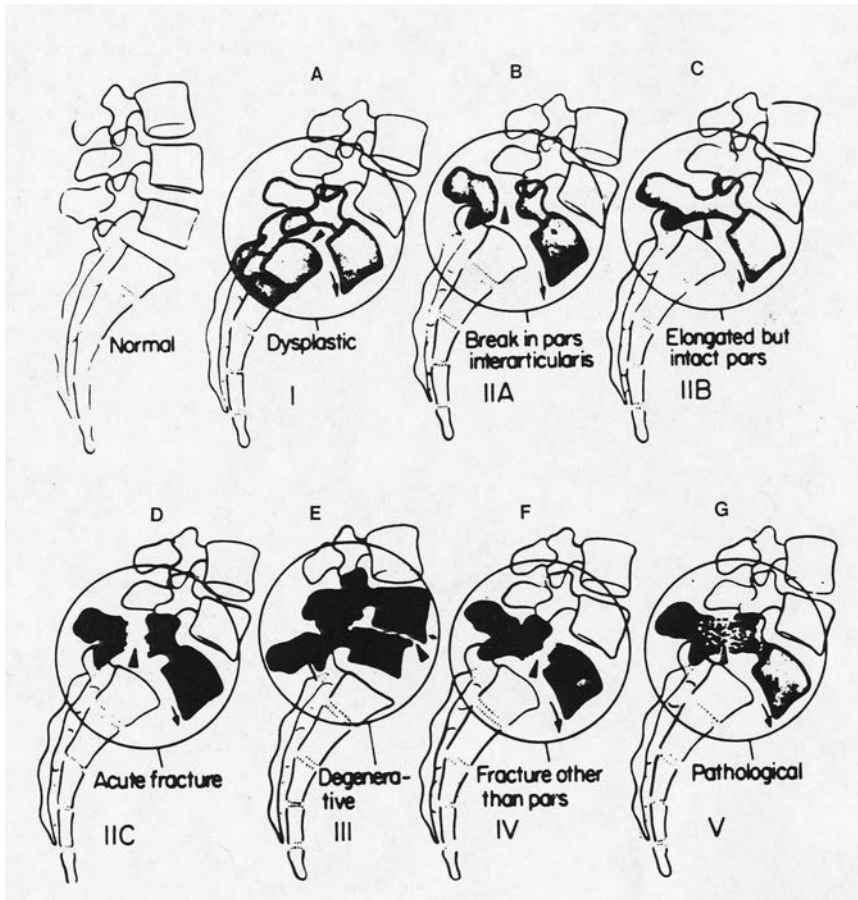

In congenital or dysplastic spondylolisthesis displacement occurs early in life and is often severe. Overall, congenital slips account for approximately 15% of cases, and affects females to a greater extent (1). The pars may remain intact, but is usually underdeveloped.

Isthmic spondylolisthesis is the most common form of spondylolisthesis. Isthmic spondylolisthesis is defined as an anterior slip of the upper lumbar vertebrae, as well as separation of the anterior aspect of the vertebrae from the posterior neural arch (3,4). The fibrous defect in the pars allows for the future displacement (2,3,5–10).

Degenerative slips typically occur at the L4-5 level, and result from long-standing instability secondary to disc and facet degeneration (1).

Traumatic spondylolisthesis refers to slips secondary to an acute injury pars/facet complex. Posterior element destruction secondary to a lytic process such as malignancy or infection, results in a pathologic spondylolisthesis. And finally, excessive surgical removal of the supporting bony and ligamentous structures results in an iatrogenic spondylolisthesis.

The severity of the slip, despite the various etiologies, has been historically based upon the slip percentage. The slip percentage is determined in a number of ways. The classically described method involves the division of the inferior end plate of the superior vertebra into four equal segments (each representing 25%). The numbers of segments anteriorly displaced determine the slip grade. Slips are classified as either low- or high-grade based upon this percentage. A low-grade slip indicates that the amount of anterior translation is less than or equal to 50%; whereas a high grade slip indicates that the amount of anterior translation exceeds 50%.

**FIG. 63-1.** Classification scheme for spondylolisthesis based on etiology and radiographic appearance. (From Frymoyer JW, ed. *The adult spine: principles and practice*. New York: Raven Press, 1991, with permission.)

**INDICATIONS**

Natural history studies have demonstrated that the majority of individuals with a pars defect remain asymptomatic. While radiographic evidence of slip progression in the adult is possible, the likelihood of this translating into clinical symptoms is low. Although patients may experience back pain with or without extremity pain, the overall incidence of low back symptoms is not significantly higher than that of the general population (4,11,12).

The treatment options are quite variable for those individuals with significant complaints despite an adequate course of supervised conservative management. Clinically, patients can present with a variety of symptoms.

1. Mechanical low back pain with normal neurologic examination
2. Mechanical low back pain with extremity pain and normal neurologic examination
3. Mechanical low back pain and either unilateral or bilateral radicular leg pain (13).

In addition to back or leg pain, patients may also complain of postural changes, or hamstring tightness. Radiographs are helpful in this situation to determine whether the slip has progressed. Slip progression can cause or intensify radicular or back pain (6,14).

It is commonly accepted that patients who present with intractable low back pain with or without lower extremity symptoms despite adequate conservative therapy, or radicular symptoms are appropriate surgical candidates (15). Conservative management in general consists of an exercise protocol, with emphasis on trunk stability and strength training. In addition, activity/lifestyle modifications, weight loss, epidural or selective nerve root injections, and aerobic conditioning have also been shown to improve long-term function (16). Modalities such as ultrasound, massage, or traction have not been shown to make a statistical difference with respect to outcome.

**TABLE 63-1.** *Surgical options*

	Posterior	Anterior
Gill decompression		Anterior lumbar interbody fusion (ALIF)
<i>In situ</i> fusion		Combined ALIF and posterior fixation
Decompression and <i>in situ</i> fusion		
<i>In situ</i> fusion with instrumentation		
Decompression and instrumented fusion		
Direct repair of pars defect		

Once the decision for operative management has been made, the treating surgeon has several available options (Table 63-1). Surgical intervention can provide superior long-term results for appropriately selected patients (13,17–21).

### POSTERIOR DECOMPRESSION

In 1965, Gill published a study of 20 adult patients with symptomatic isthmic spondylolisthesis treated with posterior decompression consisting of wide excision of the loose lamina and inferior facets and foraminal decompression (Gill decompression) (22). It was noted that the most common root involved in this condition was L5. It appeared that compression of the fifth lumbar root resulted from the buildup of fibrocartilaginous tissue at the site of the pars defect, and that the presence of a slip, either preoperatively or postoperatively, did not reliably correlate with symptoms. At an average follow-up of 36 months, Gill noted no slip progression, and only 3 fair/unsatisfactory outcomes (22a). In 1984, Gill reevaluated 52 patients (including those of the original study) ranging in age from 14 to 57 years. Twenty-one individuals demonstrated slip progression, with an average increase of 5.9% in males and 16% in females. Despite the progression, only 10% of these patients were symptomatic. Furthermore, good/excellent results were noted in 82% of those individuals without radiographic evidence of progression.

### DECOMPRESSION AND *IN SITU* FUSION

Despite such encouraging reports of posterior decompression, the increased risk of slip progression has prevented this technique from gaining greater support. The addition of a posterolateral *in situ* fusion allows one to address this added risk of progression (Fig. 63-2). Long-

term results demonstrate low rates of slip progression, excellent patient pain relief and satisfaction, and relatively low complications. Various authors have evaluated this procedure and report an approximate 80% to 85% success rate, with few (if any) reports of slip progression (13). Furthermore, those individuals with poor surgical outcomes had a significantly higher pseudoarthrosis rate (15,17). Thus, successful clinical outcomes relied heavily on the presence of a solid fusion mass (15,17,20).

### Fusion *in situ*

Realizing that the success of surgical management of low-grade nondegenerative spondylolisthesis is dependent largely upon obtaining a solid arthrodesis; *in situ* posterolateral fusion without decompression has been performed as a reliable, rapid, and easy means of treatment (23,24). Various reports demonstrate similar success rates as those seen with decompression and fusion. The only identifiable factor that has been shown to impact outcome is the presence of a pseudoarthrosis. Individuals with a nonunion were more likely to have a poor outcome as has been shown in the past.

The addition of a Gill decompression to arthrodesis for the treatment of low-grade isthmic spondylolisthesis in patients who do not demonstrate significant radicular symptoms does not appear to improve clinical outcomes.

### POSTERIOR INSTRUMENTATION AND FUSION

Given the strong correlation between radiographic fusion and clinical outcome, pedicle screw fixation is often used to increase fusion rates in this subset of patients (25–28). The use of tobacco products and nonsteroidal antiinflammatory drugs (NSAIDs) postoperatively has been demonstrated to adversely affect fusion rates. The use

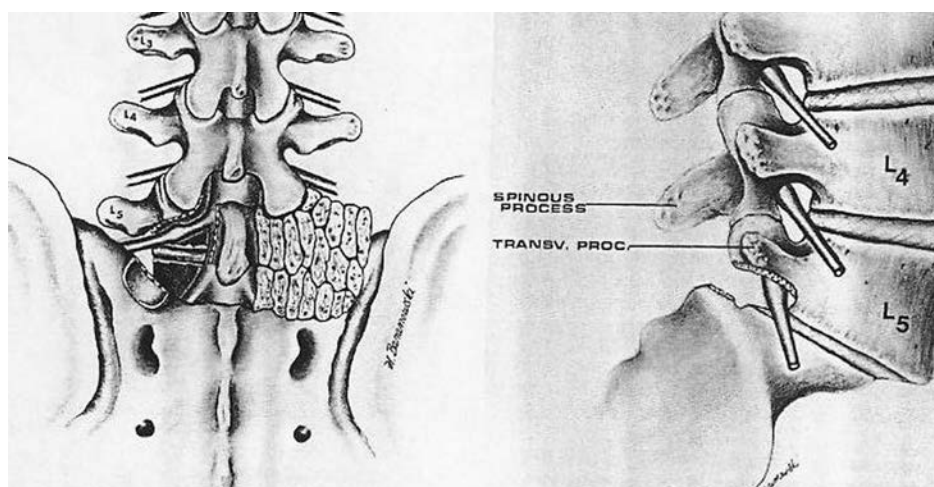

FIG. 63-2. Illustration of a posterolateral decompression and *in situ* fusion. (From Frymoyer JW, ed. The adult spine: principles and practice. New York: Raven Press, 1991, with permission.)

of supplementary instrumentation in addition to decompression, and autologous posterolateral arthrodesis has been shown to improve the clinical outcome and fusion rate for those patients who are smokers, have an iatrogenic slip, or require revision secondary to an established pseudoarthrosis (29). It should be noted that for those individuals without such predisposing risk factors, there is no significant advantage of transpedicular screw fixation in improving fusion rates or clinical outcome (29).

### **DIRECT REPAIR OF THE PARS INTRA-ARTICULARIS**

Direct pars defect repair allows for the preservation of lumbar motion segments, and restoration of the normal anatomy (30–36). In addition to the previously stated indications for operative treatment, when considering direct repair, particular attention should be paid to the quality of the disc and facets (5,37). In the setting of degenerative disc disease (DDD) there is inherent instability and abnormal motion which can lead to early facet degeneration, spur formation, and nerve root compression. Therefore, preservation of the degenerated lumbar motion segment increases the likelihood of a poor outcome (30,34,36). Direct repair is best suited for younger, symptomatic patients without concomitant DDD (36).

In addition to DDD, the incidence of spina bifida occulta among those individuals with low- grade isthmic spondylolisthesis at L5/S1 is increased. These congenital defects or absence of the posterior elements can present technical difficulties that prevent direct pars repair. Special attention should be paid to those patients in whom repair is considered at the L5/S1 level.

Overall, the reported results for direct repair in appropriate patients are quite encouraging (30–35,38). Individuals with back pain secondary to either spondylolysis or grade I spondylolisthesis treated with direct repair typically have excellent results. Reports indicate the presence of a solid bony union at approximately 6 months as well as no significant limitation in lumbar motion (30,34). Direct repair of the pars defect has been shown to provide satisfactory results with few complications, as well as the added benefit of maintaining normal lumbar motion (30,34).

### **ANTERIOR LUMBAR INTERBODY FUSION (ALIF)**

Interbody fusion involves complete anterior discectomy and interbody fusion of the affected level. Advocates of this technique indicate that the associated degenerative disc disease and instability is best addressed anteriorly (39–42). The ability to excise the disc, fuse, and possibly reduce the slipped level allows for encouraging results with relatively few postoperative complications. Not only do patients appear to improve initially, long-term results demonstrate improvement for up to 10

years after surgery (41,42). Despite such positive reports, the potential for significant complications does exist, and is increased when reduction maneuvers are attempted. Complications include vascular as well as neurologic injury. Reports range from a 0 to 30% incidence of L5, S1 nerve root injury, or cauda equina syndrome. The incidence of pseudoarthrosis secondary to shear forces is greater than that reported from posterolateral *in situ* fusion. Despite the potential risks of ALIF, no statistically significant difference in fusion rates or clinical outcome has been demonstrated when compared with posterior decompression and fusion with pedicle screw fixation (41).

### **COMBINED ALIF AND POSTERIOR INSTRUMENTATION**

The trend for higher pseudoarthrosis rates secondary to shear forces with ALIF alone lead to the use of supplemental posterior pedicle screw fixation and fusion (43). Fusion rates did appear to improve; however, the overall success rate was similar to that of either ALIF or posterior fusion. In addition, increased operative times and blood loss makes this surgical option less appealing.

### **DISCUSSION**

To date there have been many studies evaluating surgical management of low-grade nondegenerative spondylolisthesis. Regardless of the method employed, the indications for surgical intervention are quite uniform. These are low back pain with or without lower extremity pain despite an adequate trial of conservative treatment, or symptomatic slip progression.

The authors recommend the following approach to the evaluation and treatment of those individuals with symptomatic low-grade nondegenerative slips. Clinical symptoms/signs of low back pain and nerve root irritation consistent with spondylolisthesis should be documented. Anteroposterior (AP), lateral, and oblique lumbosacral plain radiographs are obtained for the purposes of classifying the type and grade of slip. The first line of treatment should be conservative; it is important to stress to the patient that nonoperative treatment does not equate to no treatment. Conservative management consists of supervised physical therapy, weight reduction, activity modification, pain blocks, and if applicable, job retraining.

For that subset of patients who complete the 6-month course of conservative care and continue to be symptomatic, surgical intervention is pursued. A magnetic resonance (MR) image and dynamic LS spine films are obtained preoperatively. Flexion/extension films provide a rough estimate of the degree of instability present and the potential need for instrumentation. The presence and extent of disc and facet degeneration can be evaluated on

MRI. In addition, discography, selective nerve root, facet, or pars blocks can better delineate the source of the patient's pain.

For young individuals (between the age of 16 and 30) with no evidence of DDD, with complaints primarily of low back pain, we recommend direct pars repair for those lesions of L4 and above. The presence of other congenital posterior defects at L5 often prohibits repair. Only in rare circumstances in which the posterior and anterior elements are normal do we recommend repair of the L5 defect. Preoperative MRI evaluation is an excellent means of evaluating the integrity of the posterior and anterior elements. In addition to plain radiographs and MRI, we also recommend diagnostic pars blocks to help differentiate the source of the patient's symptoms and signs. Although more technically demanding, the maintained motion and restoration of normal alignment provide excellent long-term patient satisfaction.

For those patients who are not candidates for direct repair, we further subclassify them based on presenting signs and symptoms. Patients can typically be separated into one of three categories:

1. Category A—mechanical low back pain with normal neurologic examination
2. Category B—mechanical low back pain with extremity pain and normal neurologic examination
3. Category C—mechanical low back pain and either unilateral or bilateral radicular leg pain.

For those patients who fall into either category A or B we recommend posterolateral *in situ* fusion with autologous bone graft as the primary surgical treatment. This can be accomplished either through a midline posterior approach or a Wiltse posterior muscle splitting approach (which is our preferred method). We do not, however, recommend dual skin incisions. Removal of the facet capsule and articular cartilage and insertion of bone graft is an important part of the procedure. We do recommend the addition of pedicle screw fixation in those individuals who have identifiable risk factors for pseudoarthrosis or demonstrate excessive motion on dynamic radiographs. Risk factors for nonunion include tobacco use, revision procedures secondary to an established nonunion, iatrogenic slip, or long-term NSAID use for other medical problems.

For patients who present with symptoms and signs consistent with a radiculopathy (category C), we elect to perform a single-level decompression and *in situ* fusion with autologous bone graft. Once again, instrumentation is used for individuals who are at greater risk of nonunion or demonstrate excessive motion.

## CONCLUSION

Each intervention presents a unique set of technical demands, potential risks, and complications. Whether

one chooses to address the condition anteriorly, posteriorly, or some combination thereof, success is directly related to achieving a solid fusion. For those individuals without degenerative disc disease or evidence of advanced facet arthritis, direct pars repair provides satisfactory results with limited loss of lumbar motion. The success rate in the presence of preexisting degenerative disc disease or abnormal facets has been clearly demonstrated to significantly diminish over time.

We recommend posterior *in situ* fusion for those symptomatic patients with evidence of disc or facet abnormality. The addition of a posterior decompression in the setting of leg pain without radicular findings does not significantly improve the results and should be avoided. The results in the presence of a true radiculopathy do improve with combined posterior decompression and fusion. Supplemental instrumentation should be considered for those patients at higher risk of developing a pseudoarthrosis, or who demonstrate motion on dynamic radiographs.

In conclusion, the key points when treating patients with symptomatic low-grade slips are to determine whether they are suitable surgical candidates, and to determine what is the most efficacious, reliable, and safest means of addressing the pathology. Regardless of the surgical procedure performed, the ability to obtain a solid fusion and thereby reduce pathologic motion and the risk of progression provides the patient with the best chance for a positive outcome.

## CHAPTER 64

# Surgery for High-Grade Spondylolisthesis

Marek Szpalski and Robert Gunzburg

---

Spondylolisthesis is a common condition reported in 5% to 6% of Caucasian males and 2% to 3% of Caucasian females (1). It can be encountered in up to 50% in Alaskan Inuits (2). In the latter case, Stewart suggested that this high frequency could be due to repeated falls on the ice may be associated with a predisposing weakness of the pars (3).

This chapter discusses high slippage isthmic spondylolisthesis classified by Wiltse as IIA (4). In the Meyerding classification, those high-grade slippages are classified as III and IV, meaning a displacement of more than 50% (5). A further degree consisting of the fall of the vertebra in front of the sacrum is referred to as spondyloptosis. Progression of slip is usually reported at 6% in adult life, so a relatively small number of subjects will fall into this category.

The existence of type I or congenital spondylolysis is controversial. Dysplastic articular process may predispose to pars elongation and separation, but we did not find any published report of spondylolysis found at birth. Spondylolysis does not therefore appear to be a congenital lesion and developmental errors are not considered relevant to its etiology (6). It does not appear that spondylolysis was ever described in newborns or very young infants. Repetitive stress seems to be the main etiologic factor although hereditary factors may predispose to the injury (7,8). Once separation of the pars occurs, however, so-called type I is indistinguishable from type IIA.

Contrary to other stress fracture locations, spondylolysis only rarely heals spontaneously.

In the vast majority of subjects, the condition is present at the L5S1 level. The frequency is higher in subjects presenting frequent lumbar hyperlordosis—dancers, gymnasts, weight lifters, javelin throwers, football linemen, and so forth.

Higher grade lesions will provoke different mechanical or neurologic problems. On the neurologic point, root impingement and stenosis (foraminal, lateral, or central) can be encountered. This can be made worse by the fre-

quent degenerative changes and disc bulge accompanying spondylolisthesis. The tension of the dural sac over the upper edge of the S1 vertebra can even induce a cauda equina syndrome.

Higher slippage degree will influence the sagittal spinopelvic alignment and balance that may be very disabling, as it will eventually involve knee flexion and spine hyperextension.

Although even high-grade lesions can be silent, symptomatic high-grade spondylolisthesis will often require adequate surgical treatment.

The surgical options will include simple decompression, fusion *in situ* with possible decompression, reduction, and fusion. Fusion can be anterior or posterior and reduction can be accompanied by partial or total resection of the slipped vertebra.

### INDICATIONS FOR SURGERY

In children and adolescents, all subjects with a slip over 50% or with documented progression of a slip from 25% to 50%, regardless of symptoms, will be candidates for surgery (9). Patients with L1 to L4 spondylolisthesis often have a poorer prognosis than those with a lower lesion. However some authors have described a very long-term follow-up of high-grade spondylolisthesis patients treated conservatively with good results, although surgical treatment resulted in a higher and faster symptomatic improvement (10).

In adults the main indication for surgery will be based on the importance of the symptoms, persistent leg pain, neurologic deficits, or cauda equina syndrome are definitive indications. The same applies in cases in which major sagittal imbalance induces severe standing, walking, or visual difficulties (11). Although back pain is more frequent in patients with higher slip (12), surgery for isolated back pain is still discussed as the exact source of nociception is unclear. Highly disabling back pain is a relative indication; however, the patient must be aware

that a full resolution of pain is not certain. Caution should be exercised before deciding to operate for isolated back pain in even high-grade spondylolisthesis patients. Only realistic surgeon and patient expectation will avoid major and some times medicolegal disappointments.

Goals of surgery in symptomatic high-grade spondylolisthesis comprise the resolution of back and leg pain as well as the restoration of anatomic balance and function by the fusion of the affected levels. This surgery, however, is extremely challenging and accompanied with a high rate of complications. The aim of achieving an anatomic reduction may lead to an increase in back or leg pain. Surgical therapy should therefore always be considered with the utmost caution.

High-grade spondylolisthesis is relatively rare and large series, especially randomized comparative studies, difficult to perform. Possible techniques include decompression, posterior fusion *in situ*, posterior decompression and posterolateral fusion without reduction, 360° *in situ* fusion, 360° fusion after reduction, L5 resection, and L4 to S1 fusion.

### Decompression

Some authors have advocated isolated decompressive laminectomy and presented satisfactory results (13) when they performed an associated partial facetectomy. However, this study treated degenerative lesions of moderate grade. Other studies present a success rate around 70% (14,15).

Laminectomy alone (even total) does not seem sufficient to decompress all the neural structures and more specifically the foramen. It is often necessary to remove the remaining pars interarticularis and all callus fragments (Gill nodules) (14). At the L5-S1 level it will sometimes be necessary to resect the sacral dome anterior to the cauda equina.

More often further slippage, with worsening of symptoms, often occurs after isolated decompressive surgery (16–18).

For all these reasons it appears that decompression alone does not seem an adequate treatment of high-grade spondylolisthesis (19), and significant decompression should be followed by fusion (12).

### Fusion *in situ*

Fusion *in situ* is a widely accepted treatment for lumbosacral spondylolisthesis (20). It is a safe and reliable procedure and excellent results have been reported in the cases of high-grade displacements. It is the most common type of surgery performed in the treatment of spondylolisthesis. Posterior, anterior, and combined procedures have been described. The number of levels involved in the fusion has been subject to discussion. It is generally

believed that in case of severe displacement at L5-S1 (Meyerding grade III and IV) the fusion should include L4 and down to the sacrum. Some authors even advocate L4-S1 fusion in lower-grade lesions (21).

### Posterolateral Fusion

Posterolateral *in situ* fusion has been routinely recommended (18,22,23), in spite of relatively high pseudoarthrosis rates (24–26).

This procedure can be performed by midline or bilateral lateral approach. In the presence of neurologic signs or symptoms, decompression will be realized. Ricciardi et al. reported good results after transpedicular fixation combined with systematic L5 root decompression (27). However, adjuvant extensive decompression may favor pseudoarthrosis and Carragee found no advantages in performing decompression in patients without serious neurologic deficits (19).

As in all posterolateral fusions obesity or a history of smoking induces of higher risk of pseudoarthrosis. In presence of nonfusion, slippage can gradually increase. Among the complications described, acute cauda equina syndrome in the early postoperative period is a rare but dramatic event. Neurologic complications and even cauda equina syndrome can also occur after *in situ* fusion (28). In a series of 189 patients, Schoenecker et al. reported a 6% cauda equina incidence in patients who had no neurologic dysfunction before surgery (28).

Some authors have attributed cauda equina lesions to mechanical damage endured during decortication before bone grafting (29). Nevertheless, good functional results have been reported at long-term follow-up. Johnson and Kirwan report an average follow-up of 14 years with favorable outcome (23). It appears that even though there is no correction of the sagittal pelvic balance, kinematic and temporal parameters of gait can be normalized after *in situ* fusion (30).

Instrumentation is widely used and transpedicular fixation appears to be the material of choice. However, the use of instrumentation remains a controversial subject. Many studies present good results with instrumentation (31), however, few are prospective and controlled. Some prospective controlled studies have reported better fusion rates but no change in outcome with instrumentation than with noninstrumented fusion (19,32). In a mixed cohort of diverse indications including spondylolisthesis, Zdeblick reported better fusion rates and outcomes (33). However, in another study Thomsen did not show any differences in fusion rate or outcome (34). The same results were reported by France in a mixed cohort (35). McGuire showed no difference in fusion rate between instrumented and noninstrumented fusion (36).

A metaanalysis of the available controlled trials showed a slightly significant advantage of instrumenta-

tion to produce bone fusion and a nonsignificant trend toward better outcomes (37). A Cochrane Review of surgery for degenerative spondylolisthesis shows no advantage of surgical treatment over conservative alternatives (38).

However, those controlled studies usually refer to low-grade or degenerative spondylolisthesis and there does not appear to be similar controlled work in the area of higher grade lesions. In slips, over 50% adjunction of instrumentation seems a reasonable and safe alternative. (17). Nevertheless, the reported pseudoarthrosis rates are high, ranging from 17% to 40%. Bending of the fusion mass and instrumentation failure have also been described and increased slippage can occur in the absence of fusion even with the use of adequate instrumentation.

### Posterior Interbody Fusion (PLIF)

The use of PLIF has been described in grade I and II spondylolisthesis (39,40) and in grade III and IV after reduction (41) but does not appear to have been described in grade III and IV *in situ* fusion.

Bohlman and Cook described a fibular strut placed posteriorly from the sacrum into the body of L5. This technique appears interesting in the stabilization of higher grade lesions (42). A similar technique has been used by Esses et al. (43).

### Anterior Interbody Fusion (ALIF)

Isolated ALIF has been suggested (44) and described for the treatment of lower-grade spondylolisthesis since the 1930s (45), and ALIF cages have been used routinely (26,46).

Some authors report a high rate of progressive slippage after ALIF when slippage is over 50% (11). In high displacement cases, the size of the contact surfaces available for fusion is very limited. It does not appear that cages have been used in the *in situ* fusion of high-grade lesions.

Verbiest has described a technique using a fibular graft placed between L4 and the sacrum in the stabilization of high-grade spondylolisthesis (47). This technique provides a good anterior column support and the anterior fibular graft has been used with success by other authors (48).

The addition of an anterior fibular strut has also been described as a salvage procedure in the treatment of failed isolated posterior fusion with good reported results (49,50).

Isolated anterior intervertebral cages or dowels are not appropriate in the treatment of spondylolisthesis as they are unable to stand the constant high shear loads encountered in lumbosacral spondylolisthesis combined with an immobile sacral segment and highly mobile lower lumbar area (51,52).

### Circumferential Fusion (360°)

Several authors propose a combined anterior and posterior stabilization, especially in the adult patient and if a wide decompression has been performed (48). Smith and Bohlmann described good results with a combined *in situ* fusion through a single posterior approach, partial resection of the first sacral segment and an anterior interbody fibular graft combined with a posterolateral fusion (53). Roca et al. (54) have also reported favorable results with the same technique in a group of patients presenting with an average slip of 77% and a slip angle of 36°.

It appears that circumferential fusion has been mostly described in combination with a reduction of the slippage.

### Reduction of Spondylolisthesis

The first trials of reducing spondylolisthesis were reported in the 1930s (55); however, poor results and major neurologic complications led to the abandonment of those procedures in favor of *in situ* fusions. In the 1970s, reduction through a two-step posterior and anterior approach with the use of Harrington rods is described (56). Other techniques describe the preoperative reduction by plaster casts followed by posterior instrumentation and fusion with good results (57). The more recent evolution of surgical techniques and efficient instrumentations brought a new interest in reduction of severe spondylolisthesis.

Several reasons can be put forward to advocate reduction of spondylolisthesis. The cosmetic appearance is a first factor to consider as *in situ* fusion does not restore the sagittal balance. Therefore, reduction will improve this cosmetic aspect (58). However, many studies have shown that cosmetic deformity was not considered a major problem by the majority of patients (10,23,31). Some authors even reported that patients who had undergone reduction were less satisfied with their appearance than those who had simple *in situ* fusion (59).

The high pseudarthrosis rate and progression of slippage associated with *in situ* fusion can be improved by performing a reduction (60,61) and avoiding high tensile shear forces across the fusion mass. Yet, this maneuver increases risk of neurologic injury, particularly to nerve root L5 (17). According to Kozak (62), routine release of the lumbosacral ligament in order to avoid injury to the L5 nerve root seems prudent. Molinari et al. (63) found *in situ* fusion to give poor results when severe dysplasia of the posterior elements of L5 are present, in particular small transverse process surfaces.

In a recent retrospective analysis of six cases in which partial lumbosacral kyphosis reduction, posterior decompression, and pedicle screw fixation were performed, Boachie-Adje et al. found that it is the partial reduction

of the slip angle and not the percentage of slip that is important in obtaining optimal results (64). With a similar technique using fibular allograft for the posterior interbody fusion, Smith et al. (65) had good clinical and radiologic results in nine cases.

According to Molinari et al. (63) the addition of long iliac screws reduces the risk of instrumentation failure. Experimental biomechanics studies have shown the advantages of screws purchasing the iliac bone down to the acetabular column (66). Other authors have advocated the use of a second set of sacral fixation points (67). Klöckner stresses the fact that the dome-shaped surface of the sacrum needs to be resected, thus allowing a monosegmental reduction (68).

Grade III and IV spondylolisthesis cases, in which the kyphosis has led to an impairment of the full upright standing position with extended hips and knees, are a primary indication for reduction. Such a reduction can be achieved by either a posterior instrumented approach, a combined anterior and posterior approach (360°), or a vertebral body resection. Slow gradual reduction by means of an external fixator followed by internal fusion and fixation has also been described (69,70). Using this method, Wild et al. report good results, an 84.5% correction of the slip and no neurologic complications (70). Only experienced surgeons should perform these operations and neurologic monitoring is certainly not a luxury. Based on a retrospective analysis of 93 cases of grade III or IV spondylolisthesis, Seitsalo et al. (18) suggested that an attempt to reduce an increased slip angle was warranted in some cases.

Some authors however believe that in adults the risks of reduction outweigh the benefits (53,71,72). These risks consist primarily of neurologic compromise of the cauda equina or the L5 nerve root by lengthening and traction or by impingement against the iliolumbar ligament. The frequency of neurologic complications reported in the literature varies from 6% to over 50% (17,24,63,67,73–76).

An experimental study Petraco et al. suggests that partial reduction be advocated since the risk of stretch injury to the L5 root is not linear and sharply increases during the second half of reduction. Reductions greater than 50% of the width of the L5 body demonstrated the higher root tension and potential for neurologic injury (77).

It appears that reduction of the slip angle is more important than reduction of the percentage slip and that partial reduction of the slip angle is often sufficient to reduce kyphosis and enable stable fixation while decreasing the neurologic problems associated with more complex reduction maneuvers (64). Furthermore, reduction of slip angle allows easier decompressive maneuvers and places the fusion mass in a more compressive position, thus decreasing the risk of fusion mass elongation and pseudoarthrosis. Furthermore, for some authors, such a partial reduction allows the use of isolated posterior

fusion without the need for additional anterior exposure. Smith and Bohlman report good results with partial reduction and fixation with a posterior interbody fibula interposition supplemented by a pedicular fixation (63). Those techniques using an isolated posterior approach decrease the burden and risk of neurologic and vascular complications associated with anterior approaches.

The advantage of the posterior reduction techniques is that they can be completed in one stage. A thorough decompression has to be performed before the reduction is attempted and a fixation by transpedicular screw is mandatory to maintain the position. It is more important to correct the kyphosis than to correct the translation (64). In a report on prospective cases Steffee and Brantigan (78) noted clinical success in 86% of patients with spondylolisthesis.

With posterolateral surgery the fusion mass is under tension. This has led to many cases of nonunion when severe slippage was present. Hu et al. (67) reported on 16 patients and found hardware failure in 5 cases. Boos et al. (79) reported 83% implant failure and pseudoarthrosis rate in patients where postreduction stabilization was performed by an isolated posterolateral fusion. They recommend a combined interbody and posterior fusion since they believe that pedicular fixation systems alone do not allow permanent stabilization.

Due to the problems reported with isolated posterior fixation, many authors have advocated the use of anterior column support (67). Molinari et al. found largely superior results after reduction in those patients with added anterior support compared with those treated by posterior fusion alone. The rate of nonfusion in the latter group was 39% compared to none in the 360° group (25). DeWald et al. also reported a very high rate of solid fusion after 2 years' follow-up after reduction and 360° fusion (24).

Indeed, the combination with anterior surgery where the graft is under compression answers a biomechanical rationale adopted by many (11,24,80,81). These two operative stages can either be performed in one or two separate stages with a one-week interval. Anterior fusion can be obtained by the use of an array of devices ranging from autologous bone (fibula, iliac crest) and allografts to cages of varying shapes and composition. Louis and Maresca have described a technique with a specific instrumentation allowing L5 to be tilted back on to S1 and progressively pushed back in place (61).

Laursen et al. reported good results following partial reduction and fixation by anterior interbody fusion and posterior pedicular screws. There were no complications and good functional outcome (82).

Circumferential fusion also decreases the occurrence of hardware failure.

Reduction of severe spondylolisthesis is a demanding and very long surgery; surgical duration is often around 8 hours (67) and blood loss may be critical. The results of reduction in severe spondylolisthesis are satisfactory but

must be balanced by the risk of permanent neurologic complications. Although for some authors this risk is acceptably low it is, nevertheless, present and much higher than in cases of *in situ* fusion. Therefore care must be taken, in postoperative planning, to compare this risk with the importance of the expected benefits.

### Vertebral Body Resection

Total resection of the fifth vertebral body and fusion of L4 to S1 has been proposed by Gaines and Nichols (83). The rationale was that the shortening would facilitate the sagittal balance realignment and reduce the risk of neurologic impairment. A high rate of complications precluding the wide application of the technique was later reported (84). Out of 16 patients, 12 had early postoperative neurologic troubles and 5 had permanent neurologic motor deficit. Four patients had a revision surgery for pseudarthrosis or fixation failure. This procedure has also been advocated by other authors (85).

The indications for this type of surgery are exceptional. Wild et al. present such a procedure for the treatment of spondyloptosis in an 18-month-old patient with good results after 10 years of follow-up (86).

### CONCLUSIONS

The goal of surgery in high-grade spondylolisthesis is to improve pain, neurologic deficits, and avoid further displacement. Restoration of sagittal balance will be a major goal if kyphosis disallows the patient to stand, walk, or look forward. Patients presenting with such severe sagittal imbalance are at risk of further slippage and subsequent neurologic damage. Cosmetic criteria do not appear to be major surgical indications in most subjects (31).

However, surgery for high-grade spondylolisthesis, and more specifically reduction techniques, carries a high incidence of major complications, mainly neurologic, which are sometimes permanent. Likewise, the incidence of revision procedures for fixation failure is high. In those conditions the risk/benefit ratio for this surgery has to be assessed carefully.

The exceptional nature of this surgery and the small sample sizes encountered in most studies make true randomized controlled studies hardly feasible. The lack of an instrument to record specific outcome makes the problem even more complex. Some authors (65) have applied the Scoliosis Research Society (SRS) outcome questionnaire described by Hafer et al. (87) and modified by Asher et al. (88). However, the SRS instrument was only validated for adolescent scoliosis and validation of the same or another instrument in the context of high-grade spondylolisthesis would be welcome.

Fusion *in situ* appears indicated for pain and minor walking disturbances in the absence of neurologic symp-

toms or deficits. Reduction (essentially partial) will be indicated in more severe cases. Complete reduction or vertebrectomy will only be indicated in a few extremely severe cases.

Surgery in high-grade spondylolisthesis and spondyloptosis is a high-risk surgery and should be restricted to those cases where conservative treatment could not significantly reduce invalidating complaints of low back pain and radiculopathy or walking or forward vision is not possible because of severe sagittal plane imbalance. It should be performed only by experienced surgeons in well-equipped centers.

# High-Grade Spondylolisthesis: Slip Reduction versus *in situ* Fusion

William C. Lauerma and Steven C. Scherping

---

Isthmic spondylolisthesis occurs because of a defect in the pars interarticularis that allows the forward slippage of one vertebra, most commonly L5, on the level below. This defect, called spondylolysis, is presumed to be a fatigue fracture, for the development of which there is a hereditary predisposition, and which is caused by repetitive hyperextension stresses (1).

Spondylolysis is common, with a prevalence of 5% to 6% of the population at skeletal maturity. Approximately 75% of individuals with spondylolysis are seen to have an associated slip, the large majority of which are in the Meyerding grade I (0 to 25%) or less commonly grade II (26% to 50%) categories. Only a small percentage of cases of spondylolisthesis involve slips that progress beyond 50%, into the realm of high-grade spondylolisthesis (2).

The occasional case of true high-grade spondylolisthesis differs from the more common lower-grade cases in several ways. While spondylolysis and isthmic spondylolisthesis, on the whole, are twice as common in males as in females, high-grade slips occur in women as much as four times as frequently as in men. Furthermore, the pathoanatomy of the high-grade slip involves more than just anterior translation of L5 on S1, a fact that has major significance in terms of presentation and, in some instances, treatment. As the L5 vertebral body translates anteriorly it also, once it passes about 50% translation, rolls anteriorly into kyphosis. This lumbosacral kyphosis, measured by the slip angle (Fig. 65-1), alters the biomechanics of the entire lumbar spine; in order to balance the trunk over the pelvis hyperlordosis, above L5, is necessary. The hyperlordosis can then lead to long-term problems including pain, facet joint arthrosis, and central and lateral recess stenosis above the lumbosacral level (3).

The well-described cosmetic alterations seen in high-grade spondylolisthesis are also a function, in large part, of this lumbosacral kyphosis. The kyphotic forward roll

of the body of L5 usually induces a backward rotation of the sacrum, measured by the sacral inclination (Fig. 65-1), with concomitant backward rotation of the entire pelvis. This accounts for the flattening of the buttocks and transverse abdominal crease, which are often cosmetically objectionable in these patients (4).

Finally, in cases of high-grade spondylolisthesis, patterns of nerve root or cauda equina compression differing from those usually seen should be considered. While L5 nerve root entrapment in the L5-S1 foramen is common in the adult with isthmic spondylolisthesis of any grade, it appears to be more common in higher grade slips. Patients with high-grade spondylolisthesis, particularly when there is significant lumbosacral kyphosis, may also manifest cauda equina symptoms due to stretching of the sacral nerve roots over the L5-S1 disc and the posterior aspect of the dome of the sacrum (5). This picture is quite rare in slips below 50%. Finally, it is not uncommon to see stenosis develop above the L5-S1 level, particularly when there has been a previous fusion, in patients with high-grade slips and compensatory proximal hyperlordosis.

### SURGICAL INDICATIONS

The adult patient with spondylolisthesis may present with back or leg pain; failing nonoperative treatment these are the most common indications for surgery in all grades of slip. Patients with higher-grade slips may also present with symptoms of cauda equina syndrome, which are usually mild and chronic and may be easy to overlook. Clear-cut evidence of urinary retention would represent an absolute indication for surgical treatment. Cosmetic considerations may also play a role in treatment decision making. While it is easy to assume that the adult has come to accept his or her deformity, this may not be the case and the patient's perception of the relative impor-

**FIG. 65-1.** Drawing illustrating the pertinent measurements to quantify the deformity in spondylolisthesis. *SI*, the sacral inclination, describes the orientation of the sacrum and pelvis. The slip angle, when positive, measures lumbosacral kyphosis. The percent slip measures the anterior translation of L5 on S1. (From Miller MD, Brinker MR. Review of orthopaedics, 3rd ed. Philadelphia: WB Saunders, 2000:367, with permission.)

tance of his or her appearance must factor into selection of the appropriate operation. In the adult slip progression can occur, although it is uncommon in the absence of prior surgery (6). The presence of progressive spondylolisthesis represents an indication for surgery, however, and current radiographs should be compared to old films, if available, always taken with the patients standing.

## SURGICAL OPTIONS

The surgical treatment of the patient with high-grade spondylolisthesis falls into two categories: fusion *in situ* or reduction and fusion. Nerve root, and sometimes cauda equina, decompression are commonly performed as part of either of these two types of surgeries; radicular or cauda equina symptoms may constitute part of the patient's symptom complex or decompression may be undertaken as a prophylactic measure. Nerve root decompression is universally recommended when reduction is undertaken and is employed by some surgeons when performing *in situ* fusion.

Fusion *in situ* is most commonly performed through a posterior approach, although circumferential fusion may be employed. Anterior fusion for high-grade spondylolisthesis is rarely employed as a stand-alone primary operation. Nerve root decompression is usually necessary as an adjunct in case of fusion *in situ* as most adults presenting

with high-grade spondylolisthesis have signs or symptoms of radiculopathy.

Posterolateral *in situ* fusion for high-grade slips generally extends from L4-S1 and the use of pedicle screw instrumentation, in addition to autologous bone grafting, is now routine in such cases. The rationale for extending the fusion to L4 in children and adults stems from the mechanically disadvantaged position of the L5 transverse processes, which are also commonly quite small, relative to the sacral ala. Extension of the bone grafting up to L4 is considered necessary in order to create a fusion bed that is under compression (L4-S1) rather than under tension (L5-S1) (4).

A significant risk of nonunion exists with posterolateral fusion, with or without instrumentation, for high-grade spondylolisthesis (7). To offset this risk Smith and Bohlman have described fusion of both the anterior and posterior columns, through a single posterior approach. In addition to traditional posterolateral fusion a fibula dowel graft is introduced through a drill hole in the sacrum, across the L5-S1 disc, and into the body of L5 (8) (Fig. 65-2). A more commonly employed alternative to the posterolateral fusion is a combined anterior and posterior approach. Transperitoneal or retroperitoneal exposure of the L5-S1 level allows for discectomy and grafting. Alternatively, a fibular strut graft can be introduced into the body of L5, across the disc space, and into the sacrum. Either anterior technique is followed by posterolateral fusion and instrumentation.

The techniques used for slip reduction have evolved over the last quarter century, and much of the experience reported has been in adolescents. Many techniques, particularly those involving cast reduction, traction, or other indirect means, are rarely employed at this time and are unsuitable for the adult patient.

The major risks of reduction of high-grade spondylolisthesis include neurologic injury and instrumentation failure, with loss of reduction (3,7,9-11). Both of these may be minimized by, and most authors stress the importance of, accepting less than complete reduction. This clearly lessens the risk of nerve root injury, a finding that Petraco et al. have explained in a study on cadavers demonstrating the disproportionate strain in the L5 root occurring during the last 50% of reduction (12). Since it is the lumbosacral kyphosis, in a high-grade slip, which causes most of the mechanical problems, it is now well accepted that kyphosis reduction, rather than complete reversal of the anterior translation, should be the primary goal of surgery (12,13).

Currently the options commonly used for reduction include a posterior instrumented reduction using gradually applied distraction, posterior translation of L5, and lumbosacral extension (Fig. 65-3). This technique, originally pioneered by Edwards, takes advantage of viscoelastic stress-relaxation and is not suitable for some

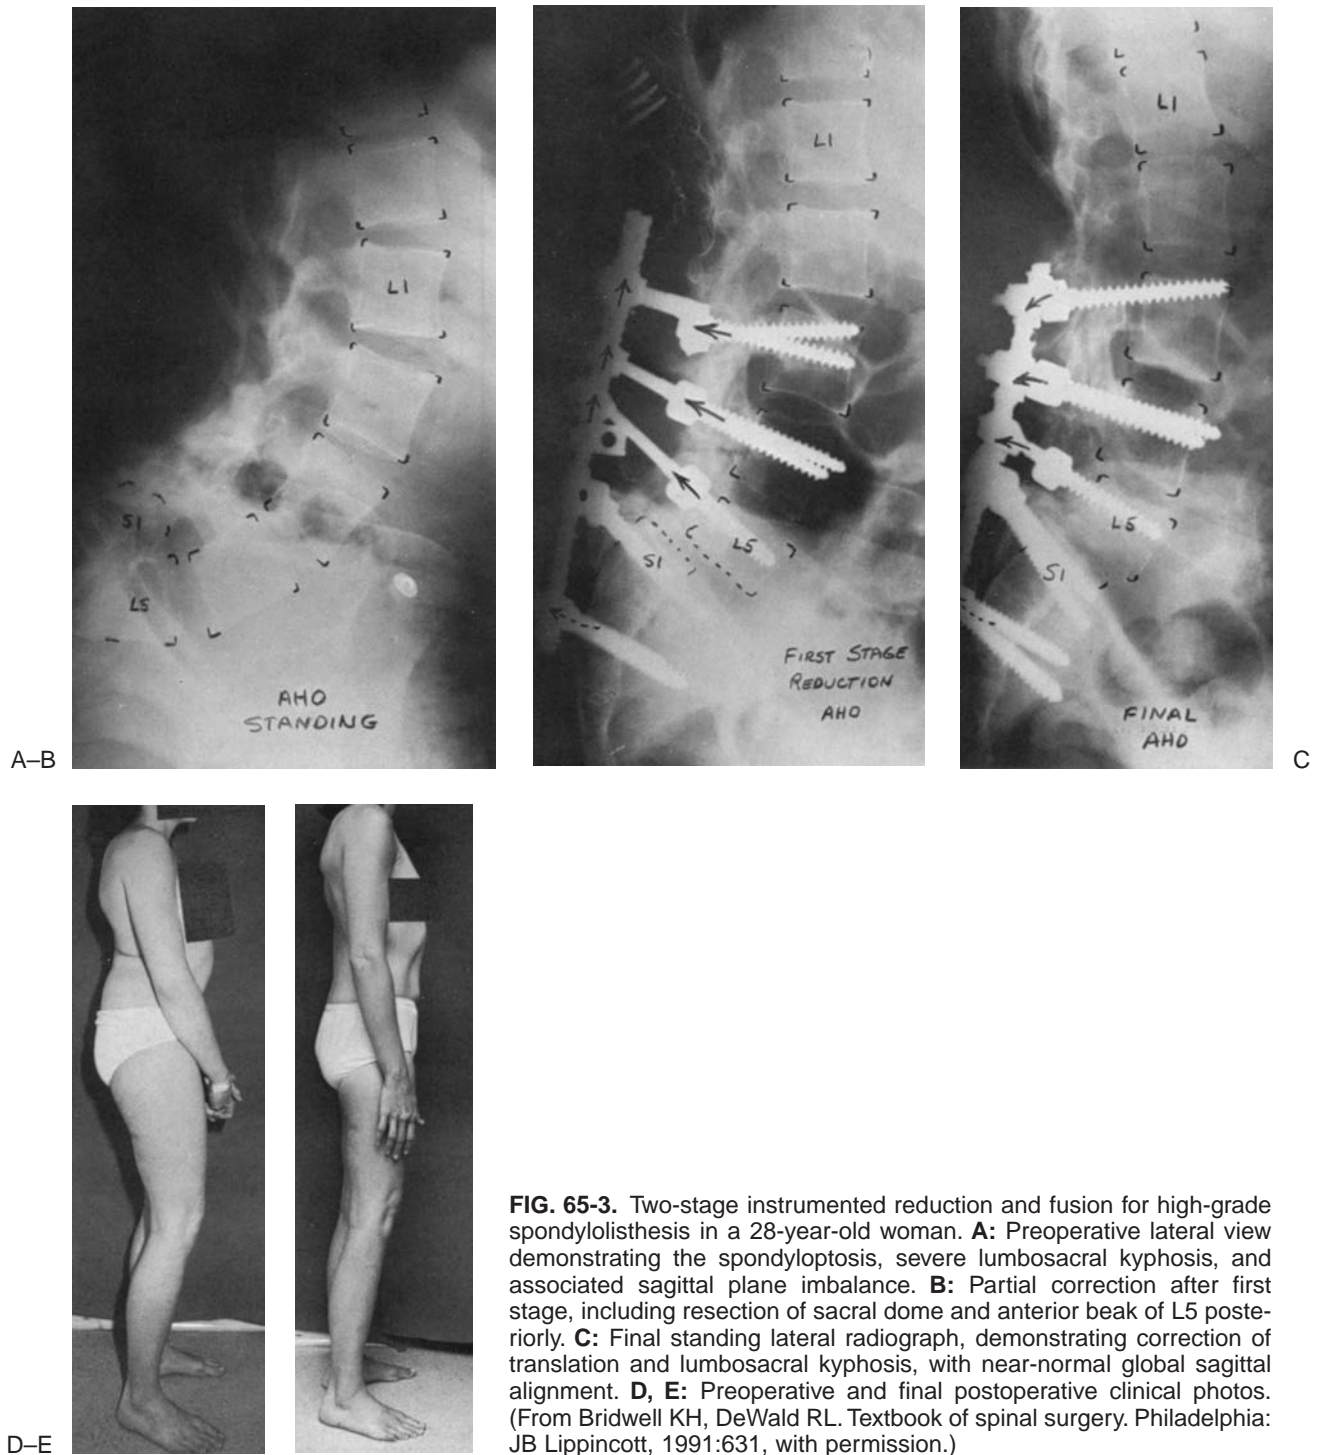

**FIG. 65-2.** A 46-year-old woman with progressive spondylolisthesis following a prior attempt at fusion. **A:** Marked lumbar kyphosis with an almost vertical sacrum. **B:** The patient's lateral radiograph shortly after the Bohlman procedure. The *arrowheads* mark the corners of the fibular strut graft. **C, D:** The anteroposterior and lateral views 7 years after the patient's second surgery. She had excellent relief of her pain. Note, however, the persistent lumbar kyphosis and compensatory hyperlordosis proximally.

adults with more rigid curves or who have had prior attempts at fusion (3).

Transforaminal interbody fusion techniques can facilitate reduction and enhance arthrodesis rates when used in conjunction with instrumented posterior reduction. Following foraminotomy and distraction, subtotal L5-S1 discectomy, working through both foramina, is performed.

This serves to increase flexibility of the deformity at the time of posterior translation and extension. The disc space can then be grafted, with a structural graft if desired, to provide fusion in both the anterior and posterior columns (14).

An alternative approach is to combine anterior L5-S1 and L4-L5 discectomy with instrumented posterior

**FIG. 65-3.** Two-stage instrumented reduction and fusion for high-grade spondylolisthesis in a 28-year-old woman. **A:** Preoperative lateral view demonstrating the spondyloptosis, severe lumbar and lumbosacral kyphosis, and associated sagittal plane imbalance. **B:** Partial correction after first stage, including resection of sacral dome and anterior beak of L5 posteriorly. **C:** Final standing lateral radiograph, demonstrating correction of translation and lumbar and lumbosacral kyphosis, with near-normal global sagittal alignment. **D, E:** Preoperative and final postoperative clinical photos. (From Bridwell KH, DeWald RL. *Textbook of spinal surgery*. Philadelphia: JB Lippincott, 1991:631, with permission.)

reduction and fusion. Greater flexibility, lending to easier reduction, is achieved with this method. In higher grade slips or cases of spondyloptosis, however, it can be exceedingly difficult to visualize the L5-S1 disc that becomes trapped between the L5 vertebral body and the front of the sacrum.

A final alternative, popularized by Gaines, is resection of the entire L5 vertebrae through a combined anterior

and posterior approach, followed by reduction of L4 onto the sacrum and instrumented L4-S1 fusion. The advantages ascribed to this technique include lesser risk of neurologic injury and ease of achieving reduction (15), although mechanical and neurologic complications have been reported (16). The Gaines procedure probably represents, however, the most reliable reduction procedure available for high-grade slips when there has been a pre-

vious attempt at fusion or when there is severe lumbosacral kyphosis resulting in the L5 vertebral body descending anterior to the sacrum (17).

Essentially all authors who describe modern techniques of slip reduction stress the importance of thorough neural decompression (3,4,12). Even in patients without overt radiculopathy, aggressive foraminotomy allows visualization of the L5 nerve roots that must be checked and rechecked many times throughout the course of the reduction of the slip. In some cases resection of the L5-S1 disc and even partial resection of the dome of the sacrum is employed to decompress the sacral roots and facilitate reduction.

### Fusion *in situ* versus Reduction

No aphorism is more appropriate, when considering the right treatment for the adult with high-grade isthmic spondylolisthesis, than that admonishing the surgeon to “fit the operation to the patient, not the patient to the operation.” Selecting the right operation requires considering individual factors in the patient’s presenting complaints and past history as well as physical findings and radiographic criteria.

What does the patient want from surgery? Most adults are reluctant to identify cosmesis as a major part of their concern. The surgeon, therefore, needs to present the effect that one operation, or another, is likely to have on the patient’s appearance. Where is the pain? While either approach is likely to relieve low back pain or leg pain, some patients have chronic fatigue pain in the upper lumbar and thoracolumbar region. This often is caused by sagittal plane imbalance induced by the lumbosacral kyphosis and relief may be less predictable with *in situ* fusion techniques (Fig. 65-4) (3).

Has the patient had surgery before? The timing and type of such surgery may have an impact on the optimal procedure. A recent decompression without fusion with rapid slip progression often lends itself to attempted reduction. On the other hand an established nonunion at the lumbosacral junction, without motion, often requires extensive surgery to achieve reduction and may be better suited to *in situ* fusion techniques.

Physical findings typically supplement factors in the history. Marked sagittal plane imbalance, manifested by compensatory hyperlordosis and a “crouched posture”, often results in fatigue-type pain in the mid-back and is only likely to be altered significantly with reduction. Other physical findings consistent with severe spondylolisthesis and sagittal plane decompensation include flattening of the buttocks, a transverse abdominal crease, and trunk shortening with the lower ribs sitting on the lateral iliac crests; these rarely improve with *in situ* fusion. Finally, certain radiographic findings favor one approach or the other, although the radiographs typically reflect what is seen on physical examination. Some patients have

**FIG. 65-4.** A 46-year-old woman, approximately 30 years after *in situ* fusion for high-grade isthmic spondylolisthesis. Lateral radiograph demonstrates sagittal plane imbalance and hyperlordosis from L1 to L5. She has chronic thoracolumbar and lumbar fatigue-type pain.

relatively high-grade slips but do not develop a particularly severe lumbosacral kyphosis; in these individuals, who often have less dramatic physical findings, *in situ* fusion is advantageous. Other patients have such severe kyphosis, and sagittal plane decompensation, that even a fusion from the transverse processes of L4 to the sacral ala would lie outside the compressive “anatomic zone”, described by Bradford as the imaginary proximal extension of the sacrum (17). These patients require either circumferential fusion *in situ* or reduction (at least partial) to establish a favorable fusion environment.

The major clear-cut advantage of *in situ* fusion is safety (3–5,9,10). While nerve root injury and even cauda equina syndrome have been reported following fusion *in situ*, major permanent deficits are uncommon. Virtually all reports of spondylolisthesis reduction, however, note the occurrence of neurologic complications. These deficits have been reported following all techniques as well, including noninstrumented reduction, L5 vertebrectomy, combined anterior and posterior approaches, and gradual instrumented reduction. The reported incidence of root deficits, usually at L5, ranges from 0 to 40% (3,4). Cauda equina syndrome following reduction is less common. The majority of neurologic deficits, including root and cauda equina, improve but most larger series contain patients with permanent disability. Amundson et al. have proposed several maneuvers that may be used at surgery to minimize the risk of neurologic injury. These include either staged reduction (with a 1- to 2-week interval) or spine shortening by virtue of a sacral dome osteotomy in cases where excessive axial lengthening, particularly of rigid deformities, is anticipated (Fig. 65-2). Neurologic

monitoring, including one or more wake-up tests, can be used to alert the surgeon to root compromise (5). As a final safeguard, accepting partial reduction often lessens the neurologic risk (13).

Other advantages of *in situ* fusion are less clear-cut. It would appear that reduction is technically more complex, with increased operating room time and cost, increased blood loss, and monitoring expenses. Some *in situ* techniques, however, call for a combined anterior and posterior approach, require extending the fusion cephalad, and may have a higher long-term failure rate from nonunion or slip progression. These “costs” may offset the complexity of reduction.

Heller et al. have described a number of potential advantages of reduction, fixation, and fusion for spondylolisthesis. These include reduced risk of postoperative progression, more rapid pain relief, the ability to more aggressively decompress the nerve roots without fearing instability, increased fusion rates, limited fusion length, and the restoration of normal spine mechanics and body posture with improved appearance (7). Only the last of these advantages is universally accepted, while the others have not been fully documented. Fusion *in situ* for spondylolisthesis has a nonunion rate reported to be between 0 and 40%, with a risk of slip progression as high as 50%. The reported incidence of nonunion following reduction and fusion for high-grade spondylolisthesis varies from 0 to 38%, sometimes with slip progression. It should be noted, however, that some of these reports, such as Bradford and Gotfried’s series in which 6 of 16 patients developed delayed union, do not involve the use of more modern instrumentation techniques (11). Other putative advantages of reduction, while potentially valid, depend somewhat on surgeon bias; advocates of *in situ* fusion do not compromise the extent of their nerve root decompression in most cases and would likely agree that the rare patient in whom partial sacrectomy, or extensive discectomy is needed to achieve adequate decompression requires instrumentation and fusion.

## CONCLUSION

Many factors in a given patient’s history, physical examination, and radiographic evaluation need to be considered when determining *if* surgery is necessary, and if so what procedure is best *for that patient*. Younger adults with high-grade isthmic spondylolisthesis frequently require surgical treatment and there is no one option that

is right for all such patients. Advocates of *in situ* fusion cite numerous advantages, the most widely accepted of which would be a decreased risk of neurologic injury. Instrumented reduction and fusion, while offering a number of potential benefits, clearly is able to restore more normal mechanics to the lumbar spine, resulting in an improved appearance and posture. Careful analysis of the patient’s pathologic anatomy, signs, and symptoms allows the surgeon to offer the patient the procedure with the most favorable risk/benefit ratio.

## CHAPTER 66

# Adult Scoliosis

Yizhar Floman

---

For many years scoliosis was considered a condition that starts exclusively during skeletal growth either in childhood or adolescence, not in adult life. Indeed, scoliosis is common in adolescence (4% of the population) and may carry forward into adult years as an untreated condition. However, more recently it has been recognized that scoliosis also can start *de novo* during adult life. For practical reasons, adult scoliosis is defined as a presentation of spinal deformity after skeletal maturity (usually after the age of 20 years). Adult scoliosis may start before skeletal maturity, but treatment may not be sought until later in adult life; alternatively, it may present as a *de novo* spinal deformity in adult life. The most frequent type, present before skeletal maturity, is idiopathic scoliosis. On the other hand, *de novo* scoliosis usually arises because of advanced degenerative disc disease, osteoporosis, or both. Adults also may present with a spinal deformity following a previous surgery for degenerative disc disease (DDD) or as a sequel to a previous fusion surgery (e.g., adjacent level disc degeneration with scoliosis or iatrogenic flat back).

The predominance of the literature dealing with scoliosis remains focused on adolescent spinal deformities. The natural history of adult spinal deformities is less known. Nevertheless, as more adults with scoliosis seek treatment, more interest and research focus on the natural history of these complex deformities in adult life and their management. Aside from the disfigurement caused by the spinal deformity, pain and disability may become a major problem. The recent awareness of the public toward quality of life issues and not just longevity may bring adult scoliosis into the focus of attention; the condition may soon become a significant health care problem.

### PREVALENCE

The prevalence of adult scoliosis is probably on the rise because of increased longevity in the Western world.

Lonstein estimated that there are about half a million adults with spinal curves (including thoracic curves) 30° or greater in the United States (1). The two most common types of curves that are encountered in adult life are idiopathic and degenerative scoliosis. The former is a condition that starts in childhood or adolescence, and progresses over the years with superimposed DDD that becomes symptomatic in adult life. On the other hand, degenerative scoliosis is a *de novo* type scoliosis secondary to DDD that developed on a formerly straight spine. Scoliosis may be the result of the asymmetric involvement of disc degeneration, facet arthrosis, and disc collapse (2). Although it is obvious that the etiology of the two conditions is completely different, adult idiopathic scoliosis and degenerative scoliosis coexist and may share a common final pathway (i.e., increasing disc degeneration with increasing spinal deformity accompanied by pain and disability).

The prevalence of adult scoliosis in the general population has been estimated to be 2% to 15% (3–7). The wide variation in the reported prevalence of adult spinal deformities is because most published reports were based on different population surveys, different gender studies, different age groups, and various inclusion criteria. Strayer (8) reviewed routine chest X-rays of 928 postpartum women and obtained standing antero-posterior (AP) views of the spine of those appearing to have a spinal deformity in the coronal plane (scoliosis). Five percent of the entire study group had curves measuring 10° to 19° and 2% had curves exceeding 20°. The vast majority of women in the study population (77%) were thought to have idiopathic scoliosis (8). Kostuik and Bentivoglio (9) studied 5,000 intravenous pyelograms of patients older than 20 years. Thoracolumbar or lumbar scoliosis greater than 10° was found in 3.9% of the study population. The incidence of lumbar curves was 2.5%, whereas the incidence of thoracolumbar curves was 1.4 % (9). Vanderpool et al. (10) found an even higher incidence of scoliosis (6%) in people 50 years of age and older. Most identified curves in the

study of Kostuik and Bentivoglio (86%) were idiopathic in nature; however, some curves were secondary to congenital or neuromuscular etiologies (9). Biot and Perdrix found 12% prevalence of lumbar curves in a retrospective study of abdominal X-rays (3). Robin (6), in a study of 3,600 persons aged 45 to 84 years who were chosen at random from electoral lists, found that 15% had a thoracolumbar or lumbar curve of more than 10°. Perennou et al. (5) described the frequency and characteristics of adult lumbar scoliosis in a prospective clinical and radiologic study. They studied 671 adults (49.8% M, 50.2% F) who were admitted to a spine rehabilitation unit for back pain during an 8-month period (5). The mean age of the patients was 50 years; 30% were older than 60 years. The prevalence of curves greater than 10° was 7.5% (55 out of the 671 patients in the study group). Seventy-two percent of the scoliotic patients were females (2:1 sex ratio). The prevalence of lumbar scoliosis increased with age: It was found to be 2% before age 45, 6% between 45 and 59 years, 15% in patients older than 60 years (5). The mean Cobb angle was 21°. Only 14% of the patients reported about a known deformity in their adolescent years. Korovesis (4) in a similar study on adult scoliosis found that right-sided lumbar curves were as common as left-sided curves (as opposed to the predominance of left-sided lumbar curve in adolescent idiopathic scoliosis).

In summary, it may be noted that the prevalence of adult scoliosis rises with age. More recent studies show more equal numbers of degenerative and idiopathic type curves while early surveys reported that the majority of adult curves were idiopathic. There are a significant number of right lumbar curves and the female to male ratio is smaller than in comparable series of patients with adolescent idiopathic scoliosis.

### PATHOGENESIS AND CLASSIFICATION

Adult scoliosis can be divided into two main subgroups; individuals with previous history of scoliosis before the end of skeletal maturity and individuals whose scoliosis started in adult life (*de novo*) (Figs. 66-1,66-2). Contributing factors for adult onset scoliosis are degenerative disc disease, osteoporosis (10,11), and prior back surgery. Although the association between adult scoliosis and DDD is obvious, it is less so in relationship to osteoporosis. Velis et al. (12) found a significant reduction in bone mineral content in young women with idiopathic scoliosis. The incidence of adult scoliosis in women with osteoporosis also is higher (10,13). Vanderpool et al. (10), Healy and Lane (13), and Velis and Thorne (14) found a positive correlation between osteoporosis and increased prevalence of scoliosis in an older adult population. Robin et al. were some of the few investigators to find no correlation between degenerative scoliosis and osteoporosis (6). Nevertheless, it is well established that vertebral osteo-

**FIG. 66-1.** Antero-posterior X-ray of the lumbar spine in a 55-year-old woman with low back pain. Note that the lumbar spine is straight with no apparent deformity.

porosis and disc degeneration with facet joint arthrosis coexist in the elderly population (15).

Regardless of the etiology, adult scoliosis is characterized by vertebral structural changes with translatory shifts (i.e., lateral olisthesis accompanied by degenerative

**FIG. 66-2.** Antero-posterior X-ray of the lumbar spine of the same patient as in Figure 66-1, 7 years later. Note that a scoliotic curve has evolved (*de novo* scoliosis) with marked rotation at L2.

**FIG. 66-3.** Antero-posterior X-ray of the lumbar spine in a 64-year-old woman with low back pain. Note the marked degenerative lumbar scoliosis with lateral spondylolisthesis at L2-3.

disc and facet joint arthrosis). Although the magnitude of these curves usually is mild, only 10% develop curves that exceed 30°; lateral vertebral subluxation (lateral spondylolisthesis) is observed more frequently (Fig. 66-3) (13,14). The degenerative process is either the primary event leading to a spinal deformity or superimposed as a secondary event on a preexisting curve that started before skeletal maturity.

Therefore, adult thoracolumbar or lumbar scoliosis may be classified as follows:

1. Primary adult curves: true adult onset deformity (*de novo* scoliosis) resulting from degenerative disc disease, osteoporosis, or both. This type of deformity is often associated with loss of lumbar lordosis (16).

2. Secondary adult curves:

- a. On the top of a previous stable adolescent curve (at the end of skeletal growth, up to 30° to 40°). In these cases, a previously stable curve becomes unstable because of superimposed degenerative changes with or without osteoporosis.

- b. On top of a previous unstable progressive adolescent curve (at the end of skeletal growth). The curve continues to increase in magnitude in adult life because of its inherent biomechanical behavior and also as a result of superimposed degenerative process.

In both primary and secondary adult scoliosis, the degenerative process plays a central role in the loss of lumbar lordosis and may even result in thoracolumbar kyphosis (Fig. 66-4).

## CLINICAL PRESENTATION

It is common for the spinal health care provider to be presented with an adult patient with a spinal deformity accompanied by loss of lumbar lordosis, trunk imbalance, and significant mechanical back pain. When obtaining the history it is important to establish whether curve progression has taken place. Previous radiographs are not available in many cases (or are inadequate to determine if curve progression took place). Important clues in the history taking are loss of height or altered waistline, increase in the size of the lumbar paraspinal hump, or the need to alter clothing. Although adult idiopathic scoliosis patients are predominantly women, the percentage of men with *de novo* degenerative scoliosis is greater.

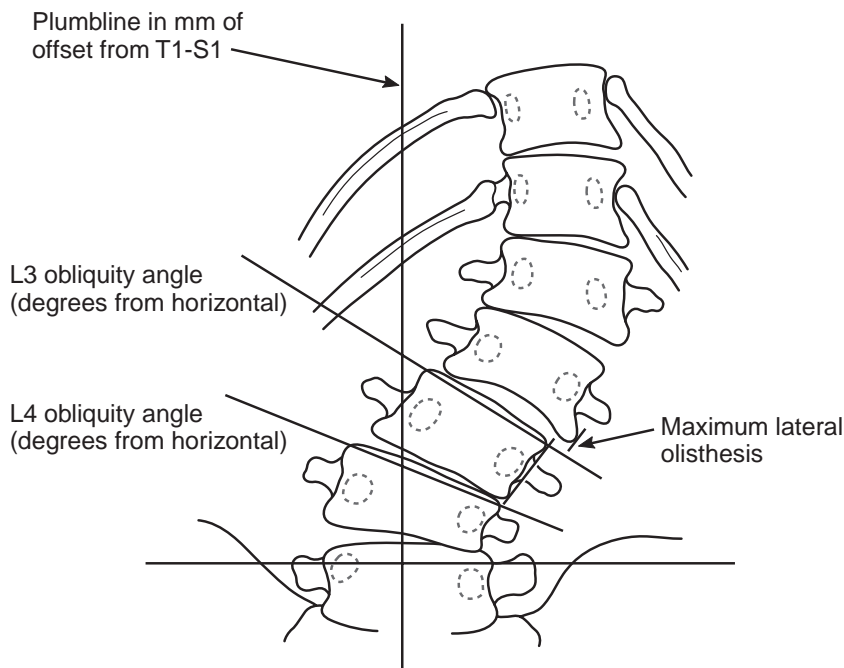

It is well established that adult scoliosis can lead to a painful progressive spinal deformity. Pain may arise not only from DDD and facet arthritis leading to symptoms of spinal stenosis, but also from muscle fatigue caused by the altered biomechanics secondary to the deformity. The latter muscle problem arises from the coronal as well as the sagittal imbalance caused by the progressive spinal deformity. In general, the incidence of back pain in the adult scoliosis patient is about equal to that in age matched controls (9,17–19). Also, the vast majority (91%) of older patients with long-standing adolescent idiopathic scoliosis exhibited degenerative changes of the involved vertebrae (20). Kostuik and Bentivoglio (9) found that 60% of adults with scoliosis had back pain; the same figure was noted in adults without spinal deformity.

However, adult patients with lumbar curves have greater pain intensity (21). When the curve progressed above 45°, prevalence and severity of pain increased (22). Patients with thoracolumbar or lumbar curve patterns, especially with lateral olisthesis tend to have a greater incidence of back pain (23). In reports from more recent studies, chronic back pain was present in 61% of the scoliotic patients versus 35% in control subjects (24). Pain may arise at the apex of the deformity or be referred lower down. A radicular component may be present, especially with advanced degenerative changes (25). Root entrapment is common and occurs more often on the concavity of the curve (5,17).

Pritchett et al. (26) studied 200 patients with degenerative scoliosis. All 200 patients had back pain aggravated by standing and walking, and 142 (72%) had lower limb symptoms including complaints of spinal claudication. Forty-five percent of the patients had neurologic symptoms, mostly paresthesias (26).

Schwab et al. (27) studied 95 patients with adult scoliosis: 33 men and 62 women, whose average age was 59 years. Most had significant back pain (74%); the average visual analog scale (VAS) of pain was 58. Fifty-four percent of the curves were classified as degenerative and 46% as idiopathic. The average lumbar curve magnitude was 36°. The authors found a highly significant correlation between the VAS of pain and the presence on radiographs of lateral olisthesis and obliquity of the L3 or L4 end plates (Fig. 66-5).

Likewise, loss of lumbar lordosis and thoraco-lumbar kyphosis were positively correlated with the self-reported

**FIG. 66-5.** Important radiographic measurements in the assessment of lumbar scoliosis taken from a standing antero-posterior X-ray of the lumbar spine. (From Schwab FJ, et al. Adult scoliosis: a quantitative radiographic and clinical analysis. Spine 2002;27:388, with permission.)

pain. On the other hand, the magnitude of the Cobb angle, the sagittal pelvic tilt index, and the plumbline offset showed no statistically significant correlation with the self-reported pain by the VAS. Symptomatic lumbar curves tended to be larger in the idiopathic group (40° versus 25° in the degenerative group).

Although the disfigurement caused by the lumbar deformity may have adverse psychological consequences, most middle-aged adults cope well with the deformity (23).

In summary, the incidence of back pain has been shown to be similar among adults with and without scoliosis although patients with lumbar curves with lateral olisthesis tend to have a greater incidence of back pain. Also, the severity and chronicity of back pain has been reported to be greater among adults with lumbar scoliosis as compared to age-matched controls without spinal deformity (17,28–31). Symptoms of neurogenic claudication are common in adults with lumbar scoliosis; however, history of pain relief by bending forward or sitting is less reliable than in patients with lumbar spinal stenosis without scoliosis (26).

## NATURAL HISTORY

The natural history of adult scoliosis should be analyzed according to the classification of adult deformities i.e. idiopathic or degenerative. It is recognized however that the two conditions may co-exist.

## IDIOPATHIC CURVES

In a review of 161 patients observed for an average of 40 years at the university of Iowa, 68% of the curves progressed after maturity (19,23,32,33). This trend continued 10 years later (total follow-up time of 50 years!) (24). Although thoracic curves progressed 1° per year, thoracolumbar curves progressed 0.5° per year and lumbar curves even less (.24° per year) (32). From this long-term study, Weinstein and Ponseti (32) identified multiple factors that were associated with curve progression (Table 66-1). For example, lumbar curves of more than 30° with apical vertebral rotation of more than 30% progressed the

most. Right-sided lumbar curves tended to progress twice as much as left lumbar curves (32). Also, marked vertebral rotation combined with translatory shift (lateral olisthesis) was associated with significant curve progression. The thoracolumbar curve pattern manifested the most pronounced amount of apical vertebral rotation. The incidence of translatory shifts increased with time. At 50 years of follow-up, 71% of patients had at least one translatory shift (24). Combined curves tended to balance with age, although the lumbar part tended to progress more than the thoracic counterpart. Weinstein and Ponseti (32) noted greater progression in lumbar curves if L5 was not well seated over the sacrum and apical vertebral rotation was more than 33%.

## DE NOVO DEGENERATIVE CURVES

Robin (6) studied AP X-rays of a randomly chosen population of 3,600 subjects aged 45 to 84 years. These individuals were part of a population survey for osteoporosis in the city of Jerusalem. The authors found that scoliosis was much more common in the elderly population than the reported incidence of scoliosis in school children. Indeed the incidence of scoliosis in various reported series shows a constant rise from childhood to old age. Although the prevalence of adolescent idiopathic scoliosis in the at-risk population (i.e., children 10 to 16 years old) is approximately 2% to 3% (19) and only 10% to 15% of these have lumbar curves, 15% of individuals over 60 years of age have lumbar curves (5).

Robin et al. (7) further analyzed 554 individuals longitudinally for 7 to 13 years (315 women, and 239 men, age range 50 to 84 years). Each individual had one supine AP X-ray of the lower thoracic and lumbar spine. One hundred seventy-nine individuals (113 F, 66 M) had curves exceeding 10°. Fifty-five individuals (10%) developed *de novo* scoliosis during this period (curve range, 1° to 20°). Left-sided curves were common in women; the sex ratio (F:M) increased with curve size. Rotatory olisthesis was found in 34% of the patients, most common at the L3-4 and L4-5 levels. In the supine position, most curves were reduced by about 30%. Korovessis et al. (4) identified 137 individuals with adult scoliosis among a group of 1,154 patients with low back pain during a 3-year period. They excluded from the study group patients with a positive history of spinal deformity, curves smaller than 10°, and osteoporotic vertebral fractures. Ninety-one patients out of the 137 (66%) were available for follow-up evaluation (18 men and 73 women, mean age 67 years). Right-sided lumbar curves were most common (55%). Average curve size was 16.5° (range, 10° to 36°). Lateral spondylolisthesis was present in most cases. Risk factors directly related to curve progression were lateral olisthesis at the apical vertebra, a high Harrington factor (Cobb angle divided by the number of vertebrae included in the curve), and the disc index (4).

Various authors calculated the annual curve progression rate to range from .3° to 3° (4,5,26). Korovessis et al. (4) noted progression of 5° or more in 72% of the curves during an average follow-up period of 3.7 years. Perennou et al. (5) studied 41 patients with a follow-up period spanning 10 to 30 years (mean, 12 years) and found that 73% of the patients showed curve progression of 10° or more (2° to 6° per year, average 3°).

Pritchett and Bortel (26) examined 200 patients with degenerative lumbar scoliosis. Inclusion criteria were a curve greater than 10° with no previous history of spinal deformity. Of the entire patient population, 151 were women and the mean age of the study population was 69 years (range, 50 to 89) (Table 66-2). Curve range was 14° to 60° (mean, 24°). Curve size was greater than 35° in about 20% of the patients. The number of vertebrae involved in the curve was 3 to 6 (mean, 3). Sixty-eight percent of the curves were left-sided. The apex of the curve was most commonly located between L2 and L3. In 67% the Moe-Nash grade of vertebral rotation was 2. An interesting finding was that *degenerative spondylolisthesis* was noted as well in more than half of the patients. (Indeed, many patients with neurogenic claudication caused by spinal stenosis also have some degree of degenerative scoliosis.) An even more common finding was a lateral spondylolisthesis (78% of the patients). Average lateral translation was 8 mm (range, 3 to 8 mm). The lumbar scoliosis was associated with a reduction in the size of lumbar lordosis in 85% of patients. Mean lumbar lordosis was 18° (range, 7° to 45°). All curves with the intercrystal line passing through L5 or L4-5 interspace with vertebral rotation of 2 or more (Moe-Nash) had curve progression. Curves greater than 30° with lateral translatory shift of 6 mm or more also had continued curve progression. Most progression occurred in curves with apices between L2-4 (26).

### ASSESSMENT: IMAGING

Full-length standing radiographs (35 × 91 cm) (postero-anterior [PA] and lateral) allow a thorough assessment of the entire length of the spinal column in both the coronal and sagittal planes. If surgical curve correction is

considered, PA and lateral supine-bending films should be taken to assess curve rigidity and flexibility. In rigid curves that do not significantly correct on side bending views, traction views have been suggested to provide better information regarding curve correctability during surgery (34,35). Others have advocated the “push-prone” view (manual lateral forced correction) for assessment of curve flexibility (36). Recently, Luk et al. (37) advocated the fulcrum bending view as a better predictor of curve correctability (the patient lies in a lateral decubitus position with the apex of the major curve placed over a large bolster) (37).

Patients with symptoms of radiculopathy, without or with neurologic deficit, are traditionally evaluated by myelography followed by post-myelography computed tomography (CT). An alternative to myelography is magnetic resonance imaging (MRI) scans. Magnetic resonance imaging may provide detailed information on central, lateral, and foraminal neural encroachment. Magnetic resonance imaging scans also may provide information regarding disc degeneration and may dictate the extent of spondylodesis. If surgery is contemplated, provocative discography may add further information as to the extent of arthrodesis needed (38). Although provocative discography remains a controversial diagnostic procedure, leading authorities such as Kostuik (39) and Bradford et al. (20,40) recommend its use in conjunction with MRI to determine the extent of distal spondylodesis. However, the lack of prospective clinical studies that prove that the use of provocative discography leads to better clinical results makes the use of discography disputable. Occasionally flexion-extension views as well as facet block injections may be considered as well to determine the extent of instrumentation and fusion (39).

### EVALUATION OF CORONAL AND SAGITTAL BALANCE

#### Coronal Balance

The Cobb angle and number of vertebrae in the curve are recorded (Figs. 66-6,66-7). Next, the end plate obliquity (from the horizontal) of the apical and the end vertebra are measured. Also, the maximal lateral olisthesis (translatory shift) is recorded as well. The central sacral line (from the spinous process of S2) is erected. The plumb line (a parallel line to the center sacral line) is drawn bisecting the center of C7 or T1. The distance between the central sacral line and the plumb line is the coronal decompensation measurement. For certain thoracolumbar curves it is better to evaluate the lateral trunk shift (LTS) (Fig. 66-8). This is calculated by first drawing a horizontal line to the edges of the ribs of the apical vertebra. A perpendicular line bisects the horizontal line. The distance between the perpendicular line and the center sacral line represents LTS (41,42).

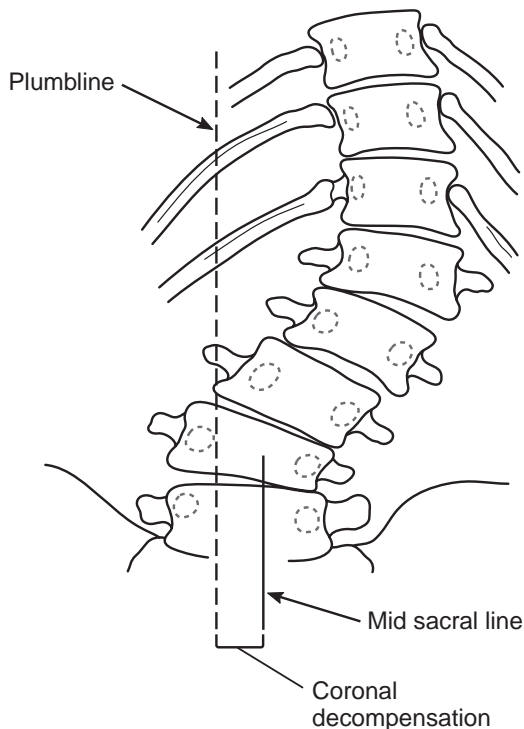

**FIG. 66-6.** Evaluation of the coronal balance. The Cobb angle and the number of vertebrae in the curve are recorded. (Modified from Spine 2002;27:388.)

Apical vertebral translation also can be evaluated by measuring the lateral distance of the apical vertebra from the plumb line.

**Sagittal Balance**

Before the 1980s, little attention was paid to the sagittal contour of the spine and assessment, and treatment of spinal deformities focused almost exclusively on the frontal or coronal plane of the spine. The sagittal contours

**FIG. 66-7.** The plumb line is drawn bisecting the center of C7 or T1. Also the central sacral line is erected. The distance between the central sacral line and the plumb line is the coronal decompensation. (Modified from Spine 2002;27:388.)

**FIG. 66-8.** Evaluation of the lateral trunk shift (LTS). This is calculated by first drawing a horizontal line to the edges of the ribs of the apical vertebra. A perpendicular line bisects the horizontal line. The distance between the perpendicular line and the center sacral line represents LTS. (From Katz DC, Durrani AA. Factors that influence outcome in bracing large curves in patients with adolescent idiopathic scoliosis. Spine 2001;26:2354–2361; Floman Y, Penny NJ, Micheli LJ, et al. Osteotomy of the fusion mass in scoliosis. J Bone Joint Surg 1982;64A:1307–1312; Spine 2001;26:2356.)

of the spine and global sagittal balance have emerged in recent years as crucial factors in assessing spinal deformities. This is especially true when one deals with thoraco-lumbar or lumbar deformities where changes in the lateral profile of spine have a central role in the severity of symptoms in patients with adult lumbar deformities. Indeed, there is a spectrum of involvement in the sagittal contour of the spine in adult scoliosis from hypolordosis to true segmental kyphosis. Therefore, the evaluation of the sagittal balance of the spine is extremely important.

Regional intervertebral relationships are important when assessing the sagittal plane balance, but the global alignment of the spine is even more important. There is a close relationship between the intervertebral angulations in the various regions of the spine (cervical, thoracic, and lumbar) and the global sagittal balance. For example, the lumbar spine compensates with lordosis if the thoracic kyphosis increases. In order to maintain a normal overall sagittal balance (a negative vertical sagittal alignment; see the following) the lumbar lordosis should exceed the thoracic kyphosis by 20° to 30° (Fig. 66-9). This is also true with cervical lordosis. The normal cervical lordosis is about 40°, to which the occipito-atlantal junction contributes about 30° (43). The mean thoracic kyphosis from

T1-12 (apex T6-7) is  $27^\circ$  to  $39^\circ$ , each disc contributing  $1^\circ$  to  $3^\circ$  of kyphosis (44). The thoracolumbar junction is a transition zone connecting the kyphotic thoracic spine to the lordotic lumbar counterpart. The L1-2 disc is the first lordotic segment. The global sagittal alignment at the thoracolumbar junction (T12-L2) is either neutral or slightly lordotic.

The simplest assessment of the sagittal contour is the lateral plumb line, which is dropped from C7 and normally falls posterior to the postero-superior corner of the lumbosacral disc (45). This is referred to as the sagittal vertical axis (SVA) and quantifies the global sagittal balance of the spine (Fig. 66-9). The SVA normally falls anterior to the thoracic spine and through or slightly posterior to the apical lumbar bodies. When the SVA falls anterior to the S1 body, it is considered positive and if it falls behind the S1 body it is considered negative. The normal SVA in adults usually is negative.

The lumbar spine is lordotic; the apex is located at the L3-4 interspace (44,45). The L4-5 and the L5-S1 segments

**FIG. 66-9.** The sagittal vertical axis. (From Gelb DE, et al. *Spine* 1995;20:1351-1358, with permission.)

provide for about 60% of the total lumbar lordosis. The lumbar discs provide for  $47^\circ$  of lordosis and the vertebral bodies only  $12^\circ$  (46). Adolescents have a greater negative sagittal spinal balance than asymptomatic adults (47).

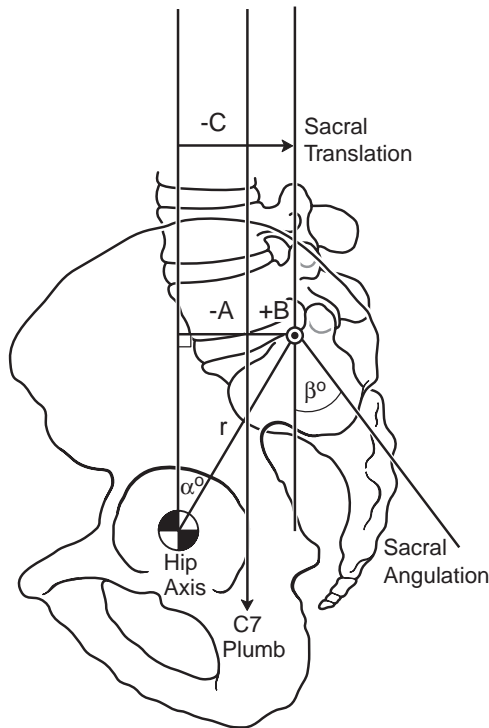

Studies of normal subjects have demonstrated a clear relationship between standing sagittal sacropelvic angulation (sacral inclination) and lumbar lordosis (Fig. 66-10) (48). Jackson and McManus (48) found that sacral inclination correlated with total lumbar lordosis and standing hip extension (hip axis). The pelvic hip axis is located midway along a line drawn between the centers of the femoral heads on the lateral radiograph. These correlations appear to be valid not only in normal volunteers but also in patients with low back pain and DDD (45,48). As segmental lordosis and total lordosis decrease in patients with DDD of the lumbar spine, the vertical sacral inclination increases with increased hip extension. The sacral angulation is an indicator of standing hip extension through the acetabular or hip axis. In patients with DDD, the sacropelvis rotates posteriorly around the hip axis as both the segmental and total lordosis decrease. This results in more vertical sacral inclination with associated hip extension. The sacrum acts as a sixth lumbar vertebra and translates around the hip axis (Fig. 66-10).

The vertical plumb line measurements have no correlation with the sacral inclination. Therefore, it is important to assess both the vertical line balance and the sacropelvic and hip axis. These important biomechanical relationships in the standing position should be kept in mind when assessing patients for fusion surgery. Preservation of lumbar lordosis and normal alignment of the thoracolumbar junction are believed to be crucial factors for the well being of the spine and also affect the long-term results of spinal fusion (49). In a case of hip flexion contracture the compensatory mechanism of spinal balance through hip extension and sacral translation may be compromised (50).

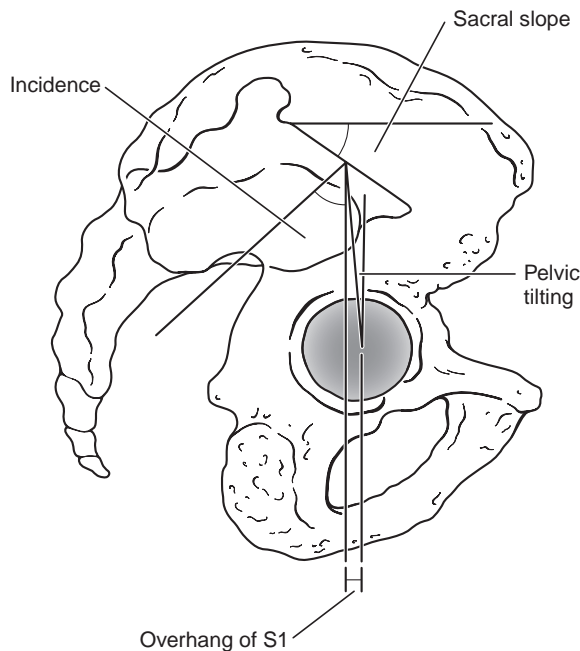

More recently, Lagaye and Duval-Beaupere described the pelvic incidence as the most important radiographic parameter in maintaining an “economical” sagittal balance (51). The pelvic incidence is the angle between the perpendicular to the sacral plate at its midpoint and the line connecting this point to the middle axis of the femoral heads (Fig. 66-11). These authors (51) found that the pelvic incidence has a key importance in the regulation of sagittal balance not only in “normal” subjects but also in scoliotic patients. The greater the apical rotation and the Cobb angle in scoliotic subjects, the lower is the pelvic incidence; the ability to maintain an “economical” sagittal balance also is reduced.

In summary, the assessment of the sagittal contours of the spine and global sagittal balance are of utmost importance in the management of spinal deformities. The sagittal vertical axis and its relationship to the lumbar spine and sacrum, the vertical sacral inclination, and the pelvic incidence are important tools in evaluation of thora-

columbar and lumbar deformities. Thus, pelvic morphology has been found to affect standing lumbosacral lordosis and pelvic balance in adult volunteers, individuals with low back pain, and scoliosis patients (51,52).

# Adult Scoliosis: Indications for Surgery

James A. Antinnes and Serena S. Hu

---

Adult scoliosis is defined as a curve that presents or undergoes treatment after the onset of skeletal maturity. Adult scoliosis can be classified into two groups. The first group is a curve that arose before skeletal maturity but is being treated as an adult curve. Most of these patients have idiopathic scoliosis; rarely congenital or paralytic curves may not require treatment until adulthood.

The second group includes curves that present *de novo*, after skeletal maturity. It may be difficult to differentiate between adult idiopathic scoliosis and *de novo* scoliosis, however the principles of treatment are the same and will be discussed in this chapter. The *de novo* type of curve is typically secondary to degeneration, but may also be due to osteoporosis, or is seen after prior spinal surgery. Patients can develop deformity after wide decompression for spinal stenosis, particularly if a pars fracture develops, but may also present as a complication of a prior fusion. Patients in the latter category may have adjacent segment degeneration or iatrogenic flatback deformities.

Conservative care is usually the initial treatment for management of pain in adult scoliosis. Advancements in spinal instrumentation, improvements in anesthetic techniques, spinal cord monitoring, and postoperative care have improved the ability to safely address complex deformities in patients with adult scoliosis.

### INDICATIONS FOR SURGERY

The indications for surgery can be based on the following criteria:

- back pain failing conservative care
- progressive leg pain or neurologic deficit
- muscle fatigue secondary to spinal imbalance
- curve progression
- progressive pulmonary compromise secondary to deformity
- severe deformity.

As with any patient with mechanical back pain, initial treatment is conservative. A physical therapy program to improve aerobic capacity, strengthen muscles, and improve flexibility and joint motion is the mainstay of treatment (1–6). Local modalities, including heat and massage, as well as nonsteroidal antiinflammatory drugs (NSAIDs), and possibly bracing may provide some relief although none has been shown to prevent curve progression (7). Finally, injections such as corticosteroid injections in facet joints, epidural space, or nerve root blocks may be of value in helping relieve a patient's pain. If surgery is eventually needed despite conservative measures, patient outcomes may be enhanced by improving baseline activity and aerobic activity prior to undertaking surgery.

Obtaining successful surgical outcomes in adult spinal deformity requires an understanding of surgical principles and how these factors apply to each patient's needs and expectations. In general, the goals of surgery in adult scoliosis are to decrease pain, to stabilize the curve, and to halt progression or improve neurologic symptoms.

Pain is the most common presenting complaint, accounting for up to 85% of surgical cases (8–12). Back pain in the area of spinal curvature is thought to be related to the degree of disc degeneration, with subsequent facet arthropathy, rotatory subluxation, and lateral listhesis. Generalized back pain is often related to muscle fatigue from either coronal or sagittal imbalance (13).

Claudicatory leg pain can be due to central lateral recess or foraminal stenosis and often corresponds to the concavity of the curve. Magnetic resonance imaging (MRI) or computed tomography (CT)-myelogram are helpful for diagnosing central lateral recess or foraminal stenosis. Foraminal stenosis can also be suspected with disc space narrowing. Rotatory subluxation can also compromise nerve roots, especially in the concavity at the apex of the curve (14). All of these mechanisms can be dynamic and relieved to some extent by position.

Curve progression in the adult with an idiopathic curve pattern has been well documented (2,7,15–17). Weinstein and Ponsetti studied 40-year follow-up data on patients with idiopathic curve patterns. Thoracolumbar curves between 50° and 75° at maturity increased an average of 22.3°. Lumbar curves had the most progression, especially when the fifth lumbar vertebra was not well seated and when the apical rotation was greater than 33% (17,18). The findings of Kostuik et al. showed similar results (19–21). Furthermore, Kostuik and Bentivoglio found that when the curves were greater than 45°, the prevalence and severity of pain increased significantly (22). This is in contrast to the research of Nachemson and Nilsson who reported that there was not a strong correlation between curve magnitude and pain intensity (4,13). Most studies do agree that the majority of pain emanates from the lumbar spine, increasing in severity if the curve is greater than 45° at skeletal maturity (22–24).

Pain may be improved by up to 70% after successful fusion, but the frequency of the pain does not necessarily improve (25,26). Complete recovery from an involved long segment decompression and fusion can take up to 2 years, especially in older or debilitated patients (27). Therefore an open dialog with the patient prior to undertaking any surgical intervention is crucial in providing the patient with reasonable expectations. As with any elective orthopedic procedure, the more certain the cause of the pain, the more likely one is of a successful outcome.

Finally, a discussion of cosmesis as an indication in the adult with scoliosis is warranted. Johnson and Holt followed 100 patients for over 10 years after a spinal fusion and retrospectively reported that body image and cosmesis played a larger role in the patient's decision to proceed with surgery than was thought at the time of the operation (10,28). While previously thought to be an uncommon indication for surgery, it may be considered after thorough discussions with patients and their families about the goals and expectations. Posterior segmental instrumentation with or without thoracoplasty (29) can often yield excellent correction of the deformity.

Adult patients appear to fall into two categories when considering surgical intervention. Patients under the age of 40 with curves greater than 50° to 60° with chronic pain not relieved by conservative management may opt for surgery. Patients with significant deformity that is unacceptable to them may also be considered for surgery.

In patients over the age of 50 with adult scoliosis it is more common to find complaints of curve progression, back and radicular pain, or pain that is claudicatory in nature. Some patients with curves greater than 90° may benefit from surgery if there is a progressive loss of pulmonary function that is not attributable to an underlying pulmonary disorder. This is not a problem with lumbar scoliosis.

## SURGICAL PLANNING

As part of the surgical planning, many factors need to be considered and the overall health of the patient as well as their expectations must not be overlooked. While many of the basic principles are the same, there are many factors that make surgery for adult scoliosis different and often more challenging than the surgical correction of adolescent idiopathic scoliosis. The presence of disc degeneration, facet arthropathy, and osteopenia are just some of the challenges of surgery in the adult population.

There is also a greater tendency for adjacent segment problems in the adult population. Progressive kyphosis at the end of constriction most commonly occurs proximally. Attention to avoiding ending a fusion at a kyphotic segment can prevent this problem, but may still occur in osteoporotic patients.

Osteopenia is a major concern, especially in older adult females, but should not be overlooked in male patients or any patient with a paralytic curve. Multiple fixation levels and supplemental fixation with sublaminar wires can be helpful (30). For curvatures in which significant correction is obtained, care must be taken not to place too much force on the end vertebra as fixation failure and fracture are certainly possible in osteopenic bone. Segmental fixation can provide increased purchase and creates a larger area for force transmission in deformity correction. A combination of transpedicular screws in the lumbar spine with either segmental hooks and sublaminar wires in the thoracic are typically used. Lumbar pedicle screws have been shown to be superior to hooks with better curve correction and greater correction of compensatory curves below the instrumented levels (31,32). Recent studies suggest that the pullout strength of thoracic pedicle screws is superior to hooks and their use in experienced hands may be warranted when increased strength is needed (33,34).

The possibility for coronal and sagittal imbalance in adults is greater as curves are stiffer than those found in adolescents. Therefore any imbalance is less tolerated in the adult population and flexibility should be assessed preoperatively with bend films and balance assessed intraoperatively with full-length radiographs. It is important to remember that in the adult patient, achievement or maintenance of coronal and sagittal balance is more important than curve correction (15,23,33–38).

In general, adult patients are at an increased risk for developing perioperative complications when compared to adolescents. Major complications include residual pain (5% to 15%), neurologic injury (up to 5%), infection (1% to 5%), pseudoarthrosis (5% to 27%), and thromboembolic event (1% to 20%) (16,21,27,36,37,39–45).

The surgical instrumentation should provide maximum stability and allow early mobilization. For combined

surgery, same day procedures are preferable to staged procedures if physiologically and technically feasible. There have been several studies, most notably by Dick et al., which showed that combined procedures had a lower infection rate than did staged procedures (46). This difference was attributed to patient malnourishment and subsequent inability to fight potential pathogens. Hu et al. further found that total parenteral nutrition improved nutritional status in patients undergoing staged anterior-posterior surgeries (47). Furthermore, Lenke et al. demonstrated that nutritional status did not return to baseline for up to 6 to 12 weeks after surgery (47a).

## SURGICAL TECHNIQUES

### Thoracolumbar and Lumbar Curves

Patients with thoracolumbar or lumbar curves with flexible secondary curves are ideal candidates for anterior correction and fusion with segmental instrumentation (Fig. 67-1). The anterior procedure has many advantages in this setting which include fusing fewer motion segments, obtaining superior correction, and obtaining higher fusion rates (49). It is important in the lumbar spine to maintain or produce lordosis by the use of structural interbody grafts or cages placed as far anteriorly as possible in the disc space (20,50).

When choosing this technique, it is crucial to make certain that the secondary curves are flexible. If there is a fixed secondary curve, especially a fixed oblique lumbosacral take-off, this procedure will result in a significant coronal imbalance.

In patients with either spinal stenosis or radiculopathy, decompression is required and in this case a posterior or combined approach is preferable. Generally, these patients are older and often have poor bone quality. Often their curves are quite stiff, and these patients are better served by a combined approach. In this set of patients, it is important to follow certain principles. Firstly, the fusion should not end at a kyphotic segment to decrease the risk of junctional kyphosis (23,51). It may be necessary to extend the fusion proximally to the upper thoracic level in some older patients.

### Double Thoracic and Lumbar Curves

In this group of patients, it is important to remember the overall goals in adult deformity surgery: achieve spinal balance, provide pain relief, and obtain a solid fusion. With that in mind, for patients with balanced curves in the thoracic and lumbar regions, posterior instrumentation, and fusion usually leads to a successful result. These patients will often have curves of less than 60°.

In more severe curves, particularly if associated with imbalance, a combined anterior and posterior procedure

is preferred. In the first stage, an anterior discectomy and fusion of the lower thoracic and lumbar levels is performed, using structural allografts or mesh cages to restore lordosis. The allografts are prevented from migrating with cancellous 6.5 mm AO (Arbeitsgemeinschaft für Osteosynthesefragen) with plastic washers as interference screws. They are supplemented with autogenous local graft. In the second stage, posterior instrumentation with generous iliac crest bone graft is performed.

### Fusion to the Sacrum

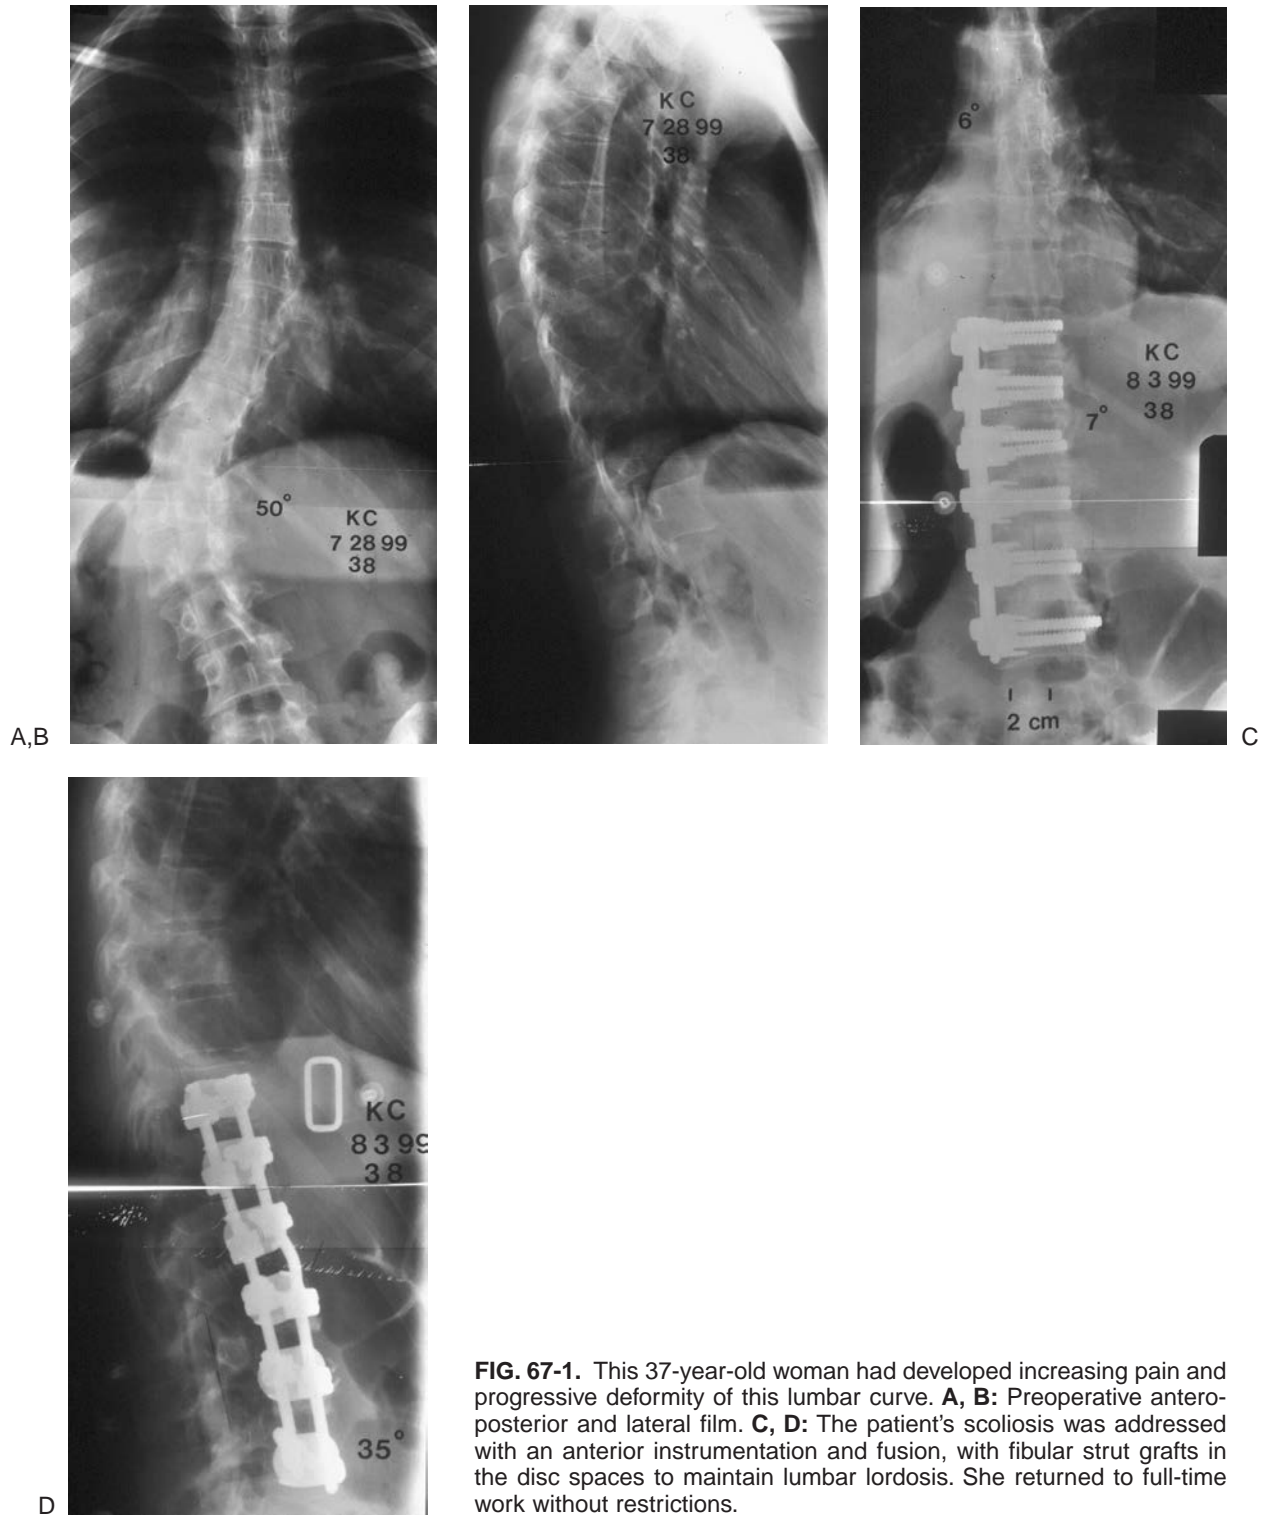

There is some controversy regarding fusion to the sacrum in adult scoliosis, with most reports claiming a higher complication rate and lower patient satisfaction rate when patients are fused to the sacrum (27,42,43, 52–55). Some recent studies reported no increase in complications or decreases in patient satisfaction in long fusions to the sacrum (42,56).

There are certain special conditions for which fusion to the sacrum should be considered:

- an unbalanced lumbosacral curve that does not correct on side bending radiographs
- the presence of substantial degeneration of the L4-5 and L5-S1 motion segments
- the need to decompress the lumbosacral junction below a lumbar fusion.

Long fusion to the sacrum always requires a circumferential fusion, generally with an anterior procedure. The allograft femoral rings can be shaped to preserve lumbar lordosis, which is important as 66% of the lumbar lordosis arises from the lowest two levels, L4-L5 and L5-S1. Structural grafting at the L4-L5 and L5-S1 levels improves fusion rates and decreases stress on the sacral screws (Fig. 67-2). If needed, the fusion can be extended to the pelvis using the Galveston technique, iliac screws, or intrasacral rods (43,52,54,55,57). S2 screws have been shown to decrease the strain on the S1 screws (57). Extension to the pelvis can provide a crucial fixation point in osteoporotic patients (43), but the iliac fixation can be prominent in thin patients and may need to be removed after fusion is achieved. For patients with good bone stock, strong anterior structural graft and sagittal balance, bicortical sacral screws may be adequate. Transforaminal or posterior interbody graft can obviate the need for a separate anterior procedure, and can also restore foraminal height and interpedicular distance (50,52,55,58,59). These results are too preliminary to endorse this technique.

If a fusion to the sacrum is undertaken, it is of utmost importance to achieve both coronal and sagittal balance (60). Care must be taken not to over correct either the thoracic or lumbar curve to prevent ending up with a fixed pelvic obliquity and severe imbalance. We routinely

**FIG. 67-1.** This 37-year-old woman had developed increasing pain and progressive deformity of this lumbar curve. **A, B:** Preoperative anteroposterior and lateral film. **C, D:** The patient's scoliosis was addressed with an anterior instrumentation and fusion, with fibular strut grafts in the disc spaces to maintain lumbar lordosis. She returned to full-time work without restrictions.

take long cassette intraoperative anterior-posterior and lateral X-rays to assess balance.

Patients who undergo extensions of their fusions to the sacrum for pain or progression of scoliosis can also have a high rate of successful outcomes. Kostuik and others showed good and fair postoperative results in up to 93%

of patients, as long as a solid fusion was obtained and lumbar lordosis was restored (42,53,54). Our experience has also been similar, however, some maintain there is a higher complication rate when fusing to the sacrum, and the decision to fuse to the sacrum should not be taken lightly (42,43).

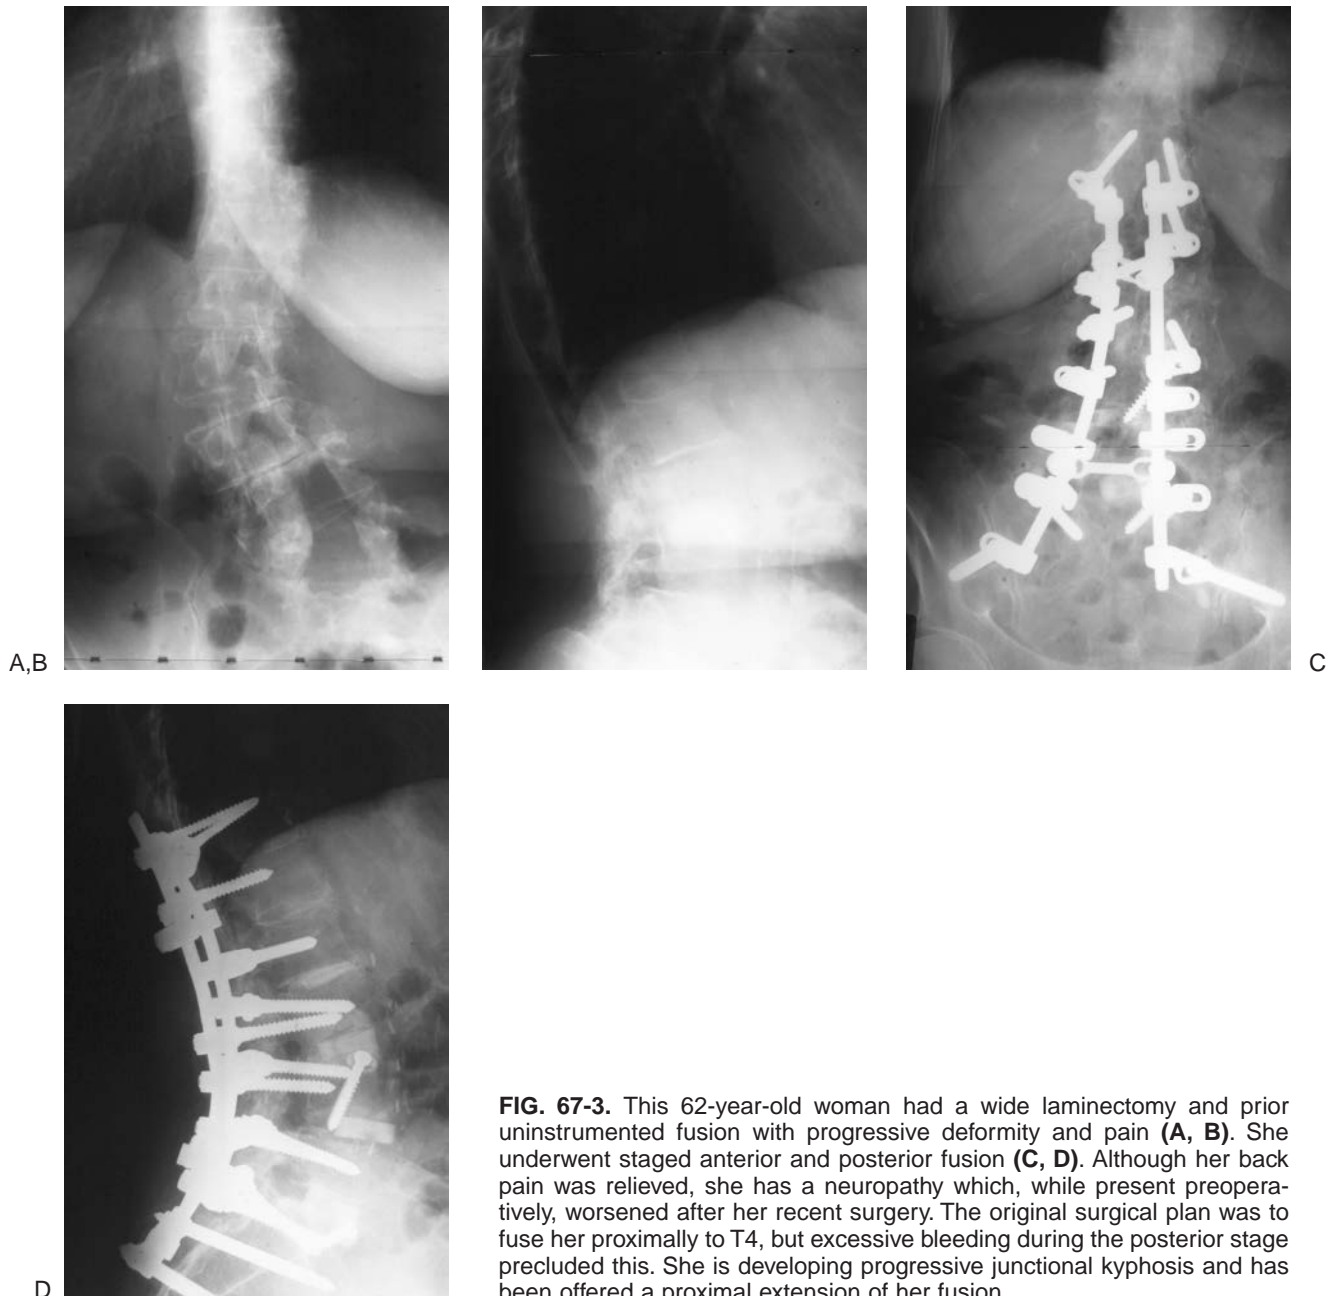

**FIG. 67-2.** This 63-year-old woman had progressive severe lumbar pain secondary to her adult scoliosis and degenerative lumbar curvature. **A, B:** Preoperative anteroposterior and lateral radiographs. She underwent staged anterior and posterior spinal fusion. **C, D:** The patient's perioperative course was complicated by a symptomatic pulmonary embolus and a deep wound infection. Nevertheless, 5 years postoperatively she is without symptoms and has a solid fusion.

As stated earlier in the chapter, determining the precise source of pain in adult scoliosis patients can be challenging. The use of lumbar discography continues to be controversial as a diagnostic tool (61,62). It is known that concordant pain in the lumbar spine may not be relieved by disc excision and interbody fusion at the concordant level. Discography, when correlated with the complete clinical picture, may provide additional information. In general we prefer to use coronal balance rather than discography to decide the distal extent of our fusion including whether to fuse to the sacrum.

### DEGENERATIVE SCOLIOSIS

Surgical treatment of degenerative scoliosis has several goals, which include decompression of the neural elements, and achieving a balanced, stable spine. In patients with stenosis and minimal curvature, decompression alone can be performed. In these patients, great care must be taken to preserve the pars interarticularis and the facet joints as much as possible. In older patients a weakened pars can later fracture and result in progressive deformity (Fig. 67-3). The presence of any signs of instability, such

**FIG. 67-3.** This 62-year-old woman had a wide laminectomy and prior uninstrumented fusion with progressive deformity and pain (A, B). She underwent staged anterior and posterior fusion (C, D). Although her back pain was relieved, she has a neuropathy which, while present preoperatively, worsened after her recent surgery. The original surgical plan was to fuse her proximally to T4, but excessive bleeding during the posterior stage precluded this. She is developing progressive junctional kyphosis and has been offered a proximal extension of her fusion.

as rotatory subluxation, lateral listhesis or spondylolisthesis, usually requires the addition of a fusion to the decompression. Patients with curves greater than 30°, if the patients are of generally good health, should be considered for fusion for the entirety of the curve.

If the patient has significant loss of lumbar lordosis with clinically significant sagittal decompensation, anterior release with an anterior fusion may be necessary in conjunction with a posterior decompression and fusion. By using structural graft, the disc height can be restored allowing more room at the foraminal level for nerve roots, and lumbar lordosis can be maintained. The morbidity of combined procedures in older adults should not be understated and careful consideration should be placed on not only the pathology, but the patient's overall needs as well. The surgeon should always keep in mind that spinal stenosis in itself causes patients to have a forward lean and that most patients with spinal stenosis and loss of lumbar lordosis do not need combined procedures.

### Salvage Procedures

Revision and salvage procedures for previous spinal deformities provide spine specialists with some of the most challenging and complex spine cases. Failed spinal deformity cases can result from several conditions and the indications for revision scoliosis surgery in the adult include:

- painful pseudoarthrosis with instrumentation failure
- pseudoarthrosis with progressive deformity
- flatback syndrome
- symptomatic adjacent segment degeneration
- unacceptable residual deformity or deformity secondary to adjacent segment degeneration
- painful hardware.

Each of the above situations requires careful consideration as each can present significant challenges. The goals of salvage surgery are the same as in primary surgery—to obtain a solid fusion, provide rigid internal fixation, and to achieve spinal balance in coronal and sagittal planes.

### Pseudoarthrosis

Management of painful pseudoarthroses depends on several conditions, including the level of pseudoarthrosis, the status of present fixation, associated deformity, and the level of pain for the patient. Any hardware failure and indeed many cases of “painful hardware” should be assumed to have a pseudoarthrosis unless thorough exploration demonstrates otherwise. In general, a painful pseudoarthrosis associated with progressive deformity and loss of fixation is a clear indication for revision surgery through a combined approach. Single-level pseudoarthrosis, particularly in the thoracic spine, with-

out loss of correction or fixation can often be treated with single-stage anterior or posterior revision with significant autogenous bone graft. As newer bone morphogenetic proteins and osteoinductive materials are developed, different techniques for salvage of pseudoarthrosis without loss of balance may emerge. In the presence of multiple pseudoarthroses, a thorough exploration of the fusion mass should be performed. In these cases reinstrumentation is the method of choice with augmentation anteriorly if not already performed. In these cases, copious autogenous bone graft is necessary (51,63,64).

### Progressive Deformity

Adult deformity may progress secondary to a pseudoarthrosis, a primary fusion that did not include the entire curve, or degeneration of levels above or below a prior fusion. For minor deformities, extension of the prior fusion with instrumentation can be performed.

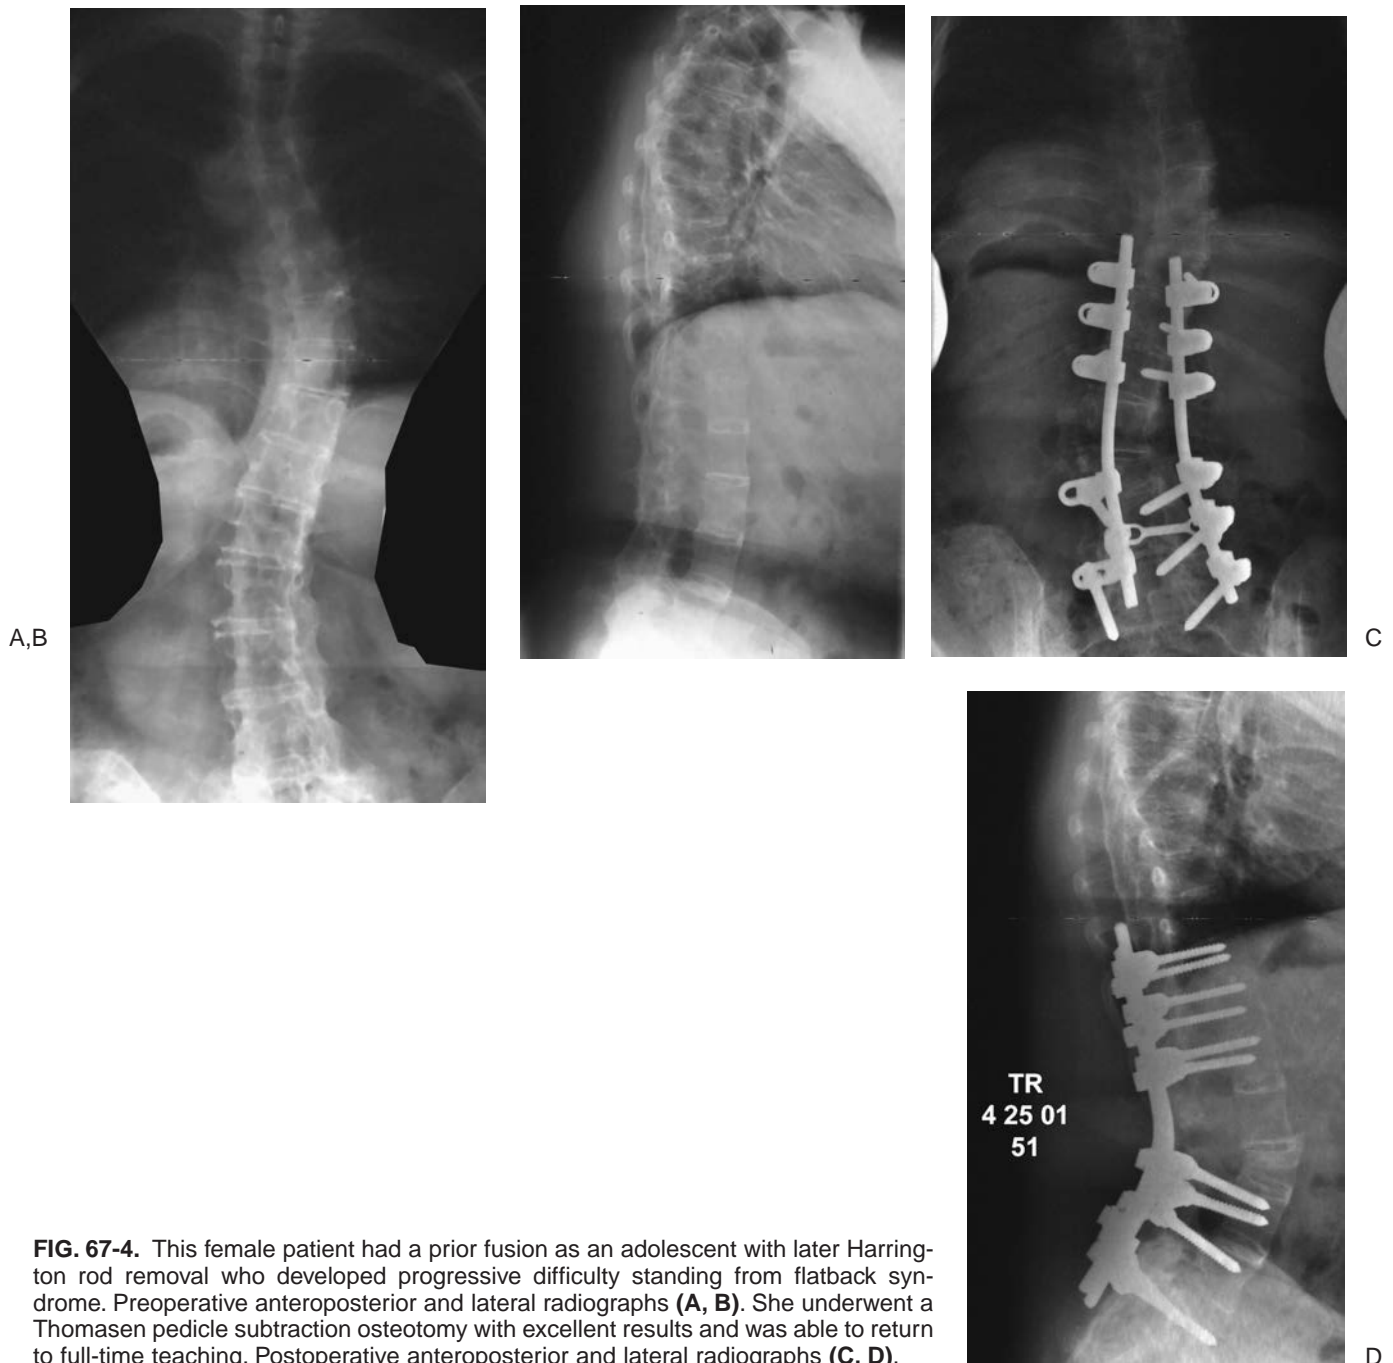

Junctional kyphosis can occur above or below the level of prior fusions. Progressive deformity often ensues and patients can complain of pain or note difficulty walking secondary to the imbalance. Junctional kyphosis can be addressed with an appropriate extension of the fusion with or without osteotomies of segments in the previously fused spine.

For patients with fixed spinal deformities and spinal imbalance, a combined anterior and posterior approach is necessary. In many cases, anterior or posterior osteotomies may be required. A pedicle subtraction osteotomy can provide a significant amount of sagittal, and to lesser degrees, coronal balance (65). For severe, rigid deformities, a spinal shortening procedure may be necessary (66,67).

### Flatback Syndrome

In general, lumbar lordosis is lost as a part of the natural aging process (68). Successful fusion with distraction instrumentation, as is typical with Harrington rod instrumentation, can create an iatrogenic flatback, especially when the fusion is created in the lumbar spine. The condition leads to a crouched position, with fatigue in the thigh musculature. Often there is associated degeneration of adjacent segments and sometimes spinal stenosis across these levels.

If there is a solid fusion posteriorly, there are several options. Multilevel Smith-Peterson osteotomies can provide correction if there is not evidence of an anterior fusion. These may need to be supplemented with anterior grafting. If osteotomies are performed across pseudoarthrosis levels, anterior fusion should also be performed. A Thomasen pedicle subtraction osteotomy can provide up to 30° to 40° of correction (Fig. 67-4) (69), and is especially useful when there is a solid anterior fusion (65).

**FIG. 67-4.** This female patient had a prior fusion as an adolescent with later Harrington rod removal who developed progressive difficulty standing from flatback syndrome. Preoperative anteroposterior and lateral radiographs (**A, B**). She underwent a Thomasen pedicle subtraction osteotomy with excellent results and was able to return to full-time teaching. Postoperative anteroposterior and lateral radiographs (**C, D**).

### *Special Reconstruction Techniques*

#### *Anterior and Posterior Osteotomies*

Reconstruction techniques include anterior osteotomies, posterior osteotomies, decancellation or pedicle subtraction osteotomies, and vertebral column resection. Anterior osteotomies are performed through the area of a fused disc space. Care must be taken to identify the foramen and the pedicles, especially in patients with a rota-

tional component to the deformity. The posterior cortex is then removed with curettes or a Kerrison rongeur.

Posterior osteotomies can be performed by resecting bone in the area of the prior fusion at the fused facet joints, removing osteophytes until mobility is achieved. If the facets are completely fused and cannot be mobilized, Kerrison rongeurs are used to remove bone from the midline through the intertransverse foramen. It may be necessary to open the midline either with a laminectomy or

at the edge of a prior laminectomy. Posterior osteotomies over multiple levels can achieve a significant amount of correction over a large area (70).

*Spinal Shortening (Spinal Column Resection)*

This procedure is only used for severe and rigid deformities with significant truncal decompensation. The first stage consists of an anterior approach on the convex side

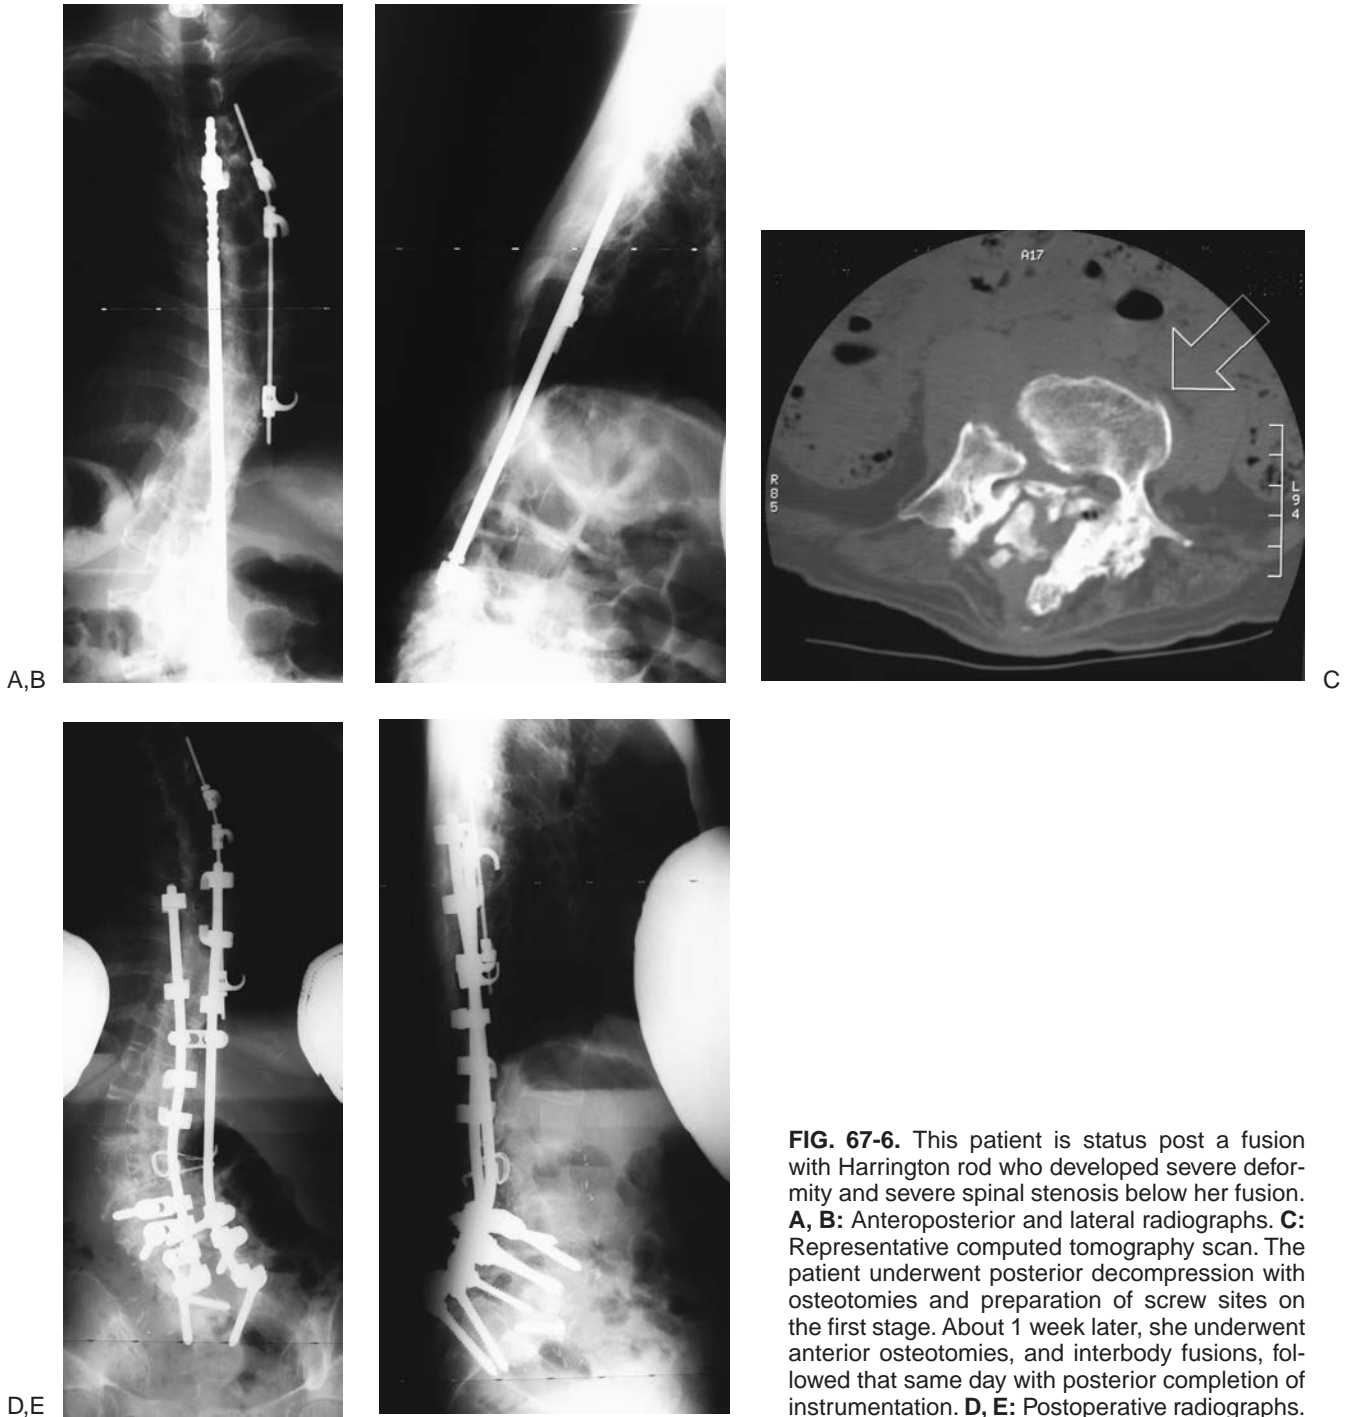

of the curve. Multiple osteotomies are performed proximally and distally to the intended resection level. An osteoperiosteal flap is raised over the apical first to third vertebrae after which the vertebral bodies are decancellated back to the posterior longitudinal ligament. The convex and concave pedicles are removed as far back as possible without risking damage to the dura or the exiting nerve roots. Gelfoam is placed over the dura and the decancellated bone is morselized and loosely laid down

**FIG. 67-5.** This patient had several prior anterior and posterior fusions for her neurofibromatosis-related scoliosis and presented with severe back pain, truncal imbalance, and progression of her deformity (A, B). She underwent a vertebral column resection with excellent correction of coronal and sagittal imbalance (C, D).

into the defect. The osteoperiosteal flap is then sutured over the top (66,67). Either at the same setting or typically 5 to 7 days later, the posterior procedure is performed. After proximal and distal osteotomies are completed posteriorly, the remainder of the spinal elements over the anteriorly resected segments (lamina and remaining pedicles) are removed. Thoracoplasty is performed on the convex side and the apical ribs are resected on the concave side. The convex rod is fixed to the upper portion of the curve above the level of the resection using segmental fixation and is then carefully cantilevered to

the spine distally, correcting the curvature and effectively shortening the vertebral column. Dural pulsations should be monitored during the cantilevering process and a wake-up test is carried out after fixation of the rod distally. If electrophysiologic monitoring is available, this can provide continuous neurologic information. Following a satisfactory wake-up test, the concave rod is inserted to help secure the correction with additional points of fixation. Additional correction is not attempted. A second wake-up test is then performed. The implants are then secured and bone grafting completed (Fig. 68-5).

**FIG. 67-6.** This patient is status post a fusion with Harrington rod who developed severe deformity and severe spinal stenosis below her fusion. **A, B:** Anteroposterior and lateral radiographs. **C:** Representative computed tomography scan. The patient underwent posterior decompression with osteotomies and preparation of screw sites on the first stage. About 1 week later, she underwent anterior osteotomies, and interbody fusions, followed that same day with posterior completion of instrumentation. **D, E:** Postoperative radiographs.

The goal is to achieve coronal and sagittal plane balance by shortening the spine and avoiding spinal cord distraction. An alternative to this procedure is the posterior eggshell approach, decancelling multiple vertebrae through the pedicles. It is effective in obtaining correction, but anterior arthrodesis may be difficult to achieve.

### *Special Considerations and Controversies*

#### *Indications for Combined Surgery*

A carefully designed operative plan includes deciding on performing combined anterior and posterior surgery versus posterior fusion alone. Most surgeons would favor combined surgeries for the following conditions:

- failed posterior fusion in lumbar spine
- rigid deformity requiring anterior release
- long fusion to sacrum
- lumbar or thoracolumbar kyphosis requiring anterior structural grafting.

While single-stage posterior fusion is attractive, combined surgery allows for both better correction and permits the reestablishment of lumbar lordosis with anterior structural grafts. This has the added benefit of increasing the probability of successful fusion. When a thoracolumbar fusion is extended across the lumbosacral junction, anterior interbody fusion becomes a requirement as the pseudoarthrosis rate can be as high as 40% to 60% with posterior fusion alone (27,53).

On some rare occasions, posterior osteotomies should be performed before anterior osteotomies, such as in cases of correction of severely decompensated, fused, rigid deformities. It is usually possible to complete the three stages under two anesthetics. The first stage includes posterior osteotomies and insertion of hardware without connecting the rods. If there is any question as to pedicle screw placement, 4.5 mm AO cortical screws can be placed as radiographic markers so that postoperative radiographs or CT can confirm screw placement. Most pedicle screws for implantation are too prominent to be placed at this time in patients with severe kyphosis. At the second stage, 5 to 7 days later, anterior release and osteotomies are accomplished and interbody fusion is performed. In the same setting, the patient is instrumented posteriorly and final correction is carried out (Fig. 68-6). It has been our experience that a two-stage procedure is better tolerated with only a slightly higher risk of infection and increased blood loss which is also advocated in the recent literature (36,46,52).

### **RESULTS AND COMPLICATIONS**

Even when the major goals of adult deformity surgery are met, pain may not be completely relieved. Residual pain after complex spinal reconstructive surgery varies between 5% and 15%.

The challenges in this type of surgery are great, but improvements in anesthesia techniques, neuromonitoring, internal fixation, and intensive care medicine have improved perioperative care such that the majority of cases can be performed with acceptable risk. Mortality remains low, but not insignificant, at less than 1%.

Neurologic injury is relatively uncommon and occurs in less than 1% to 5% of cases. Significant risk factors for major intraoperative neurologic deficits include combined anterior and posterior surgery, severe rigid curves, and hyperkyphosis (40). Direct injury of neural elements can result from instrumentation or from indirect causes, such as ischemic insult or neuropraxia from distraction. Delayed postoperative paraplegia is another devastating complication following extensive spinal reconstructive surgery that can occur several hours after the completion of the procedure. This phenomenon has been attributed to ischemia of the spinal cord from postoperative hypovolemia, mechanical tension of spinal blood vessels on the concavity of the curve, and preexisting atherosclerosis, and can often be reversed if rapid improvement of perfusion pressure and correction of anemia is performed (72). Delayed paresis may also occur with postoperative hematoma. Thus, repeat neurologic exams after completion of the surgery are essential.

Myers has reported 37 cases of visual loss as a complication of spinal reconstructive surgery that occurred as the result of ischemic optic neuropathy, retinal artery occlusion, or cerebral ischemia (44). The visual losses that were reported often did not fully resolve.

The incidence of pulmonary embolism varies from 1% to 20%, depending upon the series and appears to be increased after anterior procedures in older patients (73–75).

Infection is a relatively rare event, occurring between 1% and 8% of patients. Infection after anterior surgery alone is about 1% (18). However, the sequelae of deep postoperative infection are substantial. The use of preoperative broad-spectrum antibiotics, meticulous wound handling, and providing nutritional supplementation and augmentation for patients undergoing staged procedures decreases infection and wound healing complications. Redosing intravenous antibiotics with significant blood loss has also been shown to be an effective adjunct to help decrease infection rates (76).

Failed fusion is the most common complication of adult deformity surgery, with the highest rates occurring after revision surgery. Other factors that have been found to increase pseudoarthrosis rates include the use of allograft bone and the use of nonsegmental instrumentation in a distraction mode. Weis reported a pseudoarthrosis rate of 38% at 37-month follow-up (18). Gertzbein reported poor clinical outcomes after circumferential fusion to treat lumbar pseudoarthrosis. Only 52% of his patients reduced their pain a full category and only 53% returned to work. These poor outcomes occurred despite

a 100% fusion rate (77). We noted that patients who required reoperation at 6 months were more likely to be dissatisfied with their result (78). Persistent pain was the most commonly cited reason for dissatisfaction.

Spinal decompensation is most often the result of improper selection of fusion levels. Progressive decompensation below a fusion is possible if the fusion is stopped short of the stable vertebra or if there is significant residual obliquity of the last instrumented vertebra. As previously noted, ending a fusion at a kyphotic segment can result in junctional kyphosis and sagittal decompensation. Decompensation may result secondary to a failure to fuse all structural curves.

When dealing with the osteoporotic spine, multiple fixation points need to be used to reduce the chance of fixation failure at the bone/implant interface (30). Pedicles provide excellent fixation but may sometimes need to be supplemented with laminar hooks or sublaminar wires in severely osteoporotic spines (34,50,71,79,80).

## POSTOPERATIVE MANAGEMENT

Postoperatively, patients are mobilized within 24 to 48 hours, depending on their pain level and medical condition. Many patients with long-term narcotic usage can present a challenge in terms of pain management in the immediate postoperative period. Patient-controlled analgesia is widely used in these patients. We have also found it helpful to arrange preoperative interviews between the patient and our pharmacology department, who then assist in managing postoperative pain. Postoperative pain in fusion patients is never managed with NSAIDs, as their use has been shown to adversely affect fusion rates (81). All patients are treated with full-length antiembolic compression stockings and sequential compression devices to lower the rate of thromboembolic events. High-risk patients or those with known history of deep vein thrombosis may be considered for a vena cava filter prior to surgery as pharmacologic anticoagulation has potential for significant complications (72).

All staged patients are started on nutritional supplementation such as hyperalimentation or tube feeding until such a time after the second stage that they are able to consume enough calories to forego the supplementation. It has been shown that proper perioperative nutritional status correlates with a lower infection rate (47,48).

Patients are fitted for a custom thoracolumbosacral orthosis (TLSO) as soon as they are able to stand for a long enough period to make proper measurements, typically on the second or third postoperative day. Patients are instructed to wear the orthosis for at least 3 months whenever they are out of bed. Weaning off the brace depends upon surgeon preference, clinical improvement, and radiographic evidence of fusion mass. High extensions for fusions to the sacrum are not well tolerated, but consideration for their use is given when distal fixation is subop-

timal. Patients average a 5- to 7-day hospital stay for single procedures, with staged procedures requiring a longer hospital stay. Follow-up clinic appointments are performed at 6 weeks, 3 months, 6 months, 1 year, and 2 years, with full-length radiographs obtained at each visit to ensure progression of fusion mass and to evaluate stability of the construct and overall alignment.

## CONCLUSION

Surgery for patients with adult scoliosis requires careful preoperative evaluation and planning. The technical aspects of surgical correction and restoration of coronal and sagittal balance are challenging and complex. In addition, the number and types of complications that can occur during adult spinal reconstructive surgery are greater than those in the adolescent. Combined surgery is recommended for rigid deformities, those that involve the lumbar spine, or long fusions to the sacrum. Rigid, segmental instrumentation that will allow minimal postoperative support is advantageous and a careful preoperative workup and plan is needed.

The primary goal of surgery is the achievement of a balanced correction and a solid arthrodesis. Patients may take 6 to 12 months to fully recover from these procedures and improvement can occur for up to 2 years. Finally, proper patient selection with a frank discussion between surgeon and patient as to realistic expectations is vital to the achievement of a satisfactory outcome.

If coronal and sagittal balance is achieved and maintained with a solid fusion after the primary surgery, the outcomes are generally excellent. Correction of curvature varies from 30% to 60% and is very dependent on the nature of the preoperative curve, its flexibility, and the technique used for correction. Despite these relatively modest gains, patient satisfaction is generally high and can reach up to 90%. We retrospectively evaluated outcomes in patients over 40 years of age who underwent major spinal reconstructive surgery and found over 81% patient satisfaction with significant improvements in many areas of functional status (77). Dickson compared the outcomes of 81 adult patients undergoing operative treatment for idiopathic scoliosis with 30 patients who declined operative management (82). At an average of 5 years' follow-up, he found that treated patients reported a significantly greater decrease in pain and fatigue with improvement in self-image and functionality as compared to the nontreated group. Albert has also shown statistically significant improvements in functional outcome, pain, and body image in adults following spinal reconstructive surgery (1,83).

Outcomes tools are still being developed for evaluation of patients undergoing surgery for adult scoliosis. Most of the data available suggest that there is an improved quality of life for patients who have been carefully accepted into this type of treatment program.

# The Surgical Treatment of Sagittal Plane Deformity

Thomas J. Errico, Orin Atlas, and Juan Carlos Rodriguez Olaverri

---

Spinal deformity can affect the coronal, sagittal, or multiple planes, causing symptomatic imbalance (1). These deformities present difficult management issues for spine surgeons. Sagittal plane deformities have many etiologies and can occur at multiple locations and levels. Etiologies include postural deformity; ankylosing spondylitis; diffuse idiopathic skeletal hyperostosis; Scheuermann disease; congenital kyphosis; postlaminectomy kyphosis; and postradiation and posttraumatic kyphosis; as well as osteoporosis and metabolic bone disease (through multiple compression fractures) (2).

Physiologic sagittal alignment implies that the sagittal plumb line dropped from the center of the odontoid or the center of the seventh cervical vertebral body falls anterior to the thoracic spine, crosses the thoracolumbar junction, and falls behind the lumbar spine, ending at the middle of the sacrum. A normal thoracic kyphosis measurement ranges from 25° to 55°, with the apex located at T6-7. The normal lumbar lordosis is 40° to 70°, with an apex located at the L3-4 interspace (3). Abnormalities of normal alignment may occur at specific regional anatomic locations such as the cervical, thoracic, or lumbar spine, as well as extraspinal locations. These alterations can affect regional or global alignment of the spine. Surgical correction of sagittal plane deformities shares many of the known challenges of the correction of coronal plane abnormalities, such as curve rigidity and spinal fixation. However, it also presents unique obstacles to the spine surgeon, especially in the rigidly fused spine of iatrogenic flat back syndrome.

Patients with fixed sagittal plane deformities are often quite disabled. They may have a primary spine deformity, or may present with a failed back after previous surgical procedures. A frequent cause is iatrogenic flat back syndrome, secondary to a previous spinal fusion, with the loss of normal lumbar lordosis. Prior surgeries using distraction

instrumentation in the lower lumbar spine or malaligned lumbar fusions with a pseudoarthrosis are the main causes of disability and dysfunction in the iatrogenic group (4). Disability also may result from the use of modern segmental instrumentation, anterior release, and fusion without the use of structural graft for anterior column support, and moderate loosening of distal fixation. Patients seen at this institute, whose spinal disability condition is not related to scoliosis correction, are typically older patients, often with osteoporosis. Other less common causes are posttraumatic, neuromuscular, infectious, or degenerative conditions. Conditions not related to the spine, such as hip or knee flexion contractures, also can present with sagittal malalignment and must be ruled out.

Iatrogenic flat back syndrome is a postural disorder and a recognized complication following spine surgery, but most often occurs in the treatment of pediatric or adult scoliosis. For example, with distraction type instrumentation such as the Harrington rods, the posterior distraction force decreases the segmental and regional thoracolumbar and lumbar lordosis, resulting in sagittal imbalance (Fig. 68-1). It also may occur after surgery in adults for nonscoliotic degenerative processes or instability-related pathology. Loss of sagittal balance may be secondary to pseudoarthrosis within a fusion or degenerative changes below a previous fusion level. The degree of imbalance depends on several factors, including the alignment of the thoracic kyphosis and thoracolumbar junction, the flexibility of any mobile distal lumbar discs, and the flexibility of the hip joints. The resultant loss of lordosis results in forward inclination of the trunk, back pain, and the inability to stand erect without flexing the knees. This chapter reviews the diagnosis, pathogenesis, management, and prevention of lumbar sagittal plane deformity or flat back syndrome.

**FIG. 68-1.** A 35-year-old patient 20 years after insertion of a Harrington rod to L4. Note the loss of lumbar lordosis of the upper lumbar spine and the creation of actual kyphosis. The L4-5 disc has responded with hyperlordosis and disc degeneration.

### CLINICAL PRESENTATION

Patients with flat back syndrome most commonly present in their late twenties to forties and have had surgery as a teenager for scoliosis. These patients present with a fixed forward inclination of the trunk and an inability to

stand erect with their knees fully extended. To maintain an erect posture, the patient will flex the hips and knees and hyperextend the upper thoracic and cervical spine (Fig. 68-2). Presenting complaints usually are back pain, progressive fatigue, and, in severe cases, the classic signs of falling forward and difficulty maintaining a comfortable standing posture.

It is very important to distinguish fatigue- and alignment-related complaints from radicular complaints or pain related to instrumentation. In order to fully assess the patient, a detailed history that includes any prior diagnoses and surgical procedures should be performed. A detailed physical examination with a neurologic examination and balance assessment should be done.

### PATHOGENESIS

The physical difficulty of maintaining an erect posture for patients with flat back places select muscle groups under a constant strain and results in pain and fatigue in the otherwise unaffected areas of the spine, thighs, and buttocks. The sagittal malalignment of the flat back places high demands on the muscles, ligaments, and discs of the vertebral column. Minimal disturbances in sagittal alignment are usually compensated for by muscle action to maintain a level gaze (horizontal visual field). However, increasing loss of normal lumbar lordosis leads to a decreased paraspinal muscles lever arm, and thus significant forces and energy expenditures are required to maintain an erect posture. The progressive decompensation in alignment can be theorized as a gradual process of failure of muscle mechanics (dynamic stabilizers) to maintain posture, followed by a gradual failure of the lig-

**FIG. 68-2.** A 72-year-old man with noted progressive difficulty standing erect after a four-level laminectomy and instrumented fusion of L1-5. The patient has subsequently developed a compression fracture of the upper-instrumented L1 vertebral body. **A:** Lateral X-ray of the lumbar spine with loss of normal lumbar lordosis.

aments and capsular structures (rigid stabilizers). A progression of the deformity ensues, with persistent pain and limited function for the patient.

Scoliotic patients who otherwise have initially compensated well for their iatrogenic loss of correction often

lose this ability in the third and fourth decades of life. The largest contributing factor is disc degeneration of the remaining disc or discs below the fusion. With loss of disc height the normal lordotic angulation of the important L4-5 and L5-S1 discs is lost. This angular disc space loss plus the inability of the lower extremity muscle groups to compensate create the clinically significant deformity in the previously compensated patient (Fig. 68-3) At this age, patients frequently begin to stoop forward. When they are evaluated with plain radiographs and magnetic resonance imaging (MRI), disc space narrowing, and degenerative changes are often found that can lead to spinal stenosis and degenerative spondylolisthesis at the first mobile level below the fusion.

Scoliosis patients are not the only patients to experience these problems. A similar syndrome of pain and a sensation of imbalance with sagittal malalignment can result from surgery in degenerative disease. Long lumbar fusions for instability associated with spinal stenosis may also create iatrogenic lumbar stenosis. These patients have poor compensatory mechanisms if their long fused lumbar segments are fused with loss of normal lordosis. They have generalized weak musculature for compensation and the adjacent disc levels are frequently flat with loss of normal disc angulation. In the osteoporotic patient, an adjacent segment compression fracture can push them over the edge into a pain kyphotic deformity.

**FIG. 68-3.** Magnetic resonance image of a 41-year-old woman 26 years after fusion with a Harrington rod to L5. This patient has significant pain and flat back syndrome that has developed progressively over several years. Note the disc degeneration, translation, loss of disc height, and loss of the normal lordosis of the L5-S1 disc.

## RADIOGRAPHIC ASSESSMENT

Radiographic studies most useful in the evaluation of patients with sagittal plane imbalance include standing full-length (36-in.) antero-posterior (AP) and lateral radi-

**FIG. 68-4.** Lateral 3-foot standing X-ray of a 78-year-old patient with kyphoscoliosis. Notice the loss of sagittal balance, with the plumb line dropped from C2 falling well anterior to the sacrum.

ographs of the entire spine. Lumbar radiographs alone are insufficient to evaluate for sagittal balance. A “reasonable” 35°- to 40°-lumbar lordosis may be totally adequate for a patient with a normal thoracic kyphosis but woefully inadequate for the patient with a 65°- to 70°-thoracic kyphosis. Full length radiographs permit calculation of the frontal and sagittal plane offset of the plumb line. Using the Cobb technique, thoracic kyphosis, lumbar lordosis, and thoracolumbar junctional measurements can be obtained. Most important is the overall sagittal balance. This is determined by dropping a plumb line from the center of the odontoid or seventh cervical vertebra and measuring the distance from the anterior aspect of the sacrum to this line. Normally, this plumb line should fall within 2 cm anterior or posterior to the anterior aspect of the sacrum (Fig. 68-4).

If other pathology, such as a nonunion, is suspected, additional radiographs may be needed, including dynamic studies, to assess junctional instability. Computed tomography, MRI, or myelograms may be needed if neurologic symptoms are present (5).

### TREATMENT

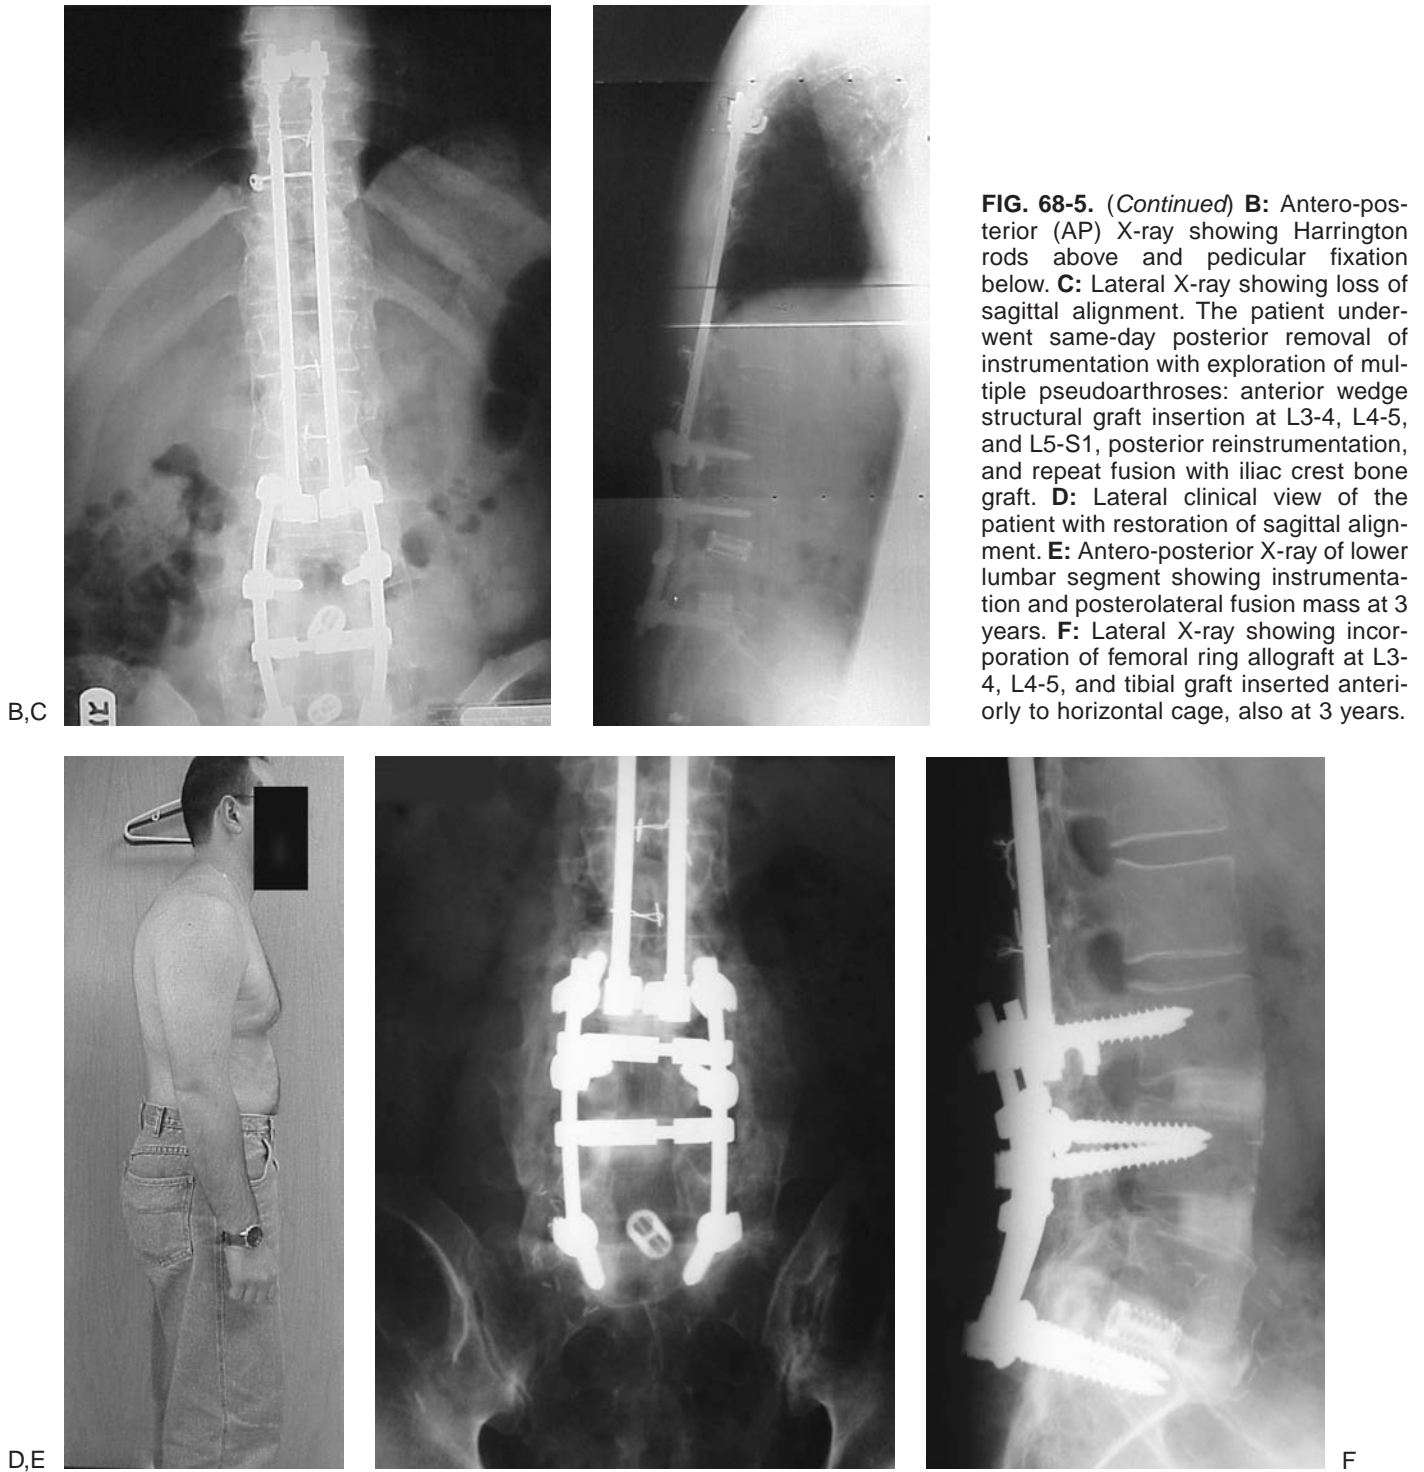

Treatment options for flat back deformity evolve around obtaining global balance in the sagittal as well as the coronal plane. A complete physical and radiologic evaluation as well as the development of a preoperative plan is paramount to performing a successful correction for deformity. The goals of treatment are to: (a) enable the patient to resume a more erect posture that decreases the strain of adjacent cephalad and caudal muscle groups, (b) restore a horizontal visual field, (c) relieve compression of abdominal viscera, (d) improve diaphragmatic respiration, and (e) improve overall cosmesis (Fig. 68-5).

A

**FIG. 68-5.** A 42-year-old patient received posterior Harrington rods and fusion for an L1 burst fracture with significant neurologic deficit. The patient had near complete return of neurologic function but progressive incapacitating back pain. An extension of the fusion to the sacrum was attempted with posterior pedicle fixation supplemented by a single horizontal cage at L4-5 and L5-S1. The patient presented within 1 year of that procedure with worsening back pain and postural deformity. **A:** Lateral clinical view of the patient with classic flat back syndrome.

**FIG. 68-5. (Continued) B:** Antero-posterior (AP) X-ray showing Harrington rods above and pedicular fixation below. **C:** Lateral X-ray showing loss of sagittal alignment. The patient underwent same-day posterior removal of instrumentation with exploration of multiple pseudoarthroses: anterior wedge structural graft insertion at L3-4, L4-5, and L5-S1, posterior reinstrumentation, and repeat fusion with iliac crest bone graft. **D:** Lateral clinical view of the patient with restoration of sagittal alignment. **E:** Antero-posterior X-ray of lower lumbar segment showing instrumentation and posterolateral fusion mass at 3 years. **F:** Lateral X-ray showing incorporation of femoral ring allograft at L3-4, L4-5, and tibial graft inserted anteriorly to horizontal cage, also at 3 years.

**NONOPERATIVE TREATMENT**

Nonoperative treatment of flat back deformity is often first-line treatment for patients with minimal symptomatic complaints, nonprogressive deformity, or patients who are not operative candidates. There is no nonoperative treatment that corrects for lumbar lordosis abnormal-

ity, but treatment may provide some symptomatic relief of the symptoms. Patients with complicated medical problems may not be candidates for further surgery. A pharmacologic approach may include nonsteroidal anti-inflammatory, non-narcotic pain medications, or even a long-term narcotic program, coordinated under the direct supervision of a pain management specialist. Rehabilita-

tive measures, including abdominal strengthening, stretching, and range of motion exercises to the hips and trunk can often compensate for a decompensated trunk and improve paraspinal strength. It also optimizes the physical condition of preoperative patients. Farcy and Schwab documented a significant improvement in pain in 20 of 48 patients who underwent aggressive rehabilitation as an alternative to revision surgery (6). However, at 4-year follow-up, many of these patients' signs and symptoms had progressed, and surgical intervention was performed in seven out of the 20 patients who initially had been controlled with nonoperative care.

## OPERATIVE TREATMENT

Surgical correction of flat back deformity involves general principles that are used in the correction of basic spinal deformities. The history of instrumentation for spinal deformity began with the correction of scoliotic curves. The original Harrington distraction rod was designed to lengthen the concavity of a scoliotic curve. Thus, the Harrington rod, which lengthened the "short side" (concavity) of a spinal curve with instrumentation was the first implant tool in the armamentarium of the modern spinal surgeon. Surgeons quickly grasped the concept that an additional tool to shorten the "long side" (convexity) of a spinal curve would be an additional benefit. The arrival of the Harrington compression rod system applied to the convexity of a scoliotic curve resulted in not only improved corrected force but also was historically closer to the more modern forms of segmental fixation. In scoliosis correction, because the "norm" is no curve, the surgeon aims for "lengthening" the short side and "shortening" the long side until ideally they are equivalent and the curve is eliminated.

Kyphotic deformities of the lumbar spine are similar but have an important difference. With a true kyphosis (not just loss of lordosis) of the lumbar spine, the surgeon aims to "lengthen" the short side (anterior column) and "shorten" the long side (posterior column) not just until they are equal but to push the correction further until the "long" side becomes the new "short" side and vice versa. In flat back syndrome this can be achieved in multiple ways. "Lengthening" of the anterior lumbar spine usually is achieved by discectomy, anterior wedging of the disc space, and maintaining correction with structural support (either structural allograft or vertical cages "shortening" of the posterior column (is achieved) through one (7) or multiple osteotomies (8). A combination procedure involving both anterior column lengthening and posterior column shortening allows for the greatest amount of overall correction of a kyphotic deformity. To maintain correction, all of these procedures must be performed with stabilizing instrumentation and fusion.

The surgical correction of the kyphotic deformity was first described, in 1945, by Smith-Peterson et al. with an

osteotomy of the spine for ankylosing spondylitis (9). They described multiple wedge posterior osteotomies and posterior closure (shortening of the posterior column); resulting in rupture of the "brittle" anterior longitudinal ligament, thereby causing extension and opening through the disc spaces (elongation of the anterior column)—the final result producing lordosis in the lumbar spine. Significant complications have resulted from the relatively uncontrolled anterior column lengthening. These included paraplegia, catastrophic rupture of the anterior vascular structures, and gastrointestinal complications. Various surgeons have modified this technique (10,11).

La Chapelle, in 1946, described a two-stage osteotomy with combined anterior and posterior approaches (12). Briggs, in 1947, reported on a posterior wedge osteotomy with bilateral foraminotomies (13). Thomassen, in 1985, reported on a corrective osteotomy with removal of the neural arch of L2 and partial removal of the bone inside the vertebral body (14). This recreated lumbar lordosis by shortening the posterior column without excessive intra-abdominal distraction. This technique purportedly allowed for 30° to 50° of correction at a single level.

Heinig popularized the eggshell decancellation procedure (15). This procedure consists of removal of cancellous bone of the apical vertebral body through a bipedal approach in order to weaken the vertebral body and create a posterior column shortening with minimal force; an advantage is that it is performed under direct observation of the neural elements. The anterior part of the decancellized vertebra acts as a pivot point for closure of the gap, and because the pedicles have been removed, there is less of a chance of neurologic injury. As well, there is no stretching of the cauda equina and less stretching of the anterior vasculature. Bone grafting and rigid segmental instrumentation are applied in order to decrease the failure rate. Results published to date report a correction of 30° to 50° at a single level using this procedure, although most of these patients were among those with a diagnosis of ankylosing spondylitis. A key point to remember during the procedure is that segmental instrumentation, decompression, and bone graft harvesting should all be completed prior to the removal of cancellous bone because of the potential for rapid blood loss.

Pedicle subtraction osteotomy also has the goal of restoring sagittal balance and obtaining a fusion (16,17). This extension osteotomy shortens the posterior column without elongating the anterior column. The procedure is optimally performed at the L3-4 level because the L3-4 disc space is the physiologic apex of lumbar lordosis, and the osteotomy can be more safely performed at that level with retraction of the cauda equina rather than the conus medullaris. As well, the bifurcation of the vascular structures is below this level so there is a minimal risk of vascular injury. A single level osteotomy results in approximately 25° of sagittal plane correction and a high fusion rate, because it involves the vertebral body and adds bone grafting to the anterior column (18).

**FIG. 68-6.** A 75-year-old patient had a previous history of lumbar laminectomy and discectomy complicated by discitis or osteomyelitis, which resulted in a progressive kyphotic deformity. **A:** Lateral lumbar X-ray showing severe lumbar kyphosis. **B:** Postoperatively lateral lumbar film after multiple lumbar osteotomies, anterior structural wedge, grafts and instrumentation, and posterior compression pedicular fixation.

Combined anterior and posterior surgery in flat back treatment offers the advantage of a controlled lengthening of the anterior column in conjunction with posterior osteotomies and shortening of the posterior column (19). The anterior column can be lengthened and held either with wedge-shaped structural allograft such as femoral shafts or with wedge-shaped vertical cages. The posterior osteotomies can be closed down and thereby shortened with pedicular instrumentation. This technique usually demands a combined postero-anterior surgical procedure rather than a single posterior approach as with the pedicle subtraction osteotomy. In many cases, the anterior approach is necessary to provide anterior fusion and support to the areas adjacent to the posterior osteotomy. Furthermore, in cases of extreme kyphotic deformity, more correction is necessary than can predictably be obtained at one posteriorly based osteotomy (Fig. 68-6).

## CONCLUSION

Flat back syndrome is an iatrogenic deformity in many cases that is usually easier to prevent than to correct. However, even in experienced hands, the deformity can develop because of loss of fixation, progressive degener-

ation, or compression fractures at the top or bottom of a surgical fusion. When surgical correction is warranted, the correction of the kyphotic deformity involves major spinal reconstructive surgery. There is no one procedure for all deformities. Certainly, vertebral wedge osteotomies are necessary either posteriorly based or in conjunction with anterior wedge strut grafting and instrumentation. The decisions are based on the surgeon's preference and experience, degree of correction needed, and location of the deformity. Single osteotomies may be used in relatively mild deformities when the principal deformity is in the mid to lower lumbar spine. Multiple osteotomies are preferred for more severe deformity to assure a better correction of the deformity, with less of a chance of neurologic injury. The decision for a combined anterior and posterior procedure often is necessitated in the patient with painful degenerated discs below long multisegment fusions with loss of lumbar lordosis, in order to not only restore sagittal balance but to relieve back pain and disability.

## CHAPTER 69

# Spinopelvic Fixation

Joseph Y. Margulies and William O. Shaffer

---

Fixation to the pelvis has had limited usage, primarily in the treatment of spine deformity. Anchoring a rod to the pelvis has been very helpful in resisting coronal and sagittal plane imbalance. This has been especially helpful in neurologic-based spinal deformities such as cerebral palsy, myelomeningocele, and the muscular dystrophies. In these entities, the Galveston rod has become the standard and most useful technique to stabilize a neurogenic scoliosis to the pelvis.

Degenerative scoliosis is yet another difficult problem where an increasing use of fixation to the sacrum and the ilium has been realized. Here the Jackson intrasacral rod has proven useful in reinforcing the lower end of a long degenerative construct. The use of the sacral alar screw or the Chopin block have been attempts to further the anchorage to the sacrum to protect the lower S2 pedicle screw in such long constructs.

Trauma constructs have lagged behind the neuromuscular and degenerative constructs. Much of this has been because the trauma to the sacrum has come under orthopedic trauma surgeon purview for some fracture patterns and that of the orthopedic spine surgeon for other fracture patterns. Complicating this has been the lack of a comprehensive approach to these difficult fractures. Orthopedic trauma surgeons have approached sacral fractures and sacroiliac joint dislocations as a posterior pelvic ring disruption. In many cases, percutaneous iliosacral screws have been a good solution to this problem. Zone 1 and nondisplaced zone 2 sacral injuries (those lateral to the sacral foramina) are simply handled by this technique. However, when serious root and cauda equina injury occur there have been few durable solutions posed in the literature. Zone 2 fractures with radicular involvement and zone 3 fractures with either radicular or cauda equina injury demand a more comprehensive approach to neural decompression and skeletal stabilization.

In tumors of the sacrum and ilium, posterior pelvic ring instability is created by the necessary resection of the

tumor and a margin of normal bone. Traditionally, allographic bone has been used to reconstruct these massive defects. Various anchors into the pelvis or remaining sacrum have been attempted and to a greater or lesser extent have been successful. However, in our experience pullout and hardware failure were all too often the result of the historical fixation such as iliac posts (rod or screw), iliac bars, iliac plates, or iliac threaded bars.

Dr. Marc Asher advanced the concept of spinal foundation for scoliosis and deformity correction in which two interconnected spinal anchors allow the forceful manipulation of the spine (1,2). The objective of this study was to develop a foundation to correct pelvic dissociation and rotation.

In 1996, we focused on the challenges of sacral tumor resections and complex sacral fractures resulting in pelvic dissociation, neurologic injuries, and severe lumbosacropelvic rotation. Reconstructive options were limited conceptually. A series of anchors were available to manipulate the pelvis or ilium but they did not allow the forceful manipulation of the pelvis in relation to the sacrum and the rest of the spine. Two possible exceptions are the Galveston rod technique (3) and the Jackson intrasacral rod (4,5). The Galveston technique, when placed in both ilia and interconnected, allows the coronal and sagittal planes in pelvic deformities to be manipulated. However, this technique suffers from a “windshield-wiper” effect because of cranial caudal pistoning of the anchor in the pelvis and the third plane was not controlled. Further, it meets the criteria for a foundation in scoliosis correction only. The Galveston rod technique cannot be applied in fracture or tumor work. The limits of all of the early pelvic anchors were related to the application of forces to the pelvis that overcame the bone implant interface in the ilium. The Jackson intrasacral rod technique places the anchors in the sacrum. The Jackson construct establishes a foundation only if the pelvis is intact, it is not an option for a disrupted pelvic ring.

This current system introduces a pelvic foundation that is applied to three distinct clinical situations. Two of these deal with pelvic dissociation. Tumor resections that sacrifice the sacrum and sacroiliac joint leave the ilium disconnected from the sacrum and the opposite ilium (6). Sacral fractures through or medial to the sacral foramina frequently result in devastating neurologic injury. The decompression of damaged neurologic structures requires reduction of these complex fractures and maintenance of the reduction requires a pelvic foundation. The third clinical situation deals with degenerative and neuromuscular scoliosis where pelvic rotations of obliquity and lumbosacropelvic kyphosis are difficult to control.

Technical guidelines have been established for constructing a foundation in the pelvis for spinopelvic fixation or for stabilizing the pelvis when loss due to tumors or fractures compromises pelvic stability.

Three distinct constructs are discussed:

1. The tumor construct consists of a two-screw iliac foundation connected either to a contralateral two-screw iliac foundation or to a spine foundation of pedicle screws.
2. The sacral fracture construct consists of a two-screw iliac foundation connected to a sacral, iliac, or lumbar anchor depending on the fracture pattern.
3. The scoliosis construct consists of a screw anchoring each ilium interconnected to form a pelvic foundation that is connected to a proximal lumbar foundation of pedicle screws.

Anatomy is the basis for modifications that have become the sacropelvic module of the spinal instrumentation system that allows the construction of the pelvic foundation (7).

## VARIOUS OPTIONS

The preliminary study focused on the anatomic characteristics of the various sacropelvic anchors generally available at the time (8). They were examined to see if a pelvic foundation could be constructed. "Foundation" is defined as a solid combination with two interconnected construct elements (anchors) on each side that create a strong purchase in the bone to allow forceful manipulation of the anatomic structure. An "anchor" is a single implant element anchored in the bone. Possible anchors for constructing foundations in the spine are:

- Pedicle screws
- Hooks and claws
- Wires and cables.

Longitudinal members connect the installed anchors into the actual foundation. Usually they are rods but they

can be plates as well. In the foundation scheme all the elements are interlocked to create a closed stable quadrilateral frame (Fig. 69-1). The interlocking mechanism consists of transverse connectors or any type of solid connection between the longitudinal elements on the right side and the left side. Any combination of connections spanned over one vertebra or more can be used to manipulate the spine.

Applying this approach to the pelvis poses the need for some adjustments. Anchors in the pelvis can be:

- S1 and S2 pedicle screws in all the possible angles suggested
- Jackson-type intrasacral rods
- Iliosacral transarticular screws
- Iliac screws
- Galveston posts
- S1-L5 transdiscal screws or dowels
- Sacral bars
- Hook claws
- Wires or cables
- Blocks (these are considered anchors because they enter the bone so close to each other that it can be considered one point).

In spite of the relatively large variety of anchors in the pelvis, application of any one of them is not always possible due to either poor bone condition or loss. Conceptually, the ideal technical solution is to create a device that uses all the available anchors to create a stable quadrilateral foundation. Integral to this concept is that the dissociated ilium in fractures and tumors can be manipulated independently of the proximal foundation. The technical solution is to design a family of rods with a variety of locking mechanisms at one of their ends. Custom rod connectors allow fixation of rod to rod. A new type of anchor with adequately sized iliac screws allows better purchase of the iliac wings. This system solidly connects all the available anchors into one true pelvic foundation (Fig. 69-2).

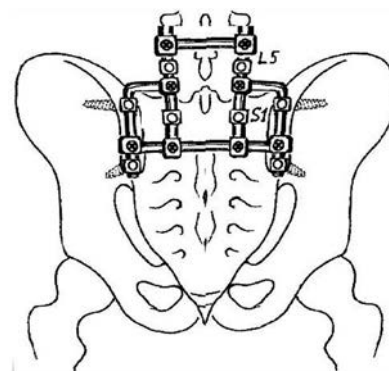

FIG. 69-1. The concept of the bilateral iliac foundation.

FIG. 69-2. Family of rods, anchors, and connectors.

**CLINICAL INDICATION**

The pelvis is instrumented in relatively rare clinical circumstances and this is as it should be. The major indications for instrumentation to the pelvis are:

- neuromuscular scoliosis
- degenerative scoliosis with deficient sacral bone stock
- sacral fracture with neurologic deficit
- sacral fracture where indirect reduction could lead to neurologic injury
- sacral tumors where posterior pelvic instability will result or pelvic dissociation is a risk.

**MATERIALS AND METHODS**

The basis of the module is a uniform locking mechanism of rods to anchors in open and closed versions. A sacropelvic module can be added to any existing spine/scoliosis system. Adapters can be introduced to combine elements from different systems. The newly developed kit contains a set of four rods with locking mechanisms on one end and a set of open and closed iliac screws 10 mm in

FIG. 69-3. 90°-90° wedging bands.

FIG. 69-4. Bolt (10 mm).

diameter. A large selection of adapters and 90°-90° wedging bands are included so that connectors can be rotated 90° to each other (Fig. 69-3). Specialized instruments to handle these specific implants are included.

**Iliac Screws**

Screws that are 10 mm in diameter (Fig. 69-4) were indicated after the preliminary anatomic study and later confirmed by the formal anatomic/computed tomography (CT) studies. The diameter size of the screw is intended to purchase the two iliac cortices. The screws are available in lengths ranging from 30 mm to 110 mm in 10 mm increments with closed and open locking mechanisms.

**Rods**

The rods are ¼-inch in diameter. The integral rod connectors are milled from ¾-inch bar stock (Fig. 69-5). This assures a strong transition from the rod to the connector. Rods with three types of locking mechanisms are available:

- Closed Isola-Groove Hollow Ground (VHG)
- Open Isola VHG type
- Side opening locking mechanism.

Each locking mechanism is attached to the rod in two ways:

- Directly at the axis of the rod
- Offset by about ½-inch to save the bending maneuver passing from the ilium medially to the sacrum

FIG. 69-5. Rod connector.

## Instruments

Standard instruments are used with the addition of a tap for the 10 mm diameter screws.

## Experimental Anatomic Study

Earlier spinopelvic instrumentation was a patchwork of anchors that attempted to fix the spine to the pelvis. Lebwohl et al. showed that iliac screws are the only ancillary fixation shown to protect S1 pedicle screws from cantilever stresses and pullout (9). To allow a better foundation and establish anchorage in the iliac bone, this study investigated alternative anchorage points and defined the dimensions of the upper and lower iliac columns (7) (Fig. 69-6). Seventeen iliac bones were sectioned in 10 mm increments to assess the cross-sectional dimensions (Fig. 69-7). The upper and lower iliac columns were measured directly on a General Electric CT workstation (Fig. 69-8).

The lower iliac column accommodates screws 10 mm in diameter to a depth of 100 mm in 100% of iliac bones. This includes even the smallest female pelvis of the series. The upper iliac column accommodates 10 mm screws up to 50 mm in length in 75% of the iliac bones. It accommodates 7.5 mm screws up to 50 mm in length in 95% of iliac bones. Preoperative CT can be used to determine the necessary screw sizes. Berry et al. have confirmed these dimensions in their study of the lower iliac column in the Hamann-Todd Osteological Collection at the Cleveland Museum of Natural History (10). Schwend et al. have recently published a confirmation of the use of the lower iliac column in neuromuscular scoliosis (11).

**FIG. 69-6.** The upper and lower iliac columns with an assembled two-bolt iliac foundation.

**FIG. 69-7.** Each hemipelvis was sectioned in 10 mm increments and the dimensions of the upper and lower iliac columns were directly measured.

The upper iliac column is as strong a structure for an anchor in the iliac crest as the lower column.

This module for reconstruction of the pelvic ring assures control over the iliac bone and builds a pelvic foundation that allows fusion of the spine to the pelvis.

**FIG. 69-8.** The reconstructed ilium could be “electronically sliced” and the dimensions of the upper and lower iliac column were then measured on the workstation monitor.

### Method of Application

Application is based on the available anchors and hence is subject to improvisation and creativity; however, the sequence is always to insert the anchors first and then to interconnect the anchors to construct a foundation.

### Insertion of Anchors

Anchors are inserted according to the availability of insertion sites.

### Iliac Approach

This is the fundamental technique for sacral fractures and tumor resections that leave the ilium dissociated from the sacrum on one or both sides. Insertion of superior and inferior iliac screws is possible (Fig. 69-1). The first screw placed is in the lower iliac column. The column will accept a 10 mm screw in almost all instances. Preparation of the starting point is important. The posterior superior iliac spine (PSIS) is essentially excised flush to the sacrum. This prepares the oval-shaped starting point for both the upper and lower iliac column approaches. This also provides an adequate graft for the fusion. The lower screw is placed in the traditional Galveston position, which is outward and slightly downward above the sciatic notch. The fingertip of the opposite hand is placed in the sciatic notch and an iliac probe is worked between the two cortical plates of the ilium just above the sciatic notch. The feel for this is akin to probing a pedicle in preparing for a pedicle screw. The average

distance accommodated is 70 mm, though the preliminary anatomic study suggested a 100 mm screw could be accommodated in most cases. The prepared channel is palpated with the ball feeler just as in the pedicle. The depth of the hole and any cortical breaches can thus be appreciated. The prepared channel is then tapped with a 10 mm tap.

The upper iliac column is approached at the superior end of the oval cancellous window created when the PSIS was excised. The iliac probe is directed outward between the iliac cortices at a slight inclination. The prepared channel is checked for depth and cortical break. The average depth is between 45 and 50 mm. The diameter of channel is assessed by direct comparison of a 7.5 versus 10 mm tap. The appropriate diameter tap is used to prepare the upper channel and a 7.5 or 10 mm screw is placed. The openings of the screws are rotated to face each other. An appropriate length of ¼-inch rod is cut and the rod is slightly contoured in order to place it through the connectors of each screw. Once unobstructed passage of the rod is confirmed the rod is withdrawn from one screw so the connector of the rod connector can be passed over the rod (Figs. 69-9A, B). Contouring of the rod connector will depend on the proposed construct. If it is to be connected across to the opposite ilium or sacrum slight bends will be needed. If the rod connector is to connect to the lumbar spine, an exaggerated lumbar lordotic curve will need to be placed in the rod. The geometry of the iliac fixation combined with the sacral pedicle screws shifts the fixation anterior, caudal, and cranial to the center of gravity of the spine, just in front of the sacrum. This placement of the instruments creates a powerful device

**FIG. 69-9.** A: Disassembled components of the two-bolt iliac foundation. B: The foundation assembled.

**FIG. 69-10.** Bilateral iliac foundation as may be used in a tumor or fracture construct.

controlling the pelvic rotations in all three planes of motion and all degrees of freedom of the pelvis in relationship to the spine.

#### *Scoliosis Approach*

The scoliosis approach is similar to the Galveston technique in that the anchors are placed into the iliac crests in the lower iliac column and S1 pedicles bilaterally. This distal placement allows the entire sacropelvis to be manipulated, rotated, and fixed to a lumbar foundation proximally.

#### *Variable Approaches*

Depending on the deformity and pathology with which one is dealing, two iliac screws may be fixed to both S1 or a contralateral S1 and S2 pedicle screw to complete a proximal anchorage. Once these two sites are connected, a transforaminal fracture is fixed. Effective fixation is accomplished by marrying the anchors with various connectors (Fig. 69-10).

#### **Construction of Foundation**

Rods, rod connectors, plates, or transverse connectors connect anchors. The desired assembly should use, as often as possible, straight segments of longitudinal members with the least possible bending maneuvers. Of the available sites to insert an anchor at least four are chosen. After all relevant considerations, the distance between the four should preferably be as long as possible for better stability. The anchors are interconnected in an attempt to close a quadrilateral shape. A spine construct may be fur-

ther connected to the pelvic “frame” by two rods at each side. Though the ideal construct consists of one or two pelvic quadrilateral frames and four rods to connect to the spinal construct, a less extensive one may suffice.

The constructs based on these foundations are characterized by three patterns discussed in the following sections.

#### *Tumor Construct*

In the treatment of sacroiliac tumor, tumor biology and specific tumor behavior must be clearly understood. Imaging studies reveal the anatomy of tumor involvement. Resection must be carefully planned with uninvolved normal spinal structures serving as resection margins. Nerve roots and stable joints often must be resected in order to achieve a curative margin.

The tumor construct consists of a two-screw iliac foundation connected either to the contralateral two-screw iliac foundation or to the spine by pedicle screw foundations (Fig. 69-10). This allows the dissociated ilium to be reduced against the remaining sacrum, or in the situation of a complete sacrectomy, the opposite ilium. The lumbar spine is connected to this substantial pelvic foundation.

Figure 69-11A shows a recurrent hemangiopericytoma of the sacrum. It was previously excised through a microscopic intralesional approach. Adequate revision required a hemisacrectomy and excision of the ilium resulting in a dissociation of the right hemipelvis from the sacrum. The S1-S5 roots on that side were excised as part of the resection. After dural repair, the pelvis was reconstructed. The distal foundation consisted of the iliac foundation described previously. The ilium was reduced to the remaining sacrum by a contralateral iliac foundation and rod connectors were attached through two wedding bands allowing the right ilium to be compressed against the remaining sacrum. This pelvic foundation was connected to a lumbar foundation consisting of the two L3 and L4 pedicle screws. Note the bend in the rod connector to connect the iliac foundation to the lumbar foundations (Figs. 69-11B, C).

#### *Sacral Fracture Construct*

Complex sacral fractures are approached surgically when neurologic deficit is present. Crushed roots require decompression of neural tissue. Stretch injuries to the neural structures require reduction of the fracture deformity.

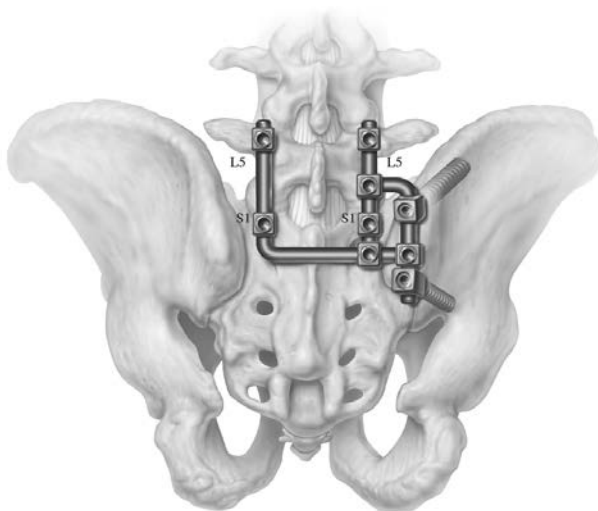

The sacral fracture construct consists of a two-screw iliac anchor connected to a sacral, iliac, or lumbar anchor depending on the fracture pattern and whether the L5-S1 articulation is involved as often occurs with these shear fractures of the sacrum (Figs. 69-10, 69-12). The result is decompression of the damaged nerve roots and control of the fracture in all three planes of rotation. Anatomic

**FIG. 69-11. A:** Preoperative myelogram with involvement of the left sacral roots by the tumor. **B:** The antero-posterior radiograph of the reconstructed pelvis using the iliac foundation bilaterally. (WOS.) **C:** The lateral view of the construct. (WOS.)

reduction is achieved under direct vision while protecting the L5 nerve root anteriorly and the S1 root within the foramina.

Figures 69-13A–E demonstrate reduction of S1–S2 spondyloptosis. These constructs are based on four iliac

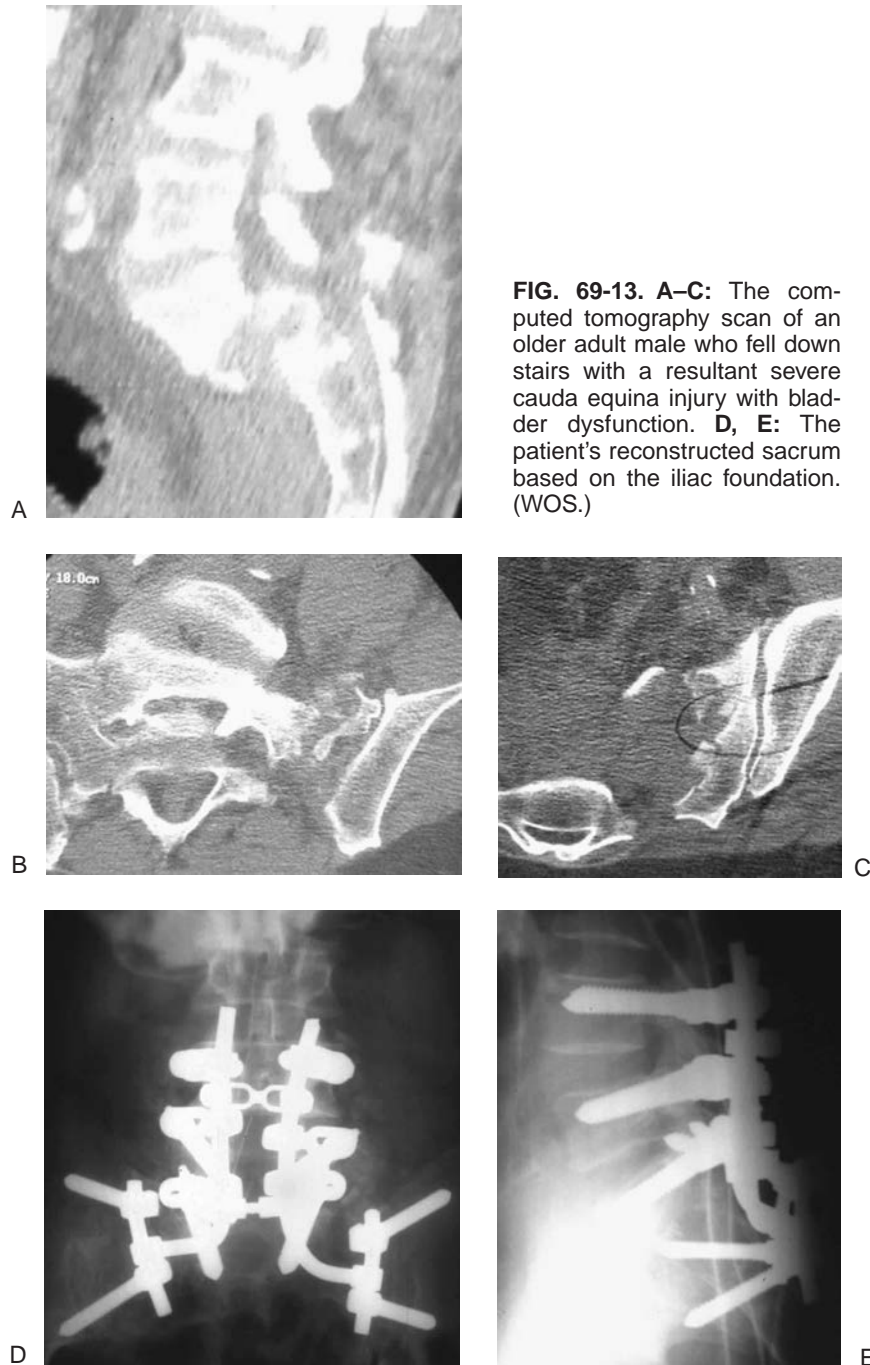

**FIG. 69-12.** Unilateral iliac foundation as may be used in a tumor or fracture construct.

screws as the distal foundations and L4–S1 screws as the proximal foundations in order to accomplish reduction. Reduction of S1 onto S2 can be predictably accomplished with a two-screw iliac post distal foundation. S1 and lumbar pedicle screws form the proximal foundation. A rod connector bridging these two foundations achieves reduction and controls the yaw, pitch, and vertical shear of these complex fractures (Figs. 69-14A–D).

The clinical example in Figures 69-15A and B show the difficulty with using standard components to treat transforaminal fractures with a severe S1 neurologic deficit and radicular pain. The S1 root was decompressed and a displaced butterfly fragment was retrieved from the S1 foramen. A modified Galveston rod and iliac screw foundation attached to proximal S1 screws stabilized the vertical shear component of the fracture. The rod required no fewer than three 90° bends to convert the distal Galveston post to engage both S1 pedicle screws and the upper iliac screw.

Figures 69-16A–D show the simplified approach to a similar transforaminal fracture with neurologic deficit using bilateral two-screw iliac anchors connected by a rod and wedding bands. This construct allows the rotation of the pelvis during reduction while controlling the neural structures within the foramen. Once the reduction is obtained the wedding band set screws are tightened and the rod connector is set to the two-bolt iliac post.

### *Scoliosis Construct*

Reconstructive options have improved with modern spinal fixation. Lumbopelvic fixation must control the three planes of pelvic rotation: yaw, pitch, and vertical shear. The two-screw rod-connector foundation meets these goals.

The scoliosis construct consists of an iliac screw in each ilium interconnected with the S1 pedicle screw to

form a pelvic foundation that is connected to a proximal lumbar pedicle screw-based foundation (Fig. 69-17A–C). This foundation allows coronal and sagittal plane sacropelvic rotations to be manipulated in relation to the proximal lumbar foundation. It is particularly helpful in controlling pelvic obliquities and lumbosacropelvic kyphosis and flat back.

**FIG. 69-14.** A, B: The computed tomography scan views of a young man who fell from a silo while sitting in a boson's chair. Note the spondyloptosis of S1 on S2 and H fracture pattern. C, D: The reduced fracture using the iliac foundation distally and pedicle screws proximally. (WOS.)

**RESULTS**

Results of these techniques are preliminary. Kukio et al. (12) showed that “bilateral iliac screws coupled with bilateral S1 screws provide excellent distal fixation for lumbosacral fusions with a high fusion rate (95.1%) in high-grade spondylolisthesis and long fusions to the sacrum.” Emami et al. have shown that there is an “unac-

ceptable high rate of pseudarthrosis and this method [Galveston rod] is not recommended for adult deformities. . . . Emami recommend using iliac fixation, although there is a higher rate of painful hardware requiring removal” (13).

In our 24 patients with spinopelvic fixation most presented with neurologic deficits that were either radicular or cauda equina. There was a small group of injuries

where zone 2 fractures presented with comminution at the S1 sacral foramina that increased the risk of neurologic injury with indirect and percutaneous techniques. A stable pelvis was achieved in all. This allowed the patient to be cared for without traction and mobilized 2 to 3 weeks after injury. If the injury was unilateral, the patient was allowed to weight bear on the uninjured hemipelvis immediately. If bilateral injury was fixed, the patient would be in bed then chair for 2 to 3 weeks prior to mobilization. Five patients suffered postoperative infections that were treatable with débridements, suction irrigation, and intravenous antibiotics. Six patients required explantation on an average of 2 years postoperatively. Neurologic improvement was seen in all patients except the two patients with cauda equina amputation. Bowel and bladder dysfunction improved or normalized in those patients without cauda equina amputation. Sexual function normalized in 70% of all patients, with better outcomes in women.

In the tumor cases we experienced one hardware failure in a patient in whom we used historical fixation anchors and two patients required explantation for infection.

## COMPLICATIONS

Infection was high in our early experience. Our original incision was a midline incision where we detached the erector spinae from the sacral and iliac insertions. We now use a lambda incision where the major limb is formed on a midline incision over the back, which is gently curved to the PSIS of the most involved side of the pelvis. We then form a 90° arm to the other PSIS. The erector spinae is left attached distally and the hardware is tunneled underneath the erector spinae. This paralleled the experience of our pediatric orthopedist who found that tunneling the Galveston rod under the erector spinae resulted in less wound problems and infection.

Blood loss is expected. It is significant for fracture cases and can be catastrophic with tumor cases. In the tumor population we have experienced two deaths among nine patients. We have had one death from uncontrollable blood loss in a complete sacrectomy for a malignant tumor. Since that case we ligate the internal iliac during the anterior release and colostomy approach in all sacrectomies. This anterior procedure is staged 3 to 5 days before the posterior resection.

**FIG. 69-17. A:** The 10 mm bolt and S1 pedicle screw as the distal foundation connected to proximal claws and pedicle screws in this degenerative scoliosis model. **B:** Note the use of a thoracic slotted connector to allow the passage of the rod from the 10 mm bolt closely by the S1 pedicle screw. **C:** The rod bend is simply an exaggerated lordotic bend rolled out laterally.

Explantation is frequent as the hardware is prominent at the PSIS. Explantation was more frequent in our early experience because we were not removing the PSIS. Now that we take the entire PSIS down offering copious bone graft, the rate of explantation has lessened. However, in thin patients one can only plan to remove the iliac hardware once healing has occurred.

## CONCLUSION

A pelvic foundation is indicated in cases where a solid foundation in the pelvis is needed for long spinal constructs and for tumors and fractures of the pelvis. It is fundamental to correcting the complexities of sacropelvic deficiencies. An assembly of available anchors and interlocking connectors achieves solid constructs. The sacropelvic module fixes pelvic dissociation, allows forceful manipulation and anatomic reduction of sacral fractures, and allows reduction of ilium to the resected sacrum. It is powerful enough to correct pelvic obliquities and lumbosacropelvic kyphosis and protects S1 pedicle screws from cantilever stresses and pullout.

## CHAPTER 70

# Paget Disease of the Spine and Its Management

Alexander G. Hadjipavlou, Ioannis N. Gaitanis, Pavlos G. Katonis,  
Michael N. Tzermiadianos, and George M. Tsoukas

---

The spine is the second most common site of involvement by Paget disease (PD) of the bone (1,2). This peculiar metabolic disorder of bone triggers abnormal bone remodeling and modeling processes that can predispose the spine to stenosis and facet joint arthritic changes.

### ETIOLOGY (3,4)

PD of bone is a mono-ostotic or polyostotic nonhormonal osteometabolic disorder. Over a century after the original disease was described by Sir John Paget (5) in 1877, and despite recent intensive studies and widespread interest, its etiology still remains obscure.

The proclivity to sarcomatous transformation, the variability of osteoblasts (Fig. 70-1) (size, shape, and staining), the peculiarity of osteoclasts (Fig. 70-2) (size and

number of nuclei, up to 100, seen also in giant cell tumors), and control of the disease by antimetabolic agents such as plicamycin (also known as mithramycin) suggest that the disease may be a benign neoplasm of the mesenchymal osteoprogenitor cell, as was hypothesized by Ramussen and Bordier in 1973 (6).

It has been postulated that the disease may be caused by a viral infection (7–10). Electron microscopy of osteoclasts reveals viral intranuclear inclusion structures resembling those of an RNA-type virus related to measles or subacute sclerosing panencephalitis (Fig. 70-3). Immunologic studies show the presence of specific viral antigens in osteoclasts and cells grown from Pagetic bone (11). There is considerable evidence in support of a viral etiology for PD (9). A characteristic feature of paramyxoviruses is their ability to persist at

FIG. 70-1. Note the variable size of osteoblasts (OB) and osteoclasts (OC).

**FIG. 70-2.** Undecalcified bone demonstrating large osteoclasts (OC) with several nuclei. Black depicts old bone.

very low levels and invade the host immune system. Factors that can be activated by virally induced Ross River virus (e.g., IL-6, C-fos, and Bcl-2) are all elevated in PD, strongly suggests viral infection.

Some reports have indicated that PD is a zoonosis, because it is associated with ownership of birds, dogs, cats, or cattle (12,13). These studies have suggested that canine distemper virus (a paramyxovirus closely related to measles), can contaminate human osteoclast cells, contributing to the development of PD (14,15). However, other studies (16,17) found no risk factors associated with animals. In addition, it should be noted that all of the claims mentioned here are only supported by circumstantial evidence garnered from electron microscopic, immunologic, and epidemiologic studies.

### PREVALENCE, DISTRIBUTION, AND GENETIC FACTORS (3,4)

PD is found more commonly in populations of Anglo-Saxon origin. PD is rarely encountered in China, Japan, Iran, India, Scandinavia, Africa, or the Middle East (18); however, Singer (19) mentioned that 10% of PD patients in the Los Angeles area are of African descent. A survey of PD in Johannesburg, South Africa, revealed a prevalence of 1.3% among the black population and 2.4% among the white population (20). These findings suggest that PD may not be as uncommon in Africans as was previously believed. Autopsy reports indicated that the overall prevalence of PD is 3.0% to 3.7% (21,22), with a tendency to increase with age. At the age of 90, the expected prevalence is about 10% (22). Radiographic studies revealed a prevalence of 3.5% (23,24). A recent report on radiographic examination of the pelvis (25) revealed an estimated overall prevalence in the United States of 1% to 2%, with near equal distribution between whites and blacks and between sexes.

Genetic factors play a role in the pathogenesis of PD, which is inherited as an autosomal-dominant trait with high penetrance (26,27). PD often occurs in more than one member of a family (28). A positive family history in siblings of patients was reported in 12.3% of cases as compared to 2.1% of controls. The prevalence of PD was approximately seven times higher in relatives of cases than controls.

Studies in families with PD have shown linkage to a region of chromosome 18q near the polymorphic locus D18S42, most likely due to gene mutation (26,29,30). Genetic heterogeneity is almost certainly present (26,31); data from some families with PD suggest the presence of at least one additional locus, which remains to be identified (26). Viral infection may also help explain the genetic predisposition, by gene mutation, of PD (9,32). Circumstantial evidence thus supports the plausible

**FIG. 70-3.** Electron microscopic examination of portion of osteoclastic cell showing a nucleus. Osteoclastic inclusions, not containing membrane, arranged in paracrystalline array, 15 nm in diameter, are shown within the nucleus. (From Hadjipavlou A, Lander P. Paget's disease. In: White AH, Schofferman JA, eds. Spine care. St. Louis: Mosby, 1995:1720-1737, with permission.)

**FIG. 70-4.** Mosaic appearance of bone in Paget disease formed by cement lines of sequential reformation of new bone without formation of typical haversian systems. (From Hadjipavlou A, Lander P. Paget's disease. In: White AH, Schofferman JA, eds. Spinal care. St. Louis: Mosby, 1995: 1720–1737, with permission.)

hypothesis that viral infection may trigger the onset of PD as well as stimulating inheritable gene mutation. Future research hopefully will cast light on these issues.

#### HISTOPATHOLOGY (3,4)

The histopathology of PD is characterized by two entities: osseous lesions and bone marrow fibrosis. The former is characterized by its so-called mosaic appearance—the hallmark of pagetic lesion (Fig. 70-4). The pagetic cellularity consists of variable sizes of osteoblasts (Fig. 70-5) and large osteoclasts with multiple nuclei (up to 100) (6). Bone marrow fibrosis is not associated with anemia, because bone marrow hemopoietic activity can expand to the appendicular skeleton (Fig. 70-6) (2).

**FIG. 70-5.** Dense fibrous tissue with large osteoblast containing numerous nuclei eroding bone spicule. Note the variable size of osteoclasts (OC).

A

B

**FIG. 70-6.** A: Bone marrow scan reveals displacement of hemopoietic activity in the appendicular skeleton. B: Proven by biopsy.

Uncommonly, extramedullary hemopoiesis occurs in the thoracic cavity (31). These phenomena compensate for the extensive bone marrow fibrosis.

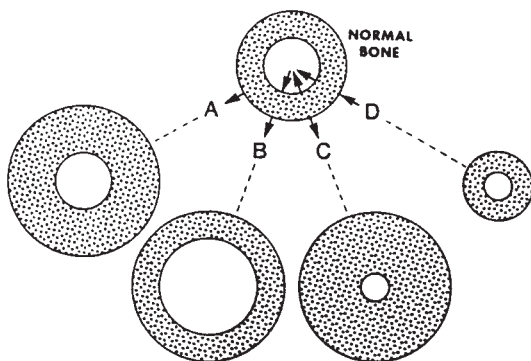

#### PREVALENCE OF BACK PAIN AND SPINAL STENOSIS (3)

The spine is the second most commonly affected site in PD (1,2,34,35), predisposing patients to low back pain

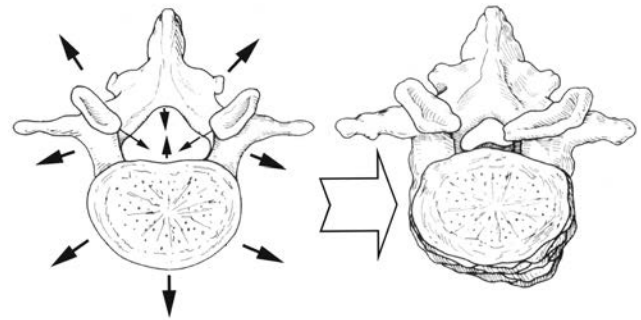

and spinal stenosis (36–39). Hartman and Dohn (40) have shown that 15.2% of patients with PD had involvement of the vertebrae, and 26% of these patients had symptoms of spinal stenosis. The reported incidence of back pain in PD ranges from 11% (41) to 34% (1), and 43% (42). The causal relationship between vertebral PD and back pain has been disputed by Altman et al. (25), who attribute the low back pain in PD to coexisting osteoarthritis of the spine in 88% of patients and to PD alone in only 12%. Others (43) consider PD to cause back pain even more rarely. However, in our population (44), 33% of patients with PD demonstrated pagetic involvement of the spine; 30% had clinical symptoms of spinal stenosis, and 54% of these patients suffered back pain (44) (24% attributed clearly to PD alone, 50% to degenerative changes, and 26% to a combination of PD and degenerative changes).

### PATHOMECHANICS OF FACET JOINT ARTHROPATHY, SPINAL STENOSIS, AND PAIN (3)

PD can be defined as a disturbance of bone remodeling, which in turn leads to abnormal modeling. Frost (45) has defined remodeling as a constant bone renewal or turnover without changes in the size and shape of bone. Disturbance of the bone remodeling process, as seen in PD, changes the bone texture and gives rise to the four phases of the disease observed radiologically: the osteolytic, mixed, and osteoblastic phases, and the inactive osteosclerotic phase, characterized by normal or decreased bone scan activity (46). Bone modeling is a process that determines the shape and geometry of the bone (47) (Fig. 70-7). In PD, disturbed

**FIG. 70-7.** Diagram of cross-sections of a long bone to demonstrate possible patterns of modeling in the periosteal and endosteal envelopes. The arrowheads show the direction of cortical drift due to bone apposition or absorption. Patterns A, B, and C all represent bone expansion. A shows apposition within the periosteal envelope, with the endosteum unchanged; B shows apposition within the periosteal envelope and absorption in the endosteal envelope resulting in a thin cortex; C shows apposition in both periosteal and endosteal envelopes, resulting in a thick cortex; D represents bone contraction; periosteal absorption with endosteal apposition causes a centripetal cortical drift. (From Lander P, Hadjipavlou A. A dynamic classification in Paget's disease. *J Bone Joint Surg Br* 1986;68:431–438, with permission.)

**FIG. 70-8.** Bone modeling of vertebra depicted diagrammatically to demonstrate tendency of bone expansion in all directions, leading to hypertrophic facet osteoarthropathy and spinal stenosis. (From Hadjipavlou A, Lander P. Paget's disease. In: White AH, Schofferman JA, eds. *Spinal care*. St. Louis: Mosby, 1995:1720–1737, with permission.)

modeling contributes to bone expansion that leads to spinal stenosis (46) (Fig. 70-8).

More specifically, pagetic spinal stenosis can be caused by posterior expansion of the vertebral body alone (least common) (Fig. 70-9), by the expansion of the neural arch and the overgrowth of the facet joints, or by a combination of these conditions (39,44,48) (Fig. 70-10).

Facet arthropathy can be produced by abnormal pagetic remodeling and modeling changes, causing the joint to become hypertrophic and incongruous, with destruction of articular cartilage, as may occur in other pagetic joints (36,49) (Fig. 70-11).

**FIG. 70-9.** T1-weighted magnetic resonance image showing posterior expansion of the vertebral body. (From Hadjipavlou A, Gaitanis I, Katonis P, et al. Paget's disease of the spine and its management. *Eur Spine J* 2001;10:370–384, with permission.)

### SPINAL STENOSIS AND NEURAL DYSFUNCTION (3)

Several distinct mechanisms have been implicated as producing neural element dysfunction in the spines of patients affected by PD:

- Compression of the neural elements by pagetic process:
  - (a) pagetic bone overgrowth (25,44,50);
  - (b) pagetic intraspinal soft tissue (44,51) (Fig. 70-12);
  - (c) ossification of the epidural fat similar to ankylosing spondylitis (52).
- Neural ischemia produced by
  - (a) blood diversion, causing the so-called arterial steal phenomenon (38,40,53,54);
  - (b) interference with blood supply to the cord due to arterial compression by the expanding pagetic bone (55) or other factors not well defined (56).
- Vertebral fracture or atlantoaxial subluxation (55,57).
- Platybasia with impingement on the medulla (58).
- Formation of syringomyelia as a complication of PD of the spine, especially after cranial settling (basilar invagination) (59,60).
- Spinal cord compression by epidural hematoma from spontaneous bleeding (33,61,62).
- Rarely, neurocompression caused by pagetic sarcomatous degeneration (63,64).

About one-third of patients with spinal involvement exhibit symptoms of clinical spinal stenosis (44). Clinical spinal stenosis can be characterized as lateral or central stenosis. Lateral spinal stenosis manifests itself as constant or intermittent leg pain of variable intensity with

specific radicular distribution associated with paraesthesias. This pain is exacerbated by walking, may improve with rest, and may be associated with motor weakness, reflex, and sensory changes. Central stenosis, on the other hand, is characterized by bizarre symptomatology, especially leg weakness and cramps with variable amounts of pain that is provoked by walking and improves with rest. Objective clinical signs are usually absent. A combination of central and lateral stenosis may also be present. Central stenosis with myelopathy is associated with upper motor neuron manifestations.

Several authors have mentioned that neural involvement is more commonly associated with PD of the thoracic spine (40,55,65) or the cervical spine (66), rather than the lumbar spine. This is attributed to the large size of the spinal cord in the thoracic and cervical regions relative to the capacity of the vertebral canal; therefore, the same proliferation of bone in all vertebrae would result in compression of the cervical and thoracic thecal sac sooner than it would in the lumbar spine (55). Involvement of the cervical and thoracic spine tends very often to predispose to clinical spinal stenosis with myelopathy (44).

Bone compression by the expanding pagetic vertebrae is by far the most common cause of neural dysfunction (44). It was first reported by Wyllie in 1923 (67). However, severe stenosis, as seen on computed tomographic (CT) scan, may remain asymptomatic, suggesting adaptability of the thecal sac and its neural elements to severe spinal stenosis without significant loss of function (44,55).

The mechanism of neural ischemia is, however, still theoretical and supported only by circumstantial evi-

**FIG. 70-12.** A 63-year-old male patient with pagetic soft tissue expansion originating from the dens and compressing the medulla as seen on: **(A)** lateral computed tomogram of dens (bony element), and **(B)** soft tissue on magnetic resonance image (*arrow*). The patient was treated successfully with surgical decompression.

**FIG. 70-13.** A 78-year-old male patient presented himself with unsteady gait and confusion. **A:** Tc-99m-methylene diphosphonate bone scan revealed increased uptake in the skull, and bone-blood flow revealed increased engorgement of the skull. **B:** After treatment with i.v. mithramycin, bone scan activity somehow improved, however bone-blood flow was restored to normal. This coincided with improvement of the patient's gait and mental status, suggesting that most likely the brain was deprived of its blood supply (steal syndrome by the skull hypervascularity).

dence. For example, patients with spinal cord symptomatology respond to calcitonin treatment better than patients with spinal nerve root lesions (58); some patients experience progressive deterioration of neural function without evidence of myelographic block, which is not easily explained by mechanical effect alone (68); neurologic signs do not always correlate with the site of skeletal involvement; and rapid clinical improvement occurs in some patients with medical antipagetic treatment alone. These observations suggest that neural dysfunction in PD may also result from mechanisms other than simple bone encroachment on the neural element (38,48,50,54,67, 69–71), such as deprivation of blood supply to the neural elements by the rapidly remodeling hypervascular pagetic bone producing “arterial steal phenomenon” (Fig. 70-13).

### SPINAL PAIN (BACK AND NECK PAIN) (3)

Pagetic facet arthropathy is a major contributing factor to both back pain and spinal stenosis, and the more advanced the facet joint arthropathy, the greater the likelihood that patients will suffer clinical spinal stenosis or back pain (44). However, this does not necessarily preclude the possibility that, though present, severe facet arthropathy may become asymptomatic (44). Back pain in PD may also be attributed to blood engorgement of the vertebral body caused by vascular and disorganized hyperactive remodeling processes (72). Other factors implicated in spinal pain may include invasion of the vertebral disc space by the pagetic process (72) and spinal stenosis (39). We hypothesize that microfractures of the

pagetic vertebral bodies, especially in the osteolytic or mixed phase, can also lead to back pain (44).

### OTHER ASSOCIATED CONDITIONS

#### Malignant Transformation (3)

Malignant transformation is relatively rare, occurring in about 0.7% (72) of cases. In our series of PD patients (73,64), we have not seen any cases with sarcomatous degeneration in the spine. In a series by Schajowicz et al. (64) of 62 patients with sarcomatous transformation, 5 malignancies occurred in the spine. These observations suggest that the incidence of malignant transformation in the spine is even more rare, and represents 7% of all sarcomatous degeneration in PD (64). The association between PD and osteosarcoma seems to be the result of a single gene or two tightly linked genes on chromosome 18q (29,30). A more recent study reported that both pagetic and sporadic osteosarcoma tumors showed loss of constitutional heterozygosity for all or part of the distal portion of chromosome 18q. Clinical presentation of Paget sarcoma-

**FIG. 70-14.** Anteroposterior radiograph of the lumbar spine showing a localized bulky juxtacortical bone expansion of the lateral aspect of L4-L5 vertebrae and resulting in bone union. The appearance of the lesion can be misconstrued as sarcomatous degeneration (pseudosarcoma or pumice bone). The cortical margins are well defined in contrast to the usual appearance of sarcomatous transformation, which remains poorly delineated. (From Hadjipavlou A, Gaitanis I, Katonis P, et al. Paget's disease of the spine and its management. *Eur Spine J* 2001;10:370–384, with permission.)

tous transformation is characterized by severe and persistent pain with rapid deterioration and eventual neurocompression and death (63). Surgical decompression offers little, if any, true relief of pain, with the longest survival reported at just over 5 months (63).

Less common is the appearance of “pseudosarcoma” or “pumice bone” in the spine, which is a localized extracortical periosteal bone expansion or a bulky juxtacortical soft tissue mass (usually seen in the long bones) giving the impression of sarcomatous transformation (26,75) (Fig. 70-14).

#### Rheumatic and Arthritic Conditions (4)

Forestier disease, or disseminated idiopathic hyperostosis (DISH), may affect patients with PD, and should not be confused with focal pagetic bone formation (46). The incidence of DISH in PD has been reported to range from 14% (44) to 30% (36). Pagetic tissue may invade the hyperostotic lesions produced by DISH and transform them into pagetic exostoses (44), which may then progress to vertebral ankylosis (76) (Fig. 70-15). Other rheumatic and arthritic conditions such as psoriatic or ankylosing spondylitis may coexist and be responsible for the clinical presentation (1,41). PD has also been noted to be associated with an increased incidence of gout (41) and pseudogout (77). Treatment with sodium etidronate may be responsible for the accumulation of pyrophosphate crystals in the synovial joint, producing pseudogout (78).

**FIG. 70-15.** Axial computed tomography scan of thoracic vertebra showing multidirectional expansion of Paget disease with transformation of flowing hyperostosis of Forestier (disseminated idiopathic hyperostosis) and contiguous with pagetic vertebral body. Note wide marrow spaces and thick cortices. (From Hadjipavlou A, Lander P. Paget's disease. In: White AH, Schofferman JA, eds. *Spinal care*. St. Louis: Mosby, 1995:1720–1737, with permission.)

Osteoarthritic changes in PD have been considered to be a nonspecific arthropathy, a coincidental finding (79), or a specific entity (80). Several distinct pathologic processes contribute to the degeneration and destruction of articular cartilage. Erosion of the subchondral bone may lead to collapse of the articular cartilage (80), which can also be eroded by accelerated endochondral ossification of the subchondral bone (81) or by invasion of aggressive pagetic change (82,83). Bone expansion and bone deformity may also produce incongruity of the articular cartilage, contributing to arthritic changes. Similarly aggressive pagetic tissue may invade and disinte-

grate the intervertebral disc (Fig. 70-16), a process that leads to fusion of the adjacent vertebrae and may be associated with pain. The incidence of intradiscal transgression in PD of the spine is reported to be 10.7% (72).

Pain originating in an arthritic Paget joint may be attributed to the occurrence of microfractures or to increased vascularity of the bone (80). Normalization of blood flow in the bone with antipagetic therapy may influence pain relief (70,84). Such treatment may also produce improvement in the appearance of bone scan and in the level of activity markers of bone remodeling, but if pain persists, conservative therapy has then failed.

**FIG. 70-16.** **A:** Lateral radiograph of the lumbosacral junction demonstrating mixed phase Paget disease of the first sacral segment with moderate narrowing of the L5-S1 disc space. **B:** Pagetic bone extension across the disc space with adjacent anterior bridging with sclerotic bone noted 3 years after the initial radiograph. **C:** The corresponding axial computed tomography scan of the L5-S1 disc demonstrates pagetic bone within the disc. **D:** Lateral computed tomogram demonstrating the intradiscal bone extension from the adjacent S1 vertebra resulting in complete bony ankylosis 4 years after the initial radiograph. (From Lander P, Hadjipavlou A. Intradiscal invasion of Paget's disease of the spine. *Spine* 1991;16:46-51, with permission.)

**TREATMENT****Treatment of Back Pain (4)**

Care must be taken before attributing back pain to PD, otherwise the results of antipagetic treatment may be disappointing (85). Suppressive therapy with EHDP (disodium etidronate) is beneficial in about one-third of cases in patients with back pain and PD of the spine (76). This suggests that unless a well-defined focus of PD is related to low back pain, antipagetic therapy is not expected to be rewarding. If such therapy is ineffective within 3 months, a concomitant nonsteroidal antiinflammatory drug and other methods of treatment for back pain should be prescribed, especially when the pain is mechanical or arthritic in nature (86,87).

**Treatment of Spinal Stenosis (3,4)**

Treatment of the symptoms of spinal stenosis in PD should begin with medical therapy (3). Calcitonin, mithramycin, sodium etidronate, pamidronate disodium, and clodronate have been reported to either improve or completely reverse the clinical symptoms of spinal stenosis (3,57,74,88–90), but subsequent relapse is not uncommon (69,74,91). Patients should be closely monitored and cyclic therapy should be continued if necessary until biochemical bone indices are normal (37,92). If symptoms still persist, surgical intervention should be considered.

Decompression of spinal stenosis should be implemented promptly after failure of antipagetic therapy. Delay in decompression may result in irreversible myelopathy or radiculopathy (44,74). The results of surgery have shown variable improvement in 85% of patients (68), with frequent relapses, which may improve with subsequent medical treatment (53,74,88,90). Surgery may fail to reverse the neurologic deficit completely (3,74,93) and may be associated with serious complications such as dangerously profuse, if not massive, bleeding (94) and a mortality rate of 11% (68). Preoperative assessment of bone vascularity by means of radionuclide studies of bone- blood flow in the affected spinal region is a reliable, simple, and reproducible test (84). In order to decrease potential bleeding during surgery, when there is an increased vascularity in the affected region, a course of medical treatment should be administered until the blood flow in the bone is normal (70). This may take 2 to 3 months with calcitonin therapy or 2 to 3 weeks with mithramycin (70). The new generation of intravenous bisphosphonates can also be used effectively in this situation. In emergencies, embolization of the region may be considered. Because of the expected torrential bleeding during laminectomy, the use of a cell saver is also suggested (74).

Surgery for spinal stenosis, when indicated, should be tailored to the abnormality responsible for neural

compression. If this is caused by the posterior vertebral elements, posterior decompression should be undertaken (70,86). If compression is caused by the posterior expansion of the vertebral body, especially when the cervical or thoracic spine is involved, an anterior approach with corpectomy and fusion should be carried out. An acute onset of spinal compression has a graver prognosis than the gradual development of symptoms (95). Surgery is also indicated as a primary treatment when neural compression is secondary to pathologic fracture, dislocation, epidural hematoma, syringomyelia, platybasia, or sarcomatous transformation (92).

**PHARMACOLOGIC TREATMENT (4)**

The progressive nature of PD, the severity of its associated complications, the potential negative impact on quality of life, and the availability of effective and relatively safe new drugs have led many experts to recommend treatment for asymptomatic patients who have active disease (86,96,97). However, there is no conclusive evidence to suggest that complications can be prevented by controlling bone remodeling by drug therapy (97). Patients who are clinically asymptomatic, but show increased activity of the disease as indicated by abnormal biochemical markers, bone-scan activity, or increased engorgement or radionuclide investigation, should be treated repeatedly until these indices return to normal values (92,96). Patients who are asymptomatic and inactive when assessed by biochemical and imaging investigations do not require treatment.

Five classes of drugs are available: bisphosphonates, calcitonin, mithramycin (plicamycin), gallium nitrate, and ipriflavone. Some of these are still under development and can be obtained only for use in clinical trials.

Several bisphosphonates have been investigated, but only those listed in Table 70-1 (39,98) have been approved for clinical use. Oral administration of alendronate has demonstrated efficacy, resulting in normalization of serum alkaline phosphatase in 63% of patients at a dose of 40 mg per day for 6 months (99). We assessed the effects of a higher dose (60 mg per day) of oral alendronate on PD over a shorter period (3 months) in 28 patients, 18 male and 10 female, with a mean age of 68 years. Ten patients had never been treated before, and 18 had previously received drug therapy. The mean period without treatment before alendronate was 14 months. Sites of PD were visually scored 1 to 4 for radiologic assessment. Quantitative uptake by region of interest (ratio of PD to normal bone) was also determined for scintigraphic examination.

Baseline alkaline phosphatase levels fell from 266.6 to 82.2 (mean difference 183.8,  $p < .000$ ) Osteocalcin levels fell from a baseline of 5.1 to 8.7 (mean difference 3.6,  $p$

**TABLE 70-1. Bisphosphonates approved for clinical use**

Drug	Dosage	Administration	Side effects	Comments
Disodium etidronate (EHDP)	5 mg/kg/d for 6 mos, or 10 mg/kg/d for 3 mos, or 20 mg/kg/d for 1 mo. Repeat every 6 mos until normalization of bone remodeling markers.	p.o. i.v. also available	Osteomalacia, pathologic fractures	May become ineffective after 6 mos of treatment
Clodronate (Cl <sub>2</sub> MBP)	800–1,600 mg/d for 6 mos, or 300 mg daily for 5 consecutive d	p.o. i.v.	Association with leukemia observed	Very potent bisphosphonate without mineralization defect
Pamidronate (ADP)	1,200 mg/d for 5 consecutive d, or 15–25 mg daily for 5–7 d, or 60 mg in 0.9 saline over 2 h, oral 180 mg/course over 3 d	p.o. i.v. i.v.	Transient febrile reactions with myalgias, transient hypocalcemia, neutropenia, and lymphopenia, mild thrombophlebitis, uveitis, scleritis. Appendicular bone loss (secondary hyperparathyroidism) close monitoring is required.	For severe forms of Paget disease, or refractory to other medications. Effective in healing lytic lesions. Further studies are needed to determine optimal dose, the length of treatment, and whether oral and i.v. therapies when combined, would allow for prolonged remission
Alendronate (amino-bisphosphonate)	40–60 mg/d for 3–6 mos, or 10 mg daily for 5 d	p.o. i.v.	Gastrointestinal (25%), esophagitis, esophageal ulcer or erosions	Potent amino-bisphosphonate. Effective in healing lytic lesions. Does not impair mineralization.
Risedronate (pyridinyl-bisphosphonate)	30 mg/d for 2–3 mos or less	p.o.	Gastrointestinal	Highly effective in osteolytic lesion after 6 mos of treatment
Neridronate (aminohexane bisphosphonate, AHBP)	400 mg/d for 1–3 mos, or 15–20 mg daily for 5 d, or 200 mg in a single dose	p.o. i.v.	No significant	Long-lasting remission, successful when other bisphosphonates fail
Ibandronate	2 mg/d	i.v.	Fever, hypocalcemia, hypophosphatemia, gastrointestinal intolerance, flu-like symptoms	Long suppression, rapid action, no significant side effects
Tilludronate (chloro-4-phenylthiomethylene bisphosphonate)	200–400 mg/d for 6 mos	p.o.	Hypophosphatemia, gastrointestinal intolerance, flu-like symptoms	Very potent 3rd generation bisphosphonate with rapid action
Aminohydroxybutylidene bisphosphonate (ABDP)	5 mg/d for 4–5 d	i.v.	Fever, neutropenia, lymphopenia	New bisphosphonate with profound inhibition of bone resorption
Olpadronate (3-dimethylamino-1-dihydroxypropylidene bisphosphonate)	200 mg/d for 12 d	p.o.		One of the latest bisphosphonates. Potency is similar to alendronate, but more soluble in the digestive system
Zoledronate (dimethylamino-1-dihydroxypropylidene bisphosphonate)	400 µg (single dose), or 200 mg/d for 10 d	i.v. p.o.		New, very potent, and promising bisphosphonate but merits further study to determine optimal dose and safety. Long-lasting effect.

(From Hadjipavlou A, Katonis P, Tzermiadianos M, et al. Principles of management of osteometabolic disorders affecting the aging spine. *Eur Spine J* 2003;12(suppl);S113–S131, with permission.)

A

**FIG. 70-18.** Scintigraphic evaluation of group I patients receiving alendronate treatment (A) had not previously received drug therapy.

**FIG. 70-18.** (Continued) Group II patients (B) had previously received drug therapy. (From Hadjipavlou A, Katonis P, Tzermiadianos M, et al. Principles of management of osteometabolic disorders affecting the aging spine. Eur Spine J 2003;12(suppl);S113–S131, with permission.)

< .0002). All patients normalized their alkaline phosphatase levels. Follow-up was carried out on all 28 patients 2 years after the 3-month treatment. All but 3 were in remission, for a rate of 89.2%. No side effects were noted in any of the patients treated. The response to therapy was similar between patients who had previously received antipagetive therapy and those who had not. Sim-

ilarly there was a marked radiologic (Fig. 70-17) and scintigraphic improvement (Fig. 70-18).

A major advantage of the bisphosphonates over calcitonin is that biochemical and histologic suppression of the disease activity may persist for many years after the cessation of treatment (100). Other antipagetive drugs are shown in Table 70-2 (39,98).

**TABLE 70-2. Other antipagetive drugs**

Drug	Dosage	Administration	Side effect	Comments
Calcitonin				
Human synthetic	0.25–0.5 mg/d for 6 mos	Subcutaneous		
Salmon calcitonin	100 MRC U/d	Subcutaneous	Mild allergic reaction	Clinical resistant
	200–400 MRC U/d for 6 mos	Nasal spray		
	300 U for 6 mos	Rectal		
Mithramycin (plicamycin)	15 µg/kg/d for 5 d (may be repeated after 7 d)	Intravenous	Toxic: liver, kidney, heart bone marrow, hypocalcemia	Very potent, with quick response, and sustained action. Indicated in severe cases especially complicated with myelopathy.
Ipriflavone (7-isopropoxy-3-phenyl-4h-1-benzopyran-4-1)	600 mg/d for 30 d	Oral	Gastrointestinal	Well-tolerated
			intolerance	
Gallium nitrate	2.5 µg/kg/d for 7 d	Intravenous	Transient hyperparathyroidism	Safe with lasting action
	0.25–0.5 µg/kg/d for 14 d (cyclic monthly repetition)	Subcutaneous		Safety and effectiveness have not yet been established

## METHODS FOR CLINICAL ASSESSMENT AND MONITORING ANTIPAGETIC DRUG TREATMENT (4)

The effects of treatment are monitored by the patient's clinical response, imaging modalities, and bone remodeling markers (74,92).

A bone scan is recommended before and 6 months after treatment, and every 12 months thereafter depending on the behavior of the pagetic lesion. A 24-hour retention scan can be used as an adjunct to bone scan (84), allowing early and objective assessment of PD when evaluating the effects of therapy (101).

Biochemical markers of bone resorption are N-telopeptides, C-telopeptides, hydroxyproline, and collagen crosslinks pyridinoline and deoxypyridinoline. The serum tartrate-resistant acid phosphatase is a marker for osteoclastic activity. Markers of bone formation include bone-specific alkaline phosphatase, procollagen type I N-terminal polypeptide (PINP) and  $\beta$ -carboxyl-terminal telopeptide of type I collagen. Osteocalcin may indicate either formation when resorption and formation are coupled or turnover when they are uncoupled; therefore it is not a practical bone marker (102).

The serum markers of bone turnover show lower biologic variability than urinary markers, and are therefore more sensitive indices of the activity of the disease. Bone alkaline phosphatase and PINP seem to best reflect pagetic activity (103,104). The total alkaline phosphatase can also be considered as a sensitive and inexpensive marker for therapeutic monitoring of PD. However, more specific markers may improve the usefulness of the biochemical assessment in certain situations (105).

Bone markers should be checked every 3 to 6 months (1). Markers of bone resorption respond approximately at 1 to 3 months, whereas markers of bone formation usually respond at 6 to 9 months after treatment begins (106).

## CONCLUSION

The natural history of PD affecting the spine is progressive. The altered remodeling unit in PD results in abnormal bone remodeling, producing structural changes precipitating or leading to facet joint osteoarthropathy and spinal stenosis (Fig. 70-4). Clinical entities are not always symptomatic. In the majority of cases, the clinical picture of pagetic spinal stenosis and facet osteoarthropathy is not expected to differ from that of degenerative spondylosis. A minority of patients (13%), however, exhibit constant spinal pain attributed to the pagetic pathologic remodeling process.

About one-third of patients with spinal involvement exhibit symptoms of clinical spinal stenosis. Ten distinct mechanisms have been implicated as producing neural element dysfunction. Bone compression by the expand-

ing pagetic vertebrae is by far the most common cause of neural dysfunction. However, severe stenosis, as seen on CT scan, may remain asymptomatic, suggesting adaptability of the thecal sac and its neural elements to severe spinal stenosis without significant loss of neural function. Pagetic facet arthropathy is a major contributing factor to both back pain and spinal stenosis, and the more advanced the facet joint arthropathy, the greater the likelihood that patients will suffer clinical spinal stenosis or back pain.

One must be careful before attributing back pain to PD, otherwise the results of antipagetic treatment may be disappointing. Treatment of pagetic spinal stenosis symptoms should start with medical antipagetic therapy. If the symptoms persist in spite of normalization of bone remodeling markers, surgery is the alternative treatment.

# Osteopenia: Basic Science, Magnitude of Problem, Classification, Clinical Presentation, and Medical Therapy

Charles W. Cha and Scott D. Boden

---

The skeleton acts as the structural foundation for the body. Despite its demands for stability, the skeleton is not a static structure. Rather, it is a fluid and dynamic structure that is constantly changing and remodeling in response to mechanical stimulus. Apart from its mechanical duties, bone possesses a dual role, serving as a key endocrine organ involved in the regulation of calcium and phosphorus homeostasis. About 99% of the body's stores of calcium are harbored within the bone. The remaining 1% is in a soluble, ionized form. This free calcium has an important role in membrane function, especially in the cells that rely heavily on calcium metabolism for proper physiologic functioning. Calcium homeostasis must be strictly regulated in order to preserve and maintain proper muscle and cardiac function.

The regulation of calcium homeostasis depends on a complex interplay of hormones, which ultimately control the deposition and release of calcium from its stores within the bone. The large number of hormonal factors and the multiple organs involved reflect the level of complexity of this process. Parathyroid hormone (PTH), vitamin D<sub>3</sub>, estrogens, corticosteroids, calcitonin, and thyroid hormone are all known to participate in the regulation of calcium homeostasis. They are produced by or act on organs such as the skin, liver, kidney, thyroid gland, parathyroid gland, gonads, adrenals, and the intestines.

The result of these endocrine interactions is the stimulation of either osteoblasts or osteoclasts within the bone, thereby stimulating bone deposition or resorption respectively. Bone mass is maintained when the level of bone deposition is equal to the level of resorption. Metabolic bone diseases occur when there is an imbalance between bone formation and destruction. Negative balance occurs when an excessive amount of bone is broken down or not

enough bone is being formed. This leads to a loss of bone mass, which is simply described as osteopenia. When bone deposition surpasses bone removal, bone mass increases, which leads to increased density as seen in clinical syndromes such as osteopetrosis and Paget disease. This chapter will focus on the former scenario where bone mass is lost resulting in osteopenia. We will review the basics of mineral metabolism, define the magnitude of the problem that osteopenia poses, classify the different types of osteopenia, outline the clinical presentation, and summarize the current medical therapies.

### BASICS OF MINERAL METABOLISM

Bone has both cortical and cancellous portions (1,2). Cortical bone accounts for about 80% of the skeleton (3). It is strong, stiff, and possesses a high resistance to bending and torsion. It is also marked by a very slow turnover rate. In contrast, cancellous bone is not nearly as dense as cortical bone. It has a spongy appearance with more elasticity than cortical bone and a smaller Young's modulus. Due to its higher turnover rate, cancellous bone is more susceptible to the factors that regulate bone remodeling. It is this portion of the bone that is primarily affected by the diseases of bone metabolism (Fig. 71-1).

There are three main cells that are present within the bone: osteocytes, osteoblasts, and osteoclasts (4). The osteocytes reside within the mature matrix of the bone and represent former osteoblasts that become trapped within the matrix. They are interconnected with each other through canaliculi and interconnecting cytoplasmic processes (5). They are not as active as the osteoblasts and osteoclasts in matrix production, but do have a role in calcium and phosphorus metabolism through the action

**FIG 71-1.** Changes in bone density and trabecular architecture related to aging in the lumbar spine. **A:** A 24-year-old female. **B:** A 63-year-old female. **C:** An 89-year-old female.

of calcitonin and PTH. The osteoblasts are primarily responsible for matrix production and are key cells in the maintenance of calcium and phosphorus homeostasis (3,6). Their action is directed through multiple hormonal receptors that are found on their surface. These cells respond directly to stimulation by PTH; 1,25 vitamin D<sub>3</sub>; steroids; prostaglandins; and estrogen (7). While the osteoblasts are derived from mesenchymal stem cells, the osteoclasts have hematopoietic cell precursors (8–10). Osteoclasts are multinucleated giant cells and primarily act to resorb bone. The osteoclasts work within cavities known as Howship lacunae. They maintain a ruffled border underneath which an acidic environment essentially dissolves the hydroxyapatite crystals, thereby releasing the calcium and phosphate components. Osteoclasts possess receptors for calcitonin. In addition to the cells, the matrix is made up of additional organic components including collagen, proteoglycans, matrix proteins, growth factors, and cytokines. The remaining 60% of the dry weight of bone is the inorganic mineral component, which is the calcium hydroxyapatite (11,12).

For proper physiologic functioning, it is essential that the body maintain the calcium concentration within a strict window. The body depends on this maintained calcium concentration for muscular function (striated, smooth, and cardiac), blood coagulation, and intracellular signal transduction. Calcium homeostasis (13) is maintained at three main areas: dietary intake absorbed in the gut, renal reabsorption of excreted calcium, and release of calcium stored within the bone reservoir. The primary regulators of calcium metabolism—PTH; 1,25 vitamin D<sub>3</sub>; and calcitonin—act by controlling the calcium traffic at these three areas.

Vitamin D is a naturally occurring steroid and, in general, acts to increase the plasma concentration of calcium through its actions on the kidney, gut, and bone. The metabolism of vitamin D is relatively complicated

(14–16). It begins at the skin where ultraviolet light from the sun converts 7-dehydrocholesterol into vitamin D<sub>3</sub>, otherwise known as cholecalciferol. The vitamin D<sub>3</sub> that is produced at the skin and absorbed by the diet is then taken to the liver where it is converted into 25OH cholecalciferol. This is then metabolized in the kidney by 1- $\alpha$ -hydroxylase into 1,25 diOH cholecalciferol. This is the active metabolite of vitamin D that strongly stimulates the intestinal absorption of calcium. It also acts to release calcium from the stores within the bone by stimulating receptors that are located on the osteoblasts. Once stimulated the osteoblasts release a secondary signal that eventually culminates in calcium release from the bone. The production of 1,25 vitamin D is stimulated by elevated PTH levels, and decreased serum calcium and phosphorus. Conversely, low levels of PTH and elevated serum calcium and PO<sub>4</sub> inhibit 1,25 vitamin D<sub>3</sub> production.

PTH is produced within the parathyroid gland in the chief cells. In concert with vitamin D<sub>3</sub>, PTH secretion acts to elevate the serum calcium. PTH stimulates the production of 1,25 OH vitamin D<sub>3</sub> at the kidney and also acts on the bone by signaling the osteoblasts to release a messenger to stimulate bone resorption. It also has direct effects on the kidney to promote calcium retention (7,17).

Calcitonin is produced by the parafollicular cells within the thyroid gland. It acts to decrease the serum calcium levels by directly inhibiting osteoclasts, thereby preventing the release of calcium from its body stores within the bone (18,19).

### MAGNITUDE OF THE PROBLEM

The most common metabolic bone disease, osteoporosis, is a major health concern. This disease affects over 20 million people in the United States (20,21). The major medical morbidity associated with osteoporosis is the occurrence of fractures, most notably of the spine, hips,

and wrists. In total, about 1.2 million fractures occur as a result of osteoporosis per annum. Five hundred thousand of these are vertebral compression fractures, another 200,000 are hip fractures, and 170,000 of these are wrist fractures (22,23). Each of these fractures takes a significant toll on the individual patient in terms of medical morbidity. There is a significant loss of function associated with these fractures and in the worst cases; these fractures can be a harbinger of death (24). In addition to the medical morbidities, there is a significant emotional cost associated with this disease due to pain, loss of function, and fear of future falls and fractures. Nearly half of all women over the age of 50 will sustain an osteoporosis-related fracture, and 13% of the men over age 50 face a similar fracture risk (25).

In 1984 the National Institutes of Health (NIH) produced a consensus statement and estimated the health care-related cost of osteoporosis in the U.S. to be around 3.8 billion dollars annually (26). Less than a decade later, this figure ballooned to an overall cost of 10 billion dollars annually. The current cost of fracture care is approaching 20 billion dollars (27). The overall medical costs will continue to increase given the current aging of our population, the number of people affected with this disease, and the number of fractures occurring because of this problem. It is projected that over the next 50 years, the number of people over the age of 65 is expected to double to 69 million. Some 15 million of these people will be over the age of 85. With these population figures, the estimated fracture associated costs could double or triple by 2050 (27–29).

## CLASSIFICATION

Osteopenia is a generic term that describes a finding of decreased bone density on plain radiographs. This term relates only to the presence of the bone density loss itself and does not imply any specific cause for the bone loss. There are a variety of diseases that can lead to osteopenia, the two most notable of which are osteoporosis and osteomalacia.

The relative balance between the mineralized and unmineralized portions of bone distinguishes osteoporosis from osteomalacia. Osteomalacia occurs when the osteoid fails to mineralize during bone formation or remodeling. The excessive accumulation of unmineralized osteoid leads to a qualitative change in the bone rather than a quantitative change. The causes of osteomalacia are varied and result from a failure of the normal processes of bone metabolism such as vitamin D deficiency, impaired vitamin D production, metabolic acidosis, hypophosphatemia, kidney dysfunction, and heavy metal intoxication.

In contrast to osteomalacia, which is a qualitative change in bone, osteoporosis is a quantitative loss of total bone mass. Both the mineralized and unmineralized por-

tions of the bone are lost in a proportionate fashion. This progressive loss of bone mass leads to bony fragility and ultimately to increased fracture risk. If an underlying causative factor for the osteoporosis can be identified, such as prolonged steroid use, then it is classified as secondary osteoporosis. Primary osteoporosis is a diagnosis of exclusion that is made when all of the causes of secondary osteoporosis have been ruled out.

Riggs and Melton (30) have further subclassified primary osteoporosis into two distinct categories. Type I, or postmenopausal osteoporosis, most commonly affects women between the ages of 51 to 65. The estrogen deficiency that accompanies the onset of menopause precipitates the bone loss. These patients lose about 2% to 3% of bone mass per year. Because mostly trabecular bone is affected, fractures occur in the skeletal regions with a high ratio of trabecular to cortical bone such as the vertebrae, distal radius, and femur. Type II, or senile osteoporosis, affects both men and women in a 2 to 1 ratio. It occurs in patients over the age of 75, and both aging and long-term calcium deficiency play a major etiologic role. In contrast to type I osteoporosis, type II osteoporosis affects cortical bone as well as trabecular bone. Therefore, fractures occur at sites with more cortical bone such as the hip, pelvis, proximal humerus, and proximal tibia.

The World Health Organization (WHO) has used bone mineral density as the main diagnostic criterion for osteoporosis (31). According to this criterion, a patient with a bone density that is below 2.5 standard deviations (SDs) from the mean density for a young adult reference population is diagnosed with osteoporosis. Osteoporotic patients who have insufficiency fractures are placed in the severe osteoporosis category. If the bone mineral density is between 1 and 2.5 SDs from the young adult mean, the patient is deemed to have low bone mass or osteopenia. These guidelines are useful for epidemiologic purposes, but they do not serve as an adequate guide for treatment.

## CLINICAL EVALUATION

In most cases the presence of a metabolic bone disease, such as osteoporosis or osteomalacia, goes relatively unnoticed by the patient or the physician because of the generalized lack of associated symptoms. Suspicion for the presence of a metabolic bone disorder is aroused when a patient sustains a low-energy fracture of the ribs, wrists, hips, or spine (32,33). In the absence of an acute event, thoracic wedge compression fractures can be inadvertently detected on routine chest radiographs. Generalized osteopenia may be detected on routine radiographs when a mineralization loss of 30% to 50% has occurred (34,35). The presence of osteopenia should alert the clinician to the presence of a metabolic bone disorder and should prompt further clinical evaluation to identify the cause of the osteopenia.

Once the presence of metabolic bone disease is suspected, the clinical evaluation begins with a careful history and physical examination. A patient suffering from generalized osteoporosis is usually asymptomatic (36). Despite the lack of clinical symptomatology, the presence of associated risk factors can help support the diagnosis of osteoporosis. For example, a patient may relate a progressive loss of body height, or a change in body shape due to an increase in thoracic kyphosis (36). Caucasian females with light skin and hair, particularly of a northern European descent, are at an increased risk for the development of osteoporosis (37). Inquiries should also be made regarding the use of cigarettes, alcohol, and caffeine (38,39). These patients may be very thin, may have been very active at one point, and may have had exercise-induced amenorrhea or the early onset of menopause (40).

If the patient with osteoporosis is symptomatic at the time of presentation, the symptoms are usually directly attributable to an insufficiency fracture. During the evaluation, the clinician should localize the pain. With spinal insufficiency fractures, pain is usually localized to the lower thoracic or upper lumbar regions. However, the pain may be referred to the low lumbar, lumbosacral, or gluteal region. The onset of pain usually occurs with some low-energy activity although there may not be an inciting event. As the fracture heals, the pain will usually subside over the ensuing months. Unfortunately, despite successful fracture healing the patient rarely returns to the baseline status. These patients often develop generalized chronic low-grade back pain. Increased spinal kyphosis, prolonged inactivity, or altered muscular mechanics that occur after the fracture may contribute to the chronic symptoms (36). Chronic abdominal pain may also occur because the progressive spinal collapse diminishes space within the abdominal cavity (41). If the fracture fails to heal and a nonunion develops, the pain will remain severe, especially when in an upright position.

Clinically, patients with osteomalacia will have nonspecific complaints. They have generalized muscle weakness and generalized skeletal aches and pains. In contrast to osteoporosis, which predominantly affects the axial skeleton, osteomalacia predominates in the appendicular skeleton. Osteomalacia can be distinguished from osteoporosis radiographically by the presence of looser zones. These radiolucent areas are aligned perpendicular to the long axis of the bone. They represent complete cortical micro stress fractures that heal with unmineralized osteomalacic bone. The looser zones are usually bilateral and symmetric. Another distinguishing feature of osteomalacia is the presence of symmetric, pathologic fractures. The clinical evaluation should be targeted to finding the underlying cause of the osteomalacia. A variety of etiologies can lead to this disease process. The most common causes are chronic renal failure, disruption of the vitamin D pathway (either from deficient intake or impaired

metabolism), hypophosphatemic syndromes, and heavy metal intoxications (42).

If a low-energy fracture or the presence of osteopenia on radiographs alerts the physician to the possibility of a metabolic bone disorder, the physician is obligated to determine the cause for the bone loss. With a low energy fracture, the first step is to rule out malignancy with magnetic resonance imaging (MRI), computed tomography (CT), or bone scan. After a malignant process has been eliminated, laboratory tests are obtained to delineate the diagnosis. Table 71-1 outlines the various laboratory values that are useful in establishing a cause for the osteopenia. A complete blood count with differential serum and urine protein electrophoresis, and an erythrocyte sedimentation rate will reveal any hematologic abnormalities. If any of these values are abnormal then a bone marrow aspirate is indicated. If these tests are negative, then the next step in the laboratory evaluation is to look for the presence of an endocrinopathy. Thyroid function tests, glucose level, cortisol level, and PTH levels help to identify the presence of Cushing disease, diabetes mellitus, hyperparathyroidism, or hyperthyroidism. If one of these diseases is discovered, they should be treated accordingly.

At this point in the evaluation, the clinician must distinguish between osteoporosis and osteomalacia as the cause of the bone loss. About 10% of these patients will have osteomalacia as the underlying diagnosis (22). Serum calcium, phosphorus, 24-hour urine calcium, parathyroid hormone, alkaline phosphatase, and 25OH vitamin D levels can help to identify about half of the cases of osteomalacia. Osteomalacia is suspected when the product of the serum calcium and serum phosphorus

is less than 25 mL/dL<sup>2</sup>, when bone-specific alkaline phosphatase is elevated, and when the 24-hour urine calcium is less than 50 mg (43). If all of the laboratory data are unable to establish a diagnosis, then a transiliac bone biopsy can make the final distinction between osteoporosis and osteomalacia (22). If the bone mineralization is found to be normal on biopsy, then the diagnosis of osteoporosis is established essentially by the exclusion of all other possibilities. Even in the setting of osteoporosis, the transiliac bone biopsy can distinguish between high turnover and low turnover osteoporosis. Additional laboratory assays are also helpful in assessing the metabolic activity of the bone with osteoporosis (44,45). Bone-specific alkaline phosphatase, osteocalcin, and procollagen-1 propeptides are indicative of bone formation. Urine pyridinoline, deoxypyridinoline, and the N-telopeptides are collagen breakdown products indicative of bone resorption or turnover.

### RADIOGRAPHIC EVALUATION

The main goal guiding the treatment of the patient with osteopenia is to prevent the occurrence of fractures. However, the severity of the bone loss exists along a continuum, and the key to guiding treatment and preventing fractures is determining the threshold of bone loss below which fractures become imminent. A variety of noninvasive imaging tools are available which allow for an estimation of bone mineral density. These density measurements have been shown to correlate directly with fracture risk. For example, a 50-year-old woman whose bone density is 1 SD below the average for a woman has a 30% risk of fracture over her lifetime whereas that same 50-year-old woman with a 2 SD decrease in her bone mineral density has a 60% fracture risk over her lifetime (33). Before placing excessive emphasis on bone densitometry, it is important to realize that bone density is just one risk factor in a multitude of risk factors that can increase to fracture risk, such as cardiovascular status, geometry of the bone, force of the insult, risk of fall, and body habitus (46–48). There are many techniques to assess bone density and each has its relative merits and limitations. Factors to consider when assessing bone densitometry techniques include cost, radiation dose, and relative precision and accuracy as well as duration of the procedure.

Given the myriad options for assessing bone density, the question arises as to which technique to use. In a clinical setting where dual-energy X-ray absorptiometry (DEXA) or quantitative CT scan is unavailable, then radiogrammetry or radioabsorptiometry are crude but effective methods for assessing bone density. DEXA is currently the method of choice to assess bone density in the osteopenic patient because it measures axial sites with high precision, high accuracy, low radiation dose, and low cost. However, in the older adult patient with osteoarthritis, adjacent calcifications, or a compression

**FIG. 71-2.** Lateral lumbar radiograph of the lumbar spine in an 85-year-old patient with new onset of back pain reveals osteopenia and an insufficiency fracture of the second lumbar vertebra. Note the prevertebral calcifications, osteophytes, and end-plate sclerosis that can falsely elevate density measurements by dual-energy X-ray absorptiometry performed in the anteroposterior projection.

fracture, quantitative CT scan is still a viable option (Fig. 71-2).

### TREATMENT

Simply put, the main goal of treatment for a patient with severe osteopenia is to prevent the occurrence of fractures by maintaining an adequate skeletal bone mass. Though declaring this goal is simple, achieving it is a more difficult matter. As outlined earlier in this chapter, the causes for significant osteopenia are varied. Currently, there are no existing means to completely replace lost bone mass, though certain medical therapies can effect some modest changes in bone mass. In addition, once the internal architecture is lost no clinical method to reestablish it exists. Since the metabolic bone diseases are clinically silent, the true denominator of the number of patients afflicted with this problem is unknown. This makes clinical investigations assessing therapeutic options difficult. Treatment of osteoporotic spine fractures, once they have occurred, will be discussed in Chapters 72 and 73.

Currently, the foundation for treatment of these disorders is to prevent skeletal bone loss. There are two ways to maximize bone mass during aging. The first is to maximize the peak bone mass obtained by an individual during growth and development. Most children do not cur-

rently receive adequate amounts of calcium in their diet (22), and this nutritional deficiency can lead to a lower peak bone mass at maturity. An ideal target for calcium supplementation during the stages of growth and development would be premenarchal adolescent girls (49). The second way to preserve bone mass later in life is to slow or stop the rate of decay of bone mass once skeletal maturity has been achieved.

A variety of factors are known to alter the rate of decline in bone mass. First, the patient needs to maximize their nutrition to make sure that they are getting adequate oral intake of minerals and hormones to maintain skeletal integrity. The diseases that are known to accelerate bone loss need to be identified and treated. Medications that stimulate bone loss should be avoided if possible, or used sparingly when necessary. These medications include steroids and the anticonvulsants (50,51). In the otherwise healthy individual without any underlying medical or pharmacologic cause for bone loss, cessation of smoking and alcohol intake are two factors that are easily addressed and can dramatically impact the rate of decay of bone mass. Impact loading exercise has been shown to positively effect bone mass (52,53). One hour of impact exercise two to three times per week can increase both the bone mineral content and the total body calcium (41). Conversely, it is well documented that sedentary people or people in antigravity settings such as astronauts can sustain a significant amount of bone loss secondary to the lack of skeletal loading (48,54). Since the ultimate goal is to prevent the occurrence of fractures, fall prevention is important in the older adult patient. Outfitting the patient's environment with appropriate assist devices for ambulation, avoiding medications that can negatively affect the mental status, and maximizing cardiovascular status can all help to lower the fall risk. Finally, there are a variety of pharmacologic interventions that can be instituted to slow down the rate of bone loss. These medical therapies are discussed subsequently in further detail.

Calcium is an essential nutrient to the body. A certain level of intake is required to maintain calcium homeostasis. The average woman requires 1 to 1.2 g per day in a premenopausal state and 1.5 g in the postmenopausal state (55). Unfortunately, the average woman does not meet these requirements. When the nutritional intake of calcium is deficient, the body will begin to deplete its store of calcium from the bone. Therefore, calcium supplementation can be beneficial by preventing this process from occurring. It has been shown to be helpful in the premenopausal patient (41). Also in the older adult patient with type II osteoporosis, calcium supplementation therapy, especially in combination with vitamin D, has been shown to lower the rate of hip fractures (56). It is interesting to note that the bone mass in these patients was unchanged and the effect may be related to crude bone quality or maintaining lower levels of PTH. Calcium supplementation therapy in the early post-

menopausal patient does not protect against bone loss (57,58). Here it seems that the effects of estrogen deficiency significantly overshadow any effect of nutritional deficiency. The current recommendations are for 1,200 mg of calcium supplementation in the premenopausal patient and 1,500 mg in the postmenopausal patient with an additional 400 to 800 units of vitamin D concurrently.

Estrogen plays a pivotal role in the development of type I osteoporosis. In the early postmenopausal period (i.e., the first 10 years) the absence of estrogen leads to a significant, accelerated bone loss. Bone responds to estrogen through receptors that are directly located in the bone (59). It also has a secondary antiresorptive effect by modulating certain cytokines, which ultimately promotes a positive calcium balance (60,61). Studies have shown that bone mass can be increased with estrogen therapy by 2% to 3% in the spine and that the fracture rate can be decreased by 50% (57,62,63). Unfortunately, this protective effect on the bone is not maintained when estrogen therapy is withdrawn. Additional benefits of estrogen therapy include treatment of the symptoms of menopause. It also imparts a cardioprotective effect by improving the cardioprotein profile (64). It also may improve cognition and decrease the risk of Alzheimer disease (65). However, estrogen therapy is not without its risk. The therapy is often poorly tolerated secondary to uterine bleeding. One of the more worrisome risks associated with estrogen therapy is the up to 30% increased risk of breast cancer that can occur with prolonged therapy (66,67). There is also an increased risk of developing uterine cancer. However, this risk can be negated by the use of combination therapy where the estrogen is given in conjunction with progestin (65). Finally, estrogen may have untoward effects on the liver, precipitating cholelithiasis.

A strong family history of osteoporosis, bone density less than 2.5 SDs below the norm, greater than 5% of bone loss per year, symptoms of menopause, and high cardiovascular risk are all indications for estrogen therapy. Contraindications to the use of estrogen therapy include a history of breast cancer regardless of receptor status, history of deep venous thrombosis (DVT) or pulmonary embolus (PE), and history of underlying liver disease or hypertension.

The selective estrogen receptor modulators (SERMs) can act either as an estrogen agonist or antagonist depending on the type of tissue that is being targeted. Their appeal rests in the ability to selectively stimulate estrogen receptors in bone, while simultaneously having an antiestrogenic effect on the breast. They therefore have the potential to retard bone loss and reduce breast cancer risk. Tamoxifen has primarily been used as a chemotherapeutic agent in women with receptor-positive breast cancer. A placebo-controlled trial in postmenopausal women revealed that tamoxifen therapy can precipitate mild increases in spinal bone mineral density (68). A second trial concluded that the overall occurrence of fractures

could be reduced by 19% with tamoxifen therapy (69). Though the estrogenic effect of tamoxifen on bone is not as potent as regular estrogen therapy, other more potent SERMs are becoming available. Raloxifene increases bone density by 2.4% in the spine and hip when compared to placebo, and the reduction of new vertebral fractures was 30% at the low dose and 50% at the higher dose (70). These drugs maintain a positive effect on the cardi-lipid profile, thereby having a beneficial effect on the heart. However, though raloxifene therapy has been shown to decrease spine fractures, the nonvertebral fracture rate remains unchanged. Further study is warranted with this class of drugs to better understand their physiologic effects and to guide development of future SERMs.

An exciting new class of drugs used in the battle against osteoporosis are the bisphosphonates. The bisphosphonates block the ability of the osteoclasts to resorb bone. A first generation bisphosphonate, etidronate, showed some promise in the early stage of treatment. However, it was becoming clear that with long-term treatment, etidronate may actually have inhibited bone mineralization (71). A second line of bisphosphonates is now available which does not inhibit mineralization long term as with the first generation bisphosphonates. Alendronate is taken orally in 5 to 10 mg doses. The main side effect is the development of upper gastrointestinal symptoms. Recent gradual dosing regimens and half-dosing regimens have limited the occurrence of these symptoms. Since it has poor absorption, alendronate must be taken on an empty stomach with a glass of water. Alendronate is equally as effective as estrogen in maintaining bone mass and decreasing fracture risk (72,73). However, unlike estrogen, the second generation of bisphosphonates maintains its efficacy after the treatment is withdrawn (74). The use of these drugs is advocated in situations where the use of estrogens is contraindicated, such as among patients with breast cancer and thrombophlebitis. In the setting of osteoporosis, one contraindication to the use of bisphosphonates is the presence of an acute fracture. Theoretically, the effect of bisphosphonates on remodeling may have an adverse impact on fracture healing.

Newer generations of bisphosphonates are rapidly becoming available which may be more potent and better tolerated than alendronate. Risedronate was evaluated in a study of 2,458 women (75). Over the 3-year course of the trial, patients taking risedronate had a 40% reduction in the incidence of new vertebral and nonvertebral fractures. Bone mineral density was increased 4.3% in the spine and 2.8% in the proximal femur. The incidence of adverse effects was equal to the placebo group. In a phase II trial, a single intravenous 4 mg dose of zoledronic acid increased bone mineral density and decreased markers of bone turnover for 1 year (76). Whether this treatment can significantly reduce fracture rates remains to be seen.

Calcitonin can down-regulate osteoclast function and has been used successfully in the treatment of Paget dis-

ease. In the osteoporotic, postmenopausal patient, calcitonin can increase total body calcium and lumbar bone mineral density (77,78). It has also been shown to decrease the spinal fracture rate by about 33% (79). The maximal effect of calcitonin is seen within the first 6 months of therapy and the elevations in bone mineral density persist over time (80). Calcitonin is indicated for female osteoporotic patients who have a high bone turnover rate on biopsy, are unable to take estrogen, are premenopausal with osteoporosis, and have persistent bone loss on estrogen, as well as for male patients with osteoporosis. Calcitonin is also very effective for use in the patient who has sustained an acute compression fracture, because calcitonin has a strong, short-term analgesic effect (81). Previously, calcitonin was administered subcutaneously, but there are bothersome side effects associated with this route of administration. The intranasal form is better tolerated. If therapy is to be initiated, 200 units should be given daily for a 6-month period.

The aforementioned therapies treat osteoporosis by preventing bone resorption; fluoride differs from these therapies because it can actually stimulate bone formation. Communities with fluorinated drinking water have a lower incidence of insufficiency fractures (82). With fluoride therapy, bone mass can be increased in the spine 4% to 5% per year (83). Initial studies evaluating treatment of osteoporosis with fluoride revealed concerns with the use of fluoride. These studies indicated that although fluoride therapy may increase bone density, it may also make the bone more fragile and more susceptible to fractures (84). These early investigations used high doses of fluoride, and did not give adequate calcium supplementation. Continuing work reveals that the rate of bone mass augmentation is important in stimulation of bone generation with the fluoride and should not outpace the ability of the body to mineralize that newly formed bone (85). It now appears that the susceptibility to bony fragility occurs when the bone is not given adequate time to mineralize. Pak et al. (83) have developed a cyclic, low-dose, slow-release fluoride form that may allow the bone to regenerate in a controlled fashion that does not jeopardize the mechanical stability of the bone. Their studies reveal a significantly decreased fracture rate with the use of this form of fluoride. This form awaits U.S. Food & Drug Administration approval. Should fluoride therapy be instituted, it must be done with low doses and supplemented with vitamin D and calcium to ensure adequate mineralization.

## CONCLUSION

The spine surgeon may be the first clinician to detect the osteopenic patient. The patient may present in the office with a simple insufficiency fracture or with decreased bone density on routine spine radiographs. When osteopenia is discovered, the clinician should take

the necessary steps to identify the underlying cause. Once a diagnosis is established with a proper history, physical examination and laboratory data; bone densitometry is useful to assess the patient's fracture risk, and to set a baseline for long-term follow-up. The most effective intervention to combat osteopenia is prevention. Patient education on proper diet, impact exercises, and avoidance of substances that promote bone loss is the cornerstone to prevention. Once osteopenia is established, there are medical therapies that can halt or retard the bone decay. In the future, new and exciting biologic technologies like gene therapy may allow us to rebuild the lost bone mass and ultimately prevent the occurrence of debilitating insufficiency fractures.

# Surgical Options and Indications: Kyphoplasty and Vertebroplasty

Christopher M. Bono, Christopher P. Kauffman, and Steven R. Garfin

---

Osteoporosis is an increasingly recognized cause of fractures in the lumbar spine in the postmenopausal and older adult population (1–6). Women are more commonly affected (7), though men are also subject to the sequelae of progressive bone loss (8,9). Histologically, osteoporotic bone is normal, with a decreased amount of bone per volumetric unit caused by an imbalance between bone production and resorption (10). In contrast to osteomalacia, mineralization is unaltered. Though newer pharmacologic agents offer a promising future for the treatment and prevention of osteoporosis, they will have minimal impact on vast numbers of individuals with already advanced disease (11).

Decreased bone mineral density is related to skeletal weakening. Although all bones are affected, some regions are at greater fracture risk. The spine is the most commonly affected area, followed by the distal radius and proximal femur (7). Osteoporotic vertebral compression fractures (VCFs) are most common in the upper lumbar and lower thoracic spine (9,12). While injuries of the wrist and hip are clinically apparent, osteoporotic spine fractures are frequently asymptomatic. Often, however, they can be a troubling source of back pain, and potentiate medical morbidity and mortality. Multiple, consecutive VCFs are common in untreated individuals, leading to numerous levels of vertebral body (VB) height loss. This can lead to progressive anterior column shortening, resulting in thoracolumbar kyphosis, which can lead to functional disability, pulmonary compromise, and eating disorders, such as early satiety, in an older adult population that is likely to have many concomitant comorbidities (1,3–5).

VB augmentation has been developed to help treat osteoporotic VCFs. Currently available techniques are vertebroplasty and kyphoplasty. Vertebroplasty was first introduced in the mid-1980s and involves direct injection of polymethylmethacrylate (PMMA) cement into the VB

(13). Cement fills the interstices of the cancellous bone under high pressure and hardens during final curing. It restores near normal stiffness and surpasses normal vertebral strength (14,15). Clinical reports of long-standing pain relief have demonstrated its effectiveness in treating symptomatic VCFs (16–19). Despite these positive attributes, vertebroplasty lacks the ability to restore VB height to a compressed segment.

Sagittal deformity (i.e., kyphosis) related to osteoporotic VCFs can lead to functional and respiratory impairment, as well biomechanically predispose the spine to further fractures (1,3). Thus, interest in minimally invasive methods of fracture reduction and stabilization has arisen. Kyphoplasty was developed in the early 1990s to fulfill these demands. Still in its infancy, it involves percutaneous insertion of an inflatable bone tamp into the VB to restore height (20,21). Cement is then injected under low pressure into the cavity created by the tamp; higher pressures are required for vertebroplasty. Preliminary clinical data indicate consistent restoration of vertebral height in addition to durable pain relief in over 90% of cases with low complication rates (20,21).

Both kyphoplasty and vertebroplasty are effective treatments of painful osteoporotic VCFs, with the former giving the added benefit of fracture reduction and deformity correction. Successful use of these techniques in the lumbar spine relies on a clear understanding of their indications, applications, complications, and outcomes.

## INDICATIONS

### **Kyphoplasty**

#### *Pain Relief*

Kyphoplasty is indicated for progressive or intractable pain associated with an osteoporotic VCF. Clinical data

suggest more than 90% pain relief (20,21). The mode of relief remains speculative, though most believe it is fracture stabilization. Some hold that bony denervation from the heat produced during cement curing might contribute, though this remains conjectural.

Successful use of kyphoplasty requires that the practitioner first determine if the symptoms are genuinely originating from the VCF. The reliability of subjective reporting alone is limited, as complaints of chronic back pain might be related to other causes. Objective evidence that the vertebrae in question are the cause of pain must be sought. This is suggested by point tenderness on percussion of the spine that correlates with the fractured level on plain radiographs. If pain and tenderness are more generalized, this determination is difficult based on plain films alone, and other advanced imaging methods can be helpful. Magnetic resonance imaging (MRI) and bone scintigraphy can be used to gauge the acuteness of the injury (22,23). A positive signal on bone scan has been correlated with good pain relief after vertebral augmentation (22). It is likely that MRI is of similar use, though this remains to be demonstrated in a clinical study.

### ***Pulmonary Function***

VCFs have significant negative effects on pulmonary function (1,24). By measuring forced expiratory volume and resting vital capacities, Schlaich et al. (1) reported a strong correlation between the severity of kyphosis and decreases in lung capacity. Kado et al. (24) reported higher mortality rates secondary to pulmonary complications in patients with kyphotic VCFs versus those without deformity. It is not presently known if the converse relationship is true (i.e., if correction of the deformity reverses or prevents these effects). However, it is reasonable to assume that kyphoplasty may favorably affect pulmonary function of correctable osteoporotic kyphosis. Further study of the specific effects of kyphoplasty on postcorrection pulmonary function is warranted.

### ***Deformity***

Kyphoplasty is a relatively new technique. As a deformity correcting procedure, its indications must adhere to basic principles. Surgeons may be tempted to perform kyphoplasty on any, and every, VCF. Consideration of spinal balance and deformity progression is a more prudent measure. Though initial reports suggest its relative safety, further investigation is required to more clearly demonstrate a positive balance between the potential benefits of kyphosis correction versus procedural complications.

For both metabolic and mechanical reasons, the risk of subsequent VCFs increases with each additional injury. Realignment may help reduce the incidence of further fractures. Acute fractures (less than 3 months old) are

more easily reduced than chronic ones (21). Although correction in VCFs one year or more after fracture have been obtained, this is difficult to predict. Severe, rigid deformities from multiple healed fractures that compromise function or quality of life might be better addressed by other surgical methods, if necessary. If detected radiographically, progressive collapse, even if not severely painful, is also an indication for kyphoplasty.

### **Vertebroplasty**

The indications for vertebroplasty are limited to the treatment of pain associated with VCFs. Numerous series have documented high rates (90% to 95%) of pain relief in patients after vertebroplasty (16–19). Though it has been suggested that some vertebral height restoration can be obtained by positioning in the prone position with early fractures, this has not been substantiated in a clinical series. Fracture reduction cannot be considered an indication for this procedure. It is unlikely that vertebroplasty would have a direct impact on pulmonary function, as the deformities will be “fixed”, although restoration of ambulation and mobility have positive effects on overall health. Kyphotic deformity related to osteoporotic VCFs cannot be considered an indication for vertebroplasty at this time.

### **CONTRAINDICATIONS**

The contraindications for both kyphoplasty and vertebroplasty are similar. They are contraindicated in stable, healed, nonpainful fractures. They are also not indicated in the presence of infection. Associated medical problems can make the procedures dangerous. Coagulopathy can lead to epidural hematoma with VB cannulation, especially if the pedicle borders or posterior VB have been breached. At this time, a burst fracture pattern with retropulsed fragments is a relative contraindication to kyphoplasty or vertebroplasty, though some surgeons have used kyphoplasty in selected cases. In some situations such as vertebral plana, these procedures may not be technically possible because of inability to cannulate the VB due to severe vertebral compression. At present, it is also not used for traumatic, nonosteoporotic fractures in young individuals.

### **BIOMECHANICS AND BASIC SCIENCE**

Osteoporotic VCFs are the result of alterations of the bone's mechanical or structural properties. Strength is diminished by decreases in quantity, while bone quality is unaffected. The proportion of mineral to bone matrix is physiologic, as a histologic sample would appear normal. The extent of osteoporosis can be assessed by measuring bone mineral density. Substantially low bone mineral density is associated with a predisposition to VCF with low-energy mechanisms.

VBs bear the majority of the axial compressive forces sustained by the spine. Flexion movements increase these forces. If they exceed the bone's capacity to resist them, fracture results. In its first stage, fractures involve the anterior aspect of the VB (i.e., anterior column). Flexion-compression fractures usually do not involve the posterior VB wall. With additional force, fracture lines can propagate into the middle column, creating a burst fracture. Alternatively, osteoporotic burst fractures can occur from pure axial loading, which might occur from a fall from height or other higher energy mechanism. These often fracture the posterior wall, and perhaps the posterior elements.

After VCF, the bone is weakened and compressed. Treatment can be directed at one or both of these problems. Medical management of osteoporosis addresses bone weakness by changing the metabolic balance of bone deposition and resorption. Agents such as alendronate, estrogen, and calcitonin have proven clinical efficacy in this manner (11). Though they are systemic treatments that affect the entire skeleton, they have limited effects on fracture risk in advanced cases.

Vertebroplasty and kyphoplasty address the bone fragility problem, but in a much more direct way than medical treatments. By injecting cement into the bone, mechanical properties are restored. Stiffness is defined as the slope of a force versus displacement curve and represents the elasticity of bone prior to permanent deformation. Strength is a reflection of the force required to permanently deform a specimen (25). Studies done *in vitro* have demonstrated that both stiffness and strength are affected with osteoporosis (14,15,25). As osteopenic bone is severely compromised, the mechanical properties of the augmented VCF are virtually entirely that of the bone cement. Thus, choice of bone filler (cement) affects the biomechanical effects of kyphoplasty and vertebroplasty.

Not all bone cements are equal. Different substances cause different changes in strength and stiffness. Orthocomp (Orthovita, Malvern, PA) has demonstrated significantly stronger and stiffer vertebrae than Simplex P (Howmedica, Rutherford, NJ) after *in vitro* vertebroplasty of human cadaveric osteopenic lumbar spinal segments (15). While Simplex P resulted in less stiffness than prefractured specimens, Orthocomp restored initial stiffness values. Similarly, other commonly used materials, such as cranioplastic cement (CMW, Blackpool, England) have demonstrated greater strength but lower stiffness than intact specimens (14). Other variables, such as the cement powder/monomer ratio and addition of media (e.g., barium) to increase the cement radiopacity, can alter material properties. The long-term clinical implications of these variables on augmentation durability remain to be seen (26). Additionally, it is not known how much strength is needed to support the osteoporotic bone and spinal column.

The volume of cement injected can influence mechanical properties after vertebral augmentation. In addition to cement viscosity, the method of injection can be a factor. In most cases a bilateral approach is recommended with kyphoplasty, while in some cases only unilateral injection might be possible. Bilateral injection maximizes cement delivery. Data from *in vitro* studies indicate significantly greater strength with bipedicular injection of 10 mL (5 mL on each side) versus unipedicular injection of 6 mL of cement in the lumbar spine (25). Interestingly, both methods resulted in restoration of initial stiffness.

Restoration of near normal levels of strength and stiffness is thought to be preferable. This procedure has limited use, however, because it is not clear what "normal" is in the osteoporotic spine. Osteoporotic VBs are weaker and more brittle than healthy specimens. In recent biomechanical studies cement augmentation resulted in strength greater than that of the prefractured state, while initial stiffness values were not exceeded. This is probably optimal. If augmentation had only restored, but not exceeded, the prefractured strength, it would have a similar risk of fracture as other osteoporotic vertebrae. However, if stiffer, it might act like a walnut in a column of banana slices, thereby increasing the chance of an adjacent segment fracture with slight compression.

### Sagittal Balance

Kyphoplasty is a tool to treat pain and deformity through fracture reduction. As such, its indications should be subject to the same rigors as other methods of open surgical treatment. This relies on an understanding of the fundamental biomechanical principles of deformity correction.

The vertebral column is naturally contoured in the sagittal plane, while normally straight in the coronal plane. Sagittal contour is achieved by a combination of cervical and lumbar lordosis with intervening thoracic kyphosis. These curvatures are radiographically measured statically and represent the spine in a standing weight-bearing state. The thoracic spine normally has an average of 30° of kyphosis, with an approximate range of 20° to 40° (27). The apex of normal thoracic curvature is at T6 or T7. Thoracic kyphosis is produced primarily from anterior wedging of the VBs. Anterior and posterior disc heights are normally equal. The rib cage is an integral component in the stability of the thoracic spine providing an additional restraint to axial motion through costovertebral junctions. The lumbar spine is in lordosis, which is primarily produced by discs that are taller anteriorly than posteriorly. Average lumbar lordosis is approximately 50°, with values ranging from 30° to 80°.

Cervical, thoracic, and lumbar curvatures must be considered in concert. Together, they attempt to achieve vertebral balance. Sagittal balance can be assessed on a full-length lateral radiograph by dropping a vertical plumb

line from the base of the occiput. Balance is realized if that line intersects the seventh cervical VB cranially and lies within 1 cm of the sacral promontory caudally. Mechanically, this ensures that the weight borne by the resting spine is acting to maintain its position within space. Relatively hyperkyphotic segments can be balanced by compensatory hyperlordosis in other segments. This carries the weight-bearing line back to its balanced position at the sacral promontory, which is centered over the hips.

Though compensation is common in other sagittal deformities, osteoporosis is usually characterized by uncompensated thoracic and lumbar kyphosis secondary to VCFs in both regions. These sagittal deformities can progress to a point at which the weight-bearing line can no longer return to its balanced position. This results in a self-propagating sagittal imbalance. To illustrate this, one can compare the hyperkyphotic spine to the Tower of Pisa. Balance is maintained if the center of mass lies within the boundaries of the base. Thus, the weight of the tower (or spine) functions to maintain its current position. However, if the tower leans over so much that the center of mass lies outside its base, the weight of the tower will cause it to fall. Corrective measures in deformity treatment attempt to restore the weight-bearing line or center of mass of the body to the anatomic base, which is the sacral promontory.

By increasing VB height at one or more levels, kyphoplasty can achieve this goal. Claims of vertebroplasty's ability to restore some vertebral height are unsupported in clinical trials, though some *in vitro* data suggest that as much as 28% can be regained with high-pressure injection (28). Laboratory investigations have demonstrated an average of 96% height restoration after kyphoplasty (28). Clinically, less height is gained if the procedure is performed more than 3 months after the fracture occurs (assuming the fracture correlates with pain onset). In an ongoing multicenter study, anterior and midline vertebral height was restored to within 99% and 92% of predicted dimensions, respectively, if performed less than 3 months after fracture occurrence (21).

## Planning and Preoperative Assessment

### History

Focus is initially on the disease course. Patients should be asked about prior workup, including results of bone densitometry (if performed), medications, and any surgery for extremity fractures. Careful evaluation by a primary care physician is helpful, as most patients have one or more comorbidities. Differential diagnoses must not be overlooked. Fevers and other constitutional symptoms can suggest infection or malignancy. A multidisciplinary approach is important, including internists, endocrinologists, and a spine surgeon.

Duration and location of pain are important factors in treatment decision making. Pain that follows an incident of low-energy trauma, such as a twist, exuberant cough, lifting a grocery bag, or opening a door suggests a VCF. The pain might be sharp and localized to one level, or dull and radiating to a number of levels. If the pain is resolving and the fracture is healing uneventfully, vertebral augmentation may not be indicated. Painless, progressive collapse, however, might be considered for reduction with kyphoplasty. A history of frequent falls may be an indicator of decompensated sagittal balance. This represents the patient's inability to overcome the forward shift of the center of gravity. Questions concerning intestinal bloating and appetite suppression are important, as this can occur with severe kyphosis from decreased abdominal volume.

### Physical Examination

If the pain has not restricted the patient to a chair, initial examination should include observing the patient walking. Severe kyphotic deformities can lead to spinal imbalance. Some patients begin to trip because of forward shift of the center of gravity, and may eventually require a walker to safely ambulate. Some are in wheelchairs because of the pain with activity. Limb-length inequalities and scoliotic deformities can alter coronal balance, which may influence decisions regarding correction. Assessment of the symmetry of chest wall expansion with inspiration can be used as a rough estimate of pulmonary function. Minimal chest expansion can also broaden the differential diagnosis to include other conditions causing spinal deformities, such as ankylosing spondylitis. Complete neurologic examination, including normal and pathologic reflexes, is requisite.

Each spinous process is then systematically percussed for tenderness, symmetry, and step-off. Optimally, percussion at a single level will be painful with nontender adjacent segments. This strongly suggests an acute fracture at that level as the major source of pain. More often, numerous levels are painful, making determination of the most symptomatic segments challenging.

### Plain Radiography

High-quality anteroposterior (AP) and lateral plain radiographs are first-line imaging modalities. Taping a radiopaque marker, such as a paper clip, to the point of maximal tenderness prior to taking radiographs can help identify symptomatic fractured regions. Sites of VB compression are visualized and Cobb angles measured. The anterior vertebral height is measured and compared to the posterior vertebral height to determine the percent of height loss. If the vertebra is uniformly compressed, height measurements are compared to those of adjacent vertebrae. Though a useful preoperative tool, plain films

are limited in their ability to differentiate fracture age. Furthermore, fractures through the middle column (i.e., burst types) are difficult to detect because of the washed-out appearance of the osteopenic bone. For these reasons, advanced imaging modalities are strongly recommended.

### Advanced Imaging

Treating physicians should obtain an MRI before deciding to perform kyphoplasty or vertebroplasty. MRI provides coronal, sagittal, and axial views of the vertebra, disc, spinal canal, and neural elements. Retropulsion is easily detected, as are epidural hematomas. Neoplasms and infections are better differentiated from VCFs with MRI than plain films. Spinal cord pathology including tumors and syringes can be visualized. Perhaps the greatest use of MRI before kyphoplasty is the ability to detect bone edema within the VB. This is an indication of the acuteness of the fracture. It must be noted, however, that increased signal intensity on T2-weighted images (i.e., edema) can remain for up to 2 years following an injury, even in clinically healed fractures. T2 images are better than T1 images in detecting bone edema, while STIR (short-time inversion recovery) images are best to differentiate malignant from benign osteoporotic fractures.

Computed tomography (CT) is useful to evaluate the bone. This study is often more helpful than MRI to differentiate tumors and infections from osteoporotic fractures. It also shows bone "quality" and defects. Another advantage of CT scan is that it is fast and readily obtainable. Often patients may not tolerate lying in the supine position for the extended period necessary with an MRI. They have decreased tolerance secondary to pain, CHF, and kyphotic deformity. In these individuals, CT may be necessary in place of MRI.

Bone scans can also be helpful in preoperative planning. By comparing the uptake at fractured versus adjacent nonfractured vertebrae, bone scans have proven highly predictive of pain relief after vertebral augmentation (22). Drawbacks include high radiation exposure and poor bony detail. For individuals in whom MRI is contraindicated, a CT combined with bone scan is a reasonable alternative to MRI.

### SURGICAL TECHNIQUE: KYPHOPLASTY

General and local anesthesia both have been used with success. General anesthesia may be more appropriate for patients undergoing multiple levels of kyphoplasty, though local anesthetic with sedation is suitable for one or two segment procedures. If general anesthesia is chosen, the patient is induced and intubated in the supine position and then logrolled prone onto a radiolucent table. Patients should be positioned on transverse rolls across the chest and thighs/iliac crests, to extend the spine and help reduce the fracture.

Adequate visualization with an image intensifier (C-arm) should be done before the procedure is initiated. The pedicle and VB should be seen clearly on posteroanterior (PA), lateral, and *en face* views. The pedicle can be viewed *en face* by angling the beam 10° toward the midline. This approximates the posterolateral to anteromedial direction of the pedicle producing an end-on appearance. Cannulation with a spinal needle should appear as a perfectly centered ring in the *en face* view. If the surgeon is confident in visualization of these landmarks, the procedure may proceed. The patient is prepped and draped in the usual sterile fashion.

### Approaches

There are three different methods of gaining access to the VB: transpedicular, extrapedicular, and posterolateral approaches. The extrapedicular approach is useful only in the thoracic spine and will not be discussed in this chapter, while the posterolateral approach is useful in the lumbar spine. The transpedicular technique is preferred and may be used at any level.

#### Transpedicular Approach

This is the preferred approach for the L1 to L5 level (Fig. 72-1). It requires a pedicle diameter of at least 4 to 5 mm. Some lumbar vertebrae are too small to safely accept the kyphoplasty instruments. Preoperative measurements on axial MRI or CT images are helpful in making this determination ahead of time. Both pedicles can be instrumented using the transpedicular approach. This approach endangers the spinal cord medially and the

FIG. 72-1. The path of the instruments using the transpedicular approach.

**FIG. 72-2.** The tip of the guidewire can be used to localize the point of insertion for the Jamshidi needle. In this case, the contralateral balloon tamp has already been placed. The guidewire tip lies directly over the center of the pedicle.

nerve root superiorly and inferiorly if the pedicle is missed or its cortex violated.

The spinous processes are palpated in the midline and the correct level of surgery is marked. This is confirmed on orthogonal views. In the PA view, the skin is marked just lateral to the lateral border of the pedicle. A spinal needle (Jamshidi needle) or guide pin is then introduced through a 1 cm longitudinal incision, angling approximately 10° toward the midline (Fig. 72-2). Needle location is then checked on a lateral to ensure proper orientation toward the pedicle center. Optimal radiographic appearance is the needle tip within the confines of the pedicle at all times. The C-arm is then moved to the *en face* or lateral position, and the needle is advanced under visual and tactile guidance.

The needle is inserted until the resistance of bone is felt. This may be difficult to discern because of the decreased bone density. With confirmation on all radiographic views, the needle is advanced to the posterior cortex of the VB. Once the needle is within the VB on the lateral view, it will appear slightly medial to the pedicle on the PA view (Fig. 72-3). As a general rule, the tip

**FIG. 72-3.** After marking the proper insertion site, the Jamshidi needle is then percutaneously inserted into the skin. It is advanced through the soft tissues to lie on top of the bone. By localizing on anteroposterior and lateral views, the needle is inserted into the pedicle. It is angled slightly medial, to match the orientation of the pedicle. Although the needle tip is entirely contained within the pedicle, once it has passed the pedicle-junction it may appear just medial to the pedicle.

should not cross the midline on the PA view at any point during insertion. If it does cross over to the contralateral side, careful investigation with a high quality *en face* view must confirm containment within the pedicle. Repositioning of the instrument should be considered if proper location cannot be ascertained.

The needle can be cranially or caudally directed through the pedicle, targeting toward a particular region of the VB. With compression of the superior end plate, the tool is directed toward the inferior half. Conversely, the needle is directed toward the superior half of the VB with compression fractures of the inferior end plate. This allows a greater amount of cancellous bone to be compressed beneath the fractured end plate. Cranial/caudal orientation is judged on the lateral view. If the vertebra is uniformly compressed the tool is advanced toward the mid-body.

### **Posterolateral Approach**

This technique is useful for kyphoplasty of the L2 to L4 vertebrae. It enters the VB through its posterolateral cortex, anterior to the transverse process (Fig. 72-4). The pedicle is not cannulated at any time. The skin entry point is different than the transpedicular approach. It lies 8 to 10 cm lateral to the midline, similar to that for a discogram. The needle is directed approximately 45° toward the midline. The *en face* view is not useful with this approach. Instead, the lateral view is more critical. The needle should lie anterior to the transverse process and neural foramen, thus avoiding injury to the exiting nerve root. Because this method can only be performed unilaterally, the needle must cross the midline to ensure adequate augmentation of the contralateral aspect of the VB.

### **Bone Tamp Insertion**

The center stylet is removed from the Jamshidi needle after confirmation of the position. A flexible guide pin is then inserted through the needle bore. The starting device (Jamshidi) is carefully removed with a twisting motion, maintaining the guidewire position within the vertebra. A centering stylet is passed over the guide pin to dilate the channel, followed by an outer cannula, which serves as the working channel. The guide pin and centering stylet can then be removed. A finger-held twist drill bit is introduced and advanced slowly to the anterior cortex of the VB. As the bone is soft, this must be performed under radiographic guidance to avoid penetration of the cortex. These steps are repeated on the opposite pedicle.

The drill bit is then removed while holding the working channel in position and the balloon tamp is inserted through the cannula. Different balloon sizes are available. The appropriate size can be determined on preoperative radiographs or MRI. In general, lumbar vertebrae can accommodate a large (20 to 25 mm) tamp.

**FIG. 72-4.** The path of the instruments using the posterolateral approach.

The balloon tamp has several important features that should be noted. Instead of being a concentrically formed sphere, the balloon is narrowed at its midpoint. This effectively creates anterior and posterior tamps that can more uniformly fill the space within the compressed vertebra. This enables “en masse” reduction of the fractured end plate. In addition, radiopaque markers located on both sides of the balloon make its ends visible on fluoroscopy. This facilitates positioning of the bone tamp, which should be centered within the VB. The tamp is then inflated under controlled pressure, using a digital manometer, with a radiopaque dye (Fig. 72-5). Pressures should initially be low and then gradually increase as the balloon meets the resistance of the cancellous bone. Pressures can intermittently drop and rise again, representing “giving” of the end plates and, hopefully, reduction. Sudden and persistent drop in pressure suggests rupture of the balloon and warrants inspection of the device before

**FIG. 72-5.** The balloon tamps are inserted and inflated. On the anteroposterior view, the surgeon must be aware of lateral breakout of the tamp through the wall of the vertebral body. This intraoperative radiograph shows excellent orientation of two tamps being inflated simultaneously.

proceeding further. Volumes are also monitored to estimate the approximate quantity of cement needed to fill the bone void. Fracture reduction is judged on the lateral C-arm view. Up to 99% of predicted height can be restored if performed within 2 to 3 months of the onset of the fracture. However, this may vary and is not always related to fracture acuteness.

### Cement Composition

The suggested formula for bone cement used during kyphoplasty includes PMMA, barium sulfate, and antibiotic powder. For consistency during each use, it is suggested that the surgeon use the same formula so as to minimize differences in curing time and consistency of cement. The following formula has been used successfully in practice: PMMA powder 40 cc, liquid monomer 10 cc, barium sulfate 6 g and antibiotic powder. Antibiotics that are heat stable include cefazolin (1 g), vancomycin (1 g), and tobramycin (1.2 g).

### Cement Delivery

The balloon tamp is deflated and removed while the working cannula is held in place. Several 3 cc syringes filled with a medium viscosity cement mixture of PMMA, barium, and antibiotic powder are prepared. These are used to fill several bone filler devices. In particularly unstable fractures, a contralateral tamp can remain inflated to maintain reduction while cement is injected ipsilaterally. Once the cement thickens to the desired consistency, the bone filler tubes are placed through the working cannula into the cavity in the VB. A stylet is then used to gently push the cement until the cavity created is filled (Fig. 72-6A,B). All steps at this point are followed fluoroscopically. Cement is injected under low pressure until one of the following occurs: cement has filled the anterior two-thirds of the VB, cement

**FIG. 72-6. A, B:** The cement is then pushed into the vertebral body under low pressure. In these lateral radiographs, it can be seen that the body is filled anterior to posterior. This is facilitated by creation of the bone void, which allows the surgeon essentially to “pour” the cement into the vertebra.

begins leaking through the VB, or it starts to fill the posterior aspect of the body or pedicle. Cement leakage through the vertebra may occur with mixtures that are too fluid. In this case, injection can be temporarily stopped, allowing the peripheral cement to begin to cure. Then, injection is resumed into the vertebra, which has sealed off its leaks. The process is repeated on the contralateral side. Typically, 2 to 6 mL of cement can be injected on each side.

During injection, possible cement extrusion should be monitored on image intensification. In most cases cement extrusion has little clinical sequelae. Cement curing can take from 5 to 10 minutes and is affected by mixture proportion, room temperature, and product brand. Once the cement is hardened, the cannula and bone filler device are twisted to dissociate it from the surrounding PMMA and carefully removed. Final radiographs are used to confirm cement placement, fracture reduction, and restoration of alignment. The patient should remain in the prone position for 10 minutes to ensure final hardening in the reduced position.

### **SURGICAL TECHNIQUE: VERTEBROPLASTY**

The setup and approach for vertebroplasty are similar to those for kyphoplasty. General or local anesthesia may be used. The techniques for cannulation of the VB are also similar. Vertebrograms can be performed before cement placement by injection of radiopaque dye through the working cannula. This gives an estimation of the path of least resistance, and thus, the most likely path of the cement. If enhancement of a nearby vessel occurs, the needle is moved to another position and retested. Mathis et al. (29) described three approaches: transpedicular, parapedicular (akin to extrapedicular), and posterolateral. The authors warn, however, of higher incidence of

cement leakage using posterolateral approaches in the lumbar spine. Leakage is probably more frequent with vertebroplasty than kyphoplasty because of the less viscous cement consistency required. In our experience, the posterolateral approach for kyphoplasty does not appear to be associated with a greater incidence of cement leakage.

Cement delivery is through a syringe filled with 2 to 3 mL of liquid PMMA cement attached to the cannulation needle. As with kyphoplasty, VB fill is monitored radiographically using the C-arm. Once cement has reached the posterior aspect of the VB, injection is stopped. The syringe is then removed, and the stylet is replaced into the needle to avoid leaving a “tail” of cement. Vertebroplasty can be performed unilaterally or bilaterally. Deramond et al. (30) recommend performing a unilateral vertebroplasty first. If adequate fill of more than 50% of the VB is achieved, this may be adequate. However, if less than 50% VB fill occurs, then contralateral augmentation is recommended. Biomechanical studies comparing unilateral versus bilateral cement injections have indicated comparable restoration of strength and stiffness with both methods (25).

### **POSTOPERATIVE CARE**

Kyphoplasty or vertebroplasty can be performed as a same day procedure. Blood loss is minimal, and pain relief is often apparent within 24 hours. If general anesthesia is used, an overnight stay might be considered in these often older adult patients. Narcotic pain medication is usually not necessary for more than 2 days postoperatively, after which pain can be managed with extra-strength acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs). Bracing is usually not recommended. In most cases, some avoidance of heavy

**FIG. 72-7. A–D:** Preoperative and postoperative radiographs after an L5 kyphoplasty. Note on the postoperative lateral view that cement was inserted until it reached the posterior border of the vertebral body. A small amount of cement entered the pedicle. This is a benign event and should not be considered extravasation. No extravasation into the spinal canal is seen. The small concentric holes noted on the anteroposterior view are the voids where the working cannulae were in place. This can be avoided by pulling the cannulae back to the pedicle-body junction during cement curing.

lifting for a few weeks is helpful for pain control and to avoid further fracture in patients who were forced to lead a sedentary lifestyle because of the pain. Follow-up radiographs should be obtained 1 month postprocedure, and repeated as indicated by the clinical picture (Fig. 72-7A–D). Radiographic follow-up may be considered for 1 year because of the propensity for subsequent fractures.

### PROBLEMS AND COMPLICATIONS

The complication rate after kyphoplasty is very low. In a recent multicenter study clinical complications occurred in 1.2% of patients and 0.7% of fractures (20,21). The most common technical complication is cement leakage. This may occur in up to 8.6% of cases. These are infrequently associated with clinical sequelae. However, in both vertebroplasty and kyphoplasty neurologic deficit has been observed secondary to cement extrusion into the canal or neural foramina (21,31).

The most common clinical complication of vertebral augmentation is transient pyrexia (30). This is most likely from a mild systemic reaction to the cement. From available data, it appears to be more frequent after vertebroplasty than kyphoplasty. This may be related to the pressure of injection. As with joint arthroplasty, cement injection can also lead to mild intraoperative hypotension, though this has not been reported after kyphoplasty. Anticoagulation, if used by the patient, should be delayed for at least 4 days to avoid epidural hematoma formation.

### Outcomes

#### *Kyphoplasty*

The senior author has had the opportunity to take part in evaluating an ongoing collection of kyphoplasty cases performed for osteoporotic VCFs. Early detailed evaluation of over 375 procedures has been reported. The results

are extremely encouraging. At up to 18 months' follow-up, over 90% of patients reported symptomatic relief and functional improvement. Anterior and midline vertebral height was restored to within 99% and 92% of predicted dimensions, respectively. These results were highly consistent between centers and technicians. Only four clinical complications occurred. In one case, transient pyrexia was associated with a brief episode of intraoperative hypoxia after cement injection. We believe this was related to the cement being in too liquid a state. The patient's blood pressure quickly rebounded with no further complications. In another case an epidural hematoma developed after heparin anticoagulation had been initiated just 8 hours after the procedure. Anticoagulant administration should be delayed for 4 days. Two patients sustained neurologic complications. One developed an anterior cord syndrome after a thoracic vertebra had been augmented through an extrapedicular approach. In reexamining the preoperative MRI, there was an unrecognized fracture at the junction of the pedicle and VB, as the body was below the pedicle. The other neurologic complication was a case in which paraplegia resulted after cement extrusion into the spinal canal. This was secondary to improper needle placement with violation of the pedicle wall, and was not related to the inflatable bone tamp itself. The patient had paraparesis of the lower extremities, which responded somewhat to emergent laminectomy and decompression of the spinal cord. Deficits are most likely related to mechanical compression of the neural structures as experimental data has demonstrated little chance of thermal damage with cement hardening. All three major complications occurred within the first 100 fractures treated. These led to technique modifications. None have occurred since then.

### **Vertebroplasty**

Numerous clinical reports of the results of vertebroplasty have been published. Barr et al. (17) retrospectively documented 95% marked or moderate pain relief in 38 patients treated for osteoporotic compression fractures. In contrast, only 50% of cases treated for metastatic lesions had substantial relief. The only neurologic complication was a case of T3 radiculitis that resolved with oral steroids.

In a similar retrospective analysis, Grados et al. (16) reported pain relief in 24 of 25 patients 1 month after the procedure. The authors used a percutaneous technique under general or local anesthesia. Unfortunately, they did not report immediate postprocedural pain relief, limiting the distinction between vertebroplasty's effects and eventual fracture healing. Two cases of transitory radiculitis treated with NSAIDs resolved. Seven cases of cement leakage into the disc space were noted on postoperative radiographs. Asymptomatic cement embolism to the lungs occurred in one patient. After an average of 48

months' follow-up, 34 new vertebral fractures occurred in 13 patients. The risk of fracture adjacent to a previously augmented level was higher than at other sites.

Heini et al. (18) performed percutaneous vertebroplasty under local anesthesia and sedation in 17 patients with 45 fractures. All patients reported significant pain relief at 1 day, 12 weeks, and 1 year after the procedure. Two patients sustained an additional fracture. The authors' rate of cement extrusion was high, with five cases of leakage into the paravertebral muscles, two cases into the spinal canal, and one case into a segmental spinal vein. However, no clinical complications were related to cement extrusion.

In response to a case of permanent nerve root deficit related to cement extrusion into the spinal canal, Wenger and Markwalder (19) performed open vertebroplasty in nine patients with osteoporotic compression fractures. Posterior cement leakage was removed under direct visualization in four cases. Interestingly, one fracture extended into the posterior VB cortex, but no PMMA leakage occurred. Internal fixation with pedicle screws was used to reinforce correction of a patient with multiple adjacent fractures. Pain relief was reported in all patients. One patient developed subsequent fractures that necessitated augmentation.

Other reported complications from vertebroplasty are transitory fever, temporary worsening of fracture pain, infection, and rib fracture (32–36). Spinal cord compression has been documented as well (31).

### **FUTURE DEVELOPMENTS**

Kyphoplasty and vertebroplasty have been used primarily for osteoporotic lumbar VCFs in older adult or postmenopausal individuals. However, the future indications for these techniques may not be so limited. Techniques of sealing off the posterior part of the VB may facilitate augmentation of burst fractures with minimal retropulsion. Also, it is probable that the indications can be expanded to include compression fractures in younger nonosteoporotic adults, particularly if other bioreabsorbable fillers are introduced. Further investigation is warranted to study the *in vitro* effects of bone tamp inflation on retropulsed bone fragments. Concern has been raised about the balloon pushing the fragments posteriorly. However, with height reduction, ligamentotaxis may in fact reduce these fragments. As vertebroplasty has been successfully used in patients with destructive neoplastic processes (37,38), kyphoplasty may find its place in the treatment of collapsed, kyphotic metastatic lesions in the spine (39). Clinical trials in selected patients are an important next step to explore these options. With the advantages of minimal invasiveness, it is likely that kyphoplasty and vertebroplasty might have substantial benefits over larger open surgical stabilization procedures.

Currently, PMMA cement has been the only material used for vertebral augmentation. Although PMMA is biocompatible, it is not resorbable. Several biologic bone cements have recently been developed and demonstrated their usefulness in extremity fractures. It would be attractive to use such materials in the augmentation of VBs. However, the biomechanical, biochemical, and clinical effects of alternative bone cements in osteoporotic VCF remains to be elucidated. An optimal material would be both osteoinductive and osteoconductive, as well as restore strength and stiffness to near normal values (40). Additionally, the balloon tamp itself should be biocompatible and resorbable. This would further enhance safety by allowing the balloon itself to be left in, as a barrier to cement leakage.

# Osteopenia: Vertebrorectomy and Fusion

Manabu Ito and Kiyoshi Kaneda

---

Primary management aims in thoracolumbar osteoporotic-fragile vertebral fractures should be alleviation of pain, early ambulation, preservation of the physiologic spinal balance with stability, and prevention of late neurologic complications. There has been a consensus that low-energy osteoporotic compression fractures in the thoracic and lumbar spine generally cause only localized pain and kyphosis without significant neurologic complications; therefore, urgent surgery is rarely indicated. Conservative treatment has been chosen for thoracolumbar compression fractures to relieve back pain. Usually these fractures can be treated successfully with a corset or hyperextension brace. Early ambulation and avoidance of prolonged bed rest are important. Late onset of vertebral

collapse can occur in patients treated conservatively; therefore, clinical and radiographic follow-up is mandatory. In this chapter, the pathology and surgical management of osteoporotic and posttraumatic vertebral collapse with increasing kyphosis with or without neurologic complications are described.

## LATE NEUROLOGIC COMPROMISE AFTER OSTEOPOROTIC FRACTURES

Gradually increasing kyphosis and late complications of the spinal cord or cauda equina can occur in some patients with an osteoporotic-fragile fracture of the thoraco-lumbar spine treated conservatively (Fig. 73-1). Taneichi et al.

**FIG. 73-1.** **A:** This 88-year-old woman had a T12 compression fracture when she stumbled and fell. **B:** One month later, the fractured vertebral body of T12 collapsed and its vertebral body height decreased. **C:** Three months later, the T12 vertebral body completely collapsed and neurologic deficits occurred.

reported that 36.6% of patients with osteoporotic vertebral fractures showed progressive collapse of the fractured vertebrae, 13.9% showed pseudarthrosis at the fracture, and 3.5% showed neurologic deficits (1). This devastating neurologic compromise is brought about by anterior impingement of the neural tissues in the anterior spinal canal with the retropulsed bony mass of the collapsed vertebra(e) (2–8).

### PATHOLOGIC FEATURES OF OSTEOPOROTIC AND POSTTRAUMATIC VERTEBRAL COLLAPSE

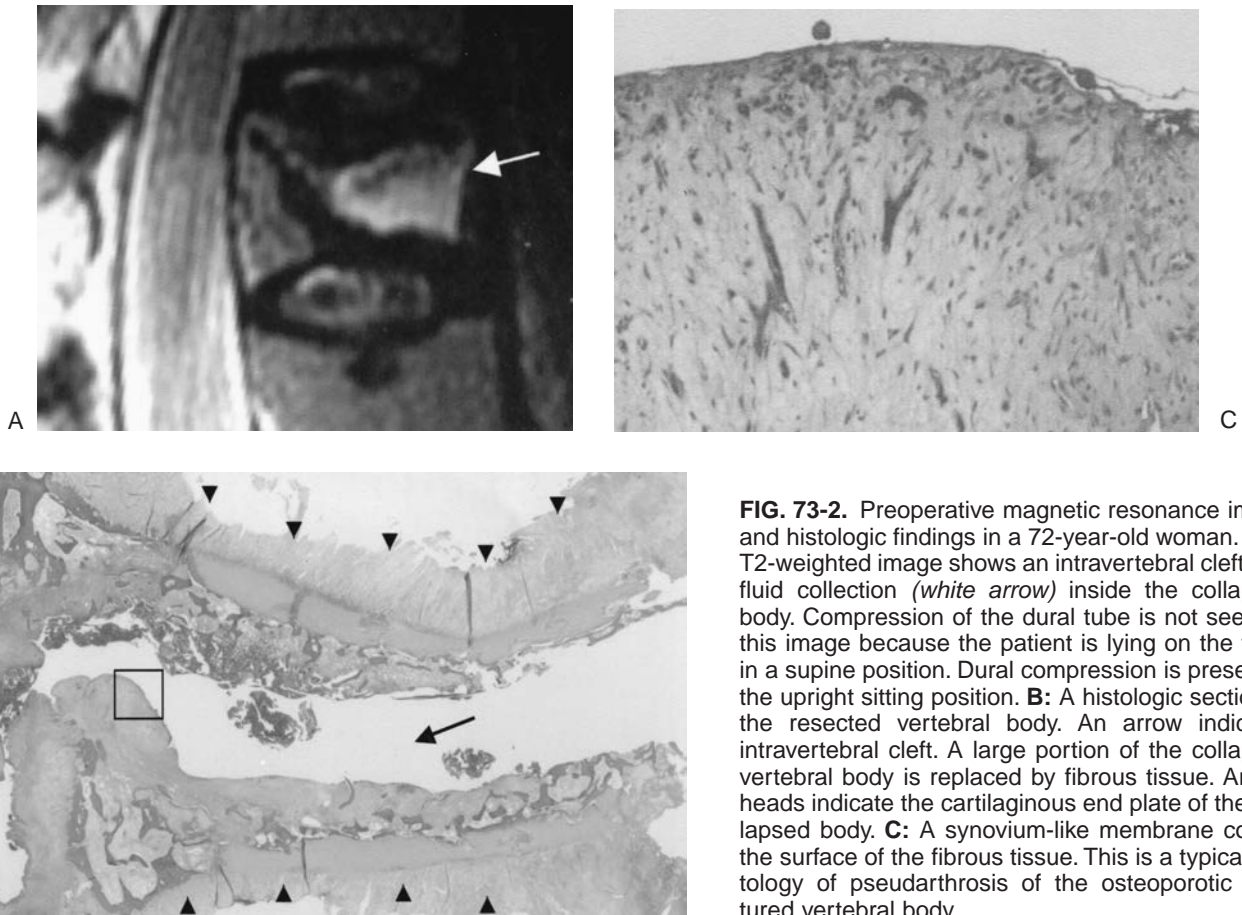

The cause of the delayed posttraumatic vertebral collapse and the mechanism of the late neurologic sequela have not been clarified completely, but it seems to be the secondary bone ischemia associated with nonhealing fractures of the vertebral trabeculae. Histology of the collapsed vertebral bodies shows massive fibrous tissues or necrotic tissues inside the collapsed vertebral bodies with minimal new bone formation (Fig. 73-2). Massive fibrous tissue of the fractured fragile trabeculae bring about disturbance of blood supply in the vertebral body, resulting in bone ischemia or pseudarthrosis, which eventually leads to vertebral collapse and neurologic compromise (9–11).

### RECONSTRUCTIVE SURGERY OF OSTEOPOROTIC AND POSTTRAUMATIC VERTEBRAL COLLAPSE

#### Patient Demographics

Between January 1987 and December 1996, 101 patients (23 men and 78 women) with osteoporotic or posttraumatic vertebral collapse of the thoracic and lumbar spines were treated surgically in our department. The average age at surgery was 68 years (range, 43 to 89 years).

Indications for surgery were devastating neurologic compromise or increasingly unstable kyphosis at the fracture site. Eighty-four (83%) of the 101 patients suffered late devastating neurologic deficits, and the other 17 (17%) had severe back pain with increasing thoracolumbar kyphosis. The intervals between neurologic compromise and fracture were 3 months in 43%, 3 to 6 months in 22%, 6 to 12 months in 9%, and more than 1 year in 13%; the interval was unknown in 13%. The neurologic symptoms in 84 patients were: lesion of the spinal cord in 51 patients, the conus medullaris with the cauda equina in 10, the cauda equina in 22, and the nerve roots in one. The causes of injuries were: a fall while walking in 43 patients, a fall from a chair onto the floor in 24, lifting a

**FIG. 73-2.** Preoperative magnetic resonance image and histologic findings in a 72-year-old woman. **A:** A T2-weighted image shows an intravertebral cleft with fluid collection (*white arrow*) inside the collapsed body. Compression of the dural tube is not seen on this image because the patient is lying on the table in a supine position. Dural compression is present in the upright sitting position. **B:** A histologic section of the resected vertebral body. An arrow indicates intravertebral cleft. A large portion of the collapsed vertebral body is replaced by fibrous tissue. Arrowheads indicate the cartilaginous end plate of the collapsed body. **C:** A synovium-like membrane covers the surface of the fibrous tissue. This is a typical histology of pseudarthrosis of the osteoporotic fractured vertebral body.

heavy weight in 11, and no history of trauma in 23. The energy of trauma was thought to be low. Such low-energy trauma would not have resulted in compression fracture of the thoraco-lumbar spine in bone of normal quality and strength. The levels of collapsed vertebra(e) were: 28% at T12, 33% at L1, 14% at L2, 5% at L3, 5% at T12 and L1, 2% at L1-2, 2% at T11-12, and 11% at other levels. Eighty of the 101 patients (79%) had osteoporotic posttraumatic vertebral collapse at the thoracolumbar junction of T12 and L1. The initial treatment was bracing with or without bed rest and prescription of nonsteroidal anti-inflammatory drugs in 75% of patients. The other 25% did not receive any treatment.

### Surgical Procedures

The procedures used in the treatment of osteoporotic and posttraumatic vertebral collapse of the thoracolumbar spine were anterior spinal canal decompression by resection of the collapsed vertebra(e), correction of kyphosis, and reconstruction of anterior column support using a vertebral spacer and anterior instrumentation (Kaneda-SR, Depuy Acromed Corp., Cleveland, OH) (12–14). Surgical exposure of the thoracolumbar spine was via the extrapleural and retroperitoneal approach from the left side. Because osteoporotic and posttraumatic vertebral collapse usually occur below T11, exposure of the surgical portion of the thoracolumbar spine was achieved without thoracotomy (Fig. 73-3A). The resection was conducted using sharp osteotomes, chisels, curettes, and Kerrison rongeurs. The posterior longitudinal ligament was left intact during anterior spinal canal decompression to reduce bleeding from the epidural vein.

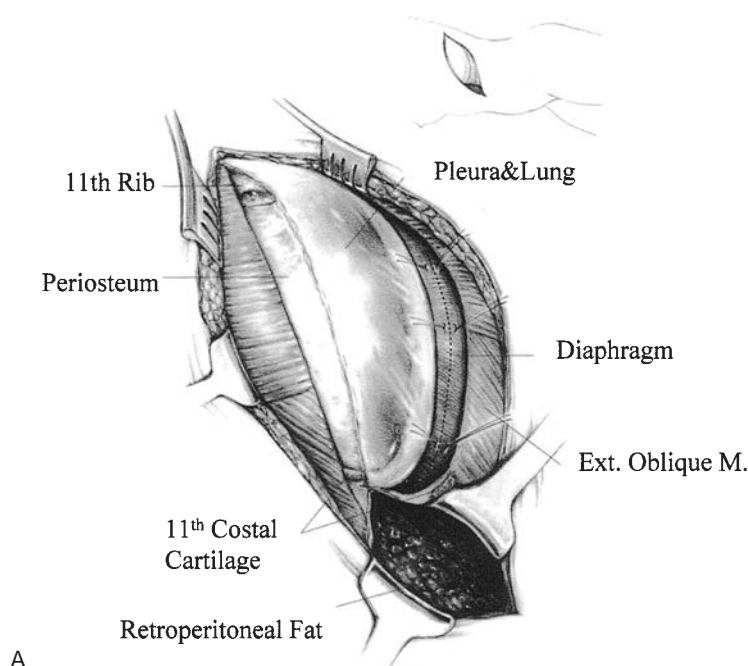

Following anterior spinal canal decompression by resection of the retropulsed bony mass compressing the neural tissue, application of Kaneda-SR anterior instrumentation was started. At first, the vertebral staples were placed properly and fixed with screws, as shown in figure 73-3.

Within 3 to 5 days after surgery, patients were encouraged to start walking with Thoraco-Lumbar Spinal Orthosis (TLSO). The brace was worn for about 6 months.

### Surgical Results

Operating time was 228 minutes, blood loss was 588 mL, and postoperative follow-up period was 68 months on the average (range, 3 to 147 months). Preoperatively, 84 (83%) of the 101 patients suffered from devastating neurologic damage resulting from late posttraumatic vertebral collapse. Eighty-two of 84 patients showed remarkable neurologic recovery. Of 59 patients with preoperative bladder-bowel disturbance, complete or incomplete recovery occurred in 44 patients. Two patients who did not show any neurologic recovery in motor function in the lower extremities or the bladder-bowel function had satisfactory pain relief with correction of increasing kyphosis. These two patients kept their paralytic status with increasing kyphosis for over 1 year without spinal canal decompression.

In terms of radiographic evaluation, stable fusion was obtained in 77 (76%) of 101 patients treated by a single anterior surgery. Twenty-two patients (22%) required posterior reinforcement after anterior surgery because of their low bone mineral density (BMD) and severe kyphosis owing to vertebral collapse at multiple levels. Solid fusion

**FIG. 73-3.** Surgical procedures. **A:** The extrapleural retroperitoneal approach. The tenth or eleventh rib usually is resected for the extrapleural retroperitoneal approach. Retroperitoneal fat tissue can be seen after splitting the costal cartilage. Abdominal muscles are divided after separating the retroperitoneal fat and peritoneal contents from the anterior abdominal muscles.

(continued on next page)

**FIG. 73-3.** (Continued) **B:** Placement of vertebral plates and screws. A vertebral plate is properly placed at the lateral aspect of vertebral body. The spikes of a plate must be placed parallel to the intervertebral space not penetrating into the disc spaces. Posterior vertebral screws must be inserted  $10^{\circ}$  to  $15^{\circ}$  anteriorly not to penetrate into the spinal canal. The screw tips must penetrate to the opposite cortex to achieve bicortical screw purchase. The screw tip is blunt to avoid additional tissue damage.

was not obtained in two patients who had postoperative deep infection. Correction of kyphotic deformity was from  $33.2^{\circ}$  preoperatively to  $16.6^{\circ}$  postoperatively and  $20.2^{\circ}$  at the survey. Overall, patients with single-level vertebral collapse with more than  $0.7 \text{ g/cm}^2$  in BMD can be successfully treated by single anterior procedure consisting of corpectomy, decompression, and reconstruction.

Subsequent compression fractures at levels other than the reconstructed site occurred in 37 patients during follow-up. There was no fracture at the fused vertebrae where the vertebral staple and screws were inserted. It was not necessary to repair the subsequent compression fractures at adjacent vertebral bodies except in two

patients with severe collagen diseases treated with long-term steroid administration.

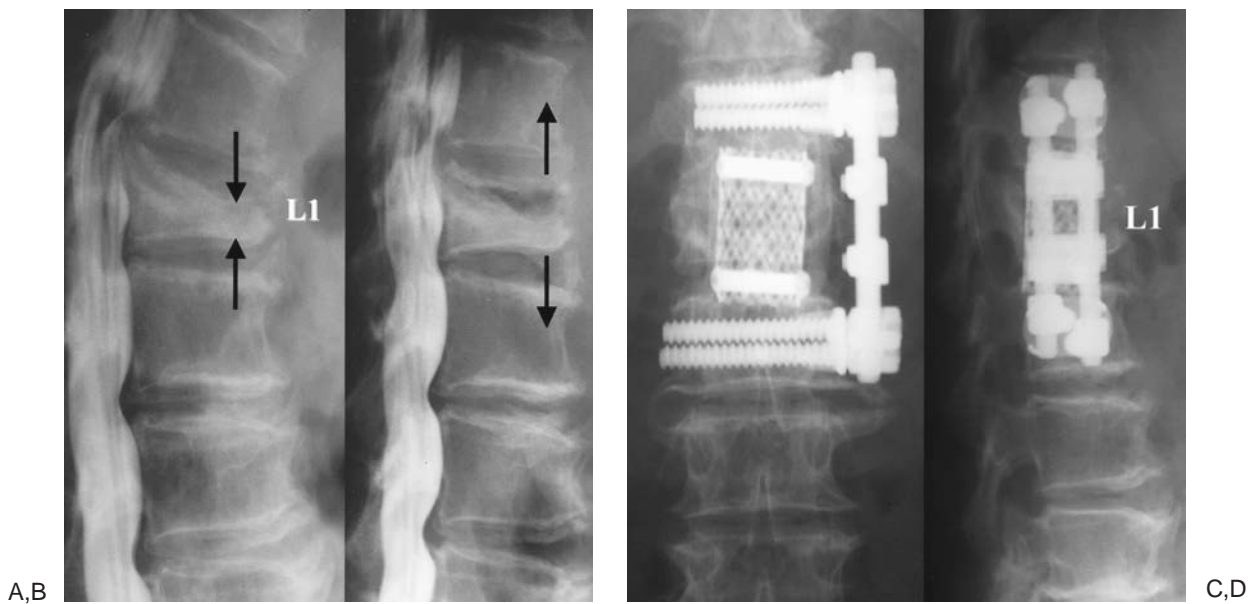

Complications were pseudarthrosis in two patients who had deep infection after surgery, dislodgement of the hooks of posterior instrumentation in one, temporary dementia in three, superficial infection in two, and urinary tract infection in one. There were no major complications including neurologic, respiratory, and circulatory complications. Death during follow-up occurred in 17 patients. Two died of pneumonia within 1 year postoperatively. Of the remaining 15 patients, four died within 1 to 2 years, six in 2 to 5 years, and five in over 5 years. The deaths had no relation to the spinal surgery.

**FIG. 73-4.** Case 1 represents a 74-year-old woman. The osteoporotic vertebral L1 collapse is shown. **A:** Myelogram under forward flexion. Arrows indicate that the intravertebral cleft closes. **B:** Myelogram under backward flexion. Arrows indicate that the cleft opens. **C, D:** X-ray films at 4 years postoperative.

Vertebral Spacer & Autogenous Rib Graft

**FIG. 73-3.** (Continued) **C:** Placement of vertebral spacer. An autogenous rib graft and vertebral spacer of proper length are inserted after correcting the regional kyphotic deformity using a spreader. An autogenous rib graft at both sides of the vertebral spacer and a chip bone graft taken from the rib or healthy part of the vertebral body must be added. **D:** Completion of the Kaneda-SR system. Kaneda-SR instrumentation is completed by applying properly sized two-rod couplers.

## CASE REPORT

A 74-year-old woman suffered an L1 osteoporotic compression fracture when she stumbled and fell. She was treated conservatively with TLSO and nonsteroidal anti-inflammatory drugs by her physician (Fig. 73-4). Six months later, she suffered from a walking disturbance caused by motor weakness in the lower extremities and severe back pain. A functional lateral radiograph showed an intravertebral cleft inside the L1, which opened under backward flexion and closed under forward flexion (Fig. 73-4). Dural tube was compressed by the posterior wall of the collapsed vertebral body. Anterior spinal decompression at L1 and stabilization from T12 to L2 using Kaneda-SR, a titanium mesh cage, and an autogenous rib graft were conducted. Four years after surgery, bony fusion was complete and sagittal alignment of the thoracolumbar spine was acceptable (Fig. 73-4).

## DISCUSSION

In our series, vertebral collapse after osteoporotic compression fracture of the thoracic and lumbar spine occurred in 41% within 3 months and 63% within 6 months. Eleven percent occurred at more than 1 year after fracture. The levels of vertebral collapse were concentrated at the T12 and L1 levels; therefore, osteoporotic compression fractures, especially at T12 and L1, should be followed-up carefully for at least 1 year after the initial fracture. Moreover, 23% of the patients in our series could not recognize the incidence of trauma in the past. If senile patients show neurologic deficits without cause, doctors should consider this pathology as a possible cause of neurologic impairment.

Causes of late vertebral collapse after osteoporotic compression fracture are unknown. From surgical findings, the collapsed vertebra was ischemic and fragile, and the resection of the collapsed vertebra could be conducted easily because of reduced bleeding owing to avascular necrosis of the collapsed body. Histologic study of the resected collapsed vertebra revealed massive necrotic or fibrous tissue, which might be the result of secondary bone ischemia. The normal fracture healing process of the osteoporotic trabeculae might be disturbed because of the fragility of the osteoporotic bone. As a result, osteoporotic fractured trabeculae led to massive scar formation, which would have disturbed the blood circulation in the vertebral body.

There were several reports of posterior reconstruction with instrumentation for treatment of this disease (15). Posterior reconstruction procedures have the following disadvantages: (a) indirect neural decompression; (b) destruction of intact posterior elements; (c) difficulty in reconstruction of anterior column support; and (d) prolonged levels of instrumentation. The pathology of the devastating neural damage and progressively unstable

kyphosis is located in the anterior pillar of the spinal column. The neural lesion is brought about by impingement of the neural tissue in the spinal canal by the retropulsed bony mass. Therefore, anterior spinal canal decompression by resection of the retropulsed bony fragment and the reconstruction of the stable anterior column support are the most reasonable choices. This concept is supported in our series and satisfactory results have been gained without severe complications even in very elderly patients.

Recently, vertebroplasty or kyphoplasty have been used by surgeons for the treatment of osteoporotic compression fractures (16). These procedures also have been performed for patients with progressive osteoporotic vertebral collapse of vertebral bodies. From the histologic point of view, cement injection to the collapsed vertebral bodies containing large fibrous or necrotic tissue may interfere with the healing process of the fractured bodies. Even though bioactive materials are injected, it is difficult to obtain biologic union by this technique because the collapsed vertebral bodies are filled with fibrous tissue and are severely ischemic. The efficacy of this new procedure awaits confirmation by long-term follow-up studies.

In conclusion, late devastating neurologic complications can be brought about by osteoporotic and posttraumatic vertebral collapse of the thoracolumbar spine. The cause of this pathology is ischemic necrosis or pseudarthrosis of fractured vertebral bodies caused by secondary circulatory disturbance resulting from the formation of fibrous tissue around the fractured trabeculae. The principle of treatment should be anterior spinal canal decompression and reconstruction of the anterior spinal column using anterior instrumentation and a vertebral spacer.

# Inflammatory Spondyloarthropathies

Philippe Goupille and David Borenstein

---

The inflammatory spondyloarthropathies (IS) are a cluster of interrelated chronic inflammatory rheumatic diseases including ankylosing spondylitis (AS), enteropathic arthritis (ulcerative colitis and Crohn disease), psoriatic arthritis (PA), and reactive arthritis (ReA) (postenteric and postvenereal arthritis) (Fig. 74-1). These disorders constitute a homogeneous group of inflammatory arthritides characterized by axial (sacroiliac and spinal joints) and peripheral enthesopathies, associated with peripheral arthritis and extraarticular (ocular, mucocutaneous, and genital) abnormalities. These disorders share a familial aggregation and a strong association with the HLA B27 antigen (1–4).

These shared characteristics of IS facilitate the use of international diagnostic validated criteria for inflammatory arthropathies (Table 74-1) (5) and group the pathogenesis of these disorders with the interaction between a predisposing immunogenetic predisposition and various environmental triggers (microorganisms).

### COMMON CHARACTERISTICS OF IS

IS have common epidemiologic and pathologic characteristics. These are discussed in the following sections.

#### Age of Onset

The age of onset of IS is often at the end of the growth period (i.e., between 16 and 30 years) (6,7). Detailed study of chronic juvenile arthritis has recently shown that true IS can occur in children. These forms of childhood onset occur more frequently in certain regions: 10% to 15% of cases occur before the age of 15 years in Europe, whereas the rate is 30% in North African countries. Onset of certain forms occasionally occurs much later (after 50 years).

#### Male Predominance

There is a predominance of IS in men but the disease is not rare in women. The sex ratio depends on the type

of IS (Table 74-2). The forms in women, which have until recently probably been confused with other types of inflammatory rheumatism, have become more frequent.

### Poorly Recognized Prevalence of Spondyloarthropathies (Table 74-2)

The prevalence reports depend on several factors such as the population studied, the diagnostic criteria used, and the study method (7). The prevalence of IS is in proportion to that of HLA B27 in all races. In black and Asian populations, where the prevalence of HLA B27 is lower than 2%, AS is much rarer than in Caucasian populations.

The prevalence of all types of IS is estimated at 0.5% of the overall population, but three tendencies warrant comment:

1. The prevalence of AS is increasing, especially because of greater awareness of childhood and female forms and undifferentiated forms.
2. The prevalence of PA also appears to be increasing because this condition is now better known.
3. The prevalence of true ReA is decreasing in Western countries, probably because of changes in ecologic bacteria and perhaps due to more frequent use of antibiotics.

### Entheses: Main Sites of Inflammatory Involvement

Entheses are formed from bony elements parallel to the collagen of the tendon, which is anchored in the bone. Between the bone and the tendon is a cartilaginous area, the function of which is to absorb constraints in traction.

Onset of inflammation in IS is typically at the level of the entheses. After an initial inflammatory phase (osteitis), which is expressed as limited erosions of the bone, there is a cicatricial process consisting of bone proliferation and periosteal apposition forming entheso-

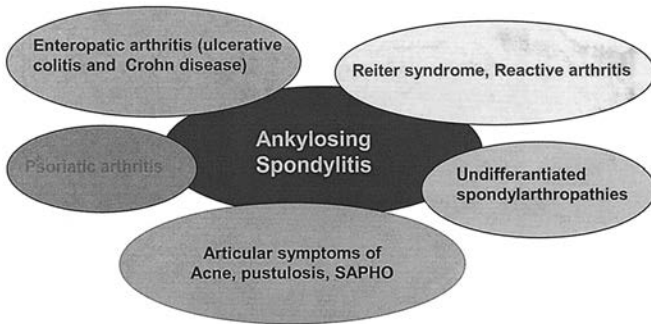

FIG. 74-1. Inflammatory spondyloarthropathies.

phytes. In developed forms the bone proliferation results in true bone fusion responsible for the ankylosing evolution of IS. This evolution explains the chronology of the osteitis-periostosis-hyperostosis triad which is characteristic of IS enthesopathies.

**Explanation of the Radiographic Features Related to Enthesopathy**

All the osteoarticular structures, which are components of entheses, may be involved.

The *sacroiliac joints* have only one very limited area of synovium because they are mainly composed of fibrous attachments. Sacroiliitis is therefore considered to be a sacroiliac enthesopathy, thus explaining the frequently observed ankylosis (Fig. 74-2).

The intervertebral disc consists of a fibrous annulus, which is a true enthesis surrounding the nucleus pulposus. The annulus is inserted into the periphery of the vertebral body and around the nucleus pulposus. The initial lesions are peripheral enthesopathies expressed as erosions of the anterior edge of the vertebra (Romanus sign), with vertebral “squaring” (Fig. 74-3). Subsequent development is then marked by the appearance of an enthesophyte known as a syndesmophyte. When there is enthesopathy of the central fibers of the annulus the lesions

TABLE 74-1. European Spondyloarthropathy Study Group (ESSG) criteria

Main criteria	Criteria
• Inflammatory spinal pain	Inflammatory spinal pain <ul style="list-style-type: none"> <li>• History or present symptoms of spinal pain in back, dorsal or cervical region, with at least 4 of the following:                             <ul style="list-style-type: none"> <li>onset before age 45</li> <li>insidious onset</li> <li>improved by exercise</li> <li>associated with morning stiffness</li> <li>at least 3 mo duration</li> </ul> </li> </ul>
• Synovitis	Synovitis <ul style="list-style-type: none"> <li>• Past or present asymmetric arthritis or arthritis predominantly in the lower limbs</li> </ul>
Secondary criteria	
• Family history	Family history <ul style="list-style-type: none"> <li>• Presence in first-degree or second-degree relatives of any of the following: ankylosing spondylitis, psoriasis, acute uveitis, reactive arthritis, and inflammatory bowel disease</li> </ul>
• Psoriasis	Psoriasis <ul style="list-style-type: none"> <li>• Past or present psoriasis diagnosed by a physician</li> </ul>
• Inflammatory bowel disease	Inflammatory bowel disease <ul style="list-style-type: none"> <li>• Past or present Crohn disease or ulcerative colitis diagnosed by a physician and confirmed by radiographic examination or endoscopy</li> </ul>
• Alternative buttock pain	Alternative buttock pain <ul style="list-style-type: none"> <li>• Past or present pain alternating between the right and left gluteal regions</li> </ul>
• Enthesopathy	Enthesopathy <ul style="list-style-type: none"> <li>• Past or present spontaneous pain or tenderness at examination of the site of the insertion of the Achilles tendon or plantar fascia</li> </ul>
• Acute diarrhea	Acute diarrhea <ul style="list-style-type: none"> <li>• Episode of diarrhea occurring within 1 mo before arthritis</li> </ul>
• Urethritis	Urethritis <ul style="list-style-type: none"> <li>• Nongonococcal urethritis or cervicitis occurring within 1 mo before arthritis</li> </ul>
• Sacroiliitis	Sacroiliitis <ul style="list-style-type: none"> <li>• Bilateral grade 2–4 or unilateral grade 3–4, according to the following radiographic grading system: 0 = normal, 1 = possible, 2 = minimal, 3 = moderate, 4 = ankylosis</li> </ul>

From Dougados M, van der Linden S, Juhlin R, et al. The European Spondylarthropathy Study Group preliminary criteria for the classification of spondylarthropathy. *Arthritis Rheum* 1991;34:1218–1227, with permission.

**TABLE 74-2.** Prevalence, association with HLA B27 and sex ratios of the different types of spondyloarthropathies

Spondyloarthropathies	Prevalence (Caucasian population) <sup>a</sup>	Association HLA B27	Relative risk <sup>b</sup>	Sex ratio men:women
Ankylosing spondylitis	0.2%–0.5%	90%–95%	90	2–3:1
Reactive arthritis	0.1%	60%–80%	35	2–6:1 for genitourinary origin 1:1 for gastrointestinal origin
Psoriatic arthritis	0.1%	40%–70%	10	1:1
Enteropathic arthritis	0.01%	30%–60%	10	1:1

<sup>a</sup>Prevalence of HLA B27 is 7%–10% in Caucasian population.

<sup>b</sup>The relative risk estimates the probability of occurrence of spondyloarthropathy in HLA B27 carriers in Caucasian population.

seen radiographically can look like “pseudoptotic” spondylodiscitis. In certain advanced forms the bone fusion of the vertebral structures gives the typical “bamboo” appearance (Fig. 74-4).

All the other peripheral entheses can be involved. The most characteristic localizations are the calcaneum, the clavicular joints (acromioclavicular and sternoclavicular), the symphysis pubis, and the distal interphalangeal joints. The example of the distal interphalangeal joints is very particular because the last phalanx is a complex enthesis system, characterized by a network of conjunctive tissue linking the last phalanx to the nail and the skin. Its characteristic involvement in PA may be expressed as true distal osteitis (sometimes without

arthritis) associated with psoriatic onychosis and known as psoriatic onychopachydermoperiostitis (8–10).

### Polymorphonuclear Neutrophils at the Origin of Inflammation in IS

The inflammatory synovial infiltrate in most inflammatory arthropathies, as in ReA, is made up of macrophages and lymphocytes. However, polymorphonuclear neutrophils (PMNs) predominate in the articular infiltrate (enthesis and synovium) in IS. This excess of PMNs is also present at the extra-articular sites such as cutaneous lesions in psoriasis and digestive lesions in enteropathies. These findings do not exclude the possi-

**FIG. 74-2.** A 45-year-old man with 10 years of inflammatory bowel disease and 5 years of low back stiffness and pain. Anteroposterior roentgenographic view of the pelvis reveals bilateral erosions and joint space widening (black arrows).

**FIG. 74-3.** Same patient as shown in Figure 74-1. A lateral roentgenographic view of the lumbar spine with squaring of the vertebral bodies (*white arrows*).

bility that the initial lesion might be lymphocytic, as demonstrated in the experimental models of IS (11,12).

#### Effectiveness of Nonsteroidal Antiinflammatory Drugs (NSAIDs)

The beneficial effects of NSAIDs can be dramatic, and this is a significant diagnostic criterion, but in certain forms of IS, NSAIDs may be only moderately or hardly effective, without changing the diagnosis.

#### Pathophysiology: Example of ReA

ReA is characterized by the interaction between a genetic predisposition and arthritogenic microorganisms (13–15).

Animal models of IS have contributed significantly to the existing understanding of the pathogenesis of IS. B27 transgenic rats, created by introducing copies of HLA B27 genes and  $\beta$ -2 microglobulin into the murine genome, develop a condition close to IS, with peripheral arthritis, colitis, genital inflammation, and skin and unguinal abnormalities (11,12). It is interesting to note that if the newborn rats are raised in a germ-free environment they develop only a combination of the skin and genital signs, without arthritis or colitis. These findings confirm the need for an interaction between genetic predisposition and microorganisms to explain the occurrence of articular signs.

#### Role of Arthritogenic Microorganisms in ReA

ReA is defined as aseptic arthritis developing in the weeks following an extra-articular infection (genitourinary or gastrointestinal). This generally accepted concept enlarges the more restrictive concept of Fiessinger-Leroy-Reiter syndrome, of which the typical oculourethrosynovial form has become rare. The classic arthritogenic bacteria are urogenital in 50% of cases of ReA, and gastrointestinal in 50%. The percentages vary according to region. Other bacteria have been causally linked, but without certainty (Table 74-3).

The risks of ReA evaluated by clinical experience show that 0.5% to 3% of the general population and 10% to 20% of HLA B27 patients develop ReA after nongonococcal urethritis (mainly *Chlamydia trachomatis* and *Ureaplasma urealyticum*). Similar figures have been recorded after gastrointestinal infections with arthritogenic enterobacteria.

**FIG. 74-4.** A 55-year-old patient with ankylosing spondylitis with bilateral sacroiliitis (*large black arrows*), bamboo spine (syndesmophytes) (*small black arrows*), and interspinous ligament calcification (*open black arrow*).

TABLE 74-3. Arthritogenic bacteria implicated in reactive arthritis

	Urogenitary tract	Gastrointestinal tract	Other
Definite role	<i>Chlamydia trachomatis</i> <i>Ureaplasma urealyticum</i>	<i>Shigella flexneri</i> <i>Salmonella enteritidis</i> <i>Salmonella typhimurium</i> <i>Yersinia enterocolitica</i> <i>Yersinia pseudotuberculosis</i> <i>Campylobacter jejuni</i>	
Possible role	<i>Neisseria gonorrhoeae</i>	<i>Shigella sonnei</i> <i>Clostridium difficile</i> <i>Leptospira icterohaemorrhagiae</i> <i>Escherichia coli</i> <i>Giardia lamblia</i> <i>Cryptosporidia</i> <i>Entamoeba histolytica</i> <i>Taenia saginata</i>	<i>Chlamydia pneumoniae</i> <i>Chlamydia psittaci</i> <i>Mycobacterium bovis</i> <i>Borrelia burgdorferi</i> <i>Streptococcus</i> <i>Staphylococcus aureus</i> <i>Propionibacterium acnes</i>

An important step in recent years has been the discovery of bacterial genomes (DNA and sometimes RNA) of *Chlamydia* in synovial samples from ReA using polymerase chain reaction (16–19). These results reinforce older studies that had already shown the existence of cytoplasmic inclusions of bacterial appearance (20).

However, for the moment questions remain unanswered, including:

- How do these bacteria persist in the articular cavity and escape from the immune system of the host?
- How can these bacteria cause arthritis?

An analysis of the microbiologic and immunologic data suggests the existence of two forms of ReA.

#### *ReA of Chronic Infectious Arthritis Type*

Certain forms of ReA could represent authentic chronic infectious arthritis caused by slow-growing organisms which are very difficult to cultivate and hence impossible to identify by the usual microbiologic methods. This hypothesis would appear to hold for *Chlamydia*, *Mycoplasma*, and *Borrelia* although not for enterobacteria. These microbes have an attenuated virulence, unlike those responsible for septic arthritis. Such forms of ReA are thus related to a “slow” intrasynovial infection, a condition also called “slow infectious arthritis” or “infectious ReA” (21).

#### *ReA of Infection-Triggered Aseptic Arthritis Type*

Some forms of ReA are probably aseptic and, if so, it is the persistence of bacterial antigens that could explain the appearance of an inflammatory reaction in the synovium. This hypothesis applies above all to enterobacteria (*Yersinia*, *Salmonella*, etc.). This type of arthritis, triggered by bacterial antigens in the absence of any viable intra-articular microbe, may be called “infection-triggered ReA.”

#### **What is the Role of HLA B27?**

HLA B27 is certainly involved in the pathogenesis of IS because the prevalence of IS is proportional to that of HLA B27 for all ethnic groups and all forms of IS are associated, to varying degrees, with HLA B27.

HLA B27 is thus a genetic factor predisposing to IS, but those are only triggered by environmental factors, most commonly bacterial. With this hypothesis, HLA B27 may have different roles (22–24), including:

- HLA B27 may serve as a presentation molecule for bacterial arthritogenic peptides (traditional theory currently highly disputed).
- HLA B27 has molecular similarities to certain bacterial proteins (*Yersinia pseudotuberculosis* and *Shigella sonnei*). Because of these similarities, HLA B27 might become a target “by homology” for the host immune system.
- All bacteria do not have the same arthritogenic potential. As an example, certain strains of *Shigella flexneri* contain a plasmid with a gene coding for a peptide sequence homologous to the HLA B27 molecule, which could confer particular arthritogenic properties (25).
- Moreover, in some genetically predisposed individuals, HLA B27 would appear to lack the capacity to eliminate infected macrophages normally, thus facilitating the intra-articular persistence of the microbe.
- Arthritogenic bacteria like *Yersinia* or *Salmonella* are capable of modulating the function and structure of HLA B27 molecules. Affected HLA B27 molecules expressed specifically by infected cells might then serve as targets for the host immune system.

Despite these arguments it is possible that IS are not directly related to HLA B27, because 10% to 50% of IS are not HLA B27-related. The prevalence of AS is 1% to 3% in the B27 Caucasian population, but it is 20% if B27 subjects are related to a patient with AS. These figures suggest a familial predisposition independent of HLA B27.

### Typical Evolution of Spondyloarthropathies

The evolution of IS has three characteristics:

1. Frequent spontaneous remissions occur in all types of IS, even in AS. This outcome is particularly characteristic of ReA, in which the first outbreak is usually followed after 1 to 6 months by complete remission. However, the condition recurs in nearly 60% of patients in 2 years, often in the same way.
2. All cases of IS can evolve toward a pattern of chronic AS. For example, 10% to 15% of patients develop an axial pattern 10 years after onset, similar to AS. The percentage reaches 25% to 40% after 15 years.
3. Transition from one form to another or the simultaneous occurrence of more than one IS is possible in the same patient. For example, the course of apparently primary AS may include episodes of ReA and, a few years later, the occurrence of true PA. These interrelationships with the different forms of IS illustrate the validity of this concept.

### SPONDYLOARTHROPATHIES: DIAGNOSTIC PROCESS

A three-stage diagnostic process requires competent knowledge of the clinical characteristics and pathophysiology of IS:

1. Evoke the diagnosis of IS by investigating a characteristic sign or symptom
2. Confirm the diagnosis of IS by eliminating other types of inflammatory arthritides and by investigating with other diagnostic procedures (Table 74-1)
3. Characterize the type of IS (Fig. 74-1).

### Aims of the Clinical Interview

Aims of the clinical interview are:

- to investigate any familial aspect of IS as far as parents and grandparents
- to investigate any personal history of enthesopathy or articular involvement
- to investigate any recent or previous extra-articular condition such as psoriasis, acne, pustulosis, enteropathy, genitourinary or gastrointestinal infection, or ocular involvement. In some cases the presence of signs in parents and grandparents may also suggest the diagnosis.

### Clinical Examination

#### *Pelvic/Spinal Syndrome*

Pelvic and spinal symptoms are mainly explained by axial enthesopathy which may involve the pelvis, spine, and anterior chest wall. Inflammatory back pain is mainly lumbar and dorsolumbar. The inflammatory nature is not

always easy to confirm but it is probable if at least four of the following five characteristics are present:

- onset before the age of 40 years
- insidious onset
- evolution for over 3 months
- morning stiffness
- stiffness improved by exercise.

One feature of such back pain is that it can be easily controlled by NSAIDs. The other symptoms (limited mobility, deformation) occur later and do not contribute to early diagnosis.

Pain in the buttocks is a manifestation of sacroiliitis. This is usually bilateral but initially may be unilateral. The inflammatory pain occurs in the upper part of the thigh(s) and may radiate to the knees and occasionally to the calves. Clinical examination is difficult because few maneuvers are specific, especially when the patient has back pain. Pain reproduced on direct palpation is one of the best clinical signs.

Anterior (sternocostoclavicular and chondrosternal) and posterior thoracic pain (costovertebral) are very specific. Anterior lesions can be manifested by a true inflammatory tumefaction of the anterior chest wall.

#### *Peripheral Enthesopathy*

Retrocalcaneal and subcalcaneal inflammatory talalgia always suggests the diagnosis of IS in young patients. The inflammatory nature of this condition is usually expressed by pain on walking when arising from bed.

Other types of enthesopathy involving the anterior tibial tuberosity, the greater trochanter, and the pubic bone are expressed by characteristic inflammatory pain which should not be confused with microtraumatic tendinopathy.

#### *Peripheral Articular Syndrome*

The typical pattern is of oligoarthritis of the lower limbs, particular involving the knees and ankles. This oligoarthritis can occur in all types of IS, but it is very characteristic of ReA. It can occasionally be monoarticular or polyarticular. The polyarticular forms must not be confused with rheumatoid arthritis. Attention should be paid to two particular areas:

- Coxofemoral involvement (coxitis) is a sign of severity of IS. It is quite frequent in IS (20% to 40% of cases), especially in AS, and occurs approximately in the first 5 years in the course of the disease.
- “Sausage-shaped” toes and fingers (dactylitis) are characterized by an inflammatory erythematous, violaceous tumefaction that occurs particularly in ReA and PA. This very specific feature is generally rare, occurring in only 5% to 10% of cases of ReA secondary to *Chlamydia trachomatis*.

These peripheral forms are related to synovitis, which is often nonspecific. Sometimes the histologic features are more characteristic, with intense vascular hyperplasia and perivascular inflammation, but without significant necrosis or synovial hyperplasia. In practice, synovial histology is not of diagnostic value.

### **Extra-articular Manifestations**

#### *General Symptoms*

Asthenia, weight loss, and fever are rare but may occur in acute ReA, particularly in forms following dysentery.

#### *Uveitis*

Uveitis is the most common extra-articular sign and takes the form of anterior uveitis expressed as red and painful eyes. The prevalence varies according to the form of IS. In AS it occurs in 30% of cases and may be an initial symptom in 2% to 5% of patients. The condition usually recovers without sequelae.

#### *Other Extra-articular Manifestations*

Various other extra-articular manifestations can occur, characteristic of each form of IS, sometimes successively and sometimes simultaneously in the same patient.

Cutaneous psoriasis, which occurs in PA, is often minimal and typically involves the scalp and body folds. Ungual involvement is very specific. Sometimes such lesions are only discovered on questioning, thus making definitive diagnosis difficult.

The gastrointestinal lesions of Crohn disease and ulcerative colitis often precede articular involvement. Occasionally the gastrointestinal involvement may be preceded, or sometimes revealed, by features of IS. In such cases the gastrointestinal signs are only detected on questioning. In practice, in the absence of any gastrointestinal signs, systematic gastrointestinal investigations (endoscopy) are not necessary, but it is interesting that systematic colonoscopies have shown inflammatory ileal lesions in more than 50% of cases of AS and ReA.

There are two types of extra-articular signs in ReA:

1. Signs of genitourinary (urethritis, prostatitis, salpingitis, cervicitis) or gastrointestinal infection (gastroenteritis) that precede onset of articular manifestations by 4 to 6 weeks. This entry route may pass unnoticed in more than half of cases, especially when it is an infection of the female genitalia.
2. Certain oculocutaneomucosal signs may mark the onset of ReA. These include: (a) common conjunctivitis, often bilateral; (b) mucosal lesions such as balanitis (20% of cases), which may be accompanied by macules or erosions on the scrotum, disappearing without sequelae; (c) lesions of the oral

mucosa such as painless erythematous plaques; (d) papules or pustules, most often palmoplantar, which form hyperkeratosis which is sometimes difficult to differentiate from psoriasis (keratoderma blennorrhagica).

#### *Other Visceral Complications of Spondyloarthropathies*

Cardiac symptoms occur (valvular disease, myocarditis, and occasionally pericarditis), especially in AS and ReA. These conditions are rare (fewer than 5% of patients). Pulmonary involvement (upper lobe fibrosis) occurs almost exclusively with AS. Amyloid renal involvement occurs in 0.5% to 1% of cases of AS. Immunoglobulin A (IgA) nephropathy has sometimes been reported in AS. Neurologic involvement related to atlanto-axial subluxation occurs in 1% to 2% of cases. Aseptic arachnoiditis has also been reported, sometimes complicated by cauda equina syndrome characterized by an enlargement of the dural sac. Osteoporosis has been reported in advanced forms of AS, sometimes revealed by vertebral fractures.

## **VALUE OF DIAGNOSTIC METHODS**

### **Value of Standard Blood Tests**

Inflammatory syndrome is found in 60% to 80% of patients but the erythrocyte sedimentation rate (ESR) is often lower than 50 mm in the first hour, and cross-reacting protein (CRP) lower than 60 mg/L. A more intense inflammatory syndrome is more frequently observed in certain peripheral forms, particular in ReA of gastrointestinal or enteropathic origin, and in certain types of PA. On the other hand inflammatory syndrome may be very slight or absent in purely axial forms. When elevated ESR and CRP are present, the biologic signs overall indicate progression of IS.

### **Is Immunologic Monitoring Necessary?**

Immunologic monitoring is of limited value but investigation of autoantibodies makes it possible to eliminate certain entities included in the differential diagnosis. In particular, it eliminates autoimmune diseases associated with peripheral articular signs (antinuclear antibodies), and particularly early RA (rheumatoid factors and anti-keratin). The only antibodies found in IS are rheumatoid factors, which are found in 5% to 10% of cases of AS and ReA and in 10% to 20% of cases of PA.

### **Is It Necessary to Biopsy the Synovium?**

The synovial fluid and membrane do not contribute to the diagnosis of IS. However, the analysis of synovial fluid may eliminate infectious or microcrystalline arthritis.

### Does an Infectious Workup Have Practical Implications?

Such a workup is only justified in ReA and undifferentiated IS. It has been demonstrated that there is *Chlamydia trachomatis* or *Ureaplasma urealyticum* infection in almost 30% of cases of undifferentiated oligoarthritis. In such cases there is a pathogenic value of identifying bacterial agents and there are therapeutic implications.

Investigation of genitourinary infection is justified, although extra-articular bacteria are rare once the articular symptoms have appeared. We currently recommend investigating the DNA of *Chlamydia trachomatis* in the first urine samples of the day in men and women and on cervical smears. This technique is more specific (about 100%) and more sensitive (about 80%) than classic methods. It also avoids the trauma of obtaining a urethral sample.

Stool samples are usually valueless in postdysentery forms because there are no pathogenetic bacteria in stools when the articular signs appear.

The practical value of routine bacteriologic studies of intra-articular samples has not been demonstrated.

Serologic investigations only occasionally provide diagnostic certainty because the presence of antibodies may simply be serologic cicatrization of a previous infection. In practice, only serologic studies are of value for *Chlamydia trachomatis*.

### Value of Investigating HLA B27

Investigation of HLA B27 is only justified in early or atypical forms of IS. Discovery of HLA B27 must always be interpreted with caution in this context because 7% to 10% of the Caucasian population has at least one HLA B27 allele.

### Value of Ophthalmologic Examination

Systematic examination for uveitis is warranted in childhood forms of IS with HLA B27.

### Value of Radiographic Examination

Radiographic examination of typical sites can be performed (sacroiliac, dorsolumbar, and calcaneal articulations), even when there is no pain, because in some cases onset of lesions can be asymptomatic (26). Certain pitfalls can be avoided:

Enthesopathy should not be confused with growth-related epiphysitis in childhood forms. It should be noted that sacroiliac X-rays cannot be interpreted in children and adolescents because of physiologic pseudo-enlargement and irregularity. In adults, sacroiliitis can be confused with sacroiliac osteoarthritis

**TABLE 74-4.** Differential diagnoses of spondyloarthropathies according to clinical or radiographic type of pelvic/spinal involvement

Unilateral sacroiliac involvement	Infectious sacroiliitis <ul style="list-style-type: none"> <li>• pyogenic infection</li> <li>• tuberculosis</li> <li>• brucellosis</li> </ul> Paget disease Tumor
Bilateral sacroiliac involvement	Osteitis condensans ilii Sacroiliac osteoarthritis Variant of normal "pseudoerosion"
Spinal involvement	Scheuerman disease Diffuse idiopathic skeletal hyperostosis Infectious or microcrystalline (chondrocalcinosis) spondylodiscitis

or osteitis condensans ilii. Axial involvement must be distinguished from benign degenerative lesions (osteophytes) or from diffuse idiopathic skeletal hyperostosis (DISH) (Table 74-4).

Computed tomography scan is particularly valuable for the exploration of sacroiliac joints (axial slices) and thoracic and spinal involvement (cervicooccipital region). Scanning of the sacroiliac joint is warranted only if standard X-ray is not sufficiently clear or if there are doubts about the diagnosis (27).

Bone scintigraphy with technetium 99-labeled bisphosphonates is of limited value for early sacroiliitis because tracer uptake is usually bilateral and weak. Scintigraphy might be of greater value in the detection of peripheral enthesopathy. It can possibly be used in early atypical forms without objective radiographic evidence, or to investigate osteoarticular complications (fractures, fistures).

Magnetic resonance imaging currently has no practical value, but it might in the future facilitate the early diagnosis of axial and peripheral enthesopathies and make possible more precise exploration of neurologic complications (28,29).

## PRACTICAL MONITORING OF CASES OF SPONDYLOARTHROPATHY

The routine aims in monitoring IS are to evaluate the evolution of the disease subjectively and objectively and to investigate extra-articular complications, particularly uveitis.

### Evaluation of Symptoms

Symptoms can be evaluated by overall estimation of the pain, stiffness, and asthenia. Various indices have been validated but one of the easiest to use is the Bath Ankylosing Spondylitis Disease Activity Index (BAS-

**TABLE 74-5.** *The Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)*

Please place a marker<sup>a</sup> on each line below to indicate your answer to each question, relating to *the past week*.

1. How would you describe the overall level of fatigue/tiredness you have experienced?
2. How would you describe the overall level of ankylosing spondylitis neck, back, or hip pain you have had?
3. How would you describe the overall level of pain/swelling in joints other than neck, back, or hip you have had?
4. How would you describe the overall level of discomfort you have had from any areas tender to touch or pressure?
5. How would you describe the overall level of morning stiffness you have had from the time you wake up?
6. How long does your morning stiffness last from the time you wake up?

<sup>a</sup>The patient places a marker on a 10 cm horizontal visual analog scale (VAS) for each question. Each VAS is scored from 0 to 10. The mean of the two scores relating to morning stiffness is taken, providing an aggregate score. The resulting 0–50 score for the overall index is converted to a 0–10 scale. The final BASDAI score has a range of 0–10.

From Garrett S, Jenkinson T, Kennedy G, et al. A new approach to defining disease status in ankylosing spondylitis: The Bath Ankylosing Spondylitis Disease Activity Index (BASDAI). *J Rheumatol* 1994;21:2286–2291, with permission.

DAI) (Table 74-5) that provides a practical and rapid estimate of a patient's functional abilities (30).

### Objective Evaluation of Osteoarticular Involvement

This is based on study of mobility by various simple measurements that assess spinal damage (Schober test, fingertips-floor and occiput-wall distances) and thoracic involvement (chest expansion). Loss of height (due to kyphosis) and number of enthesopathies and sites of arthritis may also be included.

### Blood Tests

Blood tests are of lesser value in the surveillance of IS because there is no absolute correlation between clinical evolution and increased levels of inflammatory proteins.

### Investigation of Extra-articular Complications

The only extra-articular complication that must be systematically sought is uveitis. It is also necessary to be aware of the risk of valvular disorders.

## SPECIFIC CLINICAL FEATURES

### ReA

ReA is mainly manifested by peripheral articular signs (oligoarthritis of the lower limbs), sometimes associated

with extra-articular signs. “Sausage-shaped” fingers or toes are characteristic signs but do not always occur. In 10% to 30% of cases, the evolution of the disease occurs in an axial form on average 6 years after onset. Axial involvement is comparable to that of other forms of IS, although it is often less severe, more diffuse (cervical), and of asymmetric onset (unilateral sacroiliitis).

### Psoriatic Arthritis (See Chapter 75)

### Articular Manifestations of Inflammatory Enteropathy (Crohn Disease, Ulcerative Colitis)

In 10% to 30% of patients, the complications of these forms of enteropathy are peripheral arthritis usually involving the lower limbs (enteropathic rheumatism). These forms of arthritis usually develop in parallel with the gastrointestinal condition. The chronic forms, which are occasionally destructive (coxitis), sometimes occur with Crohn disease. In 5% to 15% of cases, such enteropathy is associated with axial involvement, which in more than one-third of cases may precede the onset of gastrointestinal symptoms, sometimes by several years. This form of IS, which evolves independently of the gastrointestinal disorder, often appears to be less severe and more often asymmetric (unilateral sacroiliitis).

### Undifferentiated Spondyloarthropathies

Certain forms are characterized by oligoarthritis and enthesopathy of the lower limbs and are difficult to classify in the absence of axial symptoms and specific extra-articular manifestations. It is the clinical and immunogenetic characteristics (HLA B27 and history of familial IS) that place them in the nosologic group of IS.

## OTHER FORMS OF SPONDYLOARTHROPATHIES

### SAPHO Concept

The acronym SAPHO stands for synovitis, acne, pustulosis, hyperostosis, and osteitis. Certain dermatologic conditions (acne conglobata and fulminans, Verneuil disease, palmoplantar pustulosis) may have osteoarticular complications in the form of oligoarthritis or hyperostosis (usually sternocostoclavicular) or osteitis (31). Recurrent isolated multifocal osteitis and primary hyperostosis (Köhler disease) probably also belong to the SAPHO syndrome. Study of this group of conditions has shown that in 30% of cases there is sacroiliitis (unilateral in 50% of cases) and an association with HLA B27 in 20% to 35% of cases. It has been reported that inflammatory enteropathy occurs during the course of the disease. All of the characteristics indicate that SAPHO is a form of IS.

## THERAPEUTIC PRINCIPLES

The treatment of IS is based mainly on drugs, particularly NSAIDs, and rehabilitation.

### NSAIDs

NSAIDs are the basic treatment of IS. Several NSAIDs have been reported to be similarly effective for pain and joint mobility. It is impossible in practice to predict the most effective and best tolerated NSAID for an individual patient. It is necessary therefore to try a succession of NSAIDs, while explaining this to the patient. The initial dose prescribed is often the maximum, which will then be adapted to the course of the disease. NSAID treatment must be long term, as long as pain and stiffness persist. The prolonged treatment is of symptomatic value but it can also prevent bony ankylosis.

### Analgesics

Analgesics are of value when NSAIDs are ineffective or not tolerated. All class I and II analgesics (World Health Organization classification) can be used effectively in combination with NSAIDs.

### Disease Modifying Anti-Rheumatic Drugs (DMARDs)

Many of the DMARDs used in RA have also been used in IS. Among these are antipaladin drugs, gold salts, D-penicillamine, levamisole, sulfasalazine, methotrexate, and azathioprine. However, the efficacy is only demonstrated for peripheral IS.

### Antitumor Necrosis $\alpha$ -Therapy (See Chapter 76)

### Rehabilitation, Physiotherapy, and Rules Regarding Healthy Lifestyle

Functional rehabilitation is essential in the treatment of IS, although few studies have evaluated the real value of such measures. However, the success of rehabilitation depends largely on the motivation of the patient and the physiotherapist.

During painful phases it is necessary to use analgesics and to avoid deformation by rest and passive techniques such as positioning, analgesic physiotherapy, muscle-relaxing massage. Enthesopathy can be improved by cryotherapy and ionization. Wearing heel cushions is particularly valuable for talalgia. Corsets are prescribed in severe forms for posture and stabilization. Molded plastic antikyphosis corsets are sometimes used but they are often poorly tolerated.

**TABLE 74-6.** *Healthy lifestyle advice for patients with spondyloarthropathies*

Recommended	Not recommended
Firm mattress, low pillow	Carrying heavy loads
Alternating prone and supine lying positions	Lying on side
Sports activities (i.e., swimming)	Martial sports
Low-pain movement of affected joints	Prolonged sitting or standing
Positions and exercises several times a day	Excess body weight
	Smoking
	Exercises at home
The following exercises should be performed several times a day:	
stretching of all muscles of lower limbs	
spine stretching	
improvement of lordosis and spine mobility	
stretching of anterior chest wall and pectoral muscles	
breathing exercises.	

During pain-free phases it is necessary to reestablish mobility and good axial and peripheral musculature using medical gymnastics and appropriate activities. Sports that encourage appropriate postures and balanced stretching of the spine are beneficial. Swimming, water games, and cross-country skiing are recommended. Running on soft ground, with appropriate shoes, can be recommended because maintained effort improves breathing capacity by developing mobility of the rib cage, and is beneficial for reducing the risk of osteoporosis.

Rehabilitation must be combined with healthy lifestyle, thus necessitating education and motivation of the patient (Table 74-6).

### Local Treatment

Local treatment is particularly valuable in localized and resistant forms of arthritis.

#### *Local Corticosteroids*

The main indication for local treatment with corticosteroids is in peripheral arthritis, particularly the large joints (hips, knees, ankles). Intraarticular injection of the sacroiliac joints performed with radiographic visualization can be very beneficial (32). Enthesopathies sometimes benefit from topical corticosteroids, but injection of corticosteroids in contact with the tendon must be avoided because of the risk of secondary rupture (especially of patellar and Achilles tendons).

#### *Synoviorthosis*

Isotopic and osmic acid synoviorthosis are particularly valuable in involvement of large joints. They are much

longer acting than corticosteroids and such treatment, which may be repeated, often makes it possible to delay prosthetic surgery.

### **Surgery**

Early surgical synovectomy has not been shown to be particularly valuable, as in RA. It involves mainly surgical replacement (prosthesis) of the hip and knee. Corrective spinal surgery is the exception. It can only be envisaged where there is disabling kyphosis to improve walking or vision (inability to raise head).

### **Treatment and Prevention of Extra-articular Complications**

The main complication is uveitis, which requires urgent treatment with topical corticosteroids that are readily absorbed by the cornea. This is combined with collyrium to dilate the pupil and avoid the development of synechiae. When the uveitis is generalized and resistant to topical treatment, subconjunctival injections and sometimes short courses of systemic corticosteroids can be used.

Other complications (neurologic, cardiac, etc.) occasionally warrant surgical treatment.

## **SPECIFIC THERAPEUTIC PRINCIPLES**

### **ReA**

#### ***Should Antibiotics Be Prescribed?***

Altogether, clinical and experimental data exist to indicate that if antibacterial treatment of ReA can be started very early during the pathogenetic process, the disease can be prevented or the prognosis improved. In fully developed ReA, the value of antibacterial agents is less certain. All available evidence indicates that short-term conventional antibacterial treatment has no effect on the prognosis and final outcome of ReA, whereas prolonged (3-month) treatment with tetracycline shortens the duration of arthritis when triggered by *Chlamydia trachomatis*. Such treatment however has not proved effective in enteroarthritis (33,34). Several studies have in fact shown that cyclins, macrolides, and possibly quinolones can reduce the period of evolution of postvenereal ReA and the frequency of recurrence.

There is no ideal mode of therapy (type of antibiotic, dose, duration of treatment) and there is no consensus to date, but the principle of 3 months' antibiotic treatment with a cyclin or macrolide is accepted, especially during the first attack of postvenereal ReA. On the other hand, no study has yet to demonstrate the value of antibiotic treatment in postdysentery ReA.

### **Psoriatic Arthritis (See Chapter 75)**

### **Inflammatory Enteropathies**

#### ***How Should Peripheral Involvement of Crohn Disease and Ulcerative Colitis Be Treated?***

Treatment of gastrointestinal diseases (corticosteroids, azathioprine, methotrexate) is often effective in peripheral arthritis. Topical or systemic corticosteroids can be used.

#### ***Can NSAIDs Be Used for Axial Forms?***

Axial forms often pose complex treatment problems. NSAIDs sometimes exacerbate inflammatory episodes of enterocolitis. In practice, NSAIDs should be avoided during the active phase of enterocolitis. If the gastrointestinal disease is not actively progressing, courses of NSAIDs can be given, particularly to treat axial inflammatory signs that do not usually respond to other treatments (sulfasalazine, corticosteroids).

#### ***Which DMARDs Should Be Used?***

Sulfasalazine can be beneficial in peripheral articular involvement, whereas mesalamine, which is the salicylic part of sulfasalazine and widely used today in gastrointestinal diseases, does not appear to be effective. Low doses of methotrexate can be valuable in peripheral forms.

## **CONCLUSION**

Clinical and epidemiologic studies have shown that the seronegative types of IS can be classified as a distinct group of diseases.

However, many questions remain unresolved concerning the exact nature of the genetic haplotypes, the host's response, and the interaction between genetic factors and the suspected infectious agents.

## CHAPTER 75

# Psoriatic Arthritis

Philippe Goupille and David Borenstein

---

---

Psoriatic arthritis (PA) has common features with rheumatoid arthritis (RA) and ankylosing spondylitis (AS) and belongs in the spondyloarthropathy group. The variety of its clinical and radiologic manifestations warrants special emphasis.

### HISTORICAL REVIEW

The first case of PA was reported by Alibert in 1818; the first report on its clinical and radiologic features was performed by Bourdillon in 1888. Subsequently, numerous clinical and epidemiologic studies have proved the validity of this disorder as a separate entity (1–5).

### EPIDEMIOLOGY

The prevalence of inflammatory arthritis in patients with cutaneous psoriasis is about 5% to 7% and increases to 32% to 42% for the axial involvement (6,7); radiologic abnormalities of the sacroiliac joint have been reported in 43% of patients with cutaneous psoriasis (6,8). On the other hand, the prevalence of cutaneous psoriasis in patients with inflammatory arthritis is about 4% (9).

#### Epidemiology of Psoriasis

The prevalence of cutaneous psoriasis in the white population is about 1% to 3% (9), and lower in black Africans, black Americans, and Asians. The sex ratio is 1:1 (9) and the mean age of occurrence is 27 years.

#### Epidemiology of Psoriatic Arthritis

##### *Prevalence*

Commonly cited prevalence figures for the general population are 1 to 2 per 1,000 (10), but the lack of diagnostic criteria leads to an underestimation.

#### *Role of Age and Sex*

The age of occurrence is 30 to 50 years (11,12). The sex ratio is 1:1 (13,14), but varies according to clinical presentation. There is a predominance of men in axial (13,15) and distal interphalangeal joint involvement (12) and of women in the polyarticular forms (11).

#### *Links with Cutaneous Psoriasis*

Psoriasis precedes the arthritis in 64% to 87% of patients; the skin disease appears after the joint manifestations in about 6% to 18%; and skin and articular disease occur simultaneously in 8% to 30%.

### GENETICS AND HLA

#### **Psoriasis**

Psoriasis is associated with HLA-B13, B17, CW6, and DR7 in the white population (16).

#### **Psoriatic Arthritis**

Family and epidemiologic studies have confirmed the genetic characteristic of PA. Moll and Wright have shown the presence of PA in 8.3% of first-degree parents of patients with PA (3). The link with HLA-B13, B17, CW6, and DR7 is present but weaker than in psoriasis (17). HLA-B27 is present in 18% to 30% of patients, especially in axial involvement (35% to 64%) (18,19). The association between HLA-B27 and radiologic sacroiliac involvement has been confirmed (18,20), especially in case of bilateral involvement (HLA-B27 in 22% of unilateral sacroiliitis and 85% of bilateral sacroiliitis). On the contrary, axial involvement without sacroiliitis is not associated with HLA-B27 (19). The association HLA-B38 and HLA-B39 is debated. HLA-B38 is present in

17% to 35% of cases compared with 4% to 6% of psoriasis in the white population (21).

## **PATHOGENESIS**

Psoriasis is a multifactorial condition of hereditary and environmental pathogenesis. It is characterized by wide polymorphism of the cutaneous lesions and the presence of extracutaneous lesions, particularly articular.

The relationship between cutaneous psoriasis and articular lesions depends on the following factors.

- An epidemiologic link
- The existence of common trigger factors, particularly environmental and psychological factors
- The existence of common genetic factors
- The existence of similar elementary cutaneous and synovial membrane lesions characterized by a lymphocyte T infiltrate and excessive angiogenesis

Despite these shared factors, the following arguments suggest that the pathogenesis of skin lesions might be different from those of the articular lesions.

- The cutaneous and articular lesions begin simultaneously in only 15% of cases.
- There is no correlation between the severity and activity of the skin lesions and the severity of articular involvement.
- The articular involvement, which is particularly polymorphic, appears to be related to a particular genetic predisposition.
- Although the inflammatory cutaneous and synovial infiltrates are similar, it has been demonstrated that cutaneous and synovial lymphoid populations are different.

### **Genetic Factors**

As in cutaneous psoriasis, the familial forms and genomic associations suggest the role of genetic factors.

### **Environmental Factors**

Several environmental, microbial, mechanical, physical, drug, and psychosocial factors can cause cutaneous psoriasis. The same is the case for articular involvement, for which various trigger factors have been studied (22).

### **Infectious Factors**

#### ***Streptococci***

Vasey et al. demonstrated the more frequent existence of antiexotoxin streptococcal antibodies in PA than in cutaneous psoriasis (23). Ribosomal RNA of group A

streptococci has been detected in the peripheral blood and synovium in patients with PA (24).

#### ***Viruses***

Viruses (e.g., Epstein-Barr virus and cytomegalovirus) may act as trigger or maintaining factors, particularly in psoriatic synovitis. Human immunodeficiency virus and hepatitis C virus also may have triggering roles.

### **Toxic Factors**

In contrast to skin lesions, it appears that toxins and drugs are not trigger or exacerbating factors in PA.

### **Mechanical Factors**

Several reports have demonstrated the occurrence of posttraumatic PA defined by precise criteria (25,26). In a study of 700 patients, Punzi et al. reported posttraumatic arthritis in 8% of patients with PA compared to only 1.6% and 2% in RA and AS, respectively, in almost all cases involving peripheral forms of PA (26). The causal mechanisms might have been psychological or physical, by analogy with the reports on cutaneous lesions.

### **Immunopathology**

Psoriatic lesions are characterized by lymphoid infiltrates, cutaneous and articular deposits of immunoglobulins, and neoangiogenesis, thus suggesting immunologic mechanisms.

Cutaneously, three hypotheses make it possible to establish a schematic relationship between specific abnormalities of keratinocytes in psoriasis and the lymphoid infiltrates (27).

1. Lymphocyte theory: The abnormalities of lymphocytes may cause abnormal proliferation and differentiation of keratinocytes.
2. Keratinocyte theory: The psoriatic keratinocytes may be abnormal and produce cytokines able to activate T lymphocytes.
3. Fibroblast theory: The dermal fibroblasts may be abnormal and trigger keratinocyte proliferation.

### **Psoriatic Synovitis**

Psoriatic synovitis is not specific. Nevertheless, certain features appear to distinguish it from that of RA (i.e., less marked proliferation of synoviocytes and lymphoplasmacytic infiltrate, and presence of neoangiogenesis characterized by numerous vessels with thickened walls infiltrated by inflammatory cells).

This type of synovitis also is characterized by the early expression of various synovial membrane enzymes, metalloproteinase, cysteine proteases, and cathepsins, which must have a significant role in the occurrence of osteoarticular destruction.

Although predominantly lymphocytic, this type of synovitis can be distinguished from inflammatory cutaneous infiltrate for the following reasons.

- Injection of T lymphocytes from psoriasis plaques into severe combined immunodeficiency disease (SCID) mice does not cause arthritis.
- The infiltrate is mainly composed of CD4 T lymphocytes, which appear to be in greater quantities than in cutaneous lesions.
- Synovial T lymphocytes express fewer cutaneous lymphocyte antigen than lymphocytes of cutaneous tropism.

### Psoriatic Enthesitis

The initial feature in most cases of PA is enthesitis; an experimental model in HLA B27 transgenic rats supports this (28). In fact, such rats developed spondyloarthropathy associated with skin and ungual lesions resembling psoriasis. Nevertheless, it has been difficult to establish the relationship between skin and enthesitis lesions, except for distal involvement, which sometimes is expressed as psoriatic onycho-pachydermo-periostitis. In this case there appears to be a direct relationship between cutaneo-ungual lesions and enthesitis.

Immunohistochemical analysis of psoriatic enthesitis appears to be characterized by the accumulation of monocytes and macrophages but few lymphocytes. These findings are not compatible with the widely developed lymphoid theory on the pathogenesis of cutaneous and synovial membrane lesions. In forms that mainly involve enthesitis, synovial membrane involvement might be "contiguous" synovitis related to release of various proinflammatory cytokines by enthesitis.

### CLINICAL PRESENTATION AND DIAGNOSIS

Are there specific clinical features of PA that make it possible to differentiate it from other forms of inflammatory arthropathies? Compared to RA, PA has been reported to be equally distributed in both sexes, articular involvement is asymmetrical, there is an absence of subcutaneous nodules, frequent axial and distal interphalangeal involvement, a better prognosis, specific radiographic abnormalities, and absence of rheumatoid factor. It also has been demonstrated that among the group of patients with seronegative polyarthritis, those with psoriasis mostly have distal interphalangeal involvement, which is mainly erosive. Psoriatic arthritis includes more peripheral involvement, asymmetric sacroiliitis,

**TABLE 75-1.** *Clinical forms of psoriatic arthritis*

Involvement predominantly of distal interphalangeal joints
Mutilating arthritis
Symmetric seronegative polyarthritis
Asymmetric oligoarthritis or monoarthritis
Axial involvement (spondylitis and sacroiliitis)

and absence of masculine predominance than AS. Although spinal involvement in AS appears to progress from the lumbar spine to the cervical spine radiologically, the distribution appears more random in PA (29).

However, there are no criteria such as have been defined for lupus or RA. The usually accepted and used classification is that of Moll and Wright, which was established in 1973 (29) (Table 75-1). These clinical forms frequently overlap; reports of their respective proportions vary widely in the literature.

### Clinical Forms

Symmetric or asymmetric involvement of one or more distal interphalangeal joints, with concomitant ungual psoriasis, occurs in 25% to 60% of patients with PA, in isolation or with other manifestations (2,6,12). Its course is benign generally.

Arthritis mutilans contributes fewer than 10% of cases. Onset is often abrupt, with constitutional symptoms and severely inflammatory arthritis in multiple joints. Severely deformed flail hand can result from this form of PA.

Symmetric polyarthritis similar to RA occurs in about 25% of cases. This form is slightly more common among women. Tests for rheumatoid factor are negative 85% to 90% of the time (11).

Asymmetric oligoarthritis or monoarthritis occurs in about 70% of cases. Exacerbations lasting several months occur, often separated by prolonged remissions. The asymmetric oligoarticular nature of this arthritis can result in involvement of all three joints of a single digit. Sausage digits (dactylitis) can develop as a result of concomitant arthritis of the distal and proximal interphalangeal joints and flexor tenosynovitis.

Psoriatic axial involvement often is accompanied with other forms of PA. The symptoms are similar to those of AS but may be less severe. The sacroiliac joints are involved in 30% to 50% of cases (1,12,20,30). Extraarticular involvement (lungs, heart, and eyes) seems less common than in RA. In addition, other patterns occur.

Enthesopathy (inflammatory disorder of the tendon-bone junction) can affect the sacroiliac joints, pubic symphyses, intervertebral joints, anterior chest wall, calcaneus, and ends of the digits. Peripheral enthesopathy manifesting as heel pain and Achilles tendinitis can be the first manifestations; and coexistence of psoriatic skin lesions should prompt a search for further evidence of PA.

**TABLE 75-2.** Diagnostic criteria for psoriatic arthritis

Primary criterion
Psoriasis (cutaneous or ungueal) associated with pain and articular swelling limited mobility of at least one joint for more than 6 weeks
Secondary criteria
Pain and swelling limited movement of at least one joint for more than 6 weeks identified by physician
Inflammatory symptoms of distal interphalangeal joints, with the exclusion of Heberden nodules
“Sausage-shaped” fingers or toes
Asymmetric arthritis of hands and feet
Absence of subcutaneous nodules
Absence of rheumatoid factor
Inflammatory synovial fluid. Absence of infection and sodium urate or calcium pyrophosphate crystals.
Synovial biopsy revealing synovial hypertrophy, with infiltration predominantly of mononuclear cells and no granuloma or tumor
Erosive damage to small joints revealed on radiography of peripheral joints, without obvious osteoporosis or erosive osteoarthritis.
Axial radiography of skeleton revealing one or more of the following: sacroiliitis, syndesmophytes, or paravertebral ossification
Definite: Primary criterion and six secondary criteria.
Probable: Primary criterion and four secondary criteria.
Possible: Primary criterion and two secondary criteria.

Distinctive clinical patterns result from involvement of the foot in PA. The disease can affect the calcaneus and forefoot, particularly the great toe. Bauer toe is characterized by distal interphalangeal arthritis with psoriasis of the same toe or toenail. In psoriatic onychopachydermoperiostitis of the great toe, there is ungueal psoriasis, thickening of the distal soft tissues, and osteoperiostitis of the distal phalanx without involvement of the interphalangeal joint (31,32).

**TABLE 75-3.** Differential diagnosis of psoriatic arthritis and ankylosing spondylitis

	Psoriatic arthritis	Ankylosing spondylitis
Gender	Men = women	Men > women
Distribution	Axial and peripheral	Axial
DIP involvement	5% Of patients	Absent
Syndesmophytes	Asymmetric, random distribution	Symmetric, usually with caudocranial progression
Sacroiliitis	Often asymmetric	Usually symmetric
HLA B27	40%–50%	80%–90%

DIP, distal interphalangeal; HLA, human leukocyte antigen.

**TABLE 75-4.** Differential diagnosis of psoriatic arthritis and rheumatoid arthritis

	Psoriatic arthritis	Rheumatoid arthritis
Gender	Men = women	Women > men
Distribution	Asymmetric	Symmetric
DIP involvement	Usual	Rare
Syndesmophytes	Usual	Absent
Sacroiliitis	Usual	Rare
Rheumatoid factor	Rare	Usually present

DIP, distal interphalangeal.

Extraarticular involvement is less frequent than in AS. Ocular and cardiac involvement are the most frequently reported.

**Positive and Differential Diagnosis**

The coexistence of skin lesions is a feature of PA. The rheumatologist must be aware of the specificity of articular conditions, but he must also systematically investigate the presence or history of psoriasis in all patients with osteoarticular disorders (axial or peripheral) and check the typical areas affected (e.g., elbows, knees, scalp, nails, and buttocks). The diagnostic criteria proposed by Wright and Moll in 1976 (10), and modified by Bennet in 1979 (Table 75-2) may be used, although the experience of the clinician is fundamental for this very unusual condition.

From the dermatologic point of view, the conditions likely to cause confusion are seborrheic dermatitis and mucosal infections. From the rheumatologic point of view, the main conditions to be eliminated are AS and RA (Tables 75-3 and 75-4). Microcrystalline disorders, particularly gout, sometimes are evoked in the setting of dactylitis, and erosive osteoarthritis of interphalangeal joints can cause diagnostic difficulty.

**DIAGNOSTIC METHODS AND OUTCOME MEASURES**

**Imaging**

**Incidence**

The incidence of radiographic evidence is difficult to define because of the variations in the populations studied and the methods used.

**Typical Features**

Certain typical features indicate the diagnosis (Table 75-5).

The overall asymmetric nature of the radiographic lesions has been demonstrated mainly in the fingers and toes. The following lesions appear to be indicative of PA.

**TABLE 75-5.** Radiologic features of psoriatic arthritis

Synovial, cartilaginous involvement and entheses
Most commonly asymmetric distribution
Interphalangeal joint involvement of fingers and toes
Sacroiliitis and spondylitis with paravertebral ossifications
Coexistence of erosions and bone proliferation
Bony ankylosis
Resorption of phalangeal tufts

- Pseudoenlargement of the articular space in fingers and toes, owing to erosion affecting the ends of the bones and progressively extending to the centre of the joint
- The classic “pencil-in-cup” deformity, associated with progressive thinning of the heads of metacarpal or metatarsal bones or the phalanges, and cupula-shaped hollowing of the bases of phalanges
- Bony ankylosis of the interphalangeal joints of the fingers and toes. The diagnosis is more obvious when osteolysis is followed by bony ankylosis or the coexistence of osteolysis of one joint and ankylosis of another.
- Resorption of phalangeal tufts, often associated with damage to the distal interphalangeal joint
- Periostosis of the calcaneum; tibial and peroneal, and femoral and trochanteric diaphyses; and lateral faces of the phalanges of the fingers

### Sites of Involvement

#### Peripheral Skeleton

##### Hands

Predominance of PA in distal interphalangeal joints has been confirmed. Both erosive arthritis without osteophytes and pseudoenlargement features have been reported. Metacarpal-phalangeal, radiocarpal, and carpal joint involvement are less frequent than in RA.

##### Feet

The forefoot is a frequent site of PA and involvement of the big toe is very characteristic. This can take the form of simple osteoperiostitis of the phalanx (bone proliferation of the base, often associated with resorption of the tuft) without changes to the articular space, a very indicative and often early sign (32,33).

##### Calcaneum

Involvement of the calcaneum is more frequent in case of sacroiliitis. There may also be vague irregular posterior or plantar enthesopathy or postero-superior erosion.

#### Axial Skeleton

Involvement of the sacroiliac joint is the most common sign (Fig. 75-1). It is sometimes isolated, without spine involvement, or there is damage to the cervical spine while sparing the dorsolumbar spine. It is most often bilateral, but unilateral forms are more frequent than in AS (34). The joint may have a vague appearance in the early stages because of erosion and sclerosis usually predominating on the iliac side; later there is development into pseudoenlargement, pinching, and finally true fusion of the joint.

Spine involvement frequently is associated with sacroiliac involvement. This is characterized by the occurrence of syndesmophytes, two types of which have been described: (a) the classical features of vertical pointed ends, situated in contact with the disk perimeter, as seen in AS; and (b) more crude, irregular ossification further from the disk perimeter (and able to be confused with diffuse idiopathic skeletal hyperostosis [DISH]). Such syndesmophytes are more often asymmetrical and unilateral than in AS (29,34) and may appear at any level, and even affect only the cervical spine in contrast to AS in which progression is caudocranial (29). Involvement of the posterior dorsolumbar interapophyseal joints is rare, as are the features of osteitis, erosive Romanus spondylitis (squaring), “bamboo”-shaped spine, and symphysis pubis (29,34).

Involvement of the cervical spine, which is frequent and sometimes isolated, involves ossification of the anterior longitudinal ligament, arthritis of the posterior interapophyseal joints (particularly C3-C4, C4-C5, and C5-C6), syndesmophytes, and atlanto-axial subluxation (34,35). Finally, anterior chest wall involvement can occur, particularly of the manubriosternal and sternoclavicular joints.

**FIG. 75-1.** A 38-year-old woman who had psoriasis for 8 years and back pain for 4 years. Antero-posterior roentgenograph of the sacroiliac joints revealing bilateral erosions and reactive sclerosis (black arrows).

**TABLE 75-6.** Radiologic features differentiating psoriatic arthritis (PA) from ankylosing spondylitis (AS)

	Psoriatic arthritis	Ankylosing spondylitis
Asymmetric involvement of sacroiliac joint	++	+
Crude, asymmetric syndesmophytes	++	+
Resorption of phalangeal tufts	++	—
Osteitis	Rare	++
Vertebral "squaring"	Rare	++
Predominantly peripheral involvement	Distal (hands, feet)	Proximal (shoulders, hips)

### Differential Diagnosis

These characteristic features of PA lesions visualized by radiography make it possible to differentiate RA (a frequent problem in polyarticular forms), AS (in axial forms), and DISH (axial forms with crude, irregular, and asymmetric paravertebral ossifications) (Tables 75-6, 75-7, and 75-8).

### Laboratory Tests

Erythrocyte sedimentation rate (ESR), C reactive protein (CRP), and fibrinogen levels usually are raised (36), but can be normal, particularly in axial forms. Rheumatoid factor is present in about 10% of cases. Low levels of antinuclear antibodies may be detected, but the prevalence is not greater than 6% to 7%. Hyperuricemia, which is caused by increased cutaneous cell turnover, is present in less than 10% of patients with PA. The synovial fluid usually is inflammatory, but without any specific characteristics.

**TABLE 75-7.** Radiologic features differentiating psoriatic arthritis from rheumatoid arthritis

	Psoriatic arthritis	Rheumatoid arthritis
Areas involved	Synovial joints Symphyses Entheses	Synovial joints — —
Distal interphalangeal joints	++	—
Anterior chest wall	+	Rare
Asymmetric involvement	++	Rare
Bone proliferation	++	—
Resorption of phalangeal tufts	++	—
Articular ankylosis	Fingers, toes	Carpus
Spine and sacroiliac involvement	++	Rare

**TABLE 75-8.** Radiologic features differentiating psoriatic arthritis from DISH

	Psoriatic arthritis	DISH
Posterior interapophyseal joints	Erosion, sclerosis ankylosis	Degeneration
Sacroiliac joint	Erosion, sclerosis ankylosis	Osteophytes
Peripheral involvement	Erosion	Nonerosion

DISH, diffuse idiopathic skeletal hyperostosis.

### OUTCOME AND NATURAL HISTORY

Psoriatic arthritis is classically considered relatively benign, or at least compared to RA (7,11,14,37,38). However, this is debatable and the different clinical forms of the condition must be taken into account.

#### Severity of Psoriatic Arthritis

In view of the favorable outcome of oligoarticular forms, the rarity of deformations, and the lesser degree of severity of lesions seen radiologically (7,11,37), PA is considered a condition that is never fatal and rarely affects functional outcome. In fact, polyarticular, symmetric, and progressively destructive and deforming forms that are responsible for significant dysfunction are not rare.

Kammer et al. confirmed the preponderance of oligoarticular forms of favorable outcome, but reported many cases of symmetric, progressively destructive, and deforming polyarticular forms (14). In a series of 220 patients, the majority of whom had polyarticular forms, Gladman et al. were much more guarded in their prognosis (13): 50% had an asymmetric condition, 16% had deformations, and 11% had marked dysfunction.

#### Outcome of Psoriatic Arthritis

More than 50% of patients had oligoarticular forms of unpredictable outcome (exacerbations lasting from a few weeks to a few months, interspersed with prolonged remissions) with no sequelae (11). However, there have been few longitudinal studies (11,38–40). Of these, the series reported by Gladman et al. on a majority of polyarticular forms demonstrated that, deformations and articular damage increased even when the inflammatory condition improved (40).

#### Prognostic Factors

Although poorly understood, these include gender, age at onset, sites of involvement, and genetic factors. The extent of the cutaneous involvement does not influence the articular prognosis (13). As in RA, recognizing these factors is essential for the most effective therapy, and cer-

tain forms of PA probably have been underestimated and insufficiently treated.

## NOSOLOGY

### Place within the Spondyloarthropathy Group

There is no doubt that PA belongs in the spondyloarthropathy group in view of its clinical signs (peripheral and axial involvement, enthesopathy, and extraarticular signs), radiographic evidence (sacroiliitis), and genetic background. However, it is an individual entity within this group, with variable manifestations and the current criteria used for the diagnosis of spondyloarthropathies are sometimes inadequate. For example, in a series of 205 patients with psoriasis, 75 (36%) patients with PA were diagnosed by clinicians (41). Only 49 patients (24%) met the criteria of spondyloarthropathy according to the European Spondyloarthropathy Study Group (42), with sensitivity of criteria at 65% and specificity 99% to 100%.

## TREATMENT

The therapeutic principles are the same as for other inflammatory spondyloarthropathies, apart from certain points. Treatments for PA are influenced by: (a) its usually benign nature; (b) the variable course of the disease and uncertain prognosis making uncontrolled trials unreliable; and (c) the existence of associated dermatosis influences the choice and modalities of treatment (requires specific treatment). Few disease modifying anti-rheumatic drugs (DMARDs) have been evaluated; they are used based on their effectiveness in RA.

### Why Is There a Dearth of Data on Disease Modifying Anti-rheumatic Drugs for Psoriatic Arthritis?

Several factors may be involved. Psoriatic arthritis is widely believed to be uncommon; therefore, the market represented by this disease holds little appeal. In addition, PA was long considered a benign disease that required only nonspecific symptomatic treatments.

Because PA shares clinical and radiologic features with RA and AS, DMARDs used in these two disorders are commonly used in PA, and no pressing need for formal validation of this practice is perceived.

### What Specific Methodologic Obstacles Are Raised by Psoriatic Arthritis Evaluations?

There is no consensus about the diagnostic criteria. Thus, the criteria used for patient inclusion vary across therapeutic trials, making comparisons difficult.

Psoriatic arthritis covers a broad clinical spectrum. Most patients have a combination of these clinical patterns (e.g., oligoarthritis or axial involvement + enthesopathy, polyarthritis + distal interphalangeal arthritis, or

oligoarthritis + axial involvement). Yet, reports of therapeutic trials, particularly the earliest ones, often provide little detail on the clinical features.

The therapeutic trials published to date included patients with various forms of PA. In the overwhelming majority of cases, different treatments are used for peripheral and axial forms, and few drugs have been found effective in axial forms. Yet many of the patients included in therapeutic trials had both peripheral and axial manifestations. This decreases the likelihood of finding clear evidence of efficacy. A more rational approach is to conduct separate studies of axial disease (which is similar to AS) and polyarthritis.

There are no specific criteria for evaluating disease activity. A number of tools that evaluate disease activity and functional impairment are available for investigating the efficacy of treatments for RA (disease activity score: American College of Rheumatology [ACR], 20, 50, and 70; health assessment questionnaire [HAQ]). In contrast, no specific tools have been developed for PA. The indices developed by Calin et al. for evaluating spondyloarthropathies (Bath Ankylosing Spondylitis Disease Activity Index and Bath Ankylosing Spondylitis Functional Index) are often used for axial forms of PA (43,44) and tools for evaluating RA in peripheral forms.

The course of PA usually is erratic. A fluctuating course with unpredictable but sometimes prolonged remissions is widely believed to be the rule. Thus, open-label studies of DMARDs can provide useful information on safety but are clearly inadequate for establishing efficacy.

The concomitant skin disease influences the choice of treatment. For instance, antimalarials and, to a lesser extent, gold, can cause exacerbations in the skin lesions or other severe adverse events. Extensive skin involvement may prompt treatment with methotrexate or cyclosporine, which improves the rheumatic manifestations.

### Which Disease Modifying Anti-rheumatic Drugs Are Appropriate?

Six of the DMARDs used in RA and evaluated in polyarticular forms of PA deserve discussion: sulfasalazine, methotrexate, gold, antimalarials, cyclosporine, and azathioprine.

#### *Sulfasalazine*

Five randomized placebo-controlled studies have been published (45–49). The daily dosage was 2 to 3 g. Overall, sulfasalazine was significantly more effective than the placebo. Efficacy seemed greater with the 3 g per day dosage. Safety was satisfactory.

#### *Methotrexate*

The earliest studies used high dosages (30 to 50 mg/wk) and found incontrovertible evidence of efficacy at the

expense of major side effects. When low-dose methotrexate was found effective in RA, open-label studies of low doses (15 mg/wk) were conducted in PA. The effects were favorable. The results were inconclusive in a prospective, randomized, placebo-controlled, double-blind trial of methotrexate, 7.5 to 15 mg per week, given to 37 patients for 12 weeks (50). However, this may be ascribable to the short treatment duration or small sample size.

### **Gold**

Most studies used oral gold and found no evidence of efficacy. In contrast, efficacy has been reported in studies of intramuscular gold, including one conducted comparatively with oral gold and a placebo (51). Although controversial, the risk of skin lesion exacerbation deserves consideration.

### **Antimalarials**

No controlled studies are available, and open-label studies provide little evidence of efficacy. However, they do show that the risk of skin lesion exacerbation is small (52,53). This adverse event has been reported mainly with chloroquine. Nevertheless, careful monitoring of the skin lesions is in order even with hydroxychloroquine.

### **Cyclosporine**

Open-label studies and controlled but methodologically flawed studies suggest efficacy. Treatment-limiting side effects (e.g., arterial hypertension and serum creatinine elevation) can occur as with RA.

### **Azathioprine**

Open-label studies in small numbers of patients suggest efficacy. In sum, only sulfasalazine has been evaluated in well-designed controlled studies; strong evidence of efficacy was found. However, available data strongly suggest that methotrexate and other drugs may be effective as well. No studies specifically designed to evaluate structural effects have been published. Combinations of DMARDs have not been evaluated.

### **What Can Be Expected of Anti-Tumor Necrosis Factor- $\alpha$ Agents?**

Anti-tumor necrosis factor - $\alpha$  agents (i.e., infliximab and etanercept) were introduced recently for the treatment of RA. Several open-label studies and few controlled studies have been conducted in PA.

### **Etanercept**

The results suggest dramatic improvements in the skin and joint abnormalities (54–56). An open-label study in

10 patients showed dramatic efficacy on the joint and skin involvement (57).

A randomized, placebo-controlled, double-blind trial of etanercept (25 mg twice a week) was conducted in 60 patients with PA. Efficacy was remarkable: The response rate (Psoriatic Arthritis Response Criteria, PSARC) was 87% with etanercept and 23% with the placebo. Corresponding figures were 73% versus 13% for the ACR 20, 50% versus 3% for the ACR 50, 75% versus 5% for the painful joint score, 72% versus 19% for the swollen joint score, and 83% versus 3% for the HAQ score. All of these differences were statistically significant (58). In each group, 19 patients with psoriasis were evaluable; a 75% or greater improvement in the psoriasis area and severity index (PASI) occurred in 26% of the etanercept patients versus 0% of the placebo patients. The mean PASI improvements in these two groups were 46.2% and 8.7%, respectively. No serious adverse events were recorded.

An open-label extension of the treatment period to 24 weeks confirmed these findings: Response rates were 82% for the PSARC, 74% for the ACR 20, 56% for the ACR 50, and 30% for the ACR 70, and the mean improvement in the PASI was 62% (59). Nine months into etanercept therapy, 28% of patients had no painful joints and 42% had no swollen joints. No serious adverse events occurred.

A large multicenter, randomized study has compared etanercept (n = 101; 25 mg  $\times$  2/week subcutaneously) with placebo (n = 104) during 24 weeks (60). A statistically significant improvement of ACR 20, 50, and 70 scores (p < .001 in favor of etanercept), HAQ (p < .0001) and PASI (47% versus 0% in favor of etanercept) was observed.

### **Infliximab**

A single-center, open-label pilot study evaluated 21 patients with spondylarthropathies, including nine with PA. The dosage was 5 mg/kg as an infusion at baseline and after 2 and 6 weeks. Rapid and dramatic improvements occurred in the axial and peripheral manifestations after the first infusion; these effects persisted throughout the 12-week study period. Similar improvements occurred in the skin lesions (61).

The same group has conducted a 12-week, randomized, placebo-controlled, double-blind trial (62). Forty patients with active spondyloarthropathies, including 18 with PA, were randomly assigned to receive an intravenous loading dose (weeks 0, 2, and 6) of 5 mg/kg infliximab or placebo. The primary end points were the improvements in patient and physician global assessments of disease activity on a 100-mm visual analog scale. Both primary end points improved significantly in the infliximab group compared with the baseline value, with no improvement in the placebo group. As early as week 2 and sustained up to week 12, there was a highly statistically significant difference between the values for

these two end points in the infliximab versus the placebo group. In most of the other assessments of disease activity (laboratory measures and assessments of specific peripheral or axial disease), significant improvements were observed in the infliximab group compared with the baseline value and placebo. Moreover, preliminary studies indicate that infliximab is effective and safe in cutaneous psoriasis (63).

In the future, anti-TNF- $\alpha$  agents probably will have a place of choice in the therapeutic armamentarium for severe PA. However, several issues remain unsettled. We do not yet know whether anti-TNF- $\alpha$  agents are more likely to be effective in axial or peripheral forms of PA or whether they should be reserved for severe erosive polyarticular disease unresponsive to other DMARDs. Studies are needed to determine whether anti-TNF- $\alpha$  agents should be started immediately in patients with severe disease or only after failure of other DMARDs. Additional work will have to evaluate whether the dosage and frequency of infusions used in RA are appropriate for PA and whether the treatment should be stopped after a few infusions.

### Local Treatment

Local treatment (e.g., intra-articular injection of corticosteroids, synoviorthosis, ergotherapy, physiotherapy, splints, and surgery) is as important as in RA.

### Topical Treatment of Dermatitis

Topical treatment of dermatitis should be combined systematically, especially in preparation for surgery.

### Indications

Nonsteroidal antiinflammatory drugs (NSAIDs) and local treatments should be used in monoarticular and oligoarticular forms. Patients who fail to improve with these treatments can receive the drugs used in polyarticular forms (sulfasalazine, 2 to 3 g/d; methotrexate, 7.5 to 15 mg/d, and gold). Evaluation of the need for DMARDs in polyarticular disease relies heavily on the clinician's experience. The risk-benefit ratio of anti-TNF- $\alpha$  agents remains to be determined. Immunosuppressant therapy (e.g., azathioprine and anti-TNF- $\alpha$  agents) is in order in arthritis mutilans. In axial forms, NSAIDs and probably sulfasalazine should be used. Axial disease may be an indication for anti-TNF- $\alpha$  therapy.

Methotrexate or cyclosporine may be the best choice in patients with extensive skin disease. Extreme caution is in order regarding the use of systemic glucocorticoids, antimalarials, and gold.

# Ankylosing Spondylitis

Federico Balagué and Jean Dudler

---

Historically, ankylosing spondylitis (AS) was first explicitly described at the end of the 19th century by Bechterew, von Strümpel, and Pierre Marie (1). In the early 1950s, Forestier, Rotes-Querol, and Scandinavian authors made further major contributions to its description (2). Nowadays, AS is considered the prototype of a group of different but closely interrelated disorders called seronegative spondyloarthropathies (3,4). Originally considered variants of rheumatoid arthritis, their characterized inflammatory involvement of axial skeleton, entheses, and their strong genetic association with the presence of the histocompatibility human leukocyte antigen (HLA)-B27 has clearly separated them as a different entity (3,4). The other diseases of this group have been described in detail in the previous chapters by Goupille and Borenstein, and this chapter concentrates uniquely on AS.

Epidemiologic figures vary widely in the literature (5). Ankylosing spondylitis is the second most common inflammatory arthritis, after rheumatoid arthritis, and commonly cited prevalence figures for the general population are 1 to 3 per 1,000 (5), with values increasing to 1% when considering the white adult population (6–8). Contrary to rheumatoid arthritis, where a fairly constant worldwide prevalence is recognized (9), AS shows strong racial differences, with extreme values ranging from almost nonexistent in African-Americans to 63 per 1,000 in specific American-Indian tribes (5). These data are consistent with the strong association of HLA-B27 and AS on one hand (8,10,11), and the observed racial variations in the prevalence of B27 on the other (10,11). Prevalence figures as low as .01%, and even .0065% (11), have been reported in Japan for AS where only 1% of the population is HLA-B27+ (6). On the opposite, in the Haida First Nation people and Bella Indians where over 50% of the population harbor the HLA-B27 antigen, the prevalence of AS is as high as 6% (5).

In Europe, Finland shows one of the highest prevalence of HLA-B27 with 14% (12), as compared to the usually reported 4% to 8% for the white population (5). In that

country, the reported prevalence between 1980 and 1990 was .15% (95% confidence interval [CI]: .08% to .27%) and the annual incidence of AS requiring medication 6.9 (95% CI: 6.0 to 7.8) per 100,000 adults (13). A comparable study was repeated in 1995 with a similar incidence for AS of 6.3 (4.9 to 7.9) per 100,000 (12). Finally, a familial aggregation has been reported in different countries (14).

### ETIOLOGY AND PATHOGENESIS

Ankylosing spondylitis is inflammatory rheumatism of unknown origin, generally thought to have an autoimmune pathogenesis. It now appears that AS represents a complex polygenetic disease influenced by various environmental factors. A complete review of this extensive field of research is not within the scope of this chapter, and the reader should refer to recent reviews for further reading.

### Role of HLA-B27 and Other Genetic Factors

Despite considerable efforts since the initial description in 1973 of the strong association between HLA-B27 and AS (15,16), the links between this susceptibility gene and the observed clinical manifestations remain enigmatic (17,18).

Up to date, as much as 23 subtypes of HLA-B27 have been recognized and this number continues to increase (17,19). Some subtypes (e.g., B2706 and B2709) are not associated with AS (6), whereas variations in the respective distribution of subtypes across the world complicates epidemiologic studies, comparison among populations, and determination of their role in disease susceptibility (6,19,20). Furthermore, it appears that the risk associated with a high susceptibility subtype could be strongly influenced by the genetic background; that is, B2705 does not appear as a significant risk factor in West Africans (21).

The dominant paradigm that HLA-B27 favors a cross-reactive immune response because its antigenic structure mimics bacterial epitopes has been challenged (17,18).

There is also no compelling evidence for an arthritogenic peptide that could be uniquely presented by HLA-B27 molecules (17,18). There is growing evidence to suggest that the role of HLA-B27 is not explained by its physiologic function as an antigen-presenting protein, but rather by peculiarities of this molecule (17,18). HLA-B27 has been shown to increase the intracellular survival rate of bacteria and enhance the proinflammatory response to gram-negative infection (22,23). It also demonstrates an unusual tendency to misfold, with potential effects on the intracellular signaling (24–26). Finally, an apparently unique property to form homodimer could link HLA-B27 to autoimmunity (18,25,27,28).

Transgenic animal models have underlined the role of HLA-B27 in AS pathogenesis (29,30). However, they have not completely unraveled the mechanisms. Transgenic rats harboring multiple copies of the human HLA-B27 antigen develop a spontaneous inflammatory disease mimicking several features of human spondyloarthropathies (29,30). This observation could be interpreted as strong evidence for a role of HLA-B27 as a presenting-antigen molecule in the pathogenesis of AS, but it could also work through the nonphysiologic role of HLA-B27 on proinflammatory response, intracellular signaling, or bacterial survival. Furthermore, transgenic mice expressing functional HLA-B27 on their cell surface usually remain healthy, whereas they develop disease in the absence of mouse  $\beta$ 2-microglobulin, which prevents surface expression of mature HLA-B27 molecules. This argues for a nonphysiologic role of HLA-B27 in the pathogenesis of AS (17,31).

Even if HLA-B27 is the strongest susceptibility factor, AS is a polygenetic disease (HLA-B27, B60, and HLA-A9); the exact number of genes involved is unknown (32). It appears that HLA-B27 contributes only 16% to 50% of the total genetic risk (19). This concept helps us to understand the known familial aggregation unexplained solely by HLA-B27 status. Models have been developed that suggest that a five-locus model best fits the observed data (33). Interestingly, this is in accordance to a genome-wide scan that identified four regions of interest on chromosomes 2, 10, 16, and 19 in addition to chromosome 6, which carries the HLA complex (34). However, the details of this polygenetic disease probably are more complex. Additional regions of interest have demonstrated a potential role in conferring disease susceptibility, such as cytochrome P-450, latent membrane protein 2 (LMP2), tumor necrosis factor (TNF) promoter region, or interleukin-1 receptor antagonist (17). To complicate the matter even further, possible non-B27 protective factors have been postulated (21).

### Role of Infection and Other Environmental Factors

The importance of infection as a causative factor in reactive arthritis is well established, but the role of spe-

cific infections in the pathogenesis of AS is not as clear (35). A high fecal carriage of *Klebsiella pneumoniae* in patients with active disease, the presence of raised anti-Klebsiella antibodies, and possible molecular mimicry between HLA-B27 and bacterial antigens have led to the hypothesis that AS is a reactive arthritis to this specific bacteria (35). Despite numerous studies, such a role has not been demonstrated conclusively (35). However, animal models have underlined the importance of infection, because both transgenic rats and mice housed under specific pathogen- or germ-free conditions did not develop the disease (29,30).

Other strong arguments for the importance of environmental factor are twin studies, where the concordance rate for AS was 50% in monozygotic twins and 20% in dizygotic twins (36).

There is also a strong epidemiologic relationship between gut inflammation and the spondyloarthropathies, particularly Crohn disease, ulcerative colitis, and reactive arthritis (37). Ankylosing spondylitis patients without any known bowel disease also present with endoscopic lesions and histologic signs of gut inflammation at ileocolonoscopy (38). Finally, transgenic rats present with gut lesions reminiscent of inflammatory bowel disease (IBD) (29). However, the pathogenic relationship between gut and arthritis remains enigmatic (39), perhaps related to some increase small bowel permeability, as demonstrated in AS patients and their first-degree relatives (38). This could favor invasion, persistence, or transport of bacterial antigens as causative factors (39).

### Others Factors

Others factors have been implicated as pathogenic or as risk factors for AS. Trauma (40), androgens (41), and even low birth order (42) have been reported, but no pathogenic mechanisms have been demonstrated.

## CLINICAL PRESENTATION AND DIAGNOSIS

Ankylosing spondylitis classically presents as inflammatory rheumatism of the young male with characteristic axial involvement of the sacroiliac and spine joints and a unique propensity to affect entheses and adjacent soft tissue in the spine and peripheral skeleton. Hips and shoulders are involved more often than other peripheral joints, and various extraskelatal manifestations have been reported that underline the systemic nature of the disease (7,8,10,43).

Ankylosing spondylitis is usually a chronic, progressive disease with fluctuating activity (44), but it has been estimated that 1.5% to 10% of cases are totally asymptomatic and are diagnosed incidentally when a radiograph is taken for another reason (45,46).

Typically, AS begins in young adults. Age at time of diagnosis ranges from 6 to 61, with a mean age usually in

the third decade (8,47–52). In two studies—one from Finland (12) and the other from Belgium (53)—AS was diagnosed at a mean age of 39.6 (10.3) and 32 years, respectively. Onset is uncommon after age 50, with only 6% of patients in a German study experiencing onset after age 40 (54). However, late-onset AS is a now well-recognized entity; the diagnosis of AS should not be discarded solely because of age (54).

Ankylosing spondylitis is regarded historically as a male disease. A male to female ratio up to 10:1 was reported in a recent review paper (7), whereas more conservative figures ranging from 2:1 to 3:1 (55) appear closer to reality (pooled data from the reviewed literature including more than 4,500 patients where males represented roughly three fourths of the cases). This discrepancy could result in part from ethnic variations: Male to female ratios as high as 16:1 have been reported in Asian countries (49).

### Diagnosis and Classification Criteria

In a majority of cases, AS is diagnosed or at least suspected on clinical elements, particularly patient symptoms, family history, and physical findings (55). For a diagnosis of AS, a history of getting out of bed at night was shown to have a sensitivity of 65% and a specificity of 79%. The most sensitive items were morning stiffness (95%) and age less than 35 years (92%), whereas the most specific was relief by exercise (88%) (56). However, it has been reported in juveniles that pain usually is not relieved and sometimes is even aggravated by exercise (57). It is also important to keep in mind that the reproducibility of history-taking is not perfect, even for symptoms such as having to get out of bed at night (56).

The most commonly used set of criteria for classification is the Modified New York Criteria of 1984, where definite AS is defined by a unilateral sacroiliitis of grade 3 or 4 or bilateral grade 2 to 4, and any clinical criterion comprising low back pain of at least 3 months' duration improved by exercise and not relieved by rest, limitation of lumbar spine in sagittal and frontal planes, and chest expansion decreased relative to normal values for age and sex (55). Two more sets of criteria—the Amor criteria and those developed by the European Spondyloarthropathy Study Group (ESSG)—were published for spondyloarthropathies but actually used for AS (58). There are no validated diagnostic criteria for AS (55); the reader should keep in mind the difference between diagnostic and classification criteria (55,59). If the classification criteria of the ESSG sometimes have been used to aid diagnosis (59), their sensitivity in early cases is 66% compared to 94% in clinically definite AS, and they should not be used to establish a diagnosis of AS in individual patients (55).

The diagnosis of late-stage AS is not difficult but it can be challenging in the early stage. The delay between the

first symptoms and the actual diagnosis ranges from 0 to 29 years, with a mean from 5 to 10 years (50,60). In a cohort, only two thirds of AS cases (50% of men and 85% of women) had been initially diagnosed when the medical records were reexamined within a research project (61). On the other hand, five pain characteristics considered typical of inflammatory disorders (back pain  $\geq$  3 months, morning stiffness, age of onset  $<$  40 years, insidious onset of pain, and back pain improved by exercise) identify 10% to 15% of patients in primary care or other settings (55,62). This is much more than the prevalence of AS and represents a very high false-positive rate (55,62).

Finally, diagnosis is complicated by atypical presentations such as inflammatory back pain without radiographic sacroiliitis, inflammatory chest wall pain without sacroiliitis, juvenile onset (including tarsal enthesitis), late onset AS, acute anterior uveitis (with or without arthritis), and aortic regurgitation or complete heart block (with or without arthritis), which should be recognized as AS (55).

### Axial Involvement

Axial involvement is the hallmark of AS and affects virtually 100% of patients at some time. It is the first manifestation in about three fourths of the cases and it is the cornerstone of diagnosis (see the preceding section on diagnosis and a later section on radiology). It encompasses not only the sacroiliac joints and spine itself, but also the thoracic cage and pelvis. This section focuses on little known or unrecognized aspects of this type of manifestation.

Among the uncommon localizations, AS has been reported to involve a transitional lumbosacral joint (63) and symphysis pubis (64). Pascual et al. (cited by Le) reported that up to 82% of AS patients with thoracic pain have an involvement of costovertebral joints with erosive lesions (65). Finally, a study including 50 patients with AS reported the following figures for the involvement of the anterior thoracic wall: interclavicular ligament and sterno-costoclavicular joint (20%), manubriosternal symphysis (32%), and chondrocostal and costoxiphoidal ligaments (4%) (66).

Erosive spondylodiscitis (i.e., destructive changes at the discovertebral junction excluding lesions that may relate to cartilaginous nodes) were found in 8% of cases in a study including 147 patients with AS. The same number of cases had single-level as multilevel involvement, with a maximum number of six levels. Only 17% of the cases were symptomatic, and it seems that patients with this type of lesion have an earlier onset of AS (67). In 50 AS patients, 22% of the cervical and lumbar zygapophyseal joints were ankylosed on standard radiographs when evaluated by means of a new score. The authors conclude that ankylosis of the posterior joints may precede the syndesmophytes (53).

Geusens et al., in a cross-sectional study to decipher the etiology of hyperkyphosis, compared 38 AS patients

with hyperkyphosis with 12 patients without such deformity. The lumbar spine did not contribute to the deformity, but thoracic disc wedging did. The sum of deformities of the thoracic vertebrae and discs explained 43% of the variance of the age-adjusted occiput-to-wall distance. There was no significant difference between genders and between patients aged more or less than 45 years (68).

An occult vertebral fracture, which may occur even with minor traumatic events, is one of the feared complications of AS. Mitra et al. compared 66 men with mild AS with 39 healthy controls. Despite the fact that the latter were roughly 15 years older, the AS patients had significantly more vertebral fractures (16.7% versus 2.6%) and significantly lower bone mineral density (BMD), both in the lumbar spine and femoral neck. However, there was no correlation between BMD and vertebral fractures in these patients (69). Kauppi et al. reported on one case and highlighted the fact that pain, neurologic symptoms, modification of the kyphosis, and increased mobility appearing after an accident should raise the suspicion of a fracture (70). Because the majority of such fractures occur at the cervico-thoracic junction, it is extremely difficult to obtain good-quality images (70). In a review of 21 cases, vertebral fractures were identified on a delayed basis and secondary neurologic deficits were described in three patients. Multiple non-contiguous fractures were found in several patients, and the diagnostic value of a specific MRI protocol was highlighted (71).

Other extensive studies with bone biopsy—like the one by Lee et al. comparing seven early patients with AS (mean duration 2 years and normal mobility) to seven late patients with AS (mean duration 27 years and limited spinal mobility) at baseline and at 15 months follow-up—confirmed the low BMD in AS but failed to demonstrate consistent change in bone turnover to explain it. It appeared that men with AS have both trabecular and cortical bone deficit that may result from genetic factors, inflammation, medication, or decreased mobility (72), whereas alteration in vitamin D metabolism and increased bone resorption-related high disease activity was suggested in another study by Lange et al. (73).

### Peripheral Joint Involvement

Hips and shoulders are involved at some stage of the disease in about one third of patients (more commonly in patients with juvenile-onset AS); this should be regarded ultimately as a type of axial involvement (43). Hip disease usually is symmetric and insidious, and can result in severe disability (74). Shoulder symptoms and loss of mobility also are common in patients with AS and, in a survey including 1,515 subjects, the prevalence of severe or very severe pain and severe or very severe stiffness were 15.2% and 13.8%, respectively. Despite the high frequency and correlation with higher pain and arthritis

impact measurement scales (AIMS) scores, shoulder symptoms were rarely disabling (75).

True peripheral joint involvement is infrequent in AS; when present, it is usually regarded as asymmetric, transient, and rarely erosive and with a tendency to resolve without deformity (43).

A special case should be made for the temporomandibular joint. In one study, involvement of the temporomandibular joint was found in almost 50% of 65 patients aged 33 ( $\pm 11$ ). Condylar erosions and flattening, and sclerosis, as well as temporal flattening were significantly increased compared with controls (76), as were condylar erosions associated with longer duration of AS, neck complaints, and atlantoaxial subluxation (76). Magnetic resonance imaging (MRI) has been reported to show a high prevalence of temporomandibular degenerative changes or disc displacement which were, however, not specific for a diagnosis of AS (77). Temporomandibular joint involvement does not seem to be correlated with AS severity or peripheral joint involvement (77).

### Entheses

Inflammation at the sites of attachment of a tendon or enthesitis can be a major disabling problem in some patients and is a hallmark of AS and the spondyloarthropathies (78,79). The entheses of the lower limbs are more frequently involved; heel enthesitis is the most common (79). Traditional methods of imaging, including plain film radiography and xeroradiography, have been supplanted by ultrasound and MRI, which demonstrated soft-tissue and bone edema and inflammation much before the classical erosions and bone proliferation seen in more advanced cases (79).

### Extra-articular Manifestations

Various extra-articular manifestations have been associated with AS. Some can be considered as plain complications, often in late-stage disease, whereas others are more strongly disease-associated with shared pathogenesis.

### Neurologic

Cauda equina syndrome (CES) is described as a rare complication of AS that manifests late in the course of the disease (46,80,81). Ahn et al. recently reviewed 52 papers on CES that included 86 patients (82). These patients had a mean age of  $58.5 \pm 2$  years, with an average of 32 years of AS history. A slow onset of neurologic deficit was reported by 98% of patients. Motor deficit was found in 62%, whereas sensory deficit, reflex deficit, and bladder dysfunction were much more common (96%, 93%, and 95%, respectively). Of note, the clinical picture was ini-

tially misdiagnosed as prostatic hyperplasia and prostatectomy was performed in almost one third of males. Sciatica was the initial symptom in 22% of cases (82). Finally, only 40% of the patients treated surgically had some form of neurologic improvement, whereas steroids had no effect at all (82).

The hallmark of CES in AS is the presence of dorsal dura diverticula associated with a widened thecal sac and scalloped erosions of the posterior vertebral arch. This syndrome has been attributed to arachnoiditis and chronic inflammation (46,80–82), even though other hypotheses (arteritis, demyelination, fibrosis, etc.) have been raised (46). A published case report describes the coexistence of AS and spinal arteriovenous malformation with vasculitic changes (83).

Other neurologic manifestations of AS include isolated nerve root, cervical myelopathy, and possible combinations of nerve root and spinal cord compression in case of fractures (80). They have been attributed to instability (owing to subluxation or fracture), inflammation (arachnoiditis or single root lesions), or compression (ossified intraspinal ligaments, granulation tissue, or foraminal stenosis) (46).

One case of bilateral optic neuritis in a woman suffering from AS has been published, suggesting the possible connection between AS and multiple sclerosis (84). Dolan and Gibson published two cases of AS with spastic paraparesis because of undetermined intrinsic spinal cord lesions where the neurologic symptoms had been attributed to associated multiple sclerosis but were indeed a complication of AS (85).

### **Gastrointestinal**

There is a clear association between IBD and the spondyloarthropathies (37). Cohorts of IBD develop inflammatory rheumatism that can be labeled as AS or enteropathic arthritis. The reader is referred to Chapter 74 by Goupille and Borenstein.

However, it is important to realize that AS patients without any known bowel disease present endoscopic lesions in 29.2% of cases and histologic signs of gut inflammation in 58.3% (acute inflammation in 8.3% acute and chronic inflammation in 50%) at ileocolonoscopy (38). This confirms previous studies where prevalence of inflammatory gut lesions observed by ileocolonoscopy ranged from 29% to 67% when looking only at the subgroup of AS patients (37).

Finally, a possible association may exist with celiac disease. Kallikorm et al. screened 18 patients with AS by means of different serologic tests (antigliadin and antireticulin antibodies—both IgA and IgG—and antientomysium IgA) and discovered one case of celiac disease, corresponding to a prevalence of 5.5% as compared with an incidence of .37:1,000 live births in the same country (86).

### **Renal**

In a cross-sectional study including 40 AS patients, 35% presented one or more renal abnormalities. The most common sign was microscopic hematuria followed by microalbuminuria, and reduced creatinine clearance. No case of proximal tubular impairment was found by means of the urinary excretion of retinol-binding protein (87).

In an extensive review of the literature, the overall prevalence of clinically relevant renal involvement in AS has been estimated to be around 10% with the following distribution: 62% of amyloidosis; 30% of IgA nephropathy; 5% of mesangioproliferative glomerulonephritis; and 1% each of membranous nephropathy, focal segmental glomerulonephritis, and focal proliferative glomerulonephritis (88). The figure for amyloidosis is in agreement with other studies. Histologic evidence of secondary amyloidosis was found in one of 15 (6.2%) specimens obtained during joint replacement procedures in AS patients without any clinical evidence of amyloidosis (aged 30, average disease duration 8.2 years) (89), whereas a systematic search for amyloidosis by subcutaneous abdominal fat aspiration in 137 patients yielded a positive test in 7% of the cases. These patients were significantly older, had longer duration of AS, and more peripheral erosive arthritis than the rest of AS patients (90). A more conservative estimate is around 3% for the prevalence of clinically recognizable secondary amyloidosis in live AS patients (89).

### **Pulmonary**

Figures for pulmonary involvement range from 0% to 30% (91). In two papers from the same group, including 26 patients (women 23%; mean age 44.8 years; mean duration of AS 18.5 years, and 12% never smokers), six were symptomatic (23%) with mainly cough or dyspnea, whereas only two (8%) had basal crepitations on chest examination. However, pulmonary functions were abnormal in 11 patients (42%) with a restrictive pattern in eight and obstructive in three. Plain chest radiographs showed abnormalities in only 15%, whereas high-resolution CT was abnormal in 69%. The most common abnormalities on CT were interstitial lung disease, bronchial wall thickening and bronchiectasias, paraseptal emphysema, mediastinal lymphadenopathy, tracheal dilatation, and apical fibrosis unexplained by a history of smoking alone and suggesting a possible association between AS and interstitial lung disease (91,92). Others have reported similar findings. In a highly selected group of patients, where patients with histories of smoking or exposure to inhaled gases as well as patients with abnormal chest radiographs were excluded, prevalence of abnormalities was 71% for thin-section CT and 57% for pulmonary function tests, all with a restrictive pattern. The main types of lesions were interlobular septal thickening, linear septal thickening,

thickening of bronchial walls and pleural thickening (21 patients, mean age  $43 \pm 12$ , mean duration of AS  $13 \pm 7.5$  years) (93).

Finally, a small study showed that smoking was associated with a poor outcome in terms of mobility and functional index in AS patients (60).

### **Cardiac**

Several types of valve disease, arrhythmias, myocardial diseases, and pericarditis have been found in association with HLA-B27, most of them in patients with AS (94). A longitudinal study with a mean follow-up of 39 months found abnormalities of the aortic root and valves on transesophageal echocardiography in 82% of AS patients and 27% of controls ( $p < .001$ ). These findings were unrelated to clinical features of AS. Twenty-four percent of patients developed new or other aortic root or valve abnormalities during follow-up, whereas another 12% demonstrated progression to a more severe regurgitation. However, the abnormalities detected at baseline also resolved in 20% (95).

Jimenez-Balderas et al. performed a two-dimensional echo Doppler study in cardiopulmonary asymptomatic patients with AS. They compared 20 cases with juvenile-onset AS, 31 with adult-onset AS, and 20 healthy males. Several abnormalities were found significantly more often among AS patients and some differences between juvenile- and adult-onset reported. Cardiomyopathy, increased aortic root diameter, and abnormal aortic ring reflectance were more frequent among patients with adult-onset despite a higher frequency of HLA-B27 among juveniles (90% versus 51%) but no difference in terms of increased mitral valve gradient was found between both subgroups of AS (96).

### **Ocular**

Uveitis is the main type of eye involvement and the most common extra-articular manifestation (97). According to an extensive review, the likelihood of anterior uveitis in AS patients ranges from 20% to 30%. Conversely, the likelihood of AS in patients with uveitis is 15% for any uveitis, 30% to 50% for acute anterior uveitis with figures raising up to 84% to 90% for HLA-B27+ patients with acute anterior uveitis. The clinical patterns of uveitis most frequently associated with AS are the unilateral acute anterior recurrent uveitis and the unilateral acute anterior nonrecurrent uveitis (97).

### **Psychological**

Different psychological aspects have been studied in AS patients. Günther et al. assessed 76 AS male patients and 16 healthy controls for their stress coping mechanisms. Patients were divided into four groups according

to the duration of AS and overall patients differed from controls only in a few aspects. They used more cognitive coping and actionable strategies and less resignation and self-accusation, which led the authors to conclude that AS patients probably use the best coping mechanisms and that they conform with the notion of “healthy ill people” (98). Psychological well-being, as assessed by SCL-90-R, was found to be correlated with pain but neither with function nor spinal mobility measures (99).

Other studies have focused on sleep disturbances, which appear to be a significant problem for AS patients. A cross-sectional comparison of 70 AS patients and 3,558 controls demonstrated several differences between groups at all stages (i.e., pre-sleep, sleep, and wakefulness) (100). A previous study, including 11 patients and 11 controls, had already shown that sleep was different in AS patients and controls. Moreover, quality of sleep was correlated with lumbar flexibility, pain, and psychomotor performance (101). However, the same authors also stated in another study that the precise nature of the relationship among fatigue, disease activity, function, and sleep disturbance remained unclear (102).

In a study by Ward evaluating 175 patients with the Medical Outcomes Study Short Form 36 Health Survey (SF-36) among other tools, it appeared that mental health role limitations caused by emotional problems and social functioning were less affected than the rest of the subscales of the questionnaire (52). Nevertheless, it is also important to recognize that self-reported health status appeared more strongly related to personality traits than the degree of disability in a study that included 144 patients (103).

Finally, in a survey including 175 patients self-evaluated for the presence and importance of problems in 23 aspects of quality of life, the main concerns of patients were pain, stiffness, fatigue, and sleep problems. Less educated patients had lower quality of life. Moreover, women reported significantly more problems with fatigue, coping with illness, job performance, and self-care tasks. Pain and role limitations owing to physical problems are also more likely in women (52).

### **Various**

Ankylosing spondylitis patients could be predisposed to lymphoid malignancies. In a subgroup of 1,137 HLA-typed patients selected from a Chinese marrow donor registry of 18,774 volunteer, ankylosing spondylitis was found in four of the 16 HLA-B27+ patients with lymphoid malignancies (three cases of acute lymphoblastic leukemia and one of Hodgkin lymphoma) (104).

In a study of 22 female patients with AS and 22 matched controls, enlarged thyroid volume, lower basal free T3, T4 and total T3, normal levels of TSH and total T4, and increased reverse-T3 were significantly more frequent in the AS group. This “low-T3 syndrome” was cor-

related to parameters of acute inflammatory activity (105).

Focal sialadenitis was found in 58% of AS patients and secondary Sjögren syndrome in 26%, figures quite similar to that concerning rheumatoid arthritis and other inflammatory diseases (106).

The prevalence of type A vitiligo was found to be 4.6% in a cohort of patients with AS ( $n = 43$ ) versus 1.06% in a group of 468 control patients suffering from different rheumatic disorders excepted spondyloarthropathies (107).

Finally, AS patients could present with severe muscle wasting. There is no compelling evidence for an association of AS with inflammatory muscle disease, even if modest raised blood levels of muscle enzymes occasionally have been observed. Until proved otherwise, one should first exclude a neurologic complication, severe disuse, or malabsorption when a patient presents with such a clinical picture (43).

Of interest, despite AS being an inflammatory disease, it has been shown that some meteorologic variables have significant influence on the patient's quality of life as evaluated by the questionnaire (108).

### Functional Capacity and Outcome

Different studies on this topic have been published; however, they are mainly cross-sectional (48,50,99, 109–111). A systematic review was published that summarized the information available up to 2001 (112). Despite the generalized opinion that most AS patients retain full work ability, it appears overall that AS has a substantial impact in terms of work disability (3% to 50%) and sick leave (12 to 46 days per patient per year) (112), but with large differences among countries (113).

Of course, life cannot be reduced to work capacity. According to Ward, mortality, quality of life, and physiologic or anatomic impairment are the major components of health outcomes (114). To evaluate health-related quality of life in AS, one should take into account several components: symptoms, physical functioning, role functioning, social interactions, psychological functioning, adverse effects of treatment, and both direct and indirect financial costs (114).

### Juvenile Ankylosing Spondylitis

Juvenile ankylosing spondylitis (JAS) deserves a few comments. The definition is that of an ankylosing spondylitis occurring in individuals less than 16 years of age (57,115). However, no specific diagnostic criteria are available (116). The main characteristics of JAS are a male to female ratio of 7:1, mean onset age greater than 10 years, common enthesitis, HLA-B27+ in 90%, and no ANA or rheumatoid factor (115). The female to male ratio seems to increase as the age of onset decreases (117).

We have not found precise epidemiologic data, but rather indirect estimates. Lee et al. reported figures of prevalence of 10% to 15% for AS that start during childhood, with 29.2% of their patients originally diagnosed with juvenile chronic arthritis (late-onset pauciarticular type) (38). Much higher figures have been cited in selected referred rheumatic pediatric populations (57, 115,118).

Onset of JAS may be so acute that it mimics a septic disorder, or it may be much more subtle (115). Arthritis is often very episodic with long remission. The usual picture is that of an older boy with asymmetric oligoarthritis predominant in the lower limbs, often with enthesitis. Night pain and morning stiffness are characteristic. Hip joint arthritis at onset is common, and early onset is recognized as a risk factor for hip involvement (43). Multifactorial (e.g., synovitis, enthesitis, tenosynovitis, and bursitis) midfoot pain and tenderness also are frequent (115). One caveat is that evidence of arthritis of the sacroiliac joints and spine does not develop until 5 to 10 years after onset (57).

Constitutional symptoms such as high-grade fever, weight loss, muscle weakness and atrophy, fatigue, lymph node enlargement, leukocytosis, and anemia are present in 5% to 10% of patients (57). The usefulness of different imaging methods seems rather limited and they are not indicated routinely in this age group (115,116). Of note, in one study, not a single case presented with solely axial symptoms, and clinical signs in the absence of symptoms were extraordinarily rare (119).

## INVESTIGATIONS AND OUTCOME MEASURES

### Imaging

The main radiologic features of AS are: sacroiliitis, vertebral squaring, vertebral osteopenia, spondylitis anterior (Romanus lesion), shiny corner (marginal vertebral sclerosis), spondylodiscitis (Anderson lesion), joint capsule and ligament ossification, syndesmophytes, bamboo spine, and vertebral fractures (7,120).

Ankylosis of the sacroiliac joints can take years, but can also occur rapidly in approximately 20% of patients with very severe early disease (120). Sacroiliitis is central to diagnosis, and an agreement between pelvic antero-posterior (AP) views and sacroiliac joint incidences was found in 94% of cases. Therefore, the former should be preferred because they are cheaper, less irradiating, and also bring some information about the hip joints (121). A comparison of radiography, computed tomography (CT) scan, and MRI was performed in nine healthy volunteers and 24 patients with AS (mean age, 21.7 years). Magnetic resonance imaging showed the cartilage of all the sacroiliac joints of the volunteers to be normal, and both imaging techniques performed better than radiographs. Although only one patient was normal in each imaging technique, 11 sacroiliac joints

were graded 0 in AP radiographs and 16 in oblique views (122). Moreover, CT was superior to MRI to identify sclerosis; on the other hand, MRI was able to reveal early cartilage changes and bone marrow edema (122). Two other recent studies have highlighted the usefulness of MRI, with or without enhancement, to detect early sacroiliitis (123,124) or Romanus lesions (125). Interestingly, a limited MRI examination used by McNally et al. to screen 1,042 cases suffering from LBP without radiculopathy and unresponsive to conservative treatment for more than 6 weeks demonstrated seven cases of AS, among other pathologies, even though the diagnostic criteria used were not reported (126).

The contribution of pathologic radiographs of the spine, irrespective of sacroiliac changes, to the diagnosis of AS is not clear (120). Early lesions of the spine in AS occur where the disc, anterior ligament, and edge of the vertebral body meet (120), and bone formation seems to parallel ongoing inflammation (120). As stated, it had been advocated that zygapophyseal joint ankylosis precede the syndesmophytes (53). The problem of occult fractures has been highlighted before and one should be aware that anterior atlantoaxial subluxation can occur in later stages of AS (120). Bone single photon emission computed tomography, evaluated in 28 patients, demonstrated abnormalities in the vertebral body and facet joints of 15 and 16 patients, respectively. Of note, multiple sites of uptake were common, but only three patients had elevated sacroiliac scores (127). Another technique, the <sup>99m</sup>Tc human IgG scintigraphy did not demonstrate usefulness (128).

The clinico-radiologic correlation appears poor in a study including 19 patients with AS. Actually, the frequency of symptoms at different specific localizations was only 20% to 25% of the prevalence of radiologic signs. Moreover, radiologic manifestations of enthesitis at the ischiatic tuberosity were present in 95% of patients, whereas none reported clinical symptoms (129).

The main validated scoring methods for reading standard radiographs in AS has been the object of multiple studies (44,130–133) and was highlighted in reviews (134). Spoorenberg et al. compared the existing methods of scoring; that is, the New York method and the Stoke Ankylosing Spondylitis Spine Score (SASSS) for the sacroiliac joints, the Larsen method for the hip joints, the Bath Ankylosing Spondylitis Radiology Index (BASRI) for AP and lateral views of the cervical and lumbar spine, and the SASSS for the lateral anterior and posterior aspects of the cervical and lumbar spine. Reliability and sensitivity to change over 1 year using the same radiograph techniques were evaluated for all methods. Only the SASSS (spine) and BASRI index reached good reliability. Moreover, observers agreed that no change occurred over 1 year in up to 89% of cases (133). Actually, only half of patients develop severe disease after 45 years, and 25% never develop cervical involvement.

There was a lack of correlation between the individual radiologic score and duration of disease. It appears that patients with hip involvement had more severe axial disease (130). It also appears from data obtained on the BASRI score that the AP view supplies more information than the lateral view (44).

A comparison of radiologic changes and mobility measures showed significant correlations among several variables, sometimes concerning different sections of the spine (e.g., cervical mobility was correlated with sacroiliac radiography) (135). An important drawback of radiographs is that, in contrast to the clinical status, radiographs cannot improve and sequential films are considered almost useless (10).

### Laboratory Tests

Most laboratory tests are of limited value in AS. Levels of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are normal or only slightly increased in many patients with “active” AS, not allowing for further improvement (134). Neither is superior to the other in assessing disease activity (136). In their review, van den Hoogen et al. reported that raised ESR had sensitivity of .69 and specificity of .68 for diagnostic accuracy (56). Nevertheless, the latest recommendation promotes the use of ESR. Even if its predictive value and discriminative power remain to be defined by longitudinal studies (134). In a 6-week study including 443 patients, CRP was found to be increased at baseline in 39% of cases. Moreover, a reduction of CRP at follow-up occurred in 28% of cases in the placebo arm of the study (137).

Other tests, such as plasma viscosity and interleukin-6, have been used; however, laboratory tests are not very useful overall, and their correlation with the degree of impairment is minimal (10).

The strong association between HLA-B27 and AS has been discussed. A positive HL-B27 status has no real value in diagnosis. It will not make the diagnosis in a patient who failed clinical criteria. At best, AS is very unlikely with a negative result; an alternate diagnosis should be considered.

### Outcome Measures

Traditionally, clinicians have relied heavily on physical measurement as measures of the efficacy of management. Viitanen et al. compared nine measurements of the cervical spine mobility either by means of a tape or an inclinometer; the results were correlated with radiologic changes of the whole spine. The authors concluded that cervical extension and lateral flexion as well as cervical rotation and occiput- or tragus-wall distance could be recommended as long-term outcomes measures (138). A method of assessment of the thoracolumbar rotation by means of a tape (the Pavelka method) has been shown to

be a valid and reliable method in AS patients (139). The same group compared 17 repeated tests and correlated them with radiologic findings. They concluded that a modified Schober test, thoracolumbar flexion, lateral flexion, and rotation, chest expansion (after careful standardization), cervical rotation, and extension or lateral flexion could be used to assess disease progression (140). The sensitivity to change of different spinal, shoulder, and hip measurements also was tested in a 3-week inpatient course of intensive physiotherapy. Finger to floor distance, thoracolumbar rotation (Pavelka method), and thoracolumbar lateral flexion were the most sensitive, with effect sizes ranging between .32 and .43 (141). Finally, clinical and radiologic measures including dynamic radiographs were compared in 22 cases of AS with predominant involvement of the spine. The reproducibility of the clinical measures was reported to be excellent, whereas the correlation coefficients between radiologic and clinical measures ranged from .81 to .17 (142).

However, physical measurements represent only one of the different aspects or domains of the clinical evaluation. It includes taking a clinical history, physical examination, perception of the functional capacity and reported quality of life, as well as radiologic and laboratory data. Several tools have been developed specifically for AS, and core sets have been proposed for various tasks: daily clinical record keeping, evaluation of disease-modifying drugs, and evaluation of symptomatic treatments (134). This is an intense field of research still in progress (143,144). For example, a recent paper pooling five randomized controlled trials (RCTs), including more than 1,000 patients overall, proposed the use of “patient global assessment, pain, function, and inflammation” to define response to treatment or partial remission (145).

These instruments also can be used in sets defined to perform patient evaluation following the World Health Organization’s recommendations (146). The group from the Royal National Hospital for Rheumatic Diseases (Bath, UK) has defined several sets of measurements that constitute different indexes: Bath Ankylosing Spondylitis Functional Index (BASFI), Bath Ankylosing Spondylitis Metrology Index (BASMI), Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Psychological Index (BAS-PSYCH), and Bath Ankylosing Spondylitis Global status (BAS-G) (10,147–149). If these indexes are used widely in drug studies, they also may be used to evaluate impairment (BASDAI, BASMI, BAS-PSYCH, and radiographs), disability (BASFI and BAS-G), and handicap (cost, employment, and quality of life) according to Calin (10).

Numerous instruments to evaluate function are available and widely used in clinical research. They all have strengths and limitations, which should be kept in mind when evaluating an article. A recent study using data from a placebo-controlled RCT compared the most commonly used questionnaires for self-assessment of

patients’ functional capacity: the BASFI, the Dougados Functional Index (DFI), and the specific version for AS of the Health Assessment Questionnaire (HAQ-S), and concluded that the BASFI performed better to identify either improvement or deterioration (51). In another study, the DFI and HAQ-S were compared with two more generic instruments—the Health Assessment Questionnaire (HAQ) and the Arthritis Impact Measurement Scales-2 (AIMS2)—with regard to construct validity and sensitivity to change. This was a longitudinal study with a 2-year follow-up of 216 patients. The authors concluded that HAQ-S performed similarly to the HAQ but better than the AIMS-2 and the functional index (150). AIMS2 has been described as a multidimensional but not AS-specific tool. On the other hand, BASFI, DFI, and HAQ-S are AS-specific; however, several important dimensions are missing (151). For this reason, the AS Arthritis Impact Measurement Scales 2 (AS-AIMS2), a new questionnaire based on AIMS2 and HAQ-S, has been developed and validated (151). In another study the scores of BASFI and DFI showed a Spearman correlation coefficient of .89 (152). With these indexes, 12% to 30% of patients were misclassified for disease activity. Finally, the authors could not make a definite choice even though the BASFI showed a slightly higher specificity (152).

Detailed review of all the available instruments is beyond the purpose of this chapter. Some information on the instruments used for radiologic and laboratory domains have been discussed in previous sections.

## TREATMENT

Major short-term objectives of AS treatment are primarily pain relief and decrease stiffness. This should allow for long-term prevention of ankylosis, hyperkyphosis, and late-stage complications such as chest wall involvement with restrictive pulmonary failure (78,153). Finally, one could add control of inflammation, which should prevent complications such as secondary amyloidosis. It is not known if these measures prevent other long-term manifestations or complications, such as aortic insufficiency or pulmonary fibrosis.

Probably more than in most diseases, patient education and active participation in the treatment are crucial. Drug therapy is important and efficient, and the availability of biologic agents will probably radically change our approach to AS during the coming decades; however, self-management and physiotherapy remain a cornerstone in the management of AS at this time.

Monitoring the evolution of an AS patient and evaluating the efficacy of treatment is a laborious but important task. As stated, multiple domains should be considered for a thorough clinical evaluation. Core sets have been proposed to help us (143,144), but their validity in daily clinical practice for treatment guidance is unknown. Furthermore, a working knowledge of the clinically relevant

differences among instruments is still missing (78,134,154).

### Physiotherapy

Even if controlled studies are rare, physiotherapy has demonstrated its importance through the years and is widely prescribed. Probably it should be used in a classical form, administered by a physical therapist, or more importantly as a self-exercise, alone or within a group of AS patients (153,155).

Significant benefits have been demonstrated in an RCT for home physiotherapy on a short-term basis of 4 months (156); manipulative therapy also can be helpful (153). Hydrotherapy appears also particularly valuable and is widely prescribed, even if no rigorous demonstration of its efficacy is available (153,155). Before prescription, one also should be aware that if aquatic therapy has great advantages, it also has contraindications and specific requirements (157).

Even if classically it has been associated with drug therapy, physiotherapy per se has some efficacy for symptomatic relief and could be sufficient alone (153). Finally, it is essential to insist on the importance of the lifelong regular practice of exercise (153). Sports also can be advocated, but the choice should be adapted to the type of involvement, cardiovascular status, and intrinsic risk of traumatism (158).

### Drugs

#### *Analgesic*

Pure analgesics often are considered of limited value by doctors in the management of AS; however, they are widely used by patients. In one study, almost one third of patients take analgesics; this percentage increases with severity of disease (159). The use of narcotic analgesics is not uncommon because the patients' main concern is symptom relief (160). To our knowledge, there is no RCT on their efficacy in AS, but we are unaware of any demonstration that an antiinflammatory effect is necessary in AS.

#### *Nonsteroidal Antiinflammatory Drugs*

Nonsteroidal antiinflammatory drugs (NSAIDs) have been and are still extensively used in AS to provide symptomatic relief; more than 80% of the patients use them (160). The overall objective is to provide sufficient relief to allow the patient to realize free movements and regular exercise programs essential for the prevention of ankylosis (78,153,155). There is no convincing evidence to support the traditional assertion that phenylbutazone and indomethacin are the best NSAIDs for AS (even having possible effects on the calcification of syndesmophytes).

It seems that all NSAIDs are equally efficient at equivalent doses (78,153,155). It is more local preferences and conventions, rather than prospective RCT studies, that appear to dictate the use of various NSAIDs.

It is important to stress that the efficacy of an NSAID usually can be assessed within 48 hours; one should change to another drug in case of inefficacy (78). New COX-2 specific NSAIDs appear equally effective as regular NSAIDs. Celecoxib has proved to be as efficient at relieving pain in AS as ketoprofen in a 6-week RCT (161). There is no reason to believe that the benefits from COX-2 specific inhibition with reduction in serious gastrointestinal adverse events observed in large osteoarthritis studies should not apply to AS patients (162,163).

Finally, it is important to remember that there is no evidence in the literature that prolonged antiinflammatory treatment improves radiologic or functional outcomes. Usage of NSAIDs should be restricted to painful periods of disease activity, because they do not have any disease-modifying properties per se (155).

#### *Systemic Corticosteroids*

Systemic oral corticosteroids have little use in AS (78,155). Some rare patients do benefit from intravenously pulsed methylprednisolone for severe flare; however, the improvement usually is limited in time (78). Dosage of 1 g did not appear more effective than 375 mg (78).

#### *Disease-modifying Antirheumatic Drugs and Biologic Agents*

Disease-modifying antirheumatic drugs (DMARDs) are classically prescribed for severe disease resisting or insufficiently controlled by NSAIDs; however, they have no disease-modifying effect in AS. Most of the classical DMARDs used for rheumatoid arthritis have been tried in AS and proved to be either totally inefficient or efficient only in a few cases (78,153,155). They can be prescribed in severe cases resistant to other treatment, so long as one recognizes the limitations and risks of this treatment, has a clear definition of the potential benefit, and is ready to interrupt the treatment if it does not achieve the goal.

Sulfasalazine is the DMARD most used by patients and recommended by rheumatologists for AS (159). Various studies have evaluated sulfasalazine in AS, both in patients with axial and peripheral joint involvement (164,165). A meta-analysis confirmed safety and some effectiveness in the short-term treatment of AS (166). However, efficacy is mainly limited to peripheral disease (164,165). These trials indicated that there is no clinically relevant beneficial effect, except for concomitant arthritis, which represents less than 25% of patients with AS (167). Of interest, sulfasalazine has demonstrated a potential for prevention of anterior uveitis (168).

Methotrexate (mtx) is the second most recommended DMARD for AS (159), although no RCT has proved its efficacy in AS. Efficacy was evaluated in two open-label studies (169,170). An Italian study treated 17 sulfasalazine-resistant or -intolerant AS patients with 7.5 to 10 mg oral mtx per week in association with indomethacin over 3 years. Unexpectedly, they showed significant improvement in axial disease as evaluated by the visual analog scale (VAS) for night pain, well-being and physical measurements, and absence of spine or sacroiliac joint disease progression on radiographs; however, they failed to demonstrate any decrease in the number of swollen or tender joints (170). On the other hand, the axial measures were not significantly different in 34 long-standing active AS patients who failed to improve on NSAIDs and were treated with intramuscular mtx 12.5 mg per week for 1 year in a prospective study, despite the fact that 53% were considered responders with clinical improvement, reduction of more than 50% in the dosage of NSAIDs, and 25% in ESR. Also, 16 out of 26 patients with peripheral involvement had significant improvement (169). Finally, a recent 1-year RCT with 51 AS patients compared treatment with oral mtx 7.5 mg per week and naproxen with naproxen alone. This study failed to demonstrate any superiority of the association, but dosage of mtx was very low for the actual standard; possibly, a higher dosage would show some efficacy (171).

Anti-tumor necrosis- $\alpha$  (anti-TNF- $\alpha$ ) therapy has raised enormous hope in the treatment of AS and other spondyloarthropathies (172,173). In a 3-month open study, Brandt et al. demonstrated a more than 50% improvement in nine out of 11 AS patients for disease activity, as measured with the BASDAI, function, and pain scores. Disease was considered severe, with a mean duration of 5 years, and the patients received three perfusions of infliximab, an anti-TNF- $\alpha$  chimeric antibody at a dose of 5 mg/kg of weight at weeks 0, 2, and 6, a protocol similar to the one used for Crohn disease (174). These data have been confirmed in a multicenter German RCT of 70 patients with AS where 53% had significant (50%) short-term improvement in BASDAI and spinal pain on a VAS scale (175). Two randomized, double-blind studies comparing anti-TNF therapy to placebo have been published recently (176,177). In the first study, infliximab brought significant short-term (12-week) benefits in spondyloarthropathies as assessed on patient and physician global activity scales. Nineteen patients out of 40 had AS, and it should be noted that six out of 10 only had axial involvement in the placebo group, whereas six out of nine had axial and peripheral involvement in the treatment group. Treatment significantly improved primary end points and decreased CRP and ESR, but it failed to demonstrate improvement in axial involvement (176). The second study used twice-weekly subcutaneous injection of etanercept, a soluble Ig fusion receptor, in 40 AS patients. Again, there was a significant

improvement in the global assessment, BASFI, ESR, and CRP, but not in measures assessing spinal involvement with the exception of chest expansion (177). At this time, it seems that anti-TNF- $\alpha$  therapy is efficient in the short term, particularly when assessing functional capacity or quality of life. This type of treatment appears less efficient using clinical and radiologic measures, but this could be a problem of study design, in particular with short-term studies, or sensitivity of the methods. Recent studies have hinted that MRI could be a good surrogate outcome parameter in this regard (174,178,179). Moreover, it should be remembered that if biologic agents bring us to the next dimension in the treatment of AS, they also can have severe adverse effects (e.g., tuberculosis) (175,176,180), regardless of price.

Finally, and as stated, most DMARDs have been used with little success, but one can always find an anecdotal dramatic response in a severe case of refractory AS. This holds true for thalidomide (181), anti-CD4, anti-interleukin-6 (182), azathioprine (183), and others (155). The authors do not recommend the utilization of such treatments.

### Others

Pamidronate, an antiresorptive bisphosphonate, has demonstrated good efficiency in NSAID-refractory AS in two small open studies (184,185) and one 6-month RCT (186). At a dose of 60 mg intravenously monthly, pamidronate induced significant decrease in activity index (BASDAI) and improvement in function (BASFI). Interestingly, there was no significant amelioration of inflammatory parameters; the mechanisms of this beneficial effect remain enigmatic. Reduced bone marrow edema in affected joints after pamidronate has been described by the same group, which could explain some of the observed effects (185).

Finally, despite the sad experiment with induced leukemia after external spine radiotherapy (153), systemic treatment with radioisotopes has regained interest in Germany (187), but awaits the strict demonstration of its efficacy and lack of long-term adverse effects.

### Local Treatment

The limited therapeutic response to systemic therapy and the restricted involvement of entheses and peripheral arthritis make them good candidates for local treatment. Physical therapy and orthoses such as shoe insoles can be helpful, even if rigorous demonstration of their efficacy is still lacking. The same holds true for local injection of corticosteroids; one should be aware of the risk of rupture when the injection is done near the Achilles tendon. Local intra-articular corticosteroids certainly are helpful in the management of peripheral arthritis and refractory sacroil-

iac joint pain (188–190). Radioactive synovectomy has been advocated in chronic synovitis (153) despite the absence of evidence for its efficiency (191). Finally, external local radiotherapy remains indicated in rare, refractory cases of enthesitis (192).

## Surgery

The surgical treatment of AS is the subject of Chapter 77 by Simmons, Simmons, and Zhengou.

# Ankylosing Spondylitis: Operative Treatment

Edward H. Simmons, Edward D. Simmons, and Yinggang Zheng

---

It is well recognized that severe flexion deformities of the spine may occur in patients with ankylosing spondylitis. Despite emphasis on early recognition and current advances in medical treatment, patients are still seen with advanced kyphotic deformities of the trunk who are very severely disabled and who present a major challenge for definitive surgical correction of their deformity (1–4).

Lumbar osteotomy is the first type of surgical correction for kyphotic deformity of spine in ankylosing spondylitis, reported by Smith-Petersen et al. in 1945 (5). The initial procedure as reported by Smith-Petersen et al. was done under general anesthesia with the patient lying prone. This was further reported by LaChapelle, Herbert, Nunziata, Wilson and Turkell, Law, and others (6–13). To avoid difficulties with the use of the prone position for patients with kyphotic deformity, Adams recommended that surgery be done with patients on their sides. He used a three-point rack to manipulate the spine for correction (14).

Some have recommended a two-stage or double-exposure procedure with division of the longitudinal ligament anteriorly. In our experience this is not required, and correction can be consistently done from the posterior approach alone. It should be appreciated that gastric dilatation and abdominal ileus is a major and consistent complication of lumbar osteotomy. When the spine is extended with the costal margin moving away from the pelvis, the superior mesenteric artery is stretched over the third part of the duodenum, producing a functional block to the outlet of the stomach and predisposing to gastric dilatation. If this hazard is not anticipated, patients may vomit a large amount. With a stiff rigid neck in the supine position, there is a major risk of aspiration, which could prove fatal. It is necessary to have a nasogastric tube in position postoperatively with suction drainage until intestinal motility is established and the patient is passing gas.

Early workers recognized the risk of general anesthesia in the performance of lumbar osteotomy (15,16). A review of the results of all reported cases of lumbar osteotomy under general anesthesia prior to 1969 indicated that the

mortality was 8% to 10% and that neurologic deficit of some degree, including paraplegia, had an incidence of 30%. In analyzing the causes of death, two thirds appeared related to the use of general anesthesia. As a result, we routinely carried out correction on the lumbar spine under local anesthesia beginning in 1969, which was found to be a safe, reliable, and practical procedure (1,17–21).

With improvement in anesthesia (particularly the ability to carry out fiberoptic intubation with the patient awake) and the development of spinal cord monitoring, the risks of surgery under general anesthesia have markedly decreased. General anesthesia is a reasonably safe option if the patient's general health is good, if he or she has had previous surgery under general anesthesia without complication, and if reasonable neck mobility remains. Our current technique is for the patient to be intubated while awake. With the endotracheal tube in position the patient is able to stand and place himself or herself on an adjusted Tower table with the hips and knees flexed and supports adjusted for the pelvis, chest, and head. These are adjusted until the patient is comfortable, avoiding any strain on the neck or elsewhere. When comfortable, the patient gives an OK signal with the hand, and general anesthesia is commenced. Spinal cord monitoring is done throughout the procedure. It is important to have valid preoperative tracings for comparison with the findings during surgery. The use of general anesthesia makes the resection easier to perform and allows easier undercutting of the pedicles above and below, with a more thorough decompression of the nerve roots. When the hips are extended to produce anterior osteoclasis with extension of the lumbar spine, the knees should be kept flexed to avoid any sciatic nerve tension that would alter the evoked spinal responses if posterior tibial nerve stimulation is used at the ankles (Fig. 77-1).

The initial recommendation of Smith-Petersen et al. (5) was to carry out a posterior wedge resection of the mid-lumbar spine in a V-fashion, with fracturing of the anterior longitudinal ligament. A midline resection was car-

**FIG. 77-1.** **A:** Side view of a Tower table prepared for lumbar osteotomy under general anesthesia. The patient is intubated while awake and positioned on the table awake. Adjustments are made so that head is supported in a comfortable position with the eyeballs free of pressure. The chest and pelvis are supported with the abdomen free. The knees bear part of the patient's weight, with the hips and knees flexed. When the patient is comfortable, general anesthesia is begun. **B:** Lateral view of a patient with lumbar flexion deformity in position on a Tower table with knees flexed at 90 degrees. **C:** Operative view showing correction of the flexion deformity after lumbar resection-extension osteotomy. The hips are extended with the spine fracturing anteriorly and the resected defect closing posteriorly. The knees are kept flexed to avoid stretching of the sciatic nerves and interference with spinal cord monitoring. The resected defect closes, allowing Luque instrumentation with Wisconsin buttons, and grafting. **D:** Post-operative view with application of posterior shell to support the patient when turned supine. (From Simmons EH. Ankylosing spondylitis: surgical considerations. In: Herkowitz HN, Garfin SR, Balderston RA, et al, eds. Rothman-Simeone: the spine, 4th ed. Philadelphia: WB Saunders, 1999:1303–1356, with permission.)

ried upward and outward through the superior facet of the vertebrae above and the inferior facet of the vertebrae below in an oblique fashion. The obliquity of the osteotomy was to allow locking of the vertebrae following correction in an effort to prevent displacement. This technique is the basis for our current procedure.

#### INDICATIONS FOR LUMBAR OSTEOTOMY

Lumbar osteotomy is commonly done for surgical correction of lumbar hypolordosis or kyphosis giving rise to a fixed flexion deformity. The indications are variable and depend on the extent of the deformity, the degree of functional embarrassment, the age and general condition

of the patient, the feasibility of correction, and above all else, the earnest desire of the patient to accept the risks and rehabilitation measures required for correction.

The contraindications include patients who are not suitable candidates for medical reasons and where the severity of the deformity does not warrant the procedure. Severe osteopenia is also a relative contraindication.

#### ASSESSMENT OF SPINAL FLEXION DEFORMITY

In assessing patients for possible surgical correction, it is important to recognize the primary site of the deformity and accurately measure the angle of deformity.

**FIG. 77-2.** **A:** Lateral view of a 57-year-old woman referred for correction of "spinal" deformity. She had been deformed in this position for 16 years. The distance between the floor and her nose was 32 inches. **B:** Lateral view showing the effect of the fused hip joint, creating trunk deformity and "teeter totter" movement. **C:** Antero-posterior radiograph showing ankylosing of the spine and sacroiliac joints. **D:** Radiograph demonstrating complete ankylosis of both hip joints. **E:** Early postoperative standing view after bilateral total replacement arthroplasties with correction of the main clinical deformity. (From Simmons EH. Ankylosing spondylitis: surgical considerations. In: Herkowitz HN, Garfin SR, Balderston RA, et al, eds. Rothman-Simeone: the spine, 4th ed. Philadelphia: WB Saunders, 1999:1303-1356, with permission.)

The surgeon may attempt to improve spinal alignment and patient function by operating at a level somewhat distant from the area of primary deformity; however, if any major correction is to be attempted, the correction must be done at the site of the main deformity. If this is not done, disturbance of balance could occur and the ability to walk and stand upright could be impaired. Patients who present with apparent spinal deformity may have the main deformity in their hip joints rather than their spine. The main deformity may be in the lumbar, thoracic, or even cervical spine (4).

Figure 77-2A shows a 57-year-old woman who was referred for correction of her "spinal" deformity. Once a woman of normal height, she was flexed so much that the distance from her nose to the floor was only 32 inches. She had been held rigidly in this position for 16 years. Her knees were held inflexibly together in adduction, and she wore a protective pad on her right knee as a result of impingement of one knee against the other. The spine and hip joints were both solidly ankylosed so that she could be moved up and down in a "teeter totter" fashion by lifting up on her extremities or pushing down on her head (Fig. 77-2, B—D). It was evident also that her main flexion deformity was at the fused hip joints, and if her lower limbs were placed below her, in line with her trunk, the main deformity would be corrected. She was not treated by spinal osteotomy, but by bilateral total hip replacement arthroplasties mobilizing the hips and correcting the hip

flexion deformities, placing the lower limbs in more normal alignment below the trunk. After this she was able to stand and look ahead (Fig. 77-2E). As far as she was concerned, her main problem had been relieved. She continued to progress well, walking with aids, and was able to look after her own home.

Accurate assessment and measurement of lumbar flexion deformity are required in planning surgical treatment and evaluating its results. The most effective and consistent measure of trunk flexion deformity is the chin-brow to vertical angle. This is a measure of the angle from a line extending from the chin to the brow measured to the vertical, when the patient stands with the hips and knees extended and the neck in its neutral or fixed position. Based on this, the size of the wedge in lumbar spine to be removed posteriorly is determined (Fig. 77-3).

The patient is admitted prior to the proposed surgery for careful medical assessment, including pulmonary function tests and electrocardiography. A physiotherapy program of deep breathing and extremity exercises is given, to be used postoperatively. Psychological preparation includes preoperative visits by the anesthetist as well as the surgeon, to explain the whole procedure to the patient and gain his or her confidence (21).

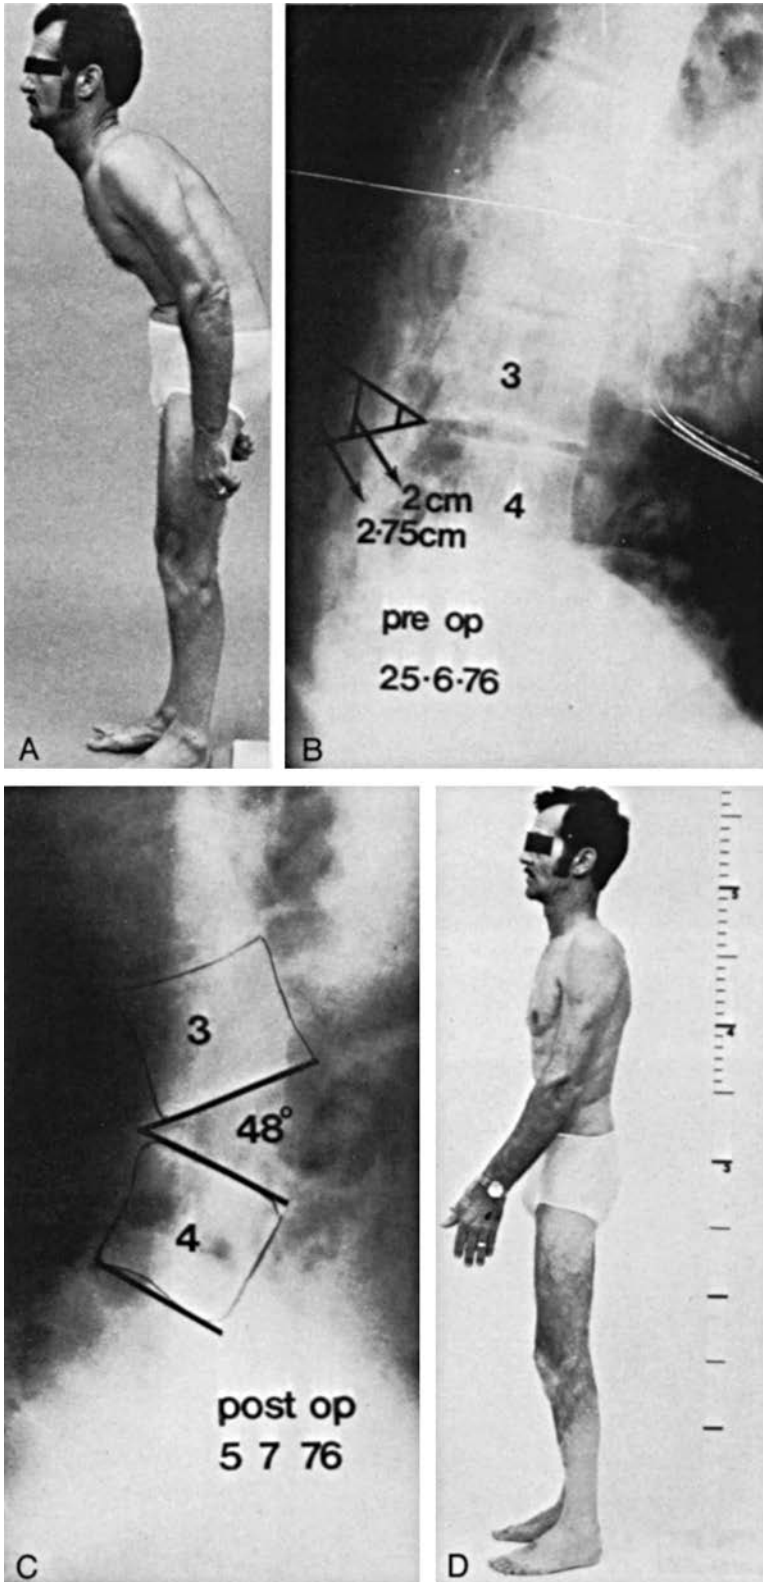

## TECHNIQUES

Patients who have primarily a lumbar kyphotic deformity with loss of lumbar lordosis are selected. The deformity is determined by clinical and radiologic assessment. The angle of lumbar spine correction that is required is indicated by measurement of the chin-brow to vertical angle. This angle is transposed to a lateral radiograph of the lumbar spine, with the apex of the angle at the posterior longitudinal ligament of the L3-4 disc space (Fig. 77-4).

The osteotomy is done at the L3-4 level, which is the normal center of lumbar lordosis. This is also below the conus medullaris and the spinal canal volume is fairly reasonable at this level. It is at or below the bifurcation of the aorta. A preoperative computed tomography scan should be done to evaluate the spinal canal preoperatively. A midline exposure is made and the proposed osteotomy site is confirmed radiographically, because operative localization is difficult owing to the fused confluent nature of the posterior elements of the spine. The posterior elements are removed in a V-fashion to accomplish the realignment of the spine. Following resection of the angle and closure posteriorly, an opening wedge of the same amount is created anteriorly, which results in correction of the patient's deformity. It is essential that full correction be obtained and that the weight-bearing line of gravity be shifted posterior to the osteotomy site, so that gravity will tend to maintain and even increase correction as well as stimulate bone formation across the osteotomy site at the resected fused posterior masses of the spine (Fig. 77-5).

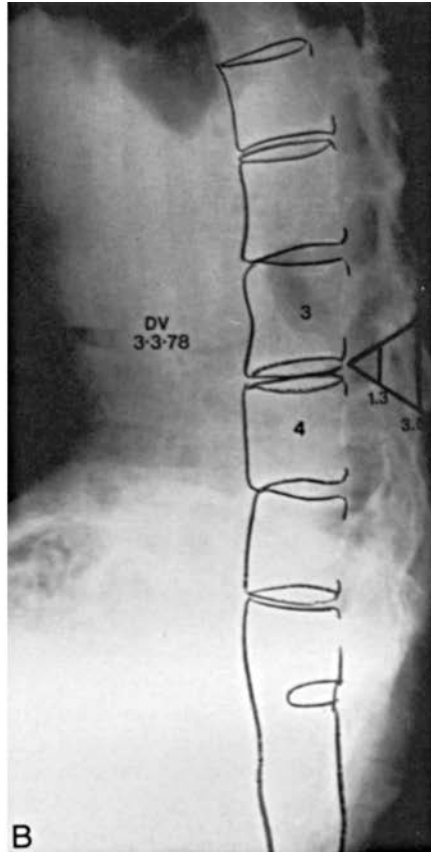

**FIG. 77-3.** Technique for measuring the degree of flexion deformity of the spine in ankylosing spondylitis. The chin-brow to vertical angle is measured from the brow to the chin to the vertical, with the patient standing with the hips and knees extended and the neck in its fixed or neutral position. (From Simmons EH. *Surgery of the spine in ankylosing spondylitis and rheumatoid arthritis*. In: Chapman MW, ed. *Operative orthopaedics*, vol. 3. Philadelphia: JB Lippincott, 1988:2077-2114, with permission.)

**FIG. 77-4.** **A:** Lateral view of a patient standing with hips and knees extended. This patient still had mobility of his cervical spine and was compensating with the neck hyperextended. When the neck was in the neutral or comfortable position, he had a chin-brow to vertical angle of 45 degrees. **B:** Lateral radiograph of lumbar spine showing the chin-brow to vertical angle superimposed with the apex at the L3-4 disc space. The amount of bone to be resected is indicated at each depth posteriorly. **C:** Postoperative lateral radiograph showing the angle of correction obtained after closure of the resected defect posteriorly with an opening osteoclast at L3-4 of 48 degrees. The weight-bearing line has been shifted posterior to the osteotomy site. **D:** Postoperative standing lateral radiograph showing complete correction of the deformity following removal of a calculated wedge of bone based on preoperative assessment. (From Simmons EH. *Surgery of the spine in ankylosing spondylitis and rheumatoid arthritis*. In: Chapman MW, ed. *Operative orthopaedics*, vol. 3. Philadelphia: JB Lippincott, 1988:2077-2114, with permission.)

The reasons for greater vascular safety of osteotomies done at L3-4 or L4-5 are the increased mobility of the aortic bifurcation and iliac arteries related to lower limb motion, the segmental vessels of L5 arise from the internal iliac arteries, and that the segmental vessels of L5 and L4 are smaller vessels than higher-segmental arteries. The reasons for greater vascular risk of osteotomies at higher levels are that the aorta becomes less mobile proximally; the renal arteries arise at L2-3, adding to fixation of the aorta; and the segmental vessels increase in size proximally.

### EARLIER TECHNIQUE

Initially the operation was done under local anesthesia. This avoided pulmonary complications and mortality related to it. It provided the best intraoperative monitoring of neurologic, vascular, and other vital functions (4,17,20,22). The results of the first 64 cases done under local anesthesia were reported by Wills in 1985 (21). Stabilization of the osteotomy when performed under local anesthesia initially was based on a V-shaped locking osteotomy with plaster shells and a turning frame for 6 to 8 weeks. Later, wire-loop fixation was applied (Fig. 77-5). A Luque rectangle was then used with Drummond buttons and wires; Cotrel–Dubousset instrumentation also was used, all possible under local anesthesia. Regardless of whether or not internal fixation and the type of fixation used, the most important factor in the successful maintenance of correction is to correct the deformity completely, shifting the weight-bearing line posterior to the osteotomy site so that gravity will maintain and tend to increase correction with stimulation of bone formation through the weight-bearing lines of the fusion masses posterolaterally. Postoperative management used well-molded posterior and anterior plaster body shells extending from head to knee in which the patient could be firmly strapped for turning onto a CircOlectric bed, later a Stryker turning frame, and finally a Roto-Rest bed (23–25).

### CURRENT TECHNIQUE

Our current technique of fiberoptic intubation with the patient awake is described in the preceding. The patient is placed in the prone position on an adjusted Andrews table while awake. The patient must be carefully positioned on the operating table in a flexed knee-chest position. Careful positioning is also necessary because these patients have fixed ankylosed spines and undue pressure in any one particular area must be avoided. The thoracic chest support often must be elevated considerably to accommodate the patient on the operating table. Anesthesia is commenced when the patient is comfortable. Routine monitoring of vital signs and spinal cord monitoring are carried out throughout the procedure. A wake-up test also can be used if necessary. Pulse oximetry, CO<sub>2</sub> analyzer, and systemic blood gases are used to monitor the patient. A Doppler apparatus is fixed to the patient's chest to detect any possible air embolisms.

Be certain of the L3-4 level at which you are preparing to perform the osteotomy because the landmarks are obscured. Radiographic confirmation is necessary.

At this point pedicle screws are inserted in L1, L2, (L3), L5, and S1. The pedicle screws are inserted in a standard fashion, using anatomic and image-guided techniques as required. It is not usually possible to have screws in L4 because they will impinge on the L3 screws following extension correction of the spine.

I then carry out the resection. The interspinous ligaments usually are ossified and at the beginning, the osteotomy can be started with large bone cutters to trim away the intervening bone and spinous processes in a V-shaped fashion. The laminae can be thinned out with Leksell rongeurs and the bony fragments maintained for autogenous bone graft. A high-powered burr also can be used; however, if this is used exclusively, there will be less bone available for the bone grafting.

When the spinal canal is opened, the dura is carefully stripped from the bone with a seeker and protected with cottonoid patties. In many long-standing cases, the dura is quite atrophic, similar to that of long-standing spinal

←

**FIG. 77-5.** **A:** Standing lateral view of a female patient with gross kyphosis confined to the lumbar spine. She has no flexion deformity of the neck or thoracic spine. **B:** Lateral view of the lumbar spine showing complete loss of lumbar lordosis with kyphosis beyond the neutral. The sacrum is in a straight line with the lumbar spine. Resection-extension osteotomy of the mid-lumbar spine is ideal for this type of deformity. The amount to be resected has been indicated on the lateral radiograph with the apex at the L3-4 disc space. **C:** Postoperative lateral radiograph showing an anterior opening wedge correction of 50 degrees (following closing wedge osteotomy posteriorly). A normal lordosis has been established. **D:** Standing lateral 3-foot radiograph of the spine 6 months after surgery showing normal lordosis. The weight-bearing line is posterior to the osteotomy site. **E:** Lateral radiograph of the lumbar spine 3<fr1/2> years after surgery showing solid fusion posteriorly in the weight-bearing line. Bone is slow to form anteriorly away from the area of weight bearing. **F:** Postoperative lateral view of the patient showing complete correction of deformity with the establishment of a normal lordosis and normal chin-brow to vertical angle. (From Simmons EH. Surgery of the spine in ankylosing spondylitis and rheumatoid arthritis. In: Chapman MW, ed. Operative orthopaedics, vol. 3. Philadelphia: JB Lippincott, 1988:2077–2114, with permission.)

stenosis. In rare instances, it may be adherent to the laminae, making its separation difficult. The entire L4 lamina is removed along with a portion of the L3 and L5 laminae with undercutting of the laminae to bevel them so that there is no impingement on closure of the osteotomy site. The cauda equina must be decompressed well laterally out to the level of the pedicles. The entire superior L4 facet is removed and the L3-4 neuroforamina widely exposed laterally and undercut with a medium-angle Kerrison rongeur, again so as to prevent any impingement on closure of the osteotomy site.

The precise amount of bone removed posteriorly is calculated to arrive at the amount of correction desired. On closure of the osteotomy with osteoclasis of the spine anteriorly, the lateral masses should meet with good bone surface contact. The pedicles also must be undercut, removing the superior edge of the L4 pedicle and inferior edge of the L3 pedicle again to allow adequate room for the nerve root during the extension correction of the spine.

The osteoclasis is carried out by extending the foot-end of the table, bringing the hips and thighs up into an extended position. On doing so, pressure also can be applied manually by pushing downward at the L3-4 site, causing a fulcrum for the osteoclasis to occur. An audible and palpable osteoclasis of the spinal column often is present and the lateral masses then come together in apposition. The lower extremities and hips are now kept in an extended position, preferably with the knees flexed, to avoid any tension on the sciatic nerve roots. Rods are then cut and contoured to the appropriate length and shape for each side of the spine and then fitted into the pedicle screws and secured. Posterolateral and posterior bone grafting is done using the removed morselized bone, which is usually quite generous.

A well-molded posterior plaster shell is applied extending from head to knee. The patient is strapped into the shell and transferred in the shell to a Roto-Rest bed. It is important to recognize that this is an essential part of the procedure. A modification of this technique has been provided by Simmons. Good orthotists can make a rigid plastic shell (Crystaplex) rather than plaster. It should be emphasized that this must be rigid and not flexible so that it will give the patient rigid support. Two shells allow approximation to take up any slack caused by weight loss of the patient and provide rigid mobilization for turning activities. This has worked very effectively. However, recognize that the principle is the same.

The rigid thoracic kyphosis is more prominent than the pelvis after extension osteotomy, and if the patient is lying on a flat surface, gravity tends to push to the thorax forward and allow the pelvis and lower lumbar spine to come posteriorly. If the trap door of the bed is removed for a bowel movement, the spine is unsupported. A well-contoured padded rigid posterior plaster shell provides a contoured well-fitted surface on which the rigid trunk can

**FIG. 77-6. A:** Lateral diagrammatic view showing the contour of the corrected spine when lying supine unsupported. The posteriorly projecting thoracic hump bears most of the weight, with less support on the lumbar spine and the spine below the osteotomy. As a result the rigid thoracic hump tends to be displaced forward and the lumbar spine posteriorly. **B:** With the patient supine in a well-molded, rigid shell equal support is created throughout the spine, with elimination of any uneven contact forces that would tend toward displacement. (From Simmons EH. *Surgery of the spine in ankylosing spondylitis and rheumatoid arthritis*. In: Chapman MW, ed. *Operative orthopaedics*, vol. 3. Philadelphia: JB Lippincott, 1988:2077-2114, with permission.)

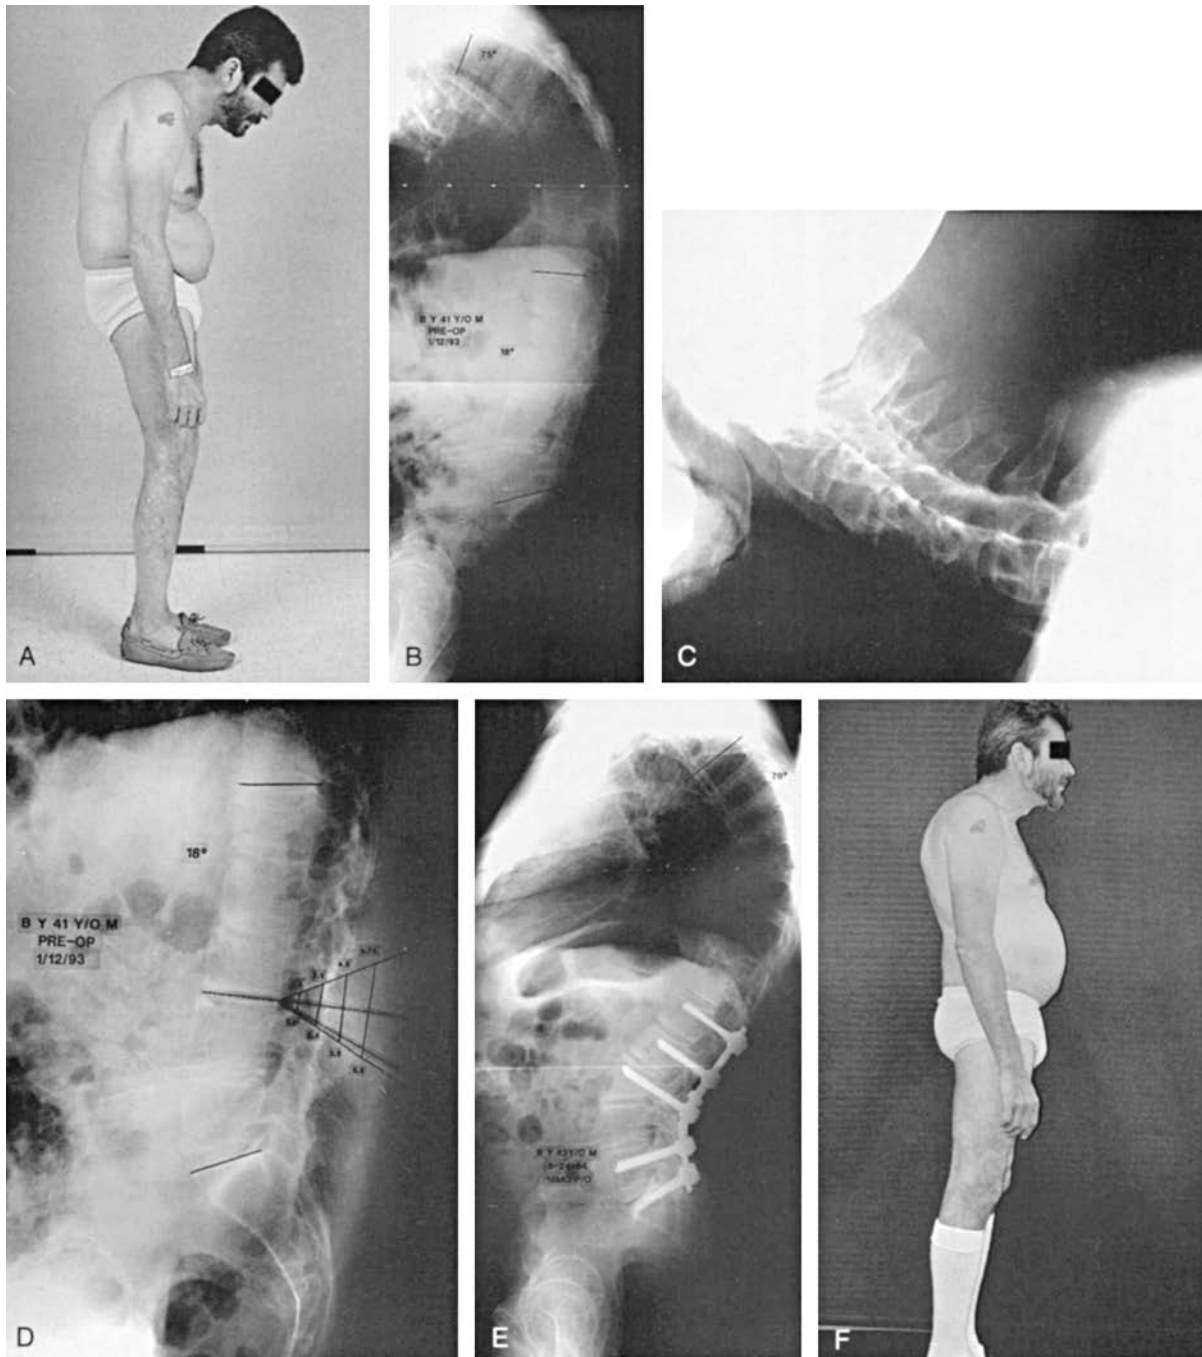

lie, protecting the osteotomy site (Fig. 77-6). A nasogastric suction tube is placed before the patient leaves the operating room. It is maintained until the patient is passing gas, with normal gastric function.

The advantages of the current technique are that it allows easier and more liberal decompression. It provides more rigid internal fixation with less risk of displacement, easier and more rapid mobilization, and probably greater comfort for the patient. Its disadvantages are increased operative time, the altered anatomy for screw insertion into the pedicles, and the potential risks of bone screws. At this time it appears that the advantages outweigh the disadvantages; to date it has provided excellent results (Fig. 77-7).

## RESULTS AND COMPLICATIONS

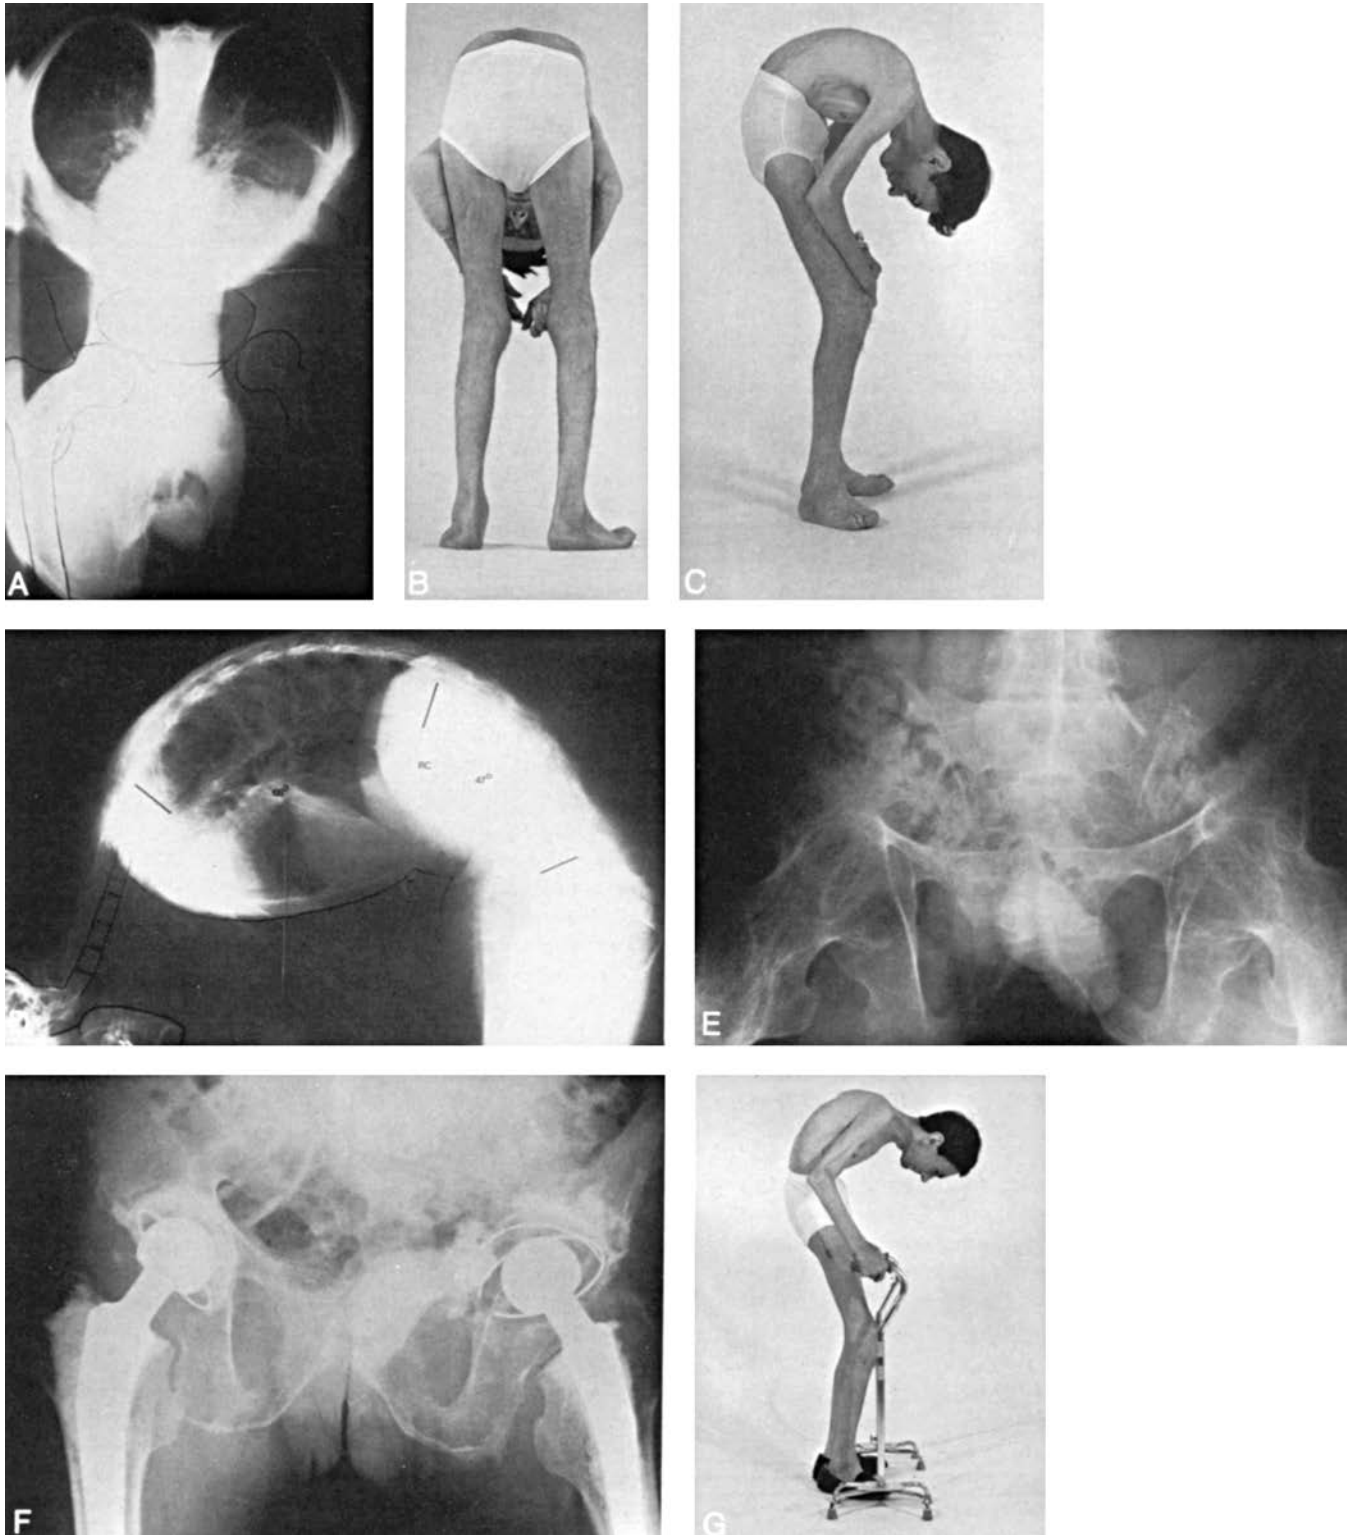

One of the concerns that have been raised about extension osteotomy of the lumbar spine is the possibility of injury to the major vessels, particularly the abdominal aorta (14,26,27). All the reported cases of major vascular injury associated with resection-extension osteotomy of the lumbar spine for ankylosing spondylitis have been reviewed, and we documented the level at which the osteotomy was performed in each case. It is noted that in all cases with injury to the abdominal aorta the osteotomy was done at T12-L1, L1-2, or L2-3. There is no reported case of aortic injury with osteotomy performed at L3-4 or

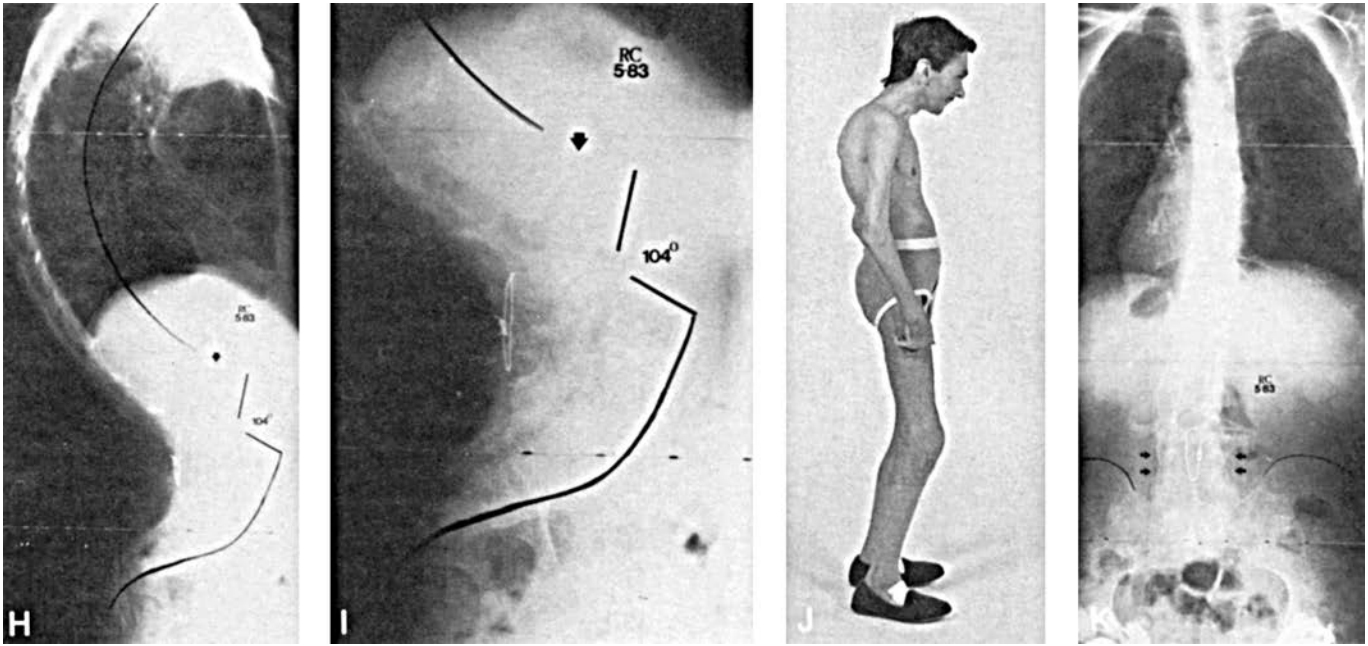

**FIG. 77-7. A:** Lateral view of a 41-year-old man with a 21-year history of ankylosing spondylitis. He had suffered with a major kyphotic deformity for 10 years, which prevented him from working for 5 to 6 years. His chin-brow to vertical angle measured 55 degrees. **B:** Lateral standing 3-foot film of the spine showing increased thoracic kyphosis measuring 75 degrees but decreased lumbar lordosis measuring 18 degrees. His weight-bearing line is well anterior to the mid-lumbar spine. **C:** Lateral standing radiograph of the cervical spine showing a compensatory increase in cervical lordosis with ossification from C2 distally. **D:** Pre-operative lateral radiograph of the lumbar spine showing planned resection-osteotomy at L3-4 of 50 to 55 degrees. **E:** Lateral standing 3-foot radiograph 16 months postoperatively showing healed osteotomy with lumbar lordosis measuring 74 degrees. Thoracic kyphosis was corrected slightly to 70 degrees. The spine is in balance. The main weight-bearing line is posterior to the osteotomy site. **F:** Standing lateral view of the patient 16 months postoperatively. He has returned to a normal lifestyle. His correction prompted an uninformed observer to state that his wife was living with "different man." (From Simmons EH. Ankylosing spondylitis: surgical considerations. In: Herkowitz HN, Garfin SR, Balderston RA, et al, eds. Rothman-Simeone: the spine, 4th ed. Philadelphia: WB Saunders, 1999:1303–1356, with permission.)

**FIG. 77-8.** **A:** Standing anteroposterior radiograph of spine of a patient with severe combined deformity. The anteroposterior film of the chest resembles a computed tomography axial view. **B:** Posterior standing view of patient. The patient could only see and moved about by walking backward. **C:** Standing lateral view showing chin-brow to vertical angle of 134 degrees. Assessment reveals combined deformities of thoracic kyphosis, gross lumbar flexion deformity, and hip flexion deformity. **D:** Standing lateral radiograph showing thoracic kyphosis of 68 degrees, complete loss of normal lordosis and 47 degrees of lumbar kyphosis, with hip flexion deformities. **E:** Antero-posterior radiograph showing fused hip joints. **F:** Postoperative view following bilateral total hip replacement arthroplasties. **G:** Standing lateral view of patient following bilateral hip arthroplasties. The deformity is improved but the patient can now see neither backward nor forward for walking.

**FIG. 77-8.** (Continued) **H:** Standing lateral radiograph of spine following resection-extension osteotomy of 104 degrees done under local anesthesia. The weight-bearing line has been shifted posterior to the osteotomy site. **I:** Lateral radiograph of the lumbar spine showing osteotomy with weight-bearing line posteriorly. Patient had associated spondylodiscitis (arrow), which has gone on to healing. **J:** Postoperative standing lateral view of patient showing correction of major deformities. He still has some flexion deformity of the knees and neck, but is able to stand, look ahead, and walk ahead in a normal fashion. (From Simmons EH. Surgery of the spine in ankylosing spondylitis and rheumatoid arthritis. In: Chapman MW, ed. Operative orthopaedics, vol. 3. Philadelphia: JB Lippincott, 1988:2077-2114, with permission.)

L4-5. One hundred sixteen consecutive lumbar osteotomies performed by us also were reviewed. Of these, 113 were done at L3-4, two at L4-5, and only one at L2-3. There was no incidence of major arterial injury. The presence of previous radiation or atheromatous change did not result in major vessel injury. The extent of correction also was not a factor. Correction ranged from 40 to 140 degrees, with an overall average of 58 degrees (Fig. 77-8).

The only vascular injury we encountered was an inferior vena cava thrombosis extending above the renal veins. This occurred in a markedly obese male who had undergone previous extension osteotomy at L2-3 but still had major deformity. The thrombosis was likely related to the weight of his corpulent abdomen resting on his stretched vena cava after extension correction. The patient did well in the early postoperative interval, but 4 to 5 days postoperatively gradually increasing edema developed, which became massive and extended up to the mid-chest, with his scrotum "the size of a football." There was no change in arterial pulses or evidence of arterial insufficiency. Routine Doppler studies of his lower extremities did not reveal the diagnosis initially, which was established by nuclear venography. With the increased intraspinal venous pressure, neurologic deficit

developed based on venous stasis of the conus, as described by Aboulker et al. (28). The neurologic deficit was maximal when the edema was greatest. Most patients with this disease are relatively thin, which is likely the reason that this has not been encountered in other cases. There was no change in arterial pulses or evidence of arterial insufficiency.

Regular potential complications can occur with any spinal procedure. Major neurologic problems are relatively infrequent; however, obviously it can be a major problem when they occur. Potential complications specific to this procedure include intestinal obstruction, problems related to instrumentation owing to osteopenia, and difficulty with surface landmarks in terms of inserting the instrumentation. Removal of too little or too much bone posteriorly can result in too little or too great a correction. Careful preoperative planning is necessary to determine the amount of correction desired and the appropriate amount of bone removed in accordance with this. Other possible complications, such as intraspinal hematoma, loss of fixation and correction, and other difficulties inherent to spinal surgery may occur. However, when the procedure is carefully planned and executed, the results are most gratifying both to the patient and the surgeon.

# Pyogenic and Fungal Lumbar Spine Infections

Matthew J. Geck and Frank J. Eismont

---

Vertebral osteomyelitis is an infection of the spine that can include the disc, bony elements, the epidural space, as well as adjacent structures. In the preantibiotic era, spine infections had uniformly high morbidity and mortality (1). Even today, paralysis and death can still be sequelae, especially in the immunocompromised patient. Diagnosis is often delayed even with current clinical vigilance and diagnostic testing. With adequate clinical suspicion, radiographic work-up, and biopsy and cultures to establish the offending organism, the vast majority of spine infections can be successfully treated with 6 or more weeks of the appropriate antibiotic. However, even with appropriate conservative therapy, there are patients who may need surgical treatment for a clinically significant abscess, open biopsy, severe deformity, neurologic deficit, and failure of conservative treatment with continued chronic infection.

## PYOGENIC INFECTIONS

### Incidence

Originally thought to be a rare entity, Kulowski (1) in 1936 described 102 cases, of which 60 were from his own institution, comprising approximately 4% of all the patients with musculoskeletal osteomyelitis at his home institution in the reviewed time. Nagel et al. (2) found the incidence at Yale Medical Center to be 8% of all osteomyelitis. In a review of 178 cases in the literature (3), 52% of the patients were older than age 50 (52%). Younger patients often had a history of intravenous (IV) drug use (4).

### Pathogenesis

Spine infections most often are caused by hematogenous spread from another source. Risk factors include urinary tract infections or instrumentation, soft-tissue

infections, respiratory tract infections, IV catheter infections, and IV drug abuse (3,4). Direct inoculation from surgical intervention also has been reported (3). However, it is notable that a source cannot be identified in 37% of cases. Other less common sources are salmonellosis (5), infectious endocarditis (6), otitis media (7), dental infections (8), surgery (9), and discograms (10,11).

Diabetes mellitus also has been thought to be a risk factor for vertebral osteomyelitis. In one review of patients with infections, patients with diabetes had twice the incidence versus historical controls (3). This may result from immunocompromise or diabetic-related vascular disease and peripheral neuropathy with associated soft-tissue ulcers and bladder dysfunction, both of which can lead to systemic bacteremia.

Human immunodeficiency virus (HIV) also has been associated with spine infections. In a review of patients with HIV from 1994 to 2000, Weinstein et al. (12) found that the incidence of spine infections in patients with HIV was 0.095% (17/17,717). This is higher than the incidence in the general population, but much less than originally suspected. The CD4 count in patients with pyogenic infections averaged 339.6, and the organism identified was *Staphylococcus aureus*. These patients responded to conservative treatment with IV antibiotics for 6 to 12 weeks. Six patients with spinal tuberculosis had a mean CD4 count of 57. One patient died and the others were treated with antituberculous medications. Three patients with epidural abscesses had a mean CD4 count of 21. Two of the patients had *Nocardia* as the organism and both died; the third patient had Group A streptococcus. Thus, patients with HIV have a higher incidence of spinal infection than the general population, and the organism and type of infection vary with the degree of immunocompromise. Identification of the organism is essential for the success of treatment of this complex patient population.

### Bacteriology

Hematogenous vertebral osteomyelitis is usually a single-organism infection (13). *Staphylococcus aureus* is the most common isolate and accounts for more than 50% of isolates in most series. Gram-negative infections can be seen in elderly men who have a history of urinary tract infection, as well as in IV drug abusers. Intravenous drug users on the West Coast of the United States have a significant incidence of *Pseudomonas*, as well as the more common *Staphylococcus aureus* (4). In patients with chronic low-grade infections, thought must be given to coagulase negative *Staphylococcus*, *Diphtheroids*, *Propionibacter*, or unusual gram-negative organisms (14). Owing to their slow growing time, suspect cultures should be held for 10 days before they are discarded as negative. If a low grade pathogen grows in culture, it should not be regarded as a contaminant.

### Pathophysiology

Infection by hematogenous routes typically begins in the vertebral metaphysis (15). There is a significant paravertebral venous plexus (16) as well as a rich arterial anastomosis of end arterioles within the metaphyseal region of the vertebral body (17). Both routes may play a role. Once established in the metaphysis, the infection may spread through the vasculature at the intervertebral disc periphery or more commonly rupture through the end plate into the disc and then infect the adjacent vertebral end plate and body. The disc is avascular, and once infected is rapidly broken down by bacterial enzymes and proteolytic enzymes from inflammatory cells. Untreated pyogenic infections often progress to abscess formation, into either the spinal canal as epidural abscesses (18) or the adjacent soft-tissue structures. Very often this develops into a psoas abscess in the lumbar spine.

### Clinical Presentation

The clinical presentation of vertebral osteomyelitis is dependent on the virulence of the organism involved, as well as various patient factors such as immunocompromise, age, general health, and nutrition. Fulminant presentation with subsequent high mortality is relatively uncommon today with antibiotics, diagnostic imaging, biopsy, and surgical care. However, this presentation is still often seen in the severely immunocompromised patient with a virulent organism. Very often these patients present with some degree of paralysis.

The most common complaint is localized spine pain, which occurs in about 90% of patients (3). This can be associated with tenderness and muscle spasm. Fever, defined as a temperature of greater than 100°, was present only 50% of the time. Symptom duration varied widely, with 20% less than 3 weeks, 30% 3 weeks to 3

months, and 50% with symptoms of more than 3 months' duration on presentation. The lumbar spine is the most common location of the infection (48%), followed by the thoracic spine (35%), cervical spine (6.5%), and thoracolumbar and lumbosacral junctions account for the rest. Noncontiguous infection occurs in 4% to 5% of patients (11).

Occult infections with low virulence organisms are even more difficult to properly diagnose (14). In one series of nine patients with chronic low-grade back pain (14), fever was present in only four patients, the sedimentation rate was normal in seven, and the white blood cell count (WBC) was normal in six. The average duration of symptoms was 9.5 months in this group before a diagnosis was made. The diagnosis was made by biopsy. These cases demonstrate that a normal erythrocyte sedimentation rate (ESR) and a normal WBC do not rule out infection. Only by combining clinical suspicion with history, evaluation of risk factors, and radiographic findings, as well as laboratory work-up and biopsy, can the proper diagnosis be made.

Eismont and colleagues (11) evaluated patients with vertebral osteomyelitis with paralysis, and compared them with a group of patients who were evaluated and treated in the same period in the same city, but who did not have paralysis. Factors predisposing to paralysis were older age, more cephalad level of infection, diabetes mellitus, rheumatoid arthritis, and steroid use. Youth seemed protective; the younger IV drug abusers were spared paralysis. Microbiologically, *Staphylococcus aureus* was the causative organism in the vast majority of the patients with severe paralysis.

Vertebral osteomyelitis in infants is different from pediatric discitis. In a report of four patients (19), infants 2 to 13 weeks old were treated for vertebral osteomyelitis. All four had severe dissolution of the vertebral bodies, with end plates of the adjacent vertebrae being normal or near normal, suggesting that the origin of the infection was in the vertebrae rather than the discs. The patients were uniformly systemically ill and had no neurologic deficits, and three of the four patients had septicemia from *Staphylococcus aureus*. Three patients who had short courses of antibiotics (2 weeks or less) relapsed, necessitating longer courses. The late radiographic appearance of these patients was similar to congenital kyphosis, and we recommended early bracing with posterior fusion if progression occurred.

The presence of a tumor does not eliminate the possibility of infection. Eismont and colleagues (20) reported three cases of metastatic tumors to the spine with an infection existing concurrently, with no clinical evidence to suggest infection. This was attributed to vascularity of the tumor, seeding of the necrotic portion of the tumor, and immunosuppression. Biopsy and culture should be performed in known metastatic disease if there is anything atypical on presentation (e.g., leukocytosis, fever,

sepsis, or atypical radiographic appearance). All biopsies should be sent for both culture and pathology.

Intravenous drug abusers are a subset of patients who often develop vertebral osteomyelitis. In a case report and review of the literature, Sapico and Montgomerie (4) reviewed 67 IV drug users who had vertebral osteomyelitis and noted that these patients tended to be younger (89% were 20 to 49 years old) than pyogenic infections from other sources (52% > 50) (3). One other major difference is that gram-negative rods comprised 82.5% of isolates, with *Pseudomonas* species most common followed by *Serratia*, *Klebsiella*, and *Enterobacter*. No patient had a permanent paralysis.

## Diagnosis

### Laboratory Studies

The initial work-up of vertebral osteomyelitis includes a complete blood count, differential, and other general laboratory studies. However, ESR is the only laboratory test of diagnostic value other than biopsy and culture. In two reviews of the literature (3,4) the ESR was elevated about 90% of the time in patients with biopsy-confirmed vertebral osteomyelitis on initial presentation. However, the ESR is not sensitive and only moderately specific; low-grade infections can have normal values (14).

The ESR is useful in assessing the response to treatment (4,21). In one series, the sedimentation rate was down to two thirds the presentation value at the time of successful completion of the parenteral therapy, and in most of these patients it fell to half (3). In another series, it fell to normal after the disease was fully treated (21).

For the biopsy and culture, it is important to hold the specimen a full 10 days, to allow low-grade infections to grow out in the culture media (14).

### Imaging Evaluation

Plain radiographs are negative early in the disease process, with characteristic changes not evident for 2 to 4 weeks (11,22). Narrowing of the disc space is evident in 74% of patient at presentation (3), and as the disease progresses, there are additional destructive changes evident on both sides of the disc space with erosion of the end plates (Fig. 78-1). In late stages, there is destruction of the vertebral bodies on either side of the infected disc. Gas in the disc space may be indicative of a gas-forming organism (23). In a blinded study, plain radiographs were found to have a sensitivity of 82%, specificity of 57%, and accuracy of 73% (24).

Even with treatment, radiographic findings continue to lag up to 3 months behind the clinical picture (15). Patients often develop reactive bone formation, sclerosis, and progressive disc space narrowing. Spontaneous fusion may occur in up to 50% of patients, usually in

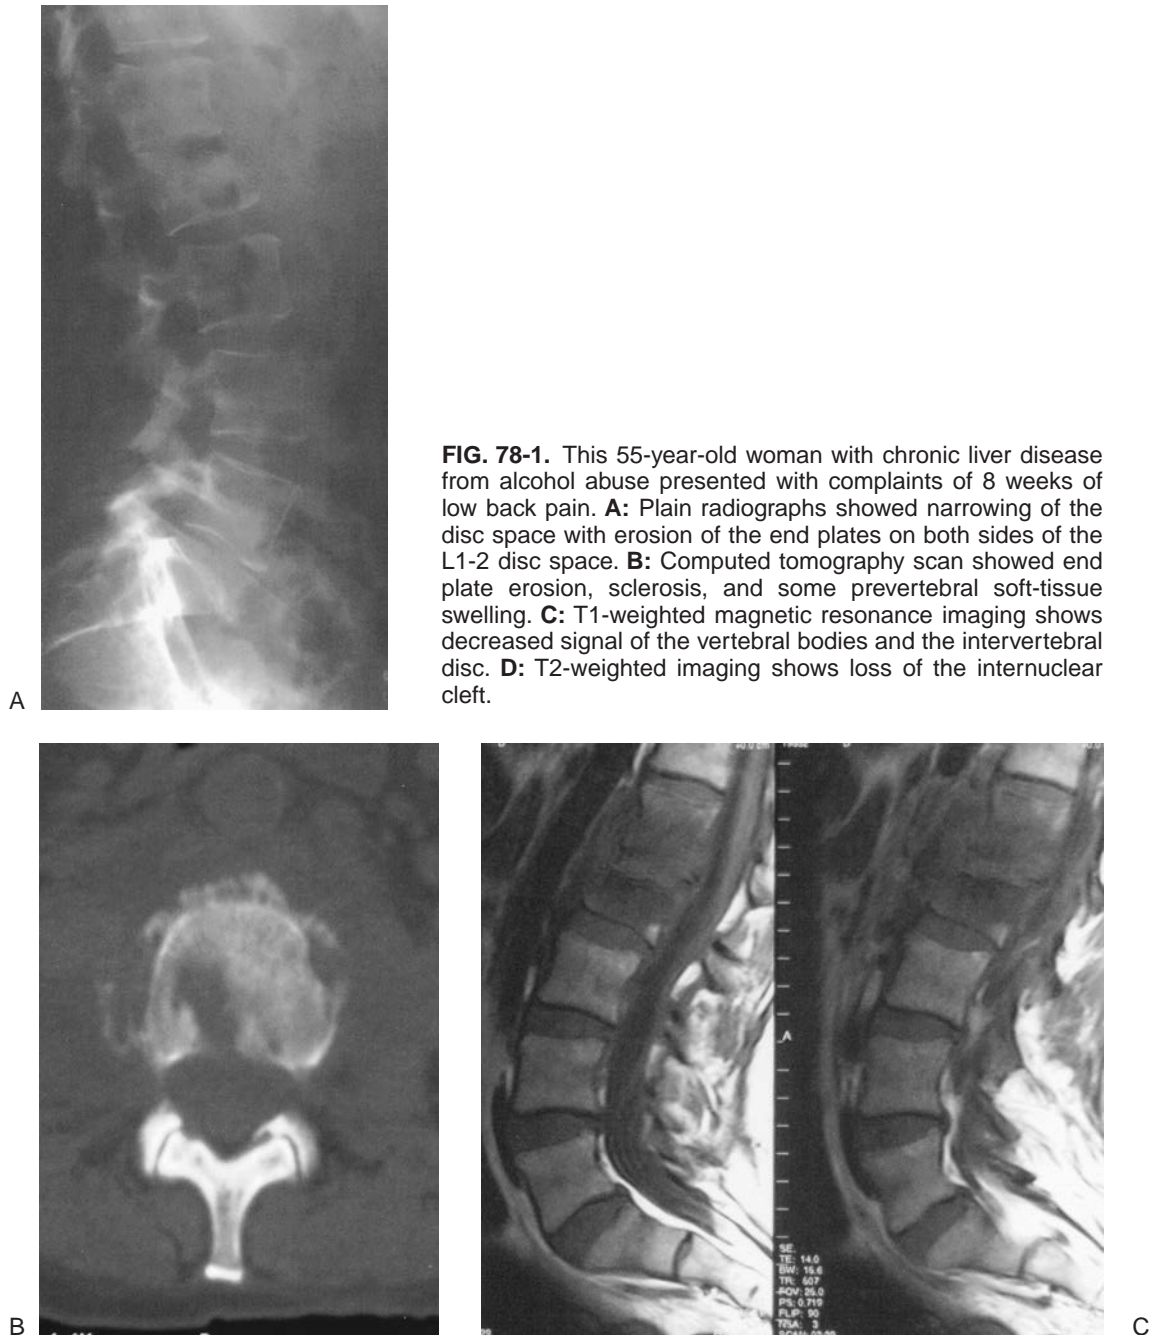

those with the most severe degrees of destruction. This fusion may take up to 5 years to consolidate (25,26).

Computed tomography (CT) scans are the best for demonstrating bony detail and erosion. Lytic areas, paraspinous soft-tissue masses, local tissue swelling, and gas formation all can be evident. Significant prevertebral soft-tissue swelling can help differentiate an infection from a tumor, because tumors usually demonstrate little or no prevertebral soft-tissue swelling (27). Computed tomography can be a valuable adjunct for biopsy localization, and myelography combined with post-myelography CT can be useful to evaluate neural compression in indicated cases.

Radionuclide studies are a useful adjunct in patients in whom magnetic resonance imaging (MRI) is contraindicated or a multifocal process is in the differential. These changes are thought to be present earlier than radiographic presentation with an animal model study of technetium scanning showing 71% positive results in 15 days and a near absolute true-positive rate over time (28). In a blinded study of 23 patients suspected of having vertebral osteomyelitis, <sup>99m</sup>technetium HDP bone scanning was found to have 90% sensitivity and 78% specificity (24). Combined with gallium-67 scanning, there was a sensitivity of 90%, specificity of 100%, and accuracy of 94%. The accuracy was not superior to MRI (24). False-negative rates have been reported for technetium scanning in infants and elderly people because of regional ischemia to the area (29). There can be a very high false-negative rate of radionuclide scanning in low-grade infections (14). Single photon emission computed tomography scanning and <sup>111</sup>indium leukocyte imaging are other radionuclide modalities that can be helpful.

Magnetic resonance imaging is considered the ideal imaging study for infections. It has multiplanar imaging capability, visualization of all compartments in and around the spine, and provides direct imaging of the disc, spinal cord, and nerve roots. Its exquisite sensitivity to changes in water content in structures makes it ideal for evaluating the vascular and edema characteristics in and around a spine infection (30). Increased water is demonstrated on MR images by areas of low signal on T1-weighted images and high signal on T2-weighted images. The addition of gadolinium-diethylenetriamine pentaacetic acid (Gd-DTPA) IV contrast enables MR imaging to detect active viable inflammatory tissue such as infected discs (31). Currently we recommend gadolinium contrast when MRI is being done for any patient for whom infection is in the differential diagnosis. In a blinded study of 37 patients, MRI was found to have a sensitivity of 96%, a specificity of 92%, and an accuracy of 94%, making it at least as accurate as combined technetium and gallium scanning.

The characteristic findings on MRI of a disc space infection are decreased signal of the vertebral bodies and the intervertebral disc on T1-weighted imaging, and sig-

nal intensity of the same bodies and disc on T2-weighted imaging with loss of the intranuclear disc cleft. Gadolinium contrast results in enhancement of both the adjacent vertebral bodies and the involved disc on T1-weighted imaging, with any sequestered abscesses spared from the enhancement (30,31).

Disadvantages of MRI include access, artifact from spinal instrumentation, poor resolution in patients who move during the scan, and contraindications such as pacemakers, aneurysm clips, metallic fragments in the eye or spinal cord, and severe claustrophobia.

### *Biopsy Techniques*

Despite the excellent characteristics of the current imaging studies, especially MRI, definitive diagnosis and treatment require either microscopic or bacteriologic confirmation by biopsy. The only case in which biopsy can be avoided is in the patient with clear radiographic and clinical signs of spondylitis and positive blood cultures (15). However, blood cultures are positive in only 25% of patients with vertebral osteomyelitis (3).

**FIG. 78-1.** (Continued). **D:** T2-weighted imaging shows loss of the internuclear cleft. **E:** Addition of gadolinium contrast to a fat/saturation image again showed the increased uptake in the adjoining vertebral bodies. Computed tomography-guided biopsy grew a pan-sensitive *Staphylococcus aureus* that was treated conservatively with a 6-week course of antibiotics. The sedimentation rate dropped to half. Clinical follow-up showed no recurrence of infection.

Percutaneous closed biopsy techniques are safe (32) and their use is widespread. Fluoroscopic or CT guidance is routine. Craig needle biopsy instrumentation is preferred because of the larger sample size and bone coring capacity (15). Diagnostic yield varies but was 70% in a review of the literature (3). Needle biopsy is possible in all areas of the spine, but open biopsy may be preferable in the cervical spine and occasionally in the thoracic spine for reasons of safety, access, and risk of paralysis. Even after a negative first closed biopsy, it is recommended that a second closed biopsy be obtained. This second biopsy often is positive when the first was negative. This is advisable only if it is medically safe to continue to withhold antibiotics.

Indications for open biopsy include failed or nondiagnostic initial closed biopsy, unsafe closed biopsy, or need for concurrent surgical treatment and débridement. Similarly, an open biopsy is recommended if the first closed biopsy is negative and antibiotics can no longer be withheld. The advantage of an open biopsy is primarily that this allows a larger sample and has a lower false-negative rate. In one compilation of the literature, open biopsy had a false-negative rate of 14% compared with 30% for closed biopsies (3). Failure of closed biopsy often results from empiric treatment with antibiotics without a full or proper work-up.

### Nonoperative Management

Historically, mortality has ranged from 25% to 70% for pyogenic infections of the spine (1,33). In one early series

of 102 cases, mortality was 25%, with an increase in mortality to 50% with the additional onset of central nervous system involvement such as neural compression, meningitis, subdural purulence, or infarction of the cord (1). However, morbidity and mortality can be controlled, mortality of the disease reduced to less than 5%, and residual neurologic deficits reduced to less than 7% with modern management, including full medical work-up, modern antibiotics, reversal of metabolic defects and hypoxia, improved control of systemic illnesses such as diabetes mellitus, and source and alternate foci control (3). One key issue is the withholding of antibiotics until an organism is identified. If the patient has severe sepsis, maximal broad-spectrum antibiotic therapy should be instituted once an adequate biopsy has been performed. If there is vertebral osteomyelitis but a negative open biopsy, then a full course of this broad-spectrum therapy must be given for 6 to 8 weeks.

Antibiotic choice for spine infections is paramount. The antibiotic must be specific for the organism diagnosed, and the least toxic agent should be used. Some studies show that bone penetration for normal and osteomyelitic bone is equal to serum concentration for such large molecules as cephalosporins. However, for disc tissue and abscesses, penetration may be more class dependent (34–39). Vancomycin, teicoplanin, gentamicin, tobramycin, and clindamycin penetrate the nucleus pulposus with adequate concentrations (34,35,39). Cephalosporins and penicillins are less reliable with regard to penetration (35,37,39) and are even lower with increased serum binding (38). In general, antibiotics with a positive

charge and smaller size have a better chance of penetrating the intervertebral disc (40).

At least 6 weeks of IV antibiotic therapy has been the mainstay of conservative treatment of spine infections (11). Four weeks of IV therapy followed by 2 weeks of an appropriate oral antibiotic may be sufficient as well (25,41). However, with regimens of less than 4 weeks, the relapse rate goes up to 25% (3).

Progress of therapy should be monitored with clinical signs, physical examination, and laboratory data. Patients with signs of sepsis, continued unrelenting pain, or laboratory values that remain elevated warrant further evaluation of the progress of treatment. The sedimentation rate should be a useful guide; in one review of the literature it decreased to two thirds of the presentation value in all patients and to less than one half the presentation value in over one half of the patients at the completion of 6 weeks of therapy (3). At final follow-up, patients with successful therapy should have a normalized sedimentation rate (21). Appropriate antibiotic therapy was noted to relieve severe pain within a few days. Bracing is recommended to control pain and prevent progression of deformity, which may otherwise be a sequela of infection (25).

### Operative Management

Most pyogenic spine infections can be managed nonoperatively with an adequate trial of specific IV antibiotics that target the causative organism. Indications for operative management include multiple negative closed biopsies; location of infection that precludes a safe closed biopsy; clinically significant abscess with spiking temperatures and a septic clinical picture; severe deformity (Fig. 78-2), body destruction, or failure of conservative management with elevated sedimentation rate; radiographic progres-

sion; and continued severe pain. The final indication is neurologic deficit with neural compression.

Historically, the decompressive operation of choice was laminectomy; however, early on it was thought to be deleterious to neural recovery in infection, prompting Seddon to state, "The operation may be of some value in certain rare forms of paraplegia, but as a routine procedure it is to be condemned." This was chiefly because of approaching an anterior disease from a posterior approach and removing the one part of the spine that is usually still intact in case of spine infection. Seddon noted a transient improvement of the clinical picture, probably because of posterior cord displacement. However, residual pressure of the anterior infection compressing the spinal cord combined with increasing instability often leads to later neurologic deterioration (42). Problems with postoperative instability and deformity have plagued the modern series of this approach to a pyogenic spine infection (11,43), especially in the cervical and thoracic spine.

Posterior laminectomy with *in situ* fusion following a thorough débridement of the disc infection, however, is a reasonable option below the level of the conus medullaris. This is with the prerequisite that there is minimal anterior body destruction and collapse and that adequate decompression can be obtained using this approach. This is effective in the lordotic lumbar spine so long as the facets are preserved. The *in situ* transverse process fusion is added to prevent unstable spondylolisthesis and foraminal narrowing that may occur with collapse. This approach is often best in patients who are medically ill and in those high-risk patients in whom a small procedure is ideal.

The majority of the time infections should be approached anteriorly. The anterior approach provides

---

**FIG. 78-2.** This 29-year-old intravenous (IV) drug user presented with complaints of axial low back pain. **A:** Initial plain radiographs showed disc space height loss with mild end plate erosion. **B:** Magnetic resonance imaging confirmed the diagnosis with gadolinium uptake in the adjoining vertebral bodies and an obvious L2-3 disc space infection. Computed tomography-guided biopsy confirmed infection of the disc space with *Staphylococcus aureus* sensitive to fluoroquinolones. The patient was discharged with a 30-day supply of medication despite leaving against medical advice. She lost the medications and never followed up in the clinic. She presented 2 months later, again complaining of severe low back pain with no neurologic symptoms, a normal examination, and normal urologic function. **C:** Plain films taken at that time show severe osteomyelitis of the L2 and L3 vertebral bodies with erosion and marked kyphosis. **D:** Magnetic resonance imaging confirmed compression of the neural elements and spread of the infection. She was brought to the operating room for urgent initial anterior débridement with subtotal carpectomies of L2 and L3, decompression of the infection out of the spinal canal, and placement of a structural autogenous iliac crest bone graft. Intraoperative cultures grew out *Staphylococcus aureus* yet again. Postoperatively she was placed on IV vancomycin. **E,F:** She was brought back a few days later for pedicle screw instrumentation and osteotomy to correct the kyphosis and stabilize the anterior graft. **G:** Computed tomography scan confirmed that the graft was in a good position. The patient was kept in the hospital for a full course of IV vancomycin, her sedimentation rate normalized, and she was discharged on Bactrim.

direct access to the infection without neural retraction; the disc space can be grafted acutely with a very high fusion rate (96%) in order to prevent collapse (44). The anterior graft heals rapidly, which facilitates rehabilitation (3,11,45,46).

In terms of technique for the anterior approach, great care must be taken with the anterior vascular structures, especially in the lower lumbar spine because these may be adherent and friable from the adjoining infection. The surgeon can check for abscess extension on the contralateral aspect of the affected vertebral bodies and explore the psoas muscle. Reconstruction with autograft iliac bone is the gold standard (44,46); however, a rib is suitable if there is no kyphosis and minimal body destruction, although it lacks the structural integrity of tricortical iliac grafts.

The use of autograft has been established as the gold standard in the literature for spine infections (44,47,48) treated with a single-stage procedure. Posterior instrumentation has been noted to be an adjunct that can be safely used (49). Single-stage anterior instrumentation has been associated with persistent infection as well as instrumentation failure from poor fixation (49). The use of cages has been advocated as well as an anterior graft in conjunction with posterior instrumentation (49) despite evidence in their series of a high rate of persistent infection in patients with anterior instrumentation or cages. In addition, cages have been associated with persistent infection requiring explantation and revision two body carpectomies with a long antero-posterior reconstruction in at least one instance (50). In the cervical spine, anterior instrumentation combined with autogenous iliac bone grafting has been very successful in treating infection.

### Surgery for Paralysis

Eismont and colleagues (11) evaluated patients with vertebral osteomyelitis with paralysis and compared them with a group of patients who did not have paralysis but who were evaluated and treated in the same period in the same city. Factors predisposing to paralysis were older age, more cephalad level, diabetes mellitus, and rheumatoid arthritis with concurrent steroid use. Youth seemed protective, with the younger IV drug abusers being spared paralysis. Microbiologically, *Staphylococcus aureus* was the causative organism in the vast majority of the patients with severe paralysis.

Patients with cervical or thoracic infections had better neurologic recovery with surgery than patients treated nonoperatively. Patients treated with a laminectomy either worsened or failed to improve neurologically. Patients treated with anterior decompressions and fusions tended to improve neurologically. However, at the root level in the lumbar spine, patients had similar

rates of recovery with operative and nonoperative treatment. Similarly, there was no difference in neurologic recovery in the lumbar spine between patients treated with anterior and posterior operations, except for one patient in whom paralysis failed to improve following a wide laminectomy and subsequent spondylolisthesis (11).

### Prognosis

The prognosis is good in the era of modern antibiotics, with mortality less than 5% (15). There is increased morbidity and mortality in patients with systemic diseases such as diabetes and rheumatoid arthritis (15,22). In terms of deformity, there is a risk of progression (25), especially in patients with significant kyphosis on presentation (51). Paralysis is a significant source of morbidity (11), but with proper treatment, less than 7% of patients have a permanent neurologic deficit (3).

### EPIDURAL ABSCESS

Spinal epidural abscess is a clinical entity that requires rapid diagnosis and treatment with appropriate antibiotics and usually surgery to minimize the significant morbidity and especially the paralysis that often occurs because of this type of infection. The incidence of epidural abscess is .2 to 1.2 cases per 10,000 hospital admissions (18). It generally is a disease of adults (52), with an equal male to female ratio, and may have a higher incidence associated with invasive procedures, IV drug abuse, and elderly patients (52). Other risk factors are diabetes mellitus, trauma, and alcoholism (53).

The source of infection can be identified in 70% to 80% of cases (18,52). The route of infection can be hematogenous (Fig. 78-3), contiguous, or by inoculation (as in a procedure or surgery). Hematogenous infection can come from skin and soft-tissue infections, respiratory tract infections, and urinary tract infections (52). Most commonly, a bacteremia seeds the epidural space, which contains fatty tissue and a rich venous plexus (18). The most common location for a spinal epidural abscess is in the posterior spinal canal (79%). The majority of the anterior epidural abscesses are from direct spread from an anterior osteomyelitis. Fourteen percent of these epidural abscesses occur in the cervical spine, 51% in the thoracic spine, and 35% in the lumbar spine. The epidural infection leads to a mass effect from the granulation tissue or pus, which produces neural element compression and paralysis. In severe paralysis owing to infection, there can be secondary subarachnoid vascular injury and thrombosis (18).

The range of organisms mirrors vertebral osteomyelitis, with *Staphylococcus aureus* responsible for

62% of the infections. Aerobic gram-negative rods are isolated in 18%, aerobic streptococci in 8%, coagulase-negative staphylococcus in 2%, anaerobes in 2%, and no organism isolated in 6% (52). A large proportion can have positive blood culture (69%) (52).

The clinical course can be acute or chronic. For an acute epidural abscess the clinical picture has been described in four phases (54): spinal ache, root pain, weakness including bowel and bladder dysfunction, and paralysis. The spinal ache usually is localized to the level of the affected spine and can bring the patient to the physician quickly. In the next few days, the patient can then get root pains radiating from the localized painful area. Fever and leukocytosis usually are present, as is an elevated sedimentation rate (18). Signs and symptoms of neurologic involvement are consistent with the level of the spine infection. Chronic infection differs in that these events occur over weeks or months, and the signs and symptoms of concurrent sepsis usually are absent. However, rapid neurologic deterioration can still be a hallmark of a chronic epidural abscess despite the initially slow course and can be the presenting feature in chronic epidural abscess (18). The differential diagnosis includes meningitis, spinal subdural abscess, acute transverse myelitis, disc herniation, vascular lesion, and tumors in the spinal canal.

Diagnosis begins with a detailed clinical history and physical examination. The majority of acute epidural abscess patients present with septicemia, with a mean peripheral WBC of about 16,000 (18,53). Chronic infections can have a normal peripheral WBC (18). The sedimentation rate is almost always elevated above 25 mm (89%), whether the infection is acute or chronic (52). Radiographs are usually normal unless there is evidence of a contributing or concurrent disc space infection. Myelography, now combined with CT, was once the diagnostic imaging modality of choice to document the neural compression. If pus was aspirated in the epidural space before the intradural space was entered, a diagnosis was established with gram stain and culture. However, this test carried the risk of converting the epidural abscess into an intradural infection, and is no longer recommended (53). Radionuclide studies are not appropriate because they are nonspecific with a false-negative rate for epidural abscess, and are time-consuming (54). Magnetic resonance imaging is the study of choice with gadolinium contrast, allowing the differentiation of the epidural abscess from adjacent compressed thecal sac that previously was not possible with noncontrast MRI (30,31).

The presence of an epidural abscess is generally regarded as a surgical emergency, especially in the presence of any neurologic deficit. Even if the patient initially has intact motor strength, the presence of root symptoms or early urine retention is a sign of possible impending

neurologic collapse (Fig. 78-3). The goals of treatment are to preserve neurologic function, eliminate infection, relieve pain, diagnose the pathogen, and stabilize the spine if necessary.

The surgical approach is dictated by abscess location and extent. Because epidural abscesses are generally posterior and can range over many levels, surgical drainage generally is performed with a laminectomy. Care is taken to preserve the facet joints for postoperative stability (18,54). In cases with an anterior abscess with concurrent vertebral osteomyelitis, anterior decompression and grafting usually are indicated for complete débridement and may require supplemental posterior laminectomy to decompress proximal and distal abscess extensions. The wounds may be closed over drains or be packed open in instances of severe tissue necrosis (52).

Antibiotic therapy should be started once an adequate spine culture has been performed and gram stain obtained. Broad-spectrum antibiotics should be administered until identification and sensitivities are available. Most authors recommend 3 to 4 weeks of parenteral therapy (18), with therapy extending to 6 to 8 weeks in the presence of a concurrent vertebral osteomyelitis.

There are small series documenting the treatment of epidural abscesses with antibiotics alone (52,55,56). The majority of these patients were neurologically intact with no signs of sepsis. However, numerous other references report neurologic progression and even cord infarction under these same circumstances (18, 52–54,57). Combined surgical decompression with appropriate antibiotic treatment remains the standard of care. Indications for initial nonoperative management include poor surgical candidates, diffuse involvement of the spinal canal, no neurologic deficit, and complete neurologic deficit for more than 3 days (55,56). Patients deteriorating neurologically should undergo surgical decompression.

With the advent of the modern antibiotic era and the facility in diagnosing spinal epidural abscess with MRI, the mortality of spinal epidural abscess has dropped from nearly universal at the turn of the 20th century, to 34% from 1954 to 1960, to 15% from 1991 to 1997 in one review of the literature (53). In regard to paralysis, Currier (58) noted in another review of the literature that 38% had full recovery, 29% had some weakness, 21% had paralysis, and 12% died. Neurologic recovery is directly related to the time and severity of the paralysis (52–54). Recovery is observed in most patients presenting with minimal paralysis or significant paresis of less than 36 hours (54). No recovery has been observed with complete paralysis of more than 36 to 48 hours (54,59). Acute onset with paralysis within 12 hours carries a poor prognosis because cord infarction may be the mechanism of paralysis as opposed to simply mechanical compression (57).

## FUNGAL INFECTIONS

Fungal infections of the spine are relatively uncommon and are typically seen in immunocompromised patients. However, these infections must be considered in the differential diagnosis of infectious spondylitis. A delay in diagnosis occurs frequently because the infectious course often is indolent. The principles of diagnosis and treatment remain the same as for pyogenic infections (Fig. 78-4). Diagnosis rests primarily on obtaining a good biopsy and a positive tissue specimen culture. Biopsies must be evaluated with fungal stains as well as cultures, because the latter may be negative or take weeks to months to become positive. The differential diagnosis should include pyogenic and tuberculous infections, metastatic disease, axial neuroarthropathy, and spinal sarcoidosis (15). Spinal infections caused by aspergillosis, candidiasis, cryptococcus, blastomycosis, and coccidioidomycosis have been reported in both immunocompetent and immunocompromised patients (Table 78-1) (15,58,60).

In one series of 11 patients with fungal spine infections with long-term follow-up (61), the source of the fungal spondylitis was hematogenous seeding from sepsis in four, postoperative spondylitis in three, local extension from an adjacent fungal infection in two, direct traumatic implantation in one, and unknown in one. All of the patients except two had risk factors consistent with immunosuppression or chronic medical illness.

At the time of clinical presentation (61), 10 of the 11 patients had severe unremitting pain localized to the level

of the infection and nine patients had some degree of paralysis. The clinical presentation was characterized by a long delay between the onset of symptoms and administration of an antifungal agent (Table 78-2), the delay ranging from 7 to 365 days (average 99 days) in 10 patients; the outlying eleventh patient had a draining sinus for 9 years. Only one patient had a fever of more than 101°F. The sedimentation rate was elevated in 10 patients, and the WBC was elevated in only three patients, and greater than 20,000 cells/mm<sup>2</sup> in only one. Radiographic presentation showed peridiscal erosions and decreased disc space height in 10 patients. In the eleventh, the most chronic patient, there was diffuse vertebral involvement.

Tissue obtained by closed or open biopsy revealed the diagnosis in all 11 patients (61). Half of the closed biopsies were negative, whereas all of the open biopsies were positive. The organism was identified with a positive fungal culture, KOH (potassium hydroxide) slide preparation, or Gomori methenamine silver stain. Seven of the 11 patients had *Candida* alone, and one patient had *Aspergillus* alone. Two of the patients had mixed infections with a fungus plus other fungi or bacteria. Ten of the 11 patients were treated with amphotericin B, and the remaining patient had a resistant organism treated with IV miconazole and oral ketoconazole.

Ten of the 11 patients were treated with surgical débridement of the spine to obtain the biopsy, débride the spine and drain abscesses, decompress the neural elements, and treat a failure of conservative treatment.

---

**FIG. 78-3.** A 34-year-old African-American woman was transferred to the medical service with the primary complaint of worsening axial low back pain. She had a long history of type 2 diabetes, and a recent history significant for a right large toe osteomyelitis that had been treated with débridement 2 weeks earlier. A Hickman catheter had been placed for long-term intravenous antibiotics, but was removed after spiking fevers and a line culture positive for methicillin-resistant *Staphylococcus aureus* (MRSA) confirmed a diagnosis of line sepsis. On initial consult, her plain films were negative for any obvious disc space erosions. She was neurologically normal, with no long tract signs, and normal perirectal sensation, rectal tone, and volition. **A–D:** Urgent magnetic resonance imaging revealed a massive epidural abscess with large psoas and paraspinous muscle abscesses. Reexamination revealed a stable, intact motor examination, with normal strength, mildly decreased distal vibratory sensation, a stocking glove distribution in both feet, and a normal sensory and volitional rectal examination. Postvoid residual, however, was 300 cc of urine. **E:** She had evidence of abscess tracking up to the mid thoracic spine but no clinical symptoms or signs of myelopathy. She was taken to the operating room for decompressive laminectomies of L2-4, and decompression and drainage of the psoas abscess through an intertransverse approach, and the paraspinous abscesses as well. Gross pus in the canal was encountered largely centered at L3-4, the level of the psoas and paraspinous abscesses. Gram stain showed gram-positive cocci in clusters, and intraoperative cultures grew methicillin-resistant *Staphylococcus aureus*. Above L2 there was no residual mass effect and instead of purulence, just some granulation tissue. She was treated with vancomycin and rifampin for 8 weeks, and afterward with Bactrim. **F,G:** Postoperative radiographs showed no instability. She had no postoperative neurologic deficit and recovered normal urodynamics.

A,B

**FIG. 78-4.** A 68-year-old woman presented to the emergency room complaining of mid-thoracic back pain for 8 months with slow worsening. She was neurologically normal, had a negative travel history of any significance, and had lived in the same city for 20 years. **A,B:** The work-up revealed a sedimentation rate of 80, and plain films with some end plate erosions at T5-6. Computed tomography (CT) scan confirmed significant prevertebral soft tissue mass at T5-6 (**C**) as well as at T8 (**D**). **E:** Magnetic resonance imaging (MRI) confirmed the pattern of disc space infection at T5-6 on T1-weighted images with some intrusion into the canal. **F:** Gadolinium-enhanced images showed the extent of the anterior infection and vertebral body edema. **G:** T2-weighted images showed the infection with a large thoracic spinal canal and no cord compression.

C

D

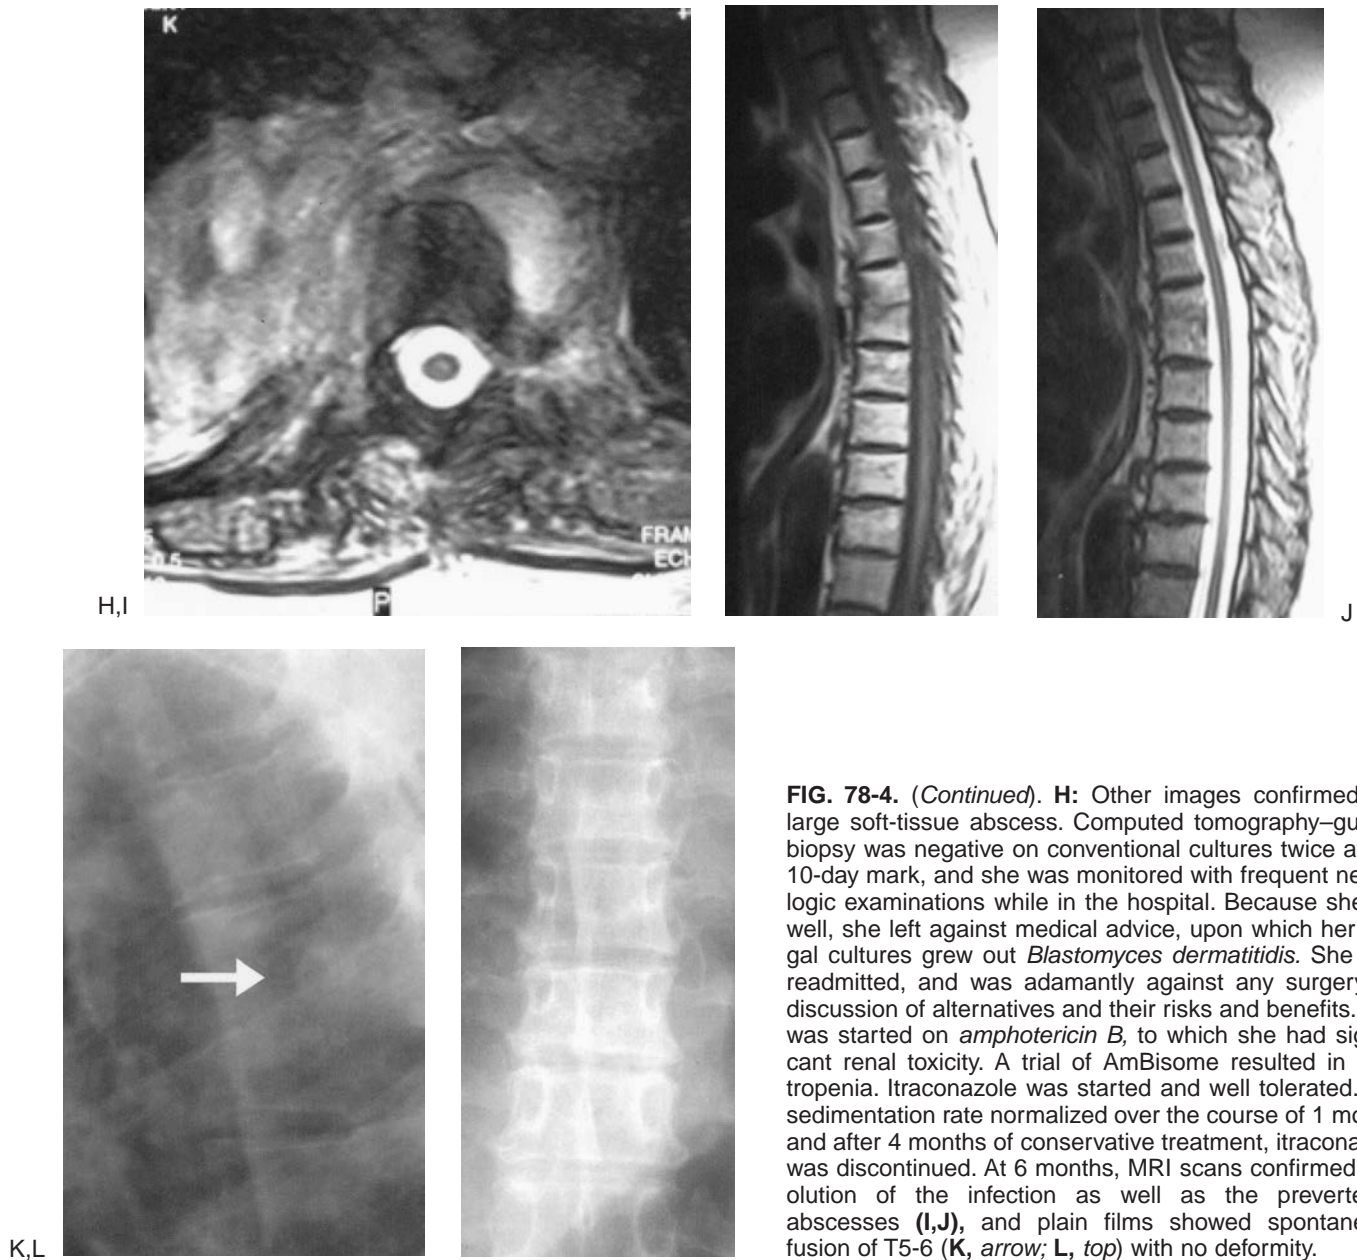

E,F

G

**FIG. 78-4.** (Continued). **H:** Other images confirmed the large soft-tissue abscess. Computed tomography-guided biopsy was negative on conventional cultures twice at the 10-day mark, and she was monitored with frequent neurologic examinations while in the hospital. Because she felt well, she left against medical advice, upon which her fungal cultures grew out *Blastomyces dermatitidis*. She was readmitted, and was adamantly against any surgery on discussion of alternatives and their risks and benefits. She was started on *amphotericin B*, to which she had significant renal toxicity. A trial of AmBisome resulted in neutropenia. Itraconazole was started and well tolerated. Her sedimentation rate normalized over the course of 1 month, and after 4 months of conservative treatment, itraconazole was discontinued. At 6 months, MRI scans confirmed resolution of the infection as well as the prevertebral abscesses (**I,J**), and plain films showed spontaneous fusion of T5-6 (**K**, arrow; **L**, top) with no deformity.

Two patients died, one of disseminated aspergillus infection, and one of a massive upper gastrointestinal hemorrhage. The authors concluded that even when neural decompression was not needed, the results were better with an anterior surgical approach. Once treatment was completed, only four of the nine survivors

were neurologically normal. Four of these nine patients had persistent mechanical spine pain, and two were functionally disabled from the pain. However, once full medical and surgical treatment was completed, no patient had a recurrence of the infection with an average of 6.3 years of follow-up.

**TABLE 78-1.** *Fungal pathogens with a propensity for spine and musculoskeletal involvement and their characteristics*

Fungal pathogen	Endemic area/ecosystem	Host	Mode of infection	Non-MSK sites	Dissemination
Coccidiomycosis	Soil, desert ecosystem Arid southwestern United States San Juaquin Valley fever	Travel, endemic exposure	Airborne spore Skin abrasions	Pulmonary Cutaneous Osseous Prostatic Central nervous system	Hematogenous
Blastomycosis	Warm moist soil rich in organic debris Mississippi and Ohio river valleys Great Lakes, St. Lawrence River	Endemic exposure	Spore inhalation	Lung, skin	Hematogenous
Cryptococcus	Throughout the world Pigeon feces and soil	AIDS	Inhalation of fungal form	Lung/central nervous system	Hematogenous
Candidiasis	Normal skin commensals Gastrointestinal tract, sputum, skin Urine of catheterized patients	Immuno- compromised Vascular access IVDA Burns	Endogenous	Blood Endocarditis Meningitis Fungemia	Hematogenous
Aspergillus	Dead plant and animal matter Threshing areas and mills	Immuno- compromised Farm workers	Inhalation of conidia	Pulmonary	Direct extension

IVDA, intravenous drug abuse; MSK, musculoskeletal.

**TABLE 78-2.** *Antifungal agents and their characteristics*

Agent	Mechanism	Route	Side effects	Indication	Pathogens
Amphotericin B	Plasma membrane permeability, cell death	IV	Bone marrow dysfunction Liver and renal toxicity	Life-threatening disease Central nervous system involvement Medically ill	Blastomycosis Coccidiomycosis
Flucytosine	Inhibits DNA synthesis	IV		With amphotericin B	Aspergillosis Candida Cryptococcus Blastomycosis Coccidiomycosis
Ketoconazole Fluconazole Itraconazole	Block the biosynthesis of fungal lipids in the cell membranes	PO		HIV Good central nervous system penetration	
Ambisome	Liposomal formulation of amphotericin B	IV	Similar amphotericin B	Fail amphotericin B Not tolerating amphotericin B	Aspergillosis Candidiasis Cryptococcal

## CONCLUSION

Diagnosis and treatment of spine infections begins with clinical suspicion, meticulous history and physical, as well as appropriate laboratory work-up. Imaging, especially MRI, can enhance clinical suspicion and guide treatment decisions. However, biopsy and culture are the key elements needed to guide antibiotic choice and the success of conservative treatment. Even with appropriate conservative therapy, there are patients who may need surgical treatment for a clinically significant abscess, open biopsy, severe deformity, neurologic deficit, or failure of conservative treatment with continued chronic infection.

## CHAPTER 79

# Tuberculosis

S. Rajasekaran

---

Tuberculosis is rampant in many parts of the world: In the year 1993 alone, more than 3 million tuberculosis-related deaths were reported (1). Roughly 3% to 4% of all tuberculous infections involve the skeletal system and more than 50% of those involve the spine. Even by a conservative estimate, there are about 3 million patients with active spinal tuberculosis in the world today (2). The eradication of the disease appears remote because of the poor economic and social standards of the developing world, increasing global travel, the emergence of multi-drug-resistant strains, and the increasing incidence of patients coinfecting with tuberculosis and acquired immunodeficiency syndrome (AIDS).

### **PATHOLOGY**

*Mycobacterium tuberculosis*, characterized by its acid-fast staining properties, is the organism commonly responsible for human infections. The spinal infection is always a secondary lesion by hematogenous spread from a pulmonary (Gans focus), gastrointestinal, or genitourinary lesion, but an active primary source is detected in less than 10% of patients. Apart from arterial channels, the spread also can occur through the Batson plexus of veins; this accounts for the increased involvement of the lumbar spine (Fig. 79-1). Skip lesions with multilevel involvement are possible and are detected in about 5% of patients with plain radiography and in 15% of patients when magnetic resonance imaging (MRI) is used.

Anterior lesions affecting the vertebral body account for 85% to 90% of the lesions (2). Many types of body involvement are seen—paradiscal, central, complete, and anterior lesions. The paradiscal variety is the most common, especially in adolescents and young adults (Fig. 79-2). Here the infection spreads through the epi-

physeal arteries, which branch to supply the paradiscal region of adjacent vertebrae. The initial picture is loss of definition of the paradiscal margins of consecutive vertebrae with narrowing of disc space; there is further destruction of the vertebral bodies with progress of the disease. Complete destruction of one or more vertebrae is commonly found in children below the age of 10 years and is predisposed by poor nutritional status (3). Here the anterior column deficit is extensive; such children are prone to buckling collapse of the spine, leading to late progress in deformity and late paraplegia. The central type of lesion is more common in children. There can be collapse of the body without any change in the disc spaces, which simulates a radiologic picture of Calves disease. Anterior lesions are frequent in the thoracic region and the infection can quickly spread beneath the anterior longitudinal ligament to many consecutive levels.

Posterior lesions affecting the pedicle, laminae, and spinous process constitute 10% to 15% of lesions; however, they are important because they are associated with late diagnosis and a higher incidence of neurologic deficit (4). Computed tomography (CT) and MRI studies must be used for an early diagnosis whenever there is a suspicion. Rarely the disease starts at the posterior margin of the body with profuse granulation tissue. The patient presents with neurologic deficit without any radiologic abnormality and the clinical picture mimics a spinal cord tumor (spinal tumor syndrome). Irregular destruction of the vertebral bodies can lead to scoliosis and may cause confusion with hemivertebrae in healed cases. Destruction of more than two vertebral bodies leads to facet dislocation during the period of collapse in children and can precipitate complete translocation of the spine, resulting in a complex deformity (Fig. 79-3).

**FIG. 79-1.** The thoracolumbar and lumbar regions are most commonly affected in spinal tuberculosis. The larger mass of bone, increased range of movements in the region, spread by Batson plexus of veins and the proximity to cisterna chyli are quoted as reasons.

A-D

**FIG. 79-2.** The various types of lesions seen commonly in spinal tuberculosis. **A:** Paradiscal lesions with destruction of the discs and involvement of the adjacent vertebral bodies is the most common lesion. **B:** With progression of the disease and especially in children, entire vertebral bodies are destroyed with the formation of caseous material and abscess. **C:** Body lesions without the involvement of discs are relatively rare. **D:** Posterior lesions without involvement of the anterior column are also rare and are more easily identified in computed tomography and magnetic resonance imaging scans.

**FIG. 79-3.** In patients with destruction of two or more vertebral bodies, the facet joints dislocate to allow the normal vertebral bodies to come into contact and consolidate anteriorly. The disruption of the posterior arch in the presence of anterior column deficit leads to global instability and the spine often heals with varying degrees of scoliosis, kyphosis, and rotation.

### THE NATURAL HISTORY OF THE DISEASE

Untreated spinal tuberculosis has a vicious clinical course of progressive destruction of vertebral bodies with potential for persistent sinuses, abscess, and early- or late-onset neurologic deficit (Pott paraplegia). Effective chemotherapy can arrest the progress at any stage with healing and consolidation of the focus. In minimal disease, the disc is destroyed early and the cancellous bone of the adjacent vertebrae consolidates with bony fusion, which is the hallmark of healing in spinal tuberculosis. In severe disease with extensive destruction of the anterior column, facet joints frequently give way and destabilize the spine. The superior healthy vertebra then rotates and descends so that its anterior surface comes into contact with the superior surface of the inferior healthy vertebra. The deformity often increases to more than 60° and in children can progress during the period of growth even after cure of the disease.

The progress of deformity depends on the age at the time of involvement, the level of lesion, and the severity of disease. The deformity progresses in two distinct phases: phase I, or the active phase, which includes changes in the first 18 months during the period of active disease. Changes that occur after the disease is cured are termed phase II, or healed phase, changes (5).

Adults have a lesser deformity at presentation, a lesser increase during phase I, and virtually no change after cure of the disease. The progression of deformity usually is less than 30° and is restricted to the first 12 to 18 months when consolidation of the focus is complete (3). In contrast, children have a higher deformity at presentation, a greater tendency for collapse during the active phase, and continued progression until growth is complete. Children are more susceptible to deformity because

of the increased severity of destruction at presentation (3,6,7), increased flexibility of the spine (8), a relative destruction of the growth plates anteriorly interfering with future growth (9,10), and the suppressive effect of the mechanical forces of kyphosis on the growth of the anterior half of the fusion mass and adjacent normal vertebrae (11).

Distinct types of progress are seen in children during the growth phase that determine the extent of the final deformity (5). Unlike other spinal deformities, which usually deteriorate with growth, there is both a beneficial or worsening effect during the period of growth spurt (Figs. 79-4 and 79-5).

#### Type 1 Progression

There is continued progress through the entire period of growth; this is noticed in 44% of children (Fig. 79-6). The increase could occur continuously after phase I (type 1A) or a lag period of 3 to 6 years after the disease is cured (type 1B). Type 1B progression is important because the lag period may result in the progression being missed. It is common practice to follow-up children only for 2 to 3 years after the disease is cured; therefore, the late increase in deformity can be missed.

#### Type II Progression

Type II progression shows beneficial effects during growth with a decrease in deformity after healing (Fig. 79-7). This can occur immediately after phase I (type II a) or a period of 3 to 6 years (type II b). Children with type II progression have the best outcome because they have lesser increase during phase I and greater improvement during phase II.

**FIG. 79-4.** Lateral radiographs of the lumbar spine of a 4-year-old child with severe destruction of L2 and L3 at the start of treatment. Follow-up shows excellent improvement with growth at 60, 120, and 180 months. The fusion mass of L2 and L3 begins to show increased anterior growth. By 15 years the fusion mass almost resembles a normal vertebra except for the attachments of the pedicles of two levels. (Reproduced with permission from Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962.)

**FIG. 79-5.** Radiographs showing extensive thoracic lesions in a 3-year-old girl with a deformity of 40° at 3-year follow-up. The disease was completely cured, but the deformity progressed to 115° at 15 years follow-up. (From Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962, with permission.)

**FIG. 79-6.** Graph showing that type 1 progression showed deterioration in the deformity even after healing of the disease. In type 1a progression, this deterioration continued throughout growth, whereas in type 1b progression there was a lag period of a few years before the deterioration started. The progression was more severe in type 1b. (From Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962, with permission.)

**FIG. 79-7.** Graph showing that in children with type 2 progression a decrease in deformity occurred during the healed phase. In type 2a the improvement started soon after healing of the disease and in type 2b after a lag period of a few years. (From Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962, with permission.)

**Type III Progression**

Children who have minimal disease or lower lumbar lesions without loss of lordosis do not have any major change in deformity during phases I and II (Fig. 79-8).

Facetal dislocation leading to spinal instability determines the course of the disease. The failure of the posterior arch and the instability that follows is identifiable by the following instability signs, termed “spine at risk” radiologic signs (Fig. 79-9)(5).

**Separation of the Facet Joints**

With progressive kyphosis, the facet joint at the apex of the curve is subluxed followed by frank dislocation. In patients with severe involvement, there is separation at more than one level, with wide distraction of the spinous processes at the corresponding levels.

**Retropulsion of the Diseased Vertebral Segments**

With progressive destruction, the remnants of the destroyed vertebral bodies are retropulsed. This is assessed by drawing two lines along the posterior surface of the normal vertebrae above and below the level of the

lesion. Retropulsion is confirmed when the diseased segments are seen to lie posterior to the drawn lines.

**Lateral Translation of the Vertebral Column**

Translation is confirmed when the line drawn from the center of a pedicle of the lower vertebrae does not intersect the pedicle of the upper vertebrae in an antero-posterior (AP) radiograph.

**Toppling Sign**

The separation of the facet joint allows the superior normal vertebral segment to tilt or topple, so that the anterior surface of the vertebra comes into contact with the superior surface of the vertebra below the level of the lesion. A line drawn along the anterior surface of the inferior vertebra intersects the superior first normal vertebra above the middle of its anterior surface.

Each of these signs is given a score of 1, with a maximum possible instability score of 4. Of all the variables, an instability score of more than 2 is the most significant factor in determining an increase of more than 30° or a final deformity of more than 60° (5). The radiologic signs of instability are found to be particularly useful because

**FIG. 79-8.** Graph showing type 3 progression had only a minimal increase during the active phase and little change during the healed phase. This was found in children with only minimal destruction or lesions of the lower lumbar region. (From Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962, with permission.)

**FIG. 79-9.** Spine at risk radiologic signs in children. **A:** Separation of the facet joint. The facet joint dislocates at the level of the apex of the curve, causing instability and loss of alignment. In severe case the separation can occur at two levels. **B:** Posterior retropulsion. This is identified by drawing two lines along the posterior surface of the first upper and lower normal vertebrae. The diseased segments are found to be posterior to the intersection of the lines. **C:** Lateral translation. This is confirmed when a vertical line drawn through the middle of the pedicle of the first lower normal vertebra does not touch the pedicle of the first upper normal vertebra. **D:** Toppling sign. In the initial stages of collapse, a line drawn along the anterior surface of the first lower normal vertebra intersects the inferior surface of the first upper normal vertebra. Tilt or toppling occurs when the line intersects higher than the middle of the anterior surface of the first normal upper vertebra. (From Rajasekaran S. The natural history of post tubercular kyphosis in children. *J Bone Joint Surg (Br)* 2001;83.B:954–962, with permission.)

they appear early during the active stage of the disease itself when surgical intervention is easier and can be performed with fewer complications.

### CLINICAL FEATURES

Pain in the region of involvement with paraspinal muscle spasm and restriction of movements is the usual mode of presentation. Weight loss, loss of appetite, malaise, and evening temperature elevation are present in most patients, but may be absent in patients with

good nutrition and health (2). Patients with extensive involvement and instability have a guarded gait and frequently exhibit reluctance to alter the position or ambulate. Deformities are present in most patients; the spinous process becomes prominent, producing a knuckle deformity when one vertebra is destroyed. A gibbus deformity of varying degree develops when many vertebrae are destroyed (Fig. 79-10). In lower lumbar lesions, lordosis protects the spine from an external kyphotic deformity and the severe collapse is manifested as foreshortening of the trunk (6).

**FIG. 79-10.** A 4-year-old child with a healed tuberculosis and a prominent kyphotic deformity of the dorsolumbar region (**A**). These lesions require early intervention; otherwise, they progress to severe deformities with risk for late-onset neurologic deficit, as seen in (**B**).

## COLD ABSCESS

Abscess is a common feature of spinal tuberculosis. Its clinical or radiologic identification greatly helps in the diagnosis of spinal tuberculosis. The abscess, composed of caseous material, serous exudates, and bone debris, spreads in various directions along the lines of least resistance and often presents subcutaneously. Absence of signs of inflammation at the site of presentation has led to the term cold abscess. In lumbar lesions, the abscess enters the psoas sheath and gravitates to form a psoas mass. It may then track down to the Petit triangle or may appear below the inguinal ligament or medial aspect of the thigh. It also can follow the great vessels into the pelvis, gluteal region, or posterior aspect of the thigh. Lesions of the sacrum and coccyx form abscess that track along the sciatic nerve to present in the posterior aspect of the thigh or popliteal region.

## NEUROLOGIC INVOLVEMENT

The incidence of a significant neurologic deficit in spinal tuberculosis is less than 3%, although some form of mild involvement can be present in up to 30% of patients (2,12). Compromise of the spinal canal with compression of the spinal cord by abscess, granulation tissue, and sequestered bone or disc material is the usual cause of paraplegia (Fig. 79-11A). The neurologic involvement caused by such compression usually progresses insidiously, but precipitous paraplegia can occur

because of infective vasculitis compromising the blood supply to the cord or a pathologic dislocation of severely destroyed vertebrae (Table 79-1). Other rare causes are spinal tumor syndrome and progressive fibrosis around the cord at the region of deformity apex.

The incidence of neurologic deficit is more common in thoracic and thoracolumbar lesions and is rare in lesions below the second lumbar vertebrae. The capacious spinal canal in the lower lumbar level and the fact that the spinal cord ends at the lower border of the first lumbar vertebra account for the lower incidence of neurologic deficit in lumbosacral lesions. When the involvement is at the cord level the disease passes through characteristic stages (Table 79-2). Lumbar lesions mainly produces radiculopathy and a full-blown cauda equina syndrome only rarely results. Magnetic resonance imaging has replaced myelography and is superior in accurately demonstrating the extent and cause of cord compression. It also shows the presence or absence of primary change in the cord and helps to prognosticate the outcome of treatment and recovery.

Paraplegia was initially divided into early and late onset, depending on its occurrence within or after 2 years of onset of the disease. This differentiation is less useful than the classification paraplegia of active disease (occurring however late) and paraplegia of healed disease. The prognosis is more favorable in paraplegia in active disease because the pathology is inflammation, and conservative treatment with adequate chemotherapy may be sufficient. Good recovery with chemotherapy is seen

**FIG. 79-11. A:** An active lumbar lesion with neurologic deficit owing to compression of the dural sac by abscess, granulation tissue, retropulsed bone debris, and disc material. **B:** In contrast, the cause for neurologic deficit in healed disease is caused by stretching the cord over the apex of the bony deformity (internal gibbus).

**TABLE 79-1.** Causes of neurologic deficit in active and healed disease

Paraplegia of active disease (occurring however late)
Compressive pathology caused by
Inflammatory edema
Granulation tissue
Caseous tissue and abscess
Sequestered bone and disc material
Infective vasculitis
Spinal tumor syndrome
Pathologic dislocation of the spine
Direct infiltration of the cord
Paraplegia of healed disease
Stretching of the cord over the apex during progressive deformity (internal gibbous)
Progressive extradural fibrosis

in the presence of active disease with an inflammatory cause of compression, incomplete involvement, short duration of deficit, minimal kyphotic deformity, younger age, and good nutritional status. When surgical decompression is indicated, surgery must be done at the earliest possible moment. Decompression done after 1 year rarely produces good results.

In paraplegia of healed disease, the pathology is mechanical compression; surgical decompression is mandatory (Fig. 79-11B). The prognosis is less favorable and surgery is fraught with complications (13).

## RADIOLOGY FINDINGS

### Plain Radiography

Radiographic appearance changes depend on the type of body lesion, severity of involvement, and stage of the disease. Osteoporosis of the vertebral body with haziness of margins of the adjacent vertebrae and narrowing of disc space are the initial findings in paradiscal lesions (Fig. 79-12A). Progressive destruction of the vertebral bodies are noted in advanced lesions, leading to gross kyphosis (Fig. 79-12B). Posterior spinal disease can be missed easily and AP radiographs are more useful in early

**FIG. 79-12.** **A:** Reduction of disc space with irregularity of the vertebral margins is the earliest radiologic sign. **B:** With progression of the disease, complete destruction of the vertebral bodies occur leading to a kyphotic deformity.

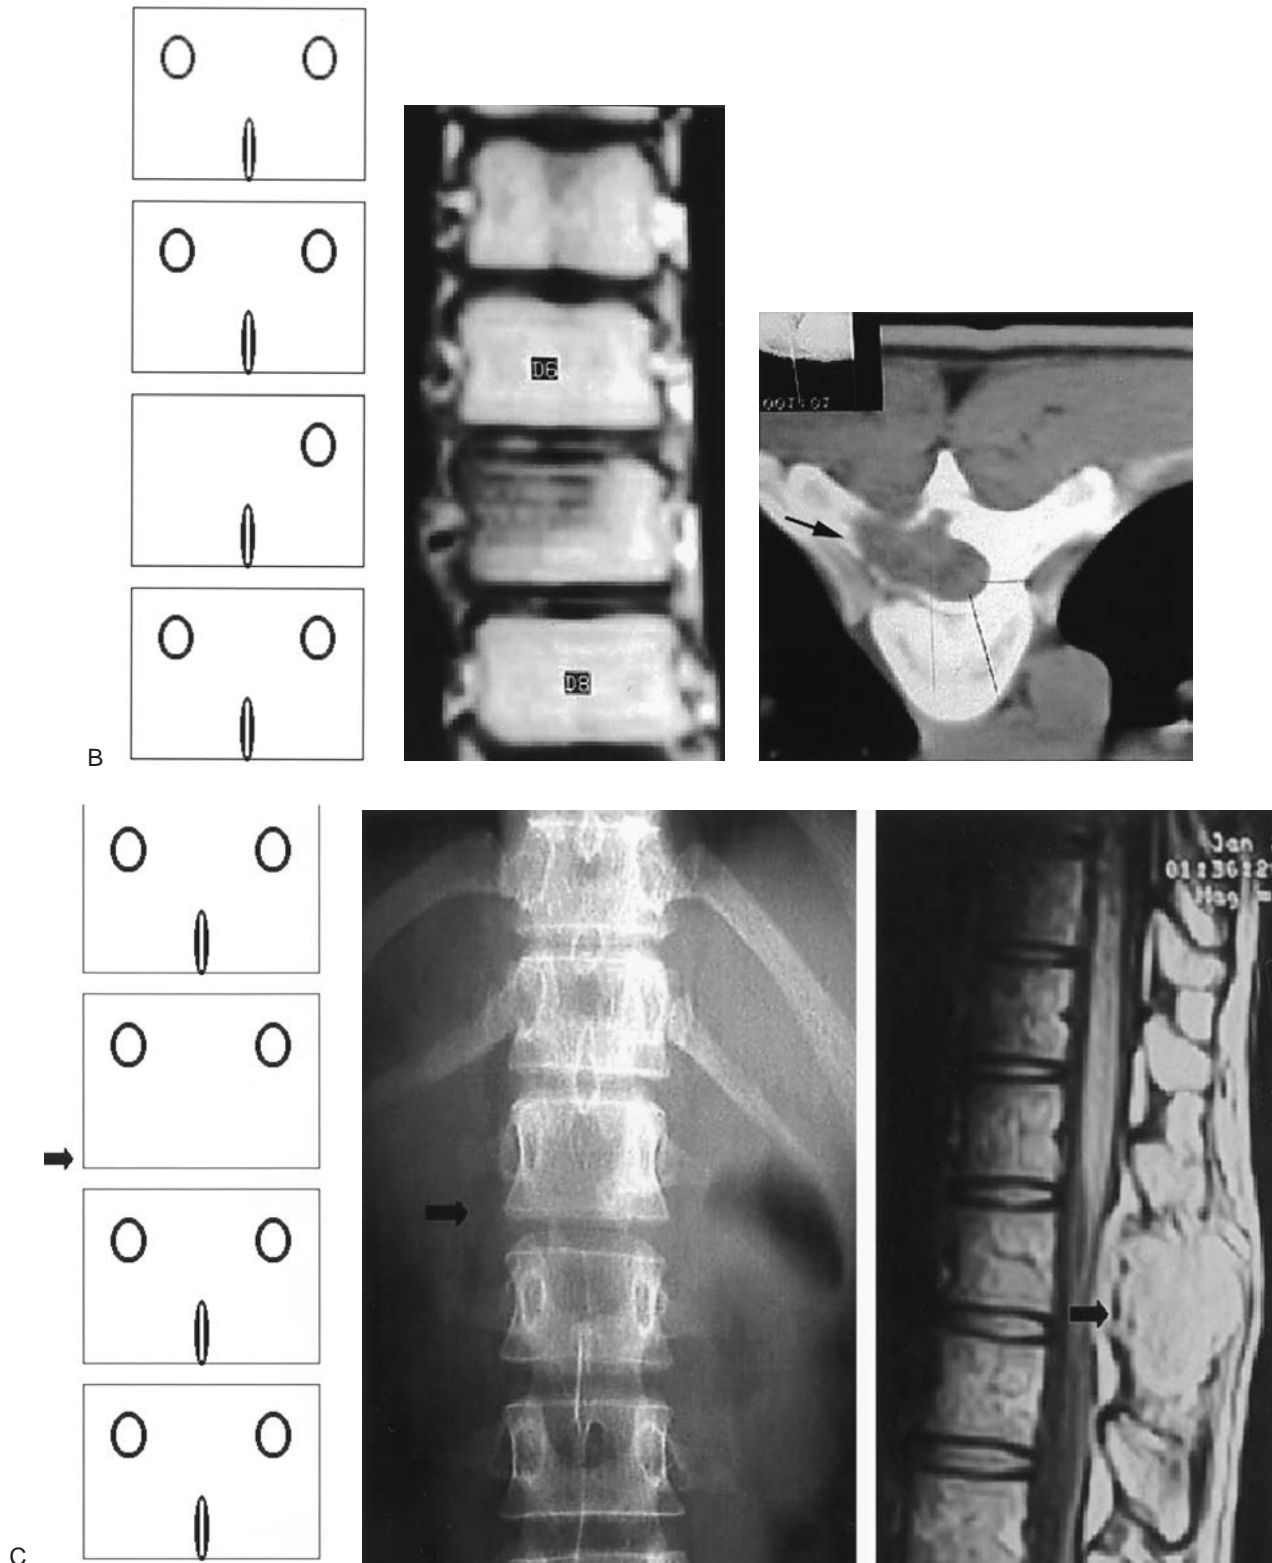

diagnosis than lateral radiographs (Fig. 79-13, A–C). Cold abscesses are seen as fusiform paravertebral shadows in the dorsal lesion and a bulge of the lateral margins of the psoas shadow in the lumbar lesions. After the start of chemotherapy, radiologic changes of healing usually

**FIG. 79-13.** **A:** In the antero-posterior radiographs, a normal vertebra has two pedicles and a spinous process resembling the eyes and the beak of an owl. A lesion of the spinous process gives rise to a loss of the beak, and a destructive lesion of the pedicle gives the appearance of a "winking" owl sign. **B:** Destruction of a pedicle as shown in the figure leads to loss of a pedicle, resulting in the "winking owl" sign. **C:** A lesion of the spinous process leads to the loss of the beak, resulting in a "beakless" owl sign.

**TABLE 79-2.** Stages of Potts paraplegia

Patient has no symptoms; physician detects plantar extensor response or ankle clonus

lag by 6 to 8 weeks after clinical improvement is noticed. Decrease in osteoporosis and sclerosis of the margins of the destroyed vertebra are the first signs of good response to treatment.

Computed tomography scans are useful in assessing the extent of bony destruction and the early diagnosis of lesions not easily visualized by plain radiography, such as those involving the craniovertebral and cervicodorsal junction, sacroiliac joint, sacrum, and posterior spinal disease.

Magnetic resonance imaging is superior in defining the extent of soft-tissue mass in both the sagittal and coronal planes and clearly differentiates the nature and extent of compression of the spinal cord (Fig. 79-11 A,B). Magnetic resonance imaging is of special use in the evaluation of the cause of compression in patients with neurologic deficit and in pure intramedullary and isolated extradural disease. Although MRI can strongly suggest tuberculosis, it is important to remember that there are no specific findings that can conclusively differentiate tuberculosis from other spinal infections or neoplasm. Gadolinium enhancement helps to accurately delineate the abscess wall from the compressed dura and localize portions of paraspinous masses most likely to yield a positive percutaneous biopsy. It is also well to remember that MRI often shows an exaggerated picture of the involvement because of signal intensity changes related to marrow edema and assessment of the extent of vertebral destruction is more accurately done by assessment from plain radiographs.

Radioisotope scans that are useful in pyogenic osteomyelitis are negative in one third of patients with tuberculosis. Gallium scans also are negative in the majority of patients, and their diagnostic value in tuberculosis is limited.

## DIAGNOSIS

A typical clinical picture of insidious onset of pain in the region of involvement, paraspinal muscle spasm with restriction of spinal movements, low-grade constitutional symptoms, and a typical radiologic picture of paradiscal type of involvement of adjacent vertebrae is considered sufficient evidence clinically to start specific antituberculous therapy in most endemic areas. Relative lymphocytosis with elevated erythrocyte sedimentation rate and a positive enzyme-linked immunosorbent assay (ELISA) test may contribute to the diagnosis, but is normal in many patients with good nutrition. The work-up must include a thorough clinical examination and tests to rule out extraskelatal involvement, which may be present in 15% of patients. In parts of the world where the incidence of tuberculosis is rare and whenever the diagnosis is in doubt, histologic confirmation by a CT-guided biopsy should be the procedure of choice. The material obtained by a thin needle routinely used for fine-needle aspiration

cytology (FNAC) is usually insufficient and the use of a thicker needle (e.g., the Jamshidi needle) is recommended. Aspiration of a paravertebral abscess also helps to establish a diagnosis, but the yield for culture from the pus is low.

Tuberculous infections have to be differentiated from pyogenic discitis and brucellosis. Pyogenic discitis has a more precipitous presentation with severe pain, high fever, and profound clinical symptoms. The organism can be isolated either by a blood culture or from needle aspiration material. Brucellosis also is common in geographic regions where tuberculosis is endemic. Undulating fever, less vertebral destruction, new bone formation (even in the active stage of the disease), marked sclerosis, and a positive serologic test for brucella antigen help to clinch the diagnosis.

Central types of lesions and pedicle involvement have to be differentiated from secondaries and myeloma in elderly patients and lymphoma and eosinophilic granuloma in young patients. The presence of paravertebral mass in MRI and a rim enhancement sign in CT scan point toward a tuberculous infection.

## TREATMENT

Modern antituberculosis drugs have made disease cure highly possible because of their ability to achieve adequate therapeutic concentration in caseous tissues and abscesses, and excellent results have been reported by conservative therapy alone (2,7,14–16). On the other hand, surgery has become safer, and has better outcomes when performed under chemotherapeutic cover, which has prompted new surgical approaches and procedures (17,18). The reasons advocated for surgery were earlier recovery owing to débridement of the disease focus, feasibility for correction of deformity, fusion with bone grafts, and the possibility of obtaining tissues for histologic confirmation. The conflicting claims prompted the international multicenter trials at the Medical Research Council, Great Britain. Their conclusions now form the basis of treatment in patients without neurologic deficit (Table 79-3) (7,14–18). Favorable status, defined as no residual neurologic impairment, sinuses, clinically evident abscess, or impairment of physical activities owing to the spinal lesion, and with radiologic quiescent disease was achieved equally by radical surgery and chemotherapy at 3 years; this was maintained at 10 years. The major advantage was that equal results could be achieved by chemotherapy in places where there was a dearth of surgical expertise, adequate anesthetic facilities, and a high postoperative standard. Also, perioperative mortality of about 4%, reported even in the hands of the originators of the surgery, could be avoided. The study in Madras, India, further proved that these results could be achieved even with short-course (9-month) chemotherapy (7,16). Ninety-eight percent of patients with chemotherapy

**TABLE 79-3. Conclusions of Medical Research Council trials**

---

Ambulant outpatient chemotherapy treatment is highly successful.  
 Daily addition of streptomycin is not necessary.  
 No extra benefit from rest in hospital.  
 No benefit from plaster jacket for first few months.  
 Débridement alone offers no advantage over ambulant chemotherapy.  
 Ambulant chemotherapy equals radical surgery in achieving of favorable status.  
 Radical surgery achieves favorable status quickly and has decreased tendency for progress in deformity.  
 Short-course chemotherapy with daily isoniazid and rifampicin for 9 months achieved higher rate (98%) of favorable status than radical surgery (88%) at 5 years.  
*Favorable status:* No residual neurologic impairment, sinuses, clinically evident abscess, or impairment of physical activities owing to the spinal lesion and with radiologically quiescent disease.  
*Inclusion criteria:* Patients with clinical and radiologic evidence of tuberculosis involving any vertebra from the first dorsal to the first sacrum and without neurologic involvement.  
*Exclusion criteria:* Presence of severe extraspinal disease, tuberculous or nontuberculous or with a previous history of antituberculous chemotherapy or surgical intervention.

---

Bony fusion and the severity of deformity were not considered in the criteria for favorable status.

achieved a favorable status, compared with only 88% with radical surgery. The rate of occurrence of bony union and the extent of deformity was identical in both groups. Achievement of solid bony fusion was considered as a desirable end of treatment because it was firm evidence for cure of the disease. Also, the chance for the further progress of the deformity was minimal. However, the increased risk for disease recurrence in the absence of bony union has not been borne out in long-term follow-up. The absence of bony union has been found to be a risk factor for increased deformity in children but not adults (7).

 Children who have partial or no fusion during adolescent growth spurt

---

The main shortcoming of the Medical Research Council (MRC) trials has been the exclusion of deformity severity as an assessment criterion for favorable status. Fifteen percent of patients treated by chemotherapy alone may end up with an unacceptable degree of deformity, and about 3% may have a deformity in excess of 60° (2,5,7,9,10). These patients would benefit from surgery, where the deformity can be corrected and solid anterior bony fusion can be achieved. It is appropriate to advocate surgery selectively to this group, because the expertise and infrastructure required for it are not freely available where tuberculosis is endemic. In patients without neurologic deficit, Tuli has proposed the "middle path" regimen, which takes advantage of the efficacy of modern antituberculous drugs and offers surgery only to the most needy (Table 79-4) (21). Here ambulant chemotherapy is advocated in all patients and surgery is advocated selectively when there is recurrence of disease, possibility of severe deformity, or onset of neurologic deficit (Table 79-5). This protocol not only helps to prevent unnecessary surgery in most patients with spinal tuberculosis, but also offers the benefits of the surgery when needed. We have followed this principle as a routine in our clinical practice; in patients without neurologic deficit, fewer than 15% require surgery.

**ANTITUBERCULOUS CHEMOTHERAPY**

It is imperative that the chemotherapy regimen consists of combination chemotherapy and lasts an adequate duration of time, so that cure is established and emergence of resistant strains is prevented. Two phases of chemotherapy are ideal in skeletal tuberculosis to increase the success rate and prevent the emergence of drug-resistant strains: an intensive phase, consisting of chemotherapy with three or four drugs, followed by a continuation phase consisting two drugs.

The current recommendation for the treatment of adults, with or without HIV infection, is 300 mg of isoniazid (INH) per day, 600 mg of rifampicin per day, and 20 to 30 mg/kg of body weight per day of pyrazinamide. In this intensive phase, which is carried on for 2 months, ethambutol (or streptomycin for children, who are too young to be monitored for visual acuity) should be included when: (a) the severity of the lesion is extensive and there are complicating factors such as neurologic

involvement; (b) the patient population has a high primary resistance to INH; and (c) there is a suspicion of drug resistance. After the 2-month intensive phase with either the three- or four-drug regimen, a continuation phase with INH and rifampicin can be continued for 9 to 12 months.

### SURGERY FOR SPINAL TUBERCULOSIS

Although chemotherapy forms the mainstay of treatment, a surgical procedure may be indicated in the following situations:

1. To obtain material for establishing diagnosis in doubtful situations
2. To drain an abscess cavity around the spine or pelvis
3. To radically débride the entire focus and perform an anterior arthrodesis with bone grafts.
4. In addition to anterior arthrodesis, to also perform a posterior fusion with or without instrumentation, either primarily or as a second stage to obtain global fusion

Computed tomography-guided biopsy and percutaneous transpedicular biopsy procedures have made indications for open biopsy rare. Similarly, abscesses (however large) clear adequately with chemotherapy; surgical intervention is required only in rare circumstances. Other than retropharyngeal abscesses, which can present as clinical emergencies with dysphagia and dyspnea, even large abscesses in other regions usually are asymptomatic and rarely require intervention. When indicated, drainage

**TABLE 79-6.** Factors leading to poor outcome after surgery

Poor nutritional status
Surgery performed without chemotherapeutic cover
Vertebral body loss of >2

Marked preoperative kyphosis
Use of grafts spanning more than two disc spaces
Spinal instability with radiological "spine at risk" signs

must be performed under the cover of antituberculous drugs and the wound must be carefully closed in layers.

Surgical procedures for obtaining disease clearance must involve complete débridement of focus and reconstruction of anterior defect with suitable bone grafts, with protection of the grafts by instrumentation whenever necessary. Débridement of the disease focus alone without addition of bone grafts gives poor results and does not add an advantage to the chemotherapy regimen. In performing a radical surgery procedure, it is important not to remove the entire bones that have been affected and to limit the débridement when the margins of the healthy bones are reached. Plain radiographs allow a better judgment of the extent of involvement than MRI. Magnetic resonance imaging studies show an exaggerated picture of bone involvement because of signal intensity changes in the marrow and may unnecessarily lead to a overly extensive débridement. Excessive removal of bone increases the deficit of the anterior column, and this leads to a high incidence of graft failure (7,20). Four types of

**FIG. 79-14.** Lumbar lesion in an adult with complete destruction of the fourth lumbar and partial involvement of the adjacent vertebrae. Fusion has been achieved with good incorporation of the tricortical iliac graft with posterior instrumentation performed in a single stage.

graft failures have been observed when the graft length exceeds two disc spaces: dislodgement, fracture, absorption, and subsidence, of which graft dislodgement is the most common (Table 79-6). Complications related to grafts are more common in the dorsal and dorsolumbar regions, and patients with one or more unfavorable factors benefit from additional posterior instrumentation and fusion, either as a single or second stage following anterior fusion (Fig. 79-14).

Spinal implants can be used safely in the presence of active tuberculous infections (21,22). Persistence of bio-material-centered infections is caused by preferential bacterial colonization of the inert surfaces and production of a biofilm (glycocalyx), which protects them from the host defenses and chemotherapeutic agents. *Mycobacterium tuberculosis* is less adhesive and produces less biofilm than other bacteria; implants and titanium cages can be used safely to achieve good results (23).

### TREATMENT IN PRESENCE OF NEUROLOGIC DEFICIT

All patients with neurologic complications warrant a thorough clinical and radiologic evaluation; the presence or absence of active infection influences patient management.

Paraplegia of active disease is caused by compression by inflammatory material and most patients respond to conservative therapy with rest and antituberculous drugs. Conservative regimen can be used confidently, especially in less privileged countries where adequate facilities for radical surgical treatment may not be available (24,25). Surgical decompression has been advocated because it may provide an earlier and higher rate of recovery, quick improvement in general condition, the reduction of deformity, and anterior spine fusion (26). Tuli has advocated a policy of selective surgical management where patients are treated with chemotherapy, bed rest, and surgery performed only for specific indications (2). Only less than 20% require surgical intervention; the remaining show good improvement with chemotherapy alone.

Surgical technique in the presence of active disease must involve complete decompression of the dura in the entire region of apex of the kyphosis and include bone-grafting procedures to prevent a collapse. Laminectomy as an isolated procedure has no role except in a rare patient in whom the lesion is confined to posterior structures and in patients with spinal tumor syndrome. The posterior approach is not an ideal route to decompress a lesion that lies anteriorly; laminectomy can completely destabilize the spine, resulting in rapid deterioration. Costotransversectomy is useful and safer in patients with very severe kyphosis and in centers where there is a lack of expertise to perform radical surgery. Paraplegia in healed disease is a much more difficult therapeutic problem and requires decompression of the spinal cord that is

stretched over the internal gibbus. Anterior decompression with removal of the internal gibbus is the treatment of choice, but it is a technically difficult surgery and the outcome is less satisfactory in comparison to those obtained in paraplegia with active disease (13).

# Postoperative Lumbar Spine Infections

Eric C. Chamberlin and Edward N. Hanley Jr.

---

Despite continuing advances in medicine and surgery, there remains a quantifiable risk of infection in lumbar spine surgery. Since the advent of antibiotics and the use of aseptic technique, there have been continuing improvements in the prevention of perioperative infection. However, coincident with improvement in prophylaxis came increases in surgical complexity and operative times, which may have served to mitigate the positive effects of these improvements. Postsurgical infection, although relatively infrequent, can be a major cause of morbidity in the patient undergoing lumbar spine surgery.

### INCIDENCE

Multiple studies have addressed the incidence of infection after spine surgery, with reported values between 0% and 11.3% depending on the study and procedure performed (1–16). Reported infection rates are approximately 2% in uninstrumented fusions and 7% for instrumented spinal fusions. As might be expected, the lowest incidence of infection has been reported in isolated disc excision surgery at less than 1%. Weinstein et al. published a .86% incidence of infection in simple discectomy procedures in their 9-year experience with 2,391 spinal operations (2).

The incidence of infection tends to increase as the complexity of the procedure and operative time increase. Massie et al. found a 1.3% incidence of infection in 376 noninstrumented spine fusions and 6.6% in 258 instrumented fusions (3). Multiple other studies have supported their conclusions. Spinal fusion without instrumentation has a reported risk of .4% to 5% (2,3). Instrumented fusions increase the incidence to .06 to 11.9%, depending on the study (1–10,12–16). Many risk factors have been identified that increase the incidence of infection.

### ETIOLOGY: PATIENT AND SURGICAL FACTORS

#### Patient

Multiple risk factors have been established that tend to increase the potential for infection in spine surgery patients. Factors such as diabetes mellitus, obesity, malnutrition, smoking, previous or ongoing metachronous infection, rheumatoid arthritis, and iatrogenic or other states of immunodeficiency all have been implicated as predisposing to infection (2,4,11,12,17–22).

Diabetes is associated with an increased incidence of infective complications with many types of surgery. Wimmer et al. reported an increased incidence of infection in patients with diabetes in a retrospective review of 850 spine surgery cases (11). This may result from the cardiovascular, peripheral vascular, renal, and immune effects of the disease as well as the altered glucose metabolism.

Obesity has been shown to increase the incidence of postoperative complications including infection (11). Karduan found that the complication rate correlated with obesity in a study of patients undergoing discectomy (23). However, other articles call obesity into doubt as an independent risk factor. Andreshak found in a prospective study of 159 patients, 55 of whom were obese, no difference in infection rates between groups. The discrepancy in the literature in part may result from differing definitions of obesity. In general, the preponderance of the literature suggests a connection between infection and obesity in those patients with morbid obesity (23,24).

The nutritional state of the patient has been shown to be crucial to the ability to heal wounds and resist infection (19,21). Klein found a strong correlation between nutrition and postoperative infection with 10 of 13 malnourished patients in a group of 114 becoming infected. Nutrition is important in both the presurgical and post-surgical period because of the catabolic state caused by

the surgery and the usual poor caloric intake associated with the perioperative period. Several markers of nutritional fitness have been suggested for use in patient evaluation. Total lymphocyte count of less than 1,500, albumin of less than 3.4, and weight loss of more than 10 pounds are all useful markers of malnutrition and can be used both preoperatively and postoperatively to monitor and optimize patient caloric intake (25).

Smoking has been shown to increase the incidence of infection as well as decrease fusion rates (26,27). Thal-gott found 90% of patients with wound infection following spine fusion to be smokers. These patients also showed an increase in incidence of myonecrosis within the infected wound (27).

### Surgery

Efforts to control the surgical factors that contribute to the incidence of infection have been continuously studied and implemented since the time of Lister. Although clouds of carbolic acid have given way to monitored air exchange, the operative environment, operative team, and patients themselves are common sources of the offending organisms. The incidence of infection increases with longer duration operations and increased operating room traffic (2,11). Both of these factors provide opportunities for wound contamination. They also allow a greater likelihood of shedding of organisms both from the patient and staff (28).

Increasing the number of operative personnel and traffic in the room significantly increases the bacterial colony counts in the operating room (29,30). Efforts should be made to eliminate excess traffic in the room, as often is done in arthroplasty procedures. Laminar flow with an air exchange rate of at least 25 times an hour has been shown to reduce colony counts in the operating room (31).

Studies have shown that over time, the skin recolonizes after surgical preparation. The source of the recolonization appears to be the hair follicles. Some have advocated re-prepping patients periodically during long cases. Zdeblick et al. reported povidone-iodine scrub and paint inferior to paint alone in decreasing bacterial counts. There were no infections in either group in their study. Night before surgery showers with hexachlorophene also decreased bacterial colony counts (32). Others have stressed the importance of shaving the patient in the immediate preoperative period. Shaving the night before surgery has been implicated in an increased incidence of infection (29).

As stated, there is an increased incidence of infection in instrumented fusions versus noninstrumented fusions. The reason for this association is most likely multifactorial. Length of procedure has been shown to be an independent influence on infection, and in general is increased with instrumentation placement. The other

important consideration is the implant itself. Instrumentation is a good medium for bacterial adherence, decreasing the host's ability to clear colonized bacteria and prevent infection. Chang stated that instrumentation acts as a nidus for bacteria, which secrete a glycocalyx. The glycocalyx serves to allow more effective colonization and protects the bacteria from the effects of antibiotics (33).

Another key advance in the decreased incidence of infection is the use of preoperative antibiotics. Although there is no universal standard regimen, studies suggest that antibiotics dosed one half to 2 hours before skin incision decrease the incidence of infection (34). The most common antibiotic used is a first-generation cephalosporin such as cephalexin. Cephalexin is excellent against gram-positive organisms and has good activity against *Escherichia coli* and *Proteus* species. Cephalexin also has the longest half-life of the first-generation cephalosporins in serum and bone. The one area that may have decreased concentrations of cephalexin is the nucleus pulposus, whose high concentration of positively charged glycosaminoglycans repels the positively charged cefazolin (35).

Boscardin tested the efficacy of cefazolin for prophylaxis of postoperative discitis. In 40 patients, serum and intradiscal samples were taken at intervals. They found that cefazolin does enter the disc and is at optimum level 15 to 80 minutes following a 2-gram dose (36).

Because of the relative frequency of gram-negative infections reported with lumbar spine surgery, some authors recommend adding gentamicin or another gram-negative effective antibiotic. Gentamicin also is negatively charged and may have better penetration of the nucleus pulposus for reasons stated previously (35). Dimick, in a review of antimicrobial prophylaxis, concluded that cefazolin should be dosed within 30 minutes of incision, redosed for blood loss greater than 1,500 cc or for duration of greater than 4 hours, and not given for more than 24 hours postoperatively. Dimick suggested the need for randomized controlled trials before adding other agents such as gentamicin to the standard prophylaxis (35).

### Microbiology

Most studies show a preponderance of gram-positive (primarily staphylococcus skin flora) organisms in spine surgery perioperative infections (2,9,35). However, Massie et al. found a significant number of gram-negative and -positive organisms in their study population. Enterobacter, serratia, pseudomonas, Acinetobacter, bacteroides, and clostridium represented the gram-negative organisms. Other gram-positive organisms were enterococcus faecalis, strep viridans and epidermidis, diphtheroids, propionibacter, Peptococcus, and Peptostreptococcus. A large number of the infections were polymicrobial, which may have been due to the postoperative regimen of body casts and long hospital stays (3).

Rechtine reported in a study of 12 infections associated with instrumented fusions for spine fractures, nine deep, and three superficial infections. Two were gram-positive only infections. Both of these were superficial infections. Three were gram-negative only infections and seven were multiple organisms. All of the deep infections were either gram-negative or multiple organisms (4).

Brook and Frazier found a large number of different organisms on aspiration of spine wound infections. They found 36% aerobic, 16% anaerobic, and 48% mixed flora. Predominant aerobes included *E. coli* and proteus species; anaerobes included *Bacteroides*, and *Peptostreptococcus*. They found increased *bacteroides* and *E. coli* infections in incontinent patients (37).

The reason for the relatively high incidence of polymicrobial and gram-negative infections reported in lumbar spine surgery is not known. Perry found a high incidence of gram-negative aerobic bacilli in patients undergoing procedures to the sacrum and in those with urinary incontinence (12). Some possible explanations include the common use of only a first-generation cephalosporin for prophylaxis, and the proximity of the incision to the perineum.

## Diagnostic Work-up

### Presentation

Superficial infections (located beneath the dermis and subcutaneous tissues and above the fascia) present most often with tenderness and local erythema, drainage, and fluctuance. Deep infections (deep to the fascia) often are more difficult to diagnose because of a lack of findings typical of infection. Patients may experience a deep back or radicular-type pain and malaise, and usually are febrile (3). Weinstein noted only 14 of 46 patients had pyrexia at presentation for infection (2). A high index of suspicion must be maintained, especially in patients with unexplained fevers. Because of the effects of pus under pressure and often a delay in diagnosis, these infections are characterized by a greater degree of tissue necrosis, and patients are more likely to be systemically affected.

Blood laboratory studies are the first step in the work-up of patient suspected of having a postoperative infection. The white blood cell count may or may not be elevated early in the infection. A left shift in the differential is often present. The primary markers of infection are the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Studies have clearly delineated the timing of rise and fall of these blood markers (38–40). Thelander found that the CRP peaks at 2- to 3 days following spine surgery and returns to normal at 5 to 14 days. The ESR peaks at 5 to 7 days and returns to normal at around 21 to 42 days (39). A peak outside of these parameters is suggestive of infection. Meyer found that with serial testing to day 5 following disc surgery, CRP was the most sensitive and specific marker (Table 80-1).

**TABLE 80-1.** Comparison of c-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and complete blood count (CBC) as markers of infection

	Sensitivity	Specificity
CRP	100%	95.8%
ESR	78.1%	38.1%
CBC	21.4%	76.8%

Adapted from Meyer B, Schaller K, Rohde V, et al. The C-reactive protein for detection of early infections after lumbar microdiscectomy. *Acta Neurochirurgica* 1995;136(3–4):145–150, with permission.

Sterile aspiration is advocated in patients with suspected deep infection (febrile, increased WBC with shift and a benign-appearing wound). Vigilant and aggressive monitoring of the postoperative spine patient can prevent unnecessary delay in diagnosis of infection.

The principal imaging diagnostic tool for postoperative infection of the lumbar spine is MRI. Magnetic resonance imaging finds fluid collections and bone and tissue edema as increased signal intensity on T2-weighted images. Because of the ability of MRI to precisely localize an abscess, it may be superior to aspiration for the evaluation of the patient suspected of having a postoperative abscess (41).

### Treatment

The primary treatment for a postoperative wound infection in the lumbar spine is surgical drainage of purulent material and complete débridement of all necrotic and grossly infected tissues (42). The débridement should progress systematically from superficial to deep by lay-

**FIG. 80-1.** Antero-posterior radiographs of a 54-year-old woman with back pain and neurogenic claudication. She had previously undergone decompressive surgery at L4-5 and L5-S1 and suffered from chronic renal failure caused by glomerulosclerosis.

**FIG. 80-2.** Lateral radiographs of a 54-year-old woman with back pain and neurogenic claudication. She had previously undergone decompressive surgery at L4-5 and L5-S1 and suffered from chronic renal failure caused by glomerulosclerosis.

ers. A sequential progression of the débridement helps to avoid infecting potentially unaffected lower levels (3,31).

The literature is inconclusive as to the optimal treatment of infected implants. Bone graft may be left in place if not grossly contaminated and, in general, removal of implants that would lead to an unstable spine may be delayed until fusion has occurred (2). Often more than one operation may be necessary to eradicate the infection. The instrumentation should be removed in a late infection in which fusion has occurred.

**FIG. 80-3.** Antero-posterior lumbar spine following repeat decompression and instrumented fusion surgery.

Broad-spectrum antibiotics should be started once intraoperative cultures have been obtained. The antibiotic coverage is then narrowed according to the culture and sensitivity results.

In general, wounds can be closed over closed suction drainage (31). Dernbach treated 10 patients with postoperative deep infections with I&D, antibiotics, and closure over large suction drains; all healed (43). However, in some cases the loss of soft tissue or the severity of infection may dictate leaving the wound open and either packing it open or placing a wound vacuum (Figs. 80-1 through 80-4). Weinstein obtained primary closure in

A

B

C

**FIG. 80-4.** **A:** Deep wound infection after débridement at beginning of subatmospheric wound vacuum dressing treatment. **B:** After 4 days. **C:** After 22 days.

only seven of 22 infections; all others underwent delayed closure (2).

Multiple studies have shown the efficacy of vacuum wound coverage (44–46). Argenta noted that subatmospheric pressure treatment removes chronic edema, leading to increased localized blood flow and resulting in an increased rate of granulation tissue formation (44). Fortunately, the muscle and soft-tissue envelope is substantial around back wounds, allowing many options for local flap coverage of defects (47–49).

## OUTCOMES AND SEQUELAE OF LUMBAR SPINE INFECTIONS

Postoperative lumbar spine infections are an infrequent, but important, source of morbidity and mortality. These infections also have further ramifications for the health care system. Capen et al. estimate that an infection increases the cost of treatment more than four times. The average cost of a postoperative infection of the lumbar spine in their study was over \$100,000. Five of 11 patients with infections went on to pseudarthrosis, and only 20% returned to work (50).

Weiss et al. studied the incidence of pseudarthrosis after postoperative wound infection in the lumbar spine. After successful débridement, 62.1% had successful arthrodesis. They found that female sex, allograft use, and extension of the fusion to the sacrum increase the rate of pseudarthrosis following postoperative infection of the lumbar spine (51).

In a direct comparison of 11 patients with low back fusion complicated by infection versus 15 patients with fusion and without infection, Calderone found a clear difference in fusion rates, but uniformly poor return rates and poor ratings of quality of life. These results are tempered by the fact that these were workers' compensation cases, but still suggest poor outcomes with infection and reinforce the finding of decreased fusion rates found in other studies (52).

## CONCLUSION

Postoperative lumbar spine infections are detrimental to the patient as well as the medical system as a whole. A quantifiable incidence of infection remains despite advances in technique and prophylaxis. In order to decrease the morbidity associated with these complications, a high degree of suspicion must be maintained by the spine surgeon during the postoperative period. Prompt diagnosis followed by meticulous and aggressive débridement as well as appropriate antibiotics are essential to eradicate the infection and prevent further damage. The infection and soft-tissue wound can in most cases be controlled; despite this, there remains an increase in the rate of pseudarthrosis and functional impairment.

## CHAPTER 81

# Primary Spine Tumors

Edward D. Simmons and Yinggang Zheng

---

Spine tumors are clinically classified into three categories: primary benign tumor, primary malignant tumor, and metastatic tumor. The treatment of spine neoplasm represents a challenge to spine care professionals. Surgery plays a major role in the selected patients with spinal tumors. To avoid disastrous complications, the existing and potential neurologic involvement must be considered. Besides the histologic nature of tumors, the anatomic complexity of spinal structure and failure to obtain en block resection of the involved spinal segment make the surgical treatment much more difficult. Fortunately, the incidence of new cases of primary malignant bone tumor is low compared with other tumors. In the United States, approximately 2,000 malignant bone tumors out of 7,000 new sarcomas are diagnosed each year. Four percent to 20% of bone tumors are spinal tumors, constituting 80 to 400 tumors (1–3).

Metastatic tumors are both the most frequent tumor of bone and the spinal column, regardless of origin of primary tumor. Cancer is the second leading cause of death in the United States, accounting for 21% of all deaths in 1981 and 25% in 1985 (4,5). Breast cancer alone strikes approximately one in nine women worldwide. There are more than one million women in the United States presently living with metastases of breast cancer (4). Each year 494,000 patients die of cancer. It is estimated that 24,700 new cases of metastatic spinal cord diseases will be diagnosed per year (3,6). It has been demonstrated that 30% to 70% of patients who die from cancer have evidence of vertebral metastases that are visible on careful postmortem examination (7,8). This number could reach 85% in women with breast cancer (9–11); however, only less than 10% of patients with spinal instability require surgical treatment, accounting for approximately 18,000 new cases yearly (12–15). Patient survival after diagnosis of malignant neoplasm has improved dramatically over the past decade concomitant with advances in chemotherapy, immunotherapy, hormonal manipulation,

radiotherapy, surgical intervention, or a combination of these modalities (4,5,14,16).

### SPINE TUMORS CLASSIFICATION

In addition to metastatic diseases to the spine, primary spine tumors are from different tissues of origin. There is no universally accepted classification of primary spine tumors. Schimidek and Schiller proposed the classification summarized in Table 81-1 (17).

### AGE

Age is an important factor when considering a differential diagnosis of bone tumors. A specific tumor has a peak incidence in a range of age (18,19). Dahlin, in a series of 8,542 bone tumors, reported 60% of benign spinal tumors occurred in the second or third decades of life (20). Tumors of the sacrum in children are more likely to be malignant (21). Benign (e.g., osteoid osteoma, osteoblastoma, and eosinophilic granuloma) and malignant tumors (e.g., osteosarcoma and Ewing sarcoma) are commonly seen in the 10- to 30-year-old age group; whereas multiple myeloma, chordoma, and chondrosarcoma are common in the 40- to 60-year-old age group. For patients aged between these two periods, other neoplasms are commonly diagnosed. They include giant cell tumor, enchondroma, lymphoma, and fibrosarcoma. There are more metastatic diseases in patients more than 60 years old. However, suspicion of metastatic tumors for spinal lesion following malignant tumor should be aroused for patients of any age (18,19,22,23).

### LOCATION

The location of neoplasm lesion within the vertebra is significantly correlated with the type of tumor, symptoms, neurologic deficit, and the choice of surgical regimens.

**TABLE 81-1.** *Classification of primary tumors of the osseous spine*

Tissue of origin	Benign tumors	Malignant tumors
Fibrous tissue	Fibroma	Fibrosarcoma
Cartilage	Fibrous dysplasia	Malignant fibrous histiocytoma
	Chondroblastoma	Chondrosarcoma
	Osteochondroma	
	Enchondroma	
Bone	Chondromyxoid fibroma	
	Osteoid osteoma	Osteosarcoma
	Osteoblastoma	Osteosarcoma associated with Paget disease and previous radiation
Hematopoietic elements		Multiple myeloma, Solitary plasmacytoma
Fate cell	Lipoma	Lymphoma
Vascular system	Hemangioma	Liposarcoma
		Angiosarcoma
Blood vessels		Hemangiopericytoma
Lymphatics	Lymphangioma	Lymphangiosarcoma
Nerve	Schwannoma (neurilemmoma)	Malignant nerve sheath tumor
	Neurofibromatosis	
	Pigmented nerve sheath tumors	
	Ganglioneuroma	
Notochord		Chordoma
Unknown	Eosinophilic granuloma	Giant cell tumor
	Aneurysmal bone cyst	Ewing sarcoma

Source: Adapted from Schimidek HH, Schiller AL. Premalignant lesions of the osseous spine and classification of primary tumors. In: Sundaresan N, Schimidek HH, Schiller AL, et al., eds. *Tumors of the spine: diagnosis and clinical management*. Philadelphia: WB Saunders, 1990:3–5, with permission.

Spine tumors occur more commonly in the thoracic, lumbar, and sacral areas than in the cervical area, and are more prevalent in the vertebral body than in posterior elements. Giant cell tumors, aneurysmal bone cysts, and eosinophilic granulomas occur more frequently in the thoracic spine than the lumbar vertebral bodies (24).

Among benign tumors, eosinophilic granuloma and hemangioma have a tendency to occur in the anterior vertebral body rather than the posterior elements, whereas osteoid osteomas and osteoblastomas almost always involve the posterior elements of the vertebra. However, aneurysmal bone cysts and giant cell tumors may affect either the vertebral body or posterior elements. Of malignant neoplasms, multiple myeloma, solitary plasmacytoma, lymphoma, chondrosarcoma, chordoma, Ewing sarcoma, and metastases are more commonly seen in the anterior column, but osteosarcomas occur either anteriorly or posteriorly (25,26).

The majority of metastases affect the vertebral body, compared with only 14% of metastases involved in posterior elements. The common portion of vertebra initially affected is the pedicle (18,27). Seventy-five percent of vertebral metastases originate from carcinoma of the breast, prostate, kidney, thyroid, or lymphoma and myeloma. Carcinomas originating from different organs spread to different spine areas because of the anatomic character of the venous system. Carcinomas of the breast or lung most commonly metastasize to the thoracic spine,

whereas prostatic carcinomas usually affect the lumbar spine, sacrum, and pelvis (28,29).

Location of a neoplasm within the vertebra is also related to symptoms and neurologic deficits. Neoplasm in the cervical and lumbar levels often causes radicular pain, whereas in the thoracic area it causes more cord compression because of the smaller vertebral canal. Lesions within vertebral bodies grow posteriorly and encroach on the anterior column of the spinal cord, causing motor function loss first. Conversely, lesions from posterior elements encroach on the spinal cord, causing sensory function loss as the initial neurologic deficit.

## PRIMARY AND METASTATIC TUMORS

### Clinical Presentation

Patients with spinal tumors commonly present with pain, spinal deformity, and neurologic deficit; and uncommonly with a palpable local mass as well. Systemic symptoms may be present in malignant lesions.

Back pain is the most common symptom (24). It may result from neurologic or mechanical compression, or the tumor itself. Pain caused by tumor is sometimes confused with pain from minimal trauma or degenerative low back pain. Pain with stiffness is often persistent, gradually worsening, and unrelieved by rest. Night pain is another symptom of certain skeletal neoplasms (e.g., osteoid

osteoma and osteoblastoma) in that pain can be relieved by aspirin. If the tumor is involved in neural structures, there is radicular pain with or without numbness, mimicking the radiculopathy of lumbar intervertebral disc herniation (30). If this happens in teenagers, suspicion of neoplasm should be aroused.

Pain with metastatic disease usually is more severe. Most metastatic tumors to the thoracic or lumbar spine involve the anterior and middle columns. Following expansion of the tumor, pathologic fracture of vertebral body can occur and cause severe acute pain similar to that seen in traumatic vertebral compression fractures. However, the former usually results from minimal or no obvious trauma. Approximately 85% of metastases causing spinal instability and neurologic compromise arise anteriorly from the vertebral body (31–33). Spinal nerve and cord compression owing to pathologic fracture or invasion of neoplasm results in local pain, radicular pain along the affected nerve roots, and myelopathy (34). In addition, it should be kept in mind that metastases frequently are asymptomatic initially. Tumors themselves often are discovered incidentally (35).

Spinal deformity such as scoliosis is also commonly seen in certain spinal tumor patients (36,37), and may be caused by primary benign tumor, malignant tumor, or metastatic disease. Benign tumors such as osteoid osteoma or osteoblastoma are often associated with scoliosis, typically presenting with paraspinal muscle spasm and stiffness. Different from adolescent idiopathic scoliosis, this type of scoliosis presents with pain, rapid progression of curve, and rigidity. Structurally, there is absence of both vertebral rotation and wedging, which usually are present in adolescent idiopathic scoliosis (25). Deformity in patients with a malignant tumor, such as spinal neuroblastoma, may result from the involvement of the spine or spinal cord (38). The etiology of spinal deformity in patients with neuroblastoma may have intrinsic causes such as involvement of the axial skeleton with the tumor or neurologic deficits from spinal nerve or cord compression (38,39). The extrinsic causes may be the treatment itself and the sequelae of asymmetric irradiation of the spine, especially in children; soft-tissue fibrosis and contracture; laminectomy; and paraplegia secondary to epidural spread of tumor. Destruction of vertebral body in metastatic tumor results in compression fracture, associated with deformity and paraspinal muscular spasm, but the kyphosis is seldom dramatic enough to warrant much notice or be the presenting complaint (24).

Benign or malignant lesions or the neurologic compromise of the spinal cord or nerve root may occur after the progression of a spinal tumor. Malignant tumors present more neurologic deficits than benign tumors because of their invasive nature. Major causes of neurologic deficits are the direct encroachment of a tumor on spinal nerve roots or the spinal cord, or pathologic fracture secondary

to destruction of vertebral body. When the nerve root is compressed, the patient presents with local back pain, radicular pain, and paresthesias that are commonly seen in lesions involving the cervical and lumbar spine. When such symptoms are persistent, thorough investigation for spinal neoplasm should be considered. Furthermore, spinal cord compromise results in more severe clinical symptoms and signs. Depending on the level of the lesion, patients may present with increasing extremity weakness, sensory disturbance, and sphincter dysfunction of bowel and bladder. Compression of the neoplasm may occur on the cervical or thoracic spinal cord, conus, and cauda equina causing varied neurologic deficits. A mixed neurologic picture may occur, particularly when metastatic lesions are present at multiple levels (40). Compression on the cervical spinal cord can cause quadriplegia, whereas neoplasm of the thoracolumbar spine can result in leg weakness, spasticity, difficult ambulation, sensory loss along the affected dermatomes, or paraplegia below the level of the lesion (41).

Although spinal tumor seldom presents with a mass as the initial finding, a local palpable mass or systemic symptoms for patients with spine tumor may be present. Tumor mass in the cranial or caudal regions of the spine is more likely to be found than in the thoracic or lumbar areas. Sacral tumors, such as chondrosarcoma or chordoma, following the growth of an anterior mass, may cause bowel or bladder symptoms and be palpable on rectal examination (24,25). Systemic symptoms usually are present in malignant lesions, especially with round cell tumors such as lymphoma and myeloma, Ewing sarcoma, and metastatic diseases. With the progression of lesions, patients present with weight loss, fever, fatigue, and general deterioration.

### Imaging Studies

A correct diagnosis of spinal tumor depends on the teamwork of clinician, radiologist, and pathologist. Diagnosis of spinal tumor includes plain radiograph, bone scan, computed tomography (CT), magnetic resonance imaging (MRI), angiography, and biopsy. Other modalities may include single photon emission computed tomography (SPECT) bone scanning (42), positron emission tomography (PET) scan, or laboratory work-up.

### Plain Radiograph

Roentgenology is the primary investigation for patients with suspicious spinal neoplasms. Antero-posterior (AP) and lateral radiographs are most commonly used. An open mouth AP view is necessary to evaluate the odontoid. The upper thoracic levels are difficult to see on the lateral view; therefore, an augmented tomography is helpful in highly suspicious cases. Specific radiographic appearance is often suggestive of different neoplasms.

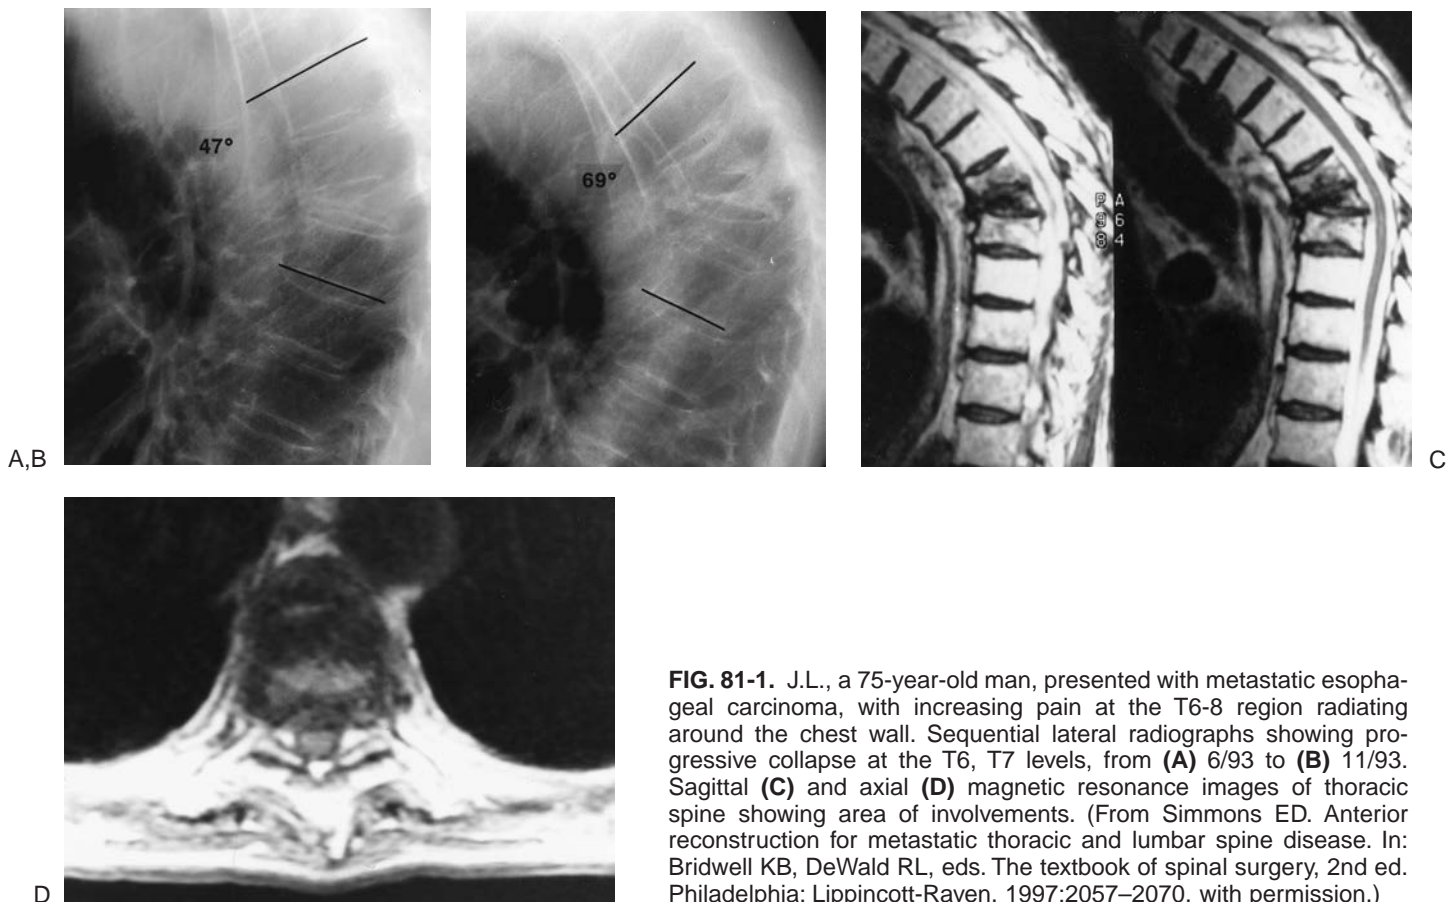

Benign and malignant tumors have different radiographic characteristics. The major radiographic appearance of neoplasm in the vertebra is osteoblastic or sclerotic, osteolytic, or mixed. The location of lesion within the vertebra, presence of calcification, and extent of mass are the important clues for diagnosis (41). According to the progression of tumor showing on radiograph, slow-growing and expanding tumors are often benign and have a better prognosis, whereas aggressive lesions usually are malignant with deterioration of general condition in a short time. As commonly seen, benign tumors, osteoid osteomas, and osteblastomas are frequently seen as sclerotic lesions in the posterior elements of the spine, with a central lytic area surrounded by reactive bone (26,43). These sclerotic lesions in the pedicles differ from the osteolytic changes of metastases (43). Certain metastases, such as prostate and breast cancer, can also show osteoblastic changes within vertebral bodies.

Lytic destruction of pedicle, contour changes of the vertebral body, sparing of the intervertebral disc, and soft-tissue invasion are the characteristics of primary malignant tumors and metastatic disease. The “winkle owl” sign seen on an AP radiograph for a destroyed pedicle is the most classic early sign of vertebral involvement, usually by malignant lesions, although the vertebral body typically is affected first. Thirty percent to 50% of the

vertebral body must be destroyed before osteolytic changes can be recognized radiographically. In contrast, minimum lysis of pedicular bone can be involved early; the pedicle can be seen well in cross section on an AP radiograph (29,44–46). Destruction of cortex and bone trabeculae by tumor results in contour change of the vertebral body, with localized kyphosis (Fig. 81-1). A pathologic compression fracture, which could happen in multiple levels, needs to be differentiated from an osteoporotic compression fracture. Bowing or “fish mouting” at multiple end plates is suggestive of diffuse osteopenia, which may be secondary to multiple myeloma (40). Usually there is no lytic change of pedicle in osteoporotic vertebra. The intervertebral disc is usually preserved in patients with neoplasms, which is different from pyogenic infection in that the disc is frequently destroyed along with the adjacent vertebral body (13). Furthermore, the soft-tissue shadow on a radiograph from extension of a vertebral body lesion is also an important sign of malignancy.

#### Bone Scan

Bone scans, using technetium-99m ( $^{99m}\text{Tc}$ ) labeled phosphate compounds, are widely used in the initial diagnosis and follow-up of bone tumors. Technetium scans

**FIG. 81-1.** J.L., a 75-year-old man, presented with metastatic esophageal carcinoma, with increasing pain at the T6-8 region radiating around the chest wall. Sequential lateral radiographs showing progressive collapse at the T6, T7 levels, from (A) 6/93 to (B) 11/93. Sagittal (C) and axial (D) magnetic resonance images of thoracic spine showing area of involvements. (From Simmons ED. Anterior reconstruction for metastatic thoracic and lumbar spine disease. In: Bridwell KB, DeWald RL, eds. The textbook of spinal surgery, 2nd ed. Philadelphia: Lippincott-Raven, 1997;2057–2070, with permission.)

are extremely sensitive to any area of increased osteoid reaction of the host to destructive processes within bone, and can detect lesions as small as 2 mm (19). They can detect as little as a 5% to 15% alteration in local bone turnover; whereas a minimum size of 1 cm and a 50% decrease in bone density are required for plain radiographs to detect a lytic lesion, and a 30% increase in bone density is required to detect sclerotic lesions. Radionuclide bone imaging is thus 50% to 80% more sensitive in detecting early skeletal metastases (47,48), and may predate radiographic changes of osteolytic or osteoblastic disease by 2 to 18 months (40–51). Total body scans can demonstrate all of the skeletal lesions, thus they are usually used: (a) as screening tests, (b) to determine whether a lesion is solitary or multifocal in expression, and (c) the local extent (47,48,52).

A high-quality radiograph should be obtained of any region where there is increased radionuclide uptake. Patients with a single or few areas of increased uptake and normal radiographs should have CT scans of these areas (10,53). Using this technique, the false-positive incidence is extremely small. Processes of new bone formation (e.g., fracture healing, infection, inflammation, and degenerative arthritis) may produce “hot spots”—focal areas of increased isotope uptake—whereas neoplastic processes that produce intense bone destruction without concomitant new bone deposition (e.g., solitary plasmacytoma, multiple myeloma, or lung carcinoma) may produce “cold spots,” or negative bone scans (47). Because the uptake of a bone-seeking radionuclide is nonspecific, a bone scan cannot be used to differentiate between benign and malignant lesions. However, when a scan is strongly positive in multiple skeletal sites, metastatic disease should be suspected, even if the primary lesion is unknown (41).

### ***Computed Tomography and Myelography***

Once the area of disease is identified by plain radiographs or bone scan, further imaging with either CT or MRI should be undertaken to fully define the extent and nature of the lesion (25,54). Computed tomography, with its excellent resolution of bone anatomy, has been used to delineate small areas of bone destruction and the nature of fragments within the canal in pathologic fracture (55). Tumor margins in bone can be clearly seen with CT, because MRI gives relatively poor images on cortical bone. Computed tomography also can help to identify soft-tissue features of lesions that are not apparent on plain radiographs (56). The emergence of spiral CT allows quick performance of thin axial sections (1 to 1.5 mm), and improved computer software allows rapid reformatting into the appropriate plane (57).

Myelography is frequently applied in the past to find out spinal canal compression. Magnetic resonance imaging is now more widely used for this purpose because it

is noninvasive. The combination of CT and myelography (myelo-CT) delineates the intrathecal structure on axial view; therefore, any encroachment on the spinal cord can be demonstrated. Myelography or myelo-CT now is used for the imaging study of patients with recurrent disease, especially those with stainless steel implants, because MRI cannot be applied owing to the artifact from this implant.

### ***Magnetic Resonance Imaging***

Magnetic resonance imaging has the advantage of producing excellent imaging in soft tissues and the axial skeleton. With its superior soft-tissue and tumor contrast, MRI can delineate the local extent of the tumor and involvement of surrounding soft tissues. Axial, sagittal, and coronal planes can be obtained without exposure to ionizing radiation (47,58). Magnetic resonance imaging is also recommended for determining the level and extent of suspected single or multiple neoplasm lesions, without the risk or invasiveness of myelography (40). It also helps in accurate local staging of tumor and obtaining adequate safety margins for surgery. For spinal canal encroachment, MRI clearly demonstrates ventral versus posterior compression. Intramedullary lesions also can be demonstrated clearly.

Unlike plain radiograph or CT, MRI provides valuable information in detecting vertebral bone marrow infiltration by tumors. Variations in MRI signal intensity depend on cellularity. Neoplasm lesions replace the normal marrow elements with higher cellularity, which results in a decreased signal on the T1-weighted images and a slightly higher signal on T2-weighted images. The benign cavernous hemangioma is the only lesion that shows increased signal relative to normal marrow on T1-weighted sequences and variable signal relative to normal marrow on T2-weighted or gradient echo sequences (58). Magnetic resonance imaging is more sensitive than a radionuclide bone scan in the detection of spinal metastases (59), and can detect metastatic lesions larger than 3 mm in size (60). The sensitivity of MRI in the detection of bone metastases is 90%, compared with the 49% sensitivity of CT (Fig. 81-1) (61).

Gadolinium-enhanced MRI provides additional information for detection of metastases. A study suggests that subarachnoid metastatic tumors enhance prominently and can be detected relatively easily against the background of nonenhanced normal nerve tissue and spinal fluid. Contrast scan also helps to distinguish disc disease from epidural tumor and select biopsy sites (62).

Magnetic resonance imaging also has been used for monitoring response to chemotherapy, and for detecting postoperative tumor recurrence. Postcontrast MRI studies are helpful for evaluating the presence or absence of tumor necrosis during chemotherapy. Dynamic MRI after intravenous bolus administration of gadolinium-diethylenetri-

amine pentaacetic acid or other paramagnetic contrast media is particularly useful for assessing response to chemotherapy. Diffusion-weighted MRI is a new technique that is potentially capable of detecting and quantitating the amount of tumor necrosis after chemotherapy or radiation therapy (63).

Magnetic resonance imaging is also applied for the differential diagnosis among tumor, infection, and fracture. For a malignant lesion, MRI shows homogeneous and diffuse vertebral signal abnormality, a convex vertebral border, pedicle involvement, and sparing of the intervertebral disc (64). For pyogenic osteomyelitis, there is decreased signal on T1-weighted images and increased signal on T2-weighted images in the vertebra, with the erosion of end plates, intervertebral disc, and adjacent vertebra. Because of the marrow changes from fracture hematoma and edema, it is sometimes difficult to differentiate osteoporotic fracture from malignant compression fracture by MRI.

Compared with CT, MRI has less signal artifact of titanium implant; however, MRI does have disadvantages. In certain tumors (e.g., osteoid osteoma, osteoblastoma, or eosinophilic granuloma), the MRI signal of the inflammatory response in the soft tissue surrounding the tumor simulates soft-tissue involvement, giving the impression of a more aggressive tumor than actually exists (25,55, 65,66).

### **Angiography**

Spinal angiography can be applied for some tumors with rich vascular structure, such as aneurysmal bone cyst, hemangiosarcoma, and metastatic renal cell. Angiography can identify the exact location and anatomic configuration of the lesion, and the vascularity of all feeding and draining vessels. Angiography with selective embolization can also be used for such lesions to reduce intraoperative blood loss (23).

### **Biopsy**

The establishment of a definite diagnosis for spinal neoplasm lesion is of the utmost importance for the treatment, either surgical or nonoperative, and the prediction of prognosis. Because surgery is still the major treatment for excisable tumors, a pathologic diagnosis is essential for surgical planning. There are two major forms of biopsy for obtaining a sample of a suspected tumor lesion: percutaneous needle biopsy and open biopsy. The open biopsy consists of excisional and incisional biopsy.

Percutaneous needle biopsy has advantages compared with open biopsy. Needle biopsy, including bone marrow biopsy, is a simple, safe, and fast technique. Needle biopsy may save the patient from an open surgical procedure, especially when the final treatment is not surgical. It has fewer complications and morbidity, with a reported

successful diagnosis in 75% to 95% of cases (67,68). The indications for needle biopsy include the following conditions: (1) confirmation of suspected round cell tumors (e.g., myeloma and lymphoma); (2) primary tumors that require reconstructive surgery; (3) eosinophilic granuloma for which aggressive surgery usually is not warranted; (4) known or suspected metastatic diseases before initiating radiotherapy or chemotherapy (69).

Fluoroscopic or CT guidance is necessary to localize the lesion and avoid neurologic and vascular complications. Computed tomographic guidance provides a great margin of safety for surrounding structures (24,69).

Obviously the limitation of needle biopsy is the small tissue sample, which sometimes makes it difficult to formulate a definite pathologic diagnosis. Large needles are recommended when performing a biopsy on osteoblastic lesions. Several specimens should be obtained because the success in obtaining positive results has been shown to be as low as 20% to 25% (70). Hemorrhage is always a concern for this procedure, especially when obtaining a sample from a suspected vascular lesion, for instance, hemangioma or aneurysmal bone cyst (67,69). When high risk for hemorrhage exists, needle biopsy should not be applied; switch to another diagnostic regimen.

A careful consideration is needed in selecting an approach for biopsy. When approaching an open biopsy, the potential need for a definitive surgical procedure must be considered. To avoid spreading tumor by contamination, the biopsy tract or incision should be placed so that it may be excised with the tumor during the definitive procedure (19). Using the most direct route to the lesion, biopsies of lesions affecting the posterior elements can be easily done with a straight posterior approach. Biopsies of lesions involving the vertebral body can be performed either from a transpedicular approach or after a costotransversectomy. Transpedicular biopsy is used for intraosseous lesions of the thoracic and especially the lumbar spine. A costotransversectomy approach is preferred in the presence of involvement of a vertebral body with an extended soft-tissue mass (41). Because of the potential morbidity involved with thoracotomies and retroperitoneal approaches, they should be reserved for definitive surgical intervention (40). An incisional biopsy should be the last step in the staging of the patient, performed just before the definitive surgical resection. Both procedures may be performed under the same anesthetic if the frozen section provides a clear diagnosis (19).

Intraoperatively, a frozen section should be obtained to confirm adequate material sampling. Adequate specimens should be obtained from the soft-tissue component accompanying lytic areas and blastic lesions, with an adequate amount of specimen allowing for pathologic diagnosis, including special stains and immunohistochemical studies. Whenever a bone biopsy is performed, blood is aspirated for cytologic analysis, and a sample is cultured to rule out infection (40).

## BENIGN PRIMARY SPINE TUMORS

### Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma of the spine are rare. Histologically, the two lesions are from the same osteoblastic origin, characterized by a rich fibrovascular stroma and abundant osteoblasts. The difference between these two lesions is their respective sizes and differing biologic behavior (71–74). An osteoblastic lesion less than 1.5 cm in size is arbitrarily defined as osteoid osteoma; one larger than that is named an osteoblastoma (75,76). Osteoid osteoma represents about 3% of primary bone tumors and 20% of reported cases in the vertebral column (20,72), whereas osteoblastoma is 1% and 41%, respectively (72,77,78).

Patients usually present in the second or third decade, with osteoid osteoma in a younger age group. The male to female ratio is 2:1 (79). These two benign lesions show a distinct propensity for spinal involvement, usually in the posterior elements. Besides being larger in size in comparison with osteoid osteoma, osteoblastoma grows more extensively and often forms extraskeletal soft tissue. The clinical manifestations include back pain and spinal scoliosis. The pain is typically persistent and presents at night in half of the patients. In the majority, weight-bearing activities aggravate the pain. Aspirin classically provides dramatic relief of pain in 30% to 73% of the patients with osteoid osteoma, but lack of a response to aspirin does not rule out the diagnosis (19,80). Scoliosis can occur in 60% to 77% of patients, with the tumor situated in the concave side of the apex (73,81,82). The neurologic deficit is seen more often in patients with osteoblastoma than in patients with osteoid osteoma (83).

Radiographically, osteoid osteoma presents as an isolated radiolucent area, surrounded by a zone of reactive sclerosis. Because of its small size, osteoid osteoma is easily obscured by the overlapping shadows of the vertebral column, whereas osteoblastoma is more apparent by its larger size in expansion of the cortical bone. Osteoblastoma has a thin rim of reactive bone between the lesion and the surrounding soft tissue; this rim separates the lesion from the rest of medullary bone. The involvement of the vertebral body is usually from the extension of tumor in the pedicle and has a limited extent (Fig. 81-2).

The radionuclide bone scan is the most sensitive and reliable screening technique of finding these two types of neoplasms (19,74). It is useful in the detection of small vertebral lesions and can usually localize the lesion to a specific level. The appearance of an osteoblastoma is a typical hot spot (84). Computed tomography scan is the best imaging procedure for defining the location of the lesion and the exact extent of the osseous involvement, and is helpful for surgical planning. For patients with neurologic deficits, MRI help in the evaluation of spinal cord and nerve compression (Fig. 81-2).

The treatment for either of these lesions is wide surgical excision of the entire lesion, with radical curettage of the surrounding normal vertebral bone (36).

### Osteochondroma

Osteochondromas are the most common primary benign bone tumors, representing approximately 12% of all bone tumors. Most of these tumors occur in the long bones and in teenagers, and only 3% of these lesions are in the spine (20,85,86). Posterior elements, especially the spinous processes, are the common sites for these lesions (85).

Osteochondromas usually are asymptomatic. When lesions grow large, they cause impingement of nearby structures and precipitate symptoms. The symptoms vary greatly, from a painful bursa over the lesion to different neurologic deficits. Some authors report neurologic compromise .5% to 1% of the time (87), whereas others show myelopathy occurring in up to 47% of cases (88–92). A growing osteochondroma with pain after puberty should always raise the suspicion of sarcomatous transformation.

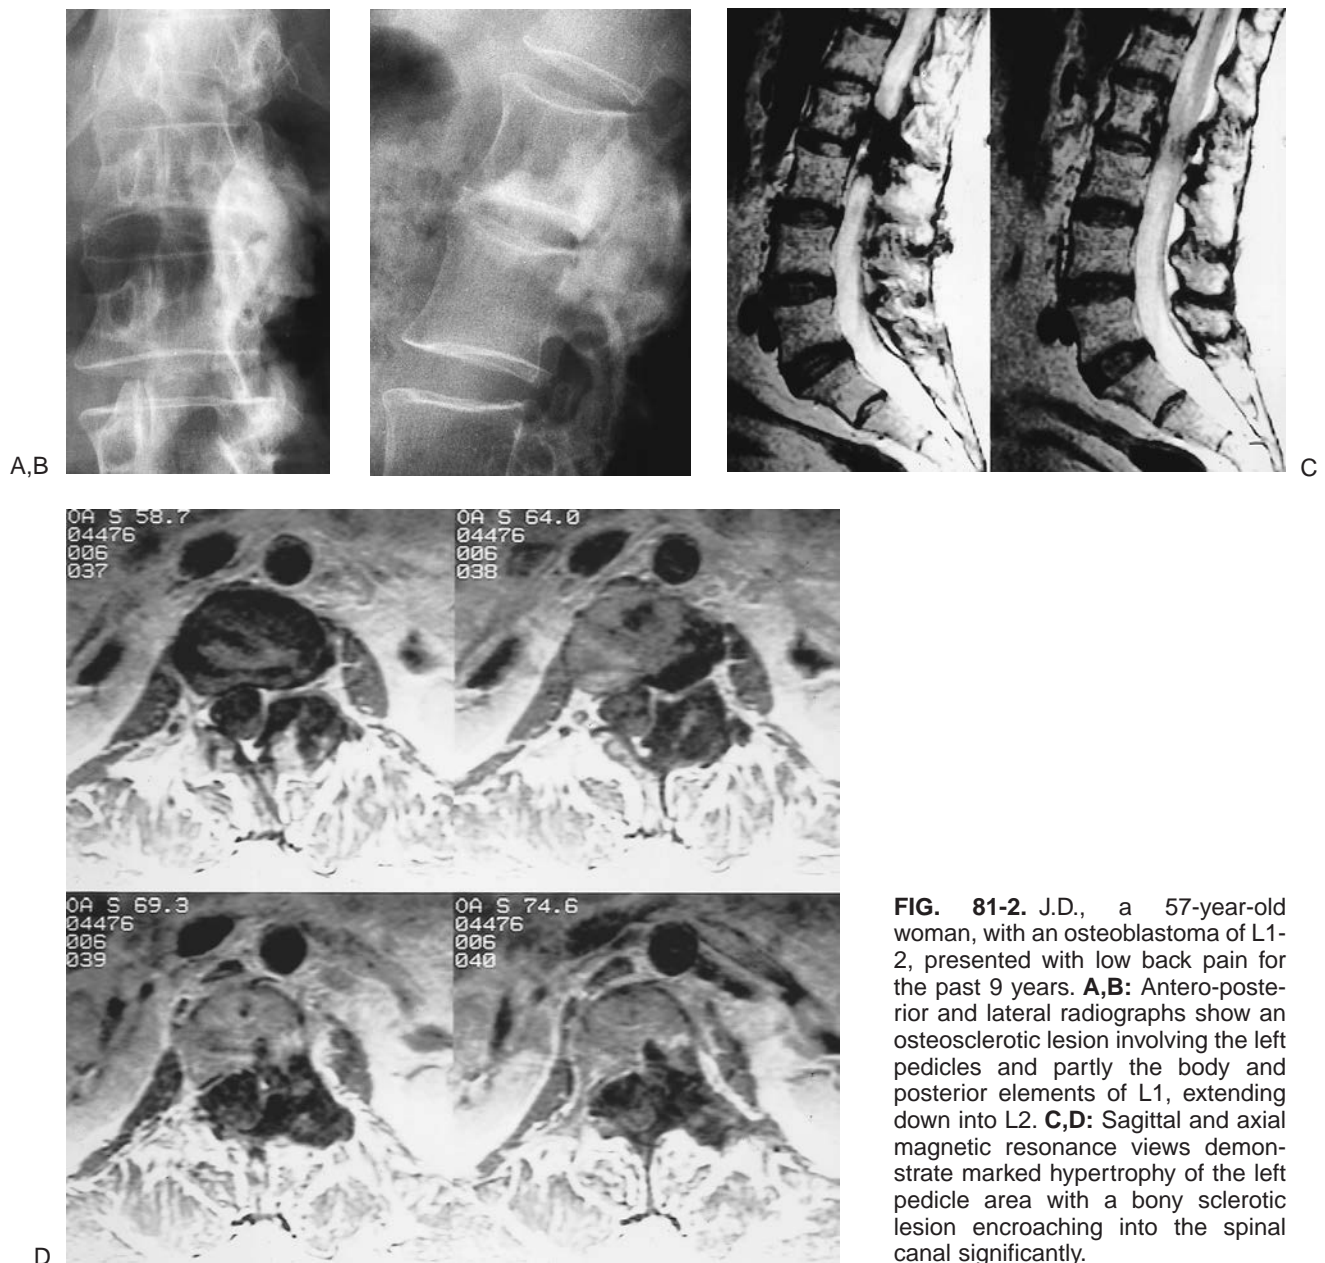

The distinguishing feature of an osteochondroma on plain radiograph is the continuity of the cortex and marrow between the normal bone and tumor, with trabeculae coursing from the tumor into the normal bone (93). Unfortunately, this characteristic does not always show on plain radiographs (88). Differential diagnosis needs further investigation by bone scan, CT, and MRI. Wide surgical excision is the choice when surgery is indicated.

### Aneurysmal Bone Cyst

Aneurysmal bone cysts (ABCs) are rare lesions, constituting only 1% of biopsied primary bone tumors. Eleven percent to 20% of these lesions are located in the spine (94,95). The etiology of aneurysmal bone cysts remains unclear, but may result from the alternation of bone hemodynamics by vascular anomaly (96).

Aneurysmal bone cysts are primarily seen in patients younger than 20 years of age (94,97). When involving the spine, these lesions are more commonly in the lumbar spine, and are seen more in the posterior elements of vertebrae than in the vertebral body. In a reported series, 60% of lesions were located in the posterior elements and 40% in the vertebral body (95). Not limited to one single level, many aneurysmal bone cysts affect adjacent vertebra. Back pain is the most common symptom. Neurologic deficits may also occur with variable presentations.

On plain films the lesion shows an expansile, osteolytic cavity with periosteal new bone formation. The cortex of the cavity is eggshell-thin, making the lesion bubbly in appearance. Computed tomography and MRI can further detail the features of these lesions. Magnetic resonance imaging with gadolinium can demonstrate the multiple septations within these lesions and is used for differentiation with other cystic or fluid-filled lesions (98). A bone

**FIG. 81-2.** J.D., a 57-year-old woman, with an osteoblastoma of L1-2, presented with low back pain for the past 9 years. **A,B:** Antero-posterior and lateral radiographs show an osteosclerotic lesion involving the left pedicles and partly the body and posterior elements of L1, extending down into L2. **C,D:** Sagittal and axial magnetic resonance views demonstrate marked hypertrophy of the left pedicle area with a bony sclerotic lesion encroaching into the spinal canal significantly.

scan usually shows increased uptake in the area of the tumor (99). Angiography provides useful information for the suspected lesions, because it can demonstrate the vascular blood-filled spaces caused by the arteriovenous shunting (96).

Management of these lesions includes embolization, surgical curettage or excision, and low-dose radiation.

### Giant Cell Tumor

Giant cell tumors (GCTs) appear as lytic lesions and are eccentrically located in the epiphysis. These lesions are histologically benign, but their clinical behavior is

sometimes unpredictable and capricious (100). Most patients are young adults with a large age range. Turcotte and coauthors reported a group of 186 Canadian patients with a mean age of 36 years (range, 14 to 72 years) (101). Giant cell tumors are slow growing and locally aggressive and have a tendency to recur locally (102,103).

Giant cell tumors are characterized by their typical location in the epiphysis of long bone (101). In the spine, they are more commonly seen in the vertebral body than the posterior elements. They are also most common in the sacrum (104,105). Patients present with local pain or a painless, slowly enlarging mass in the sacrum. Most giant cell tumors are benign but occasionally have malignant

behavior with pulmonary metastases in 3% of patients (106–108). Mononuclear round cells and randomly scattered osteoclast-type giant cells are the pathologic features of these lesions. The histologic grading system (grades I, II, and III), however, has not proved useful for prognosis (109).

The lesions are radiographically expansile, lytic, sequestered, and lack calcification. The lesions are somewhat soap bubble in appearance. Usually the lesions are limited by a rim that appears faint on plain radiograph but is well defined on CT. There is no periosteal reaction. The radiographic hallmark of these lesions is that they abut the subchondral bone plate of the adjacent joint. In the sacrum, these tumors have a tendency to occur proximally and eccentrically. This is in contradistinction to chordoma, which is more likely to be central and distal in the sacrum (103). In the vertebra, large areas of tumor are solid, accompanying blood-filled cystlike spaces that should be distinguished from aneurysmal bone cyst (109). Positive isotope scan helps with the diagnosis.

Giant cell tumor has potential to recur after treatment such as curettage or incomplete resection. The great majority of recurrences appear within 2 to 3 years (110–112), with a range of 25% to 50% (76,109, 113,114). Wide marginal resection is necessary for these lesions. To enhance surgical procedures, adjuvant measures such as liquid nitrogen, acrylic cement, and local delivered chemotherapy are applied. Reconstruction is usually done following the aggressive surgery.

### Eosinophilic Granuloma

Eosinophilic granuloma is a benign tumor-like condition that produces focal bone destruction (115). The histologic features of these lesions are sheets of histiocytes and inflammatory cells, particularly eosinophils. A defect of the immune system is considered as the major cause of this condition. Eosinophilic granulomas represent less than 1% of all tumor-like conditions of bone (116); 7% to 20% of these lesions are located in the spine (117,118). Eosinophilic granulomas are seen commonly in the first or second decades of life, with a peak incidence under the age of 10 years. Males are more likely to have this lesion than females, with a ratio of more than two to one (86).

Lesions may occur in solitary or multiple bone forms, with or without system involvement (93). Lesions of the skull are most commonly seen. Tumors are more often in the thoracic spine followed by the lumbar and then the cervical spine (119).

Back pain and stiffness are the major complaints of this lesion. Neurologic deficit is rare. System involvement termed as histiocytosis X manifests as triad of syndromes: eosinophilic granuloma, acute form of Letterer-Siwe disease, and chronic form of Hand-Schüller-Christian disease (119,120).

Vertebra plana is the typical characteristic of this lesion on plain radiograph. A lesion appears as a solitary central lytic lesion on the vertebra. The adjacent discs are usually preserved and soft-tissue mass is rare. When the vertebral body collapses and settles, radiographs demonstrate the “coin-on-end” appearance: flattened discs of dense cortical bone retained between the two intact intervertebral discs (121,122). Bone scans usually show cold images (118). Magnetic resonance imaging may show a “flare” reaction with extensive high signal areas on T2-weighted images in the surrounding bone marrow and soft tissue. Biopsy is necessary to differentiate among other malignant lesions (123–125).

Because many lesions are self-limiting and can heal spontaneously without treatment, the prognosis for recovery is excellent. Vertebral height can reconstitute spontaneously with time, even though sometime it is partial or with residual deformity (119). Aggressive surgery is only reserved for those with significant instability and neurologic compromise (123–125).

### Hemangioma

Hemangiomas are the most common benign lesions with a vascular origin. Tumors consist of thin-walled capillaries that are engorged with red blood cells. There are cavernous, capillary, or mixed types. The majority of these tumors in the spine are of the cavernous or mixed types. They can occur at any age but most commonly are found after the age of 40 (83). These tumors show no significant gender predominance (86). The vertebra of thoracolumbar or lumbar spine is most commonly involved.

Most spinal hemangiomas are asymptomatic and are found as incidental findings; therefore, they are of less clinical importance. Patients may present with pain and kyphosis or scoliosis following compression fracture. Neurologic symptoms are rare but can occur following spinal cord compression or nerve root encroachment.

The typical appearance of these lesions on plain radiograph is prominent vertical striations of thickened trabeculae within vertebral body, which can be best seen on the lateral view. The number of bone trabeculae is decreased owing to replacement by the sinusoid. This appearance is called “celery stalk” or “honeycomb” (93). At least one third of the vertebral body must be involved for the classic findings to be recognizable on plain radiograph. A significant characteristic is that compression fracture due to vertebral hemangioma is rare and can often heal with time if it happens. The cortex and disc space are usually intact on plain film, but the affected cortex, if any, can be demonstrated on the axial view of CT scan. The thickened trabeculae showed on CT are in a “polka dot” pattern (126).

Most hemangiomas do not warrant special treatment. Clinical observation is adequate. For symptomatic lesions, radiotherapy is usually the first choice because

this tumor is radiosensitive and frequently responds well. Surgery is rarely indicated with these lesions and may be necessary for some cases with spinal cord compression. Caution about severe hemorrhage should be taken when operating on these lesions. Preoperative angiography with selective embolization helps control bleeding from these vascular lesions during surgery (127–130).

## MALIGNANT PRIMARY SPINE TUMORS

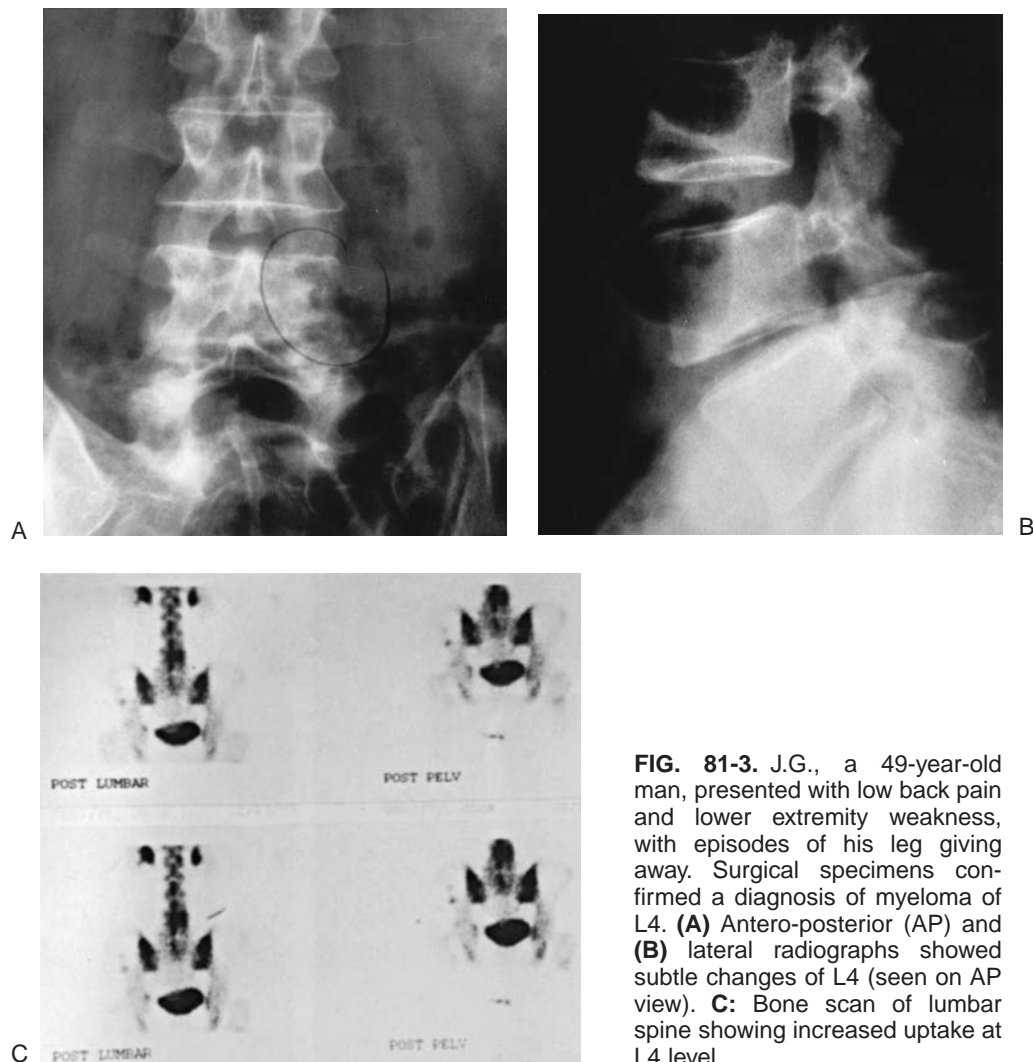

### Multiple Myeloma

Multiple myeloma is the most common primary malignant tumor either in all of the skeleton or the spinal column (25). It originates from plasma cells of marrow. This lesion is usually seen in the older age group, from 50 to 75 years, with a mean of 62 years (131,132). The hematopoietic marrow in the vertebral bodies, ribs, pelvic bone, and skull is usually affected, representing the systemic nature of this lesion. Because of the widespread

bone marrow involvement, patients usually present with normocytic and normochromic anemia. Such patients are susceptible to infection of any kind (33). The expansion of the spinal lesion can cause pain and fracture of the vertebral body.

The typical characteristics of this lesion on radiograph are punched-out lytic lesions within the bones without bone reaction. Radiographs of vertebral bodies may demonstrate osteopenia, wedging, and compression fracture. Bone scan has proved to be of little value in assessing patients with myeloma. The lack of bone reaction to the tumor lysis accounts for this poor result (133). Serum protein electrophoresis shows reversal of the albumin to globulin ratio. Bone marrow biopsy is the definitive means for making diagnosis (Fig. 81-3) (41).

Surgery is rarely indicated for multiple myeloma. The primary treatment for multiple myeloma is chemotherapy. Radiation therapy can be used for localized painful lesions. Surgical intervention is reserved for the treatment of disease complications, such as neurologic

**FIG. 81-3.** J.G., a 49-year-old man, presented with low back pain and lower extremity weakness, with episodes of his leg giving away. Surgical specimens confirmed a diagnosis of myeloma of L4. (A) Antero-posterior (AP) and (B) lateral radiographs showed subtle changes of L4 (seen on AP view). C: Bone scan of lumbar spine showing increased uptake at L4 level.

**FIG. 81-3.** (Continued). **D:** Myelograph showing involvement of spinal canal with thecal sac compression and permeative involvement of vertebral body. **E:** Computed tomography scan studies showing involvement of spinal canal with thecal sac compression and permeative involvement of vertebral body. **F:** Sagittal and **(G)** axial magnetic resonance images of lumbar spine showing involvement of L4 vertebral body and spinal canal. (From Simmons ED. Anterior reconstruction for metastatic thoracic and lumbar spine disease. In: Bridwell KB, DeWald RL, eds. The textbook of spinal surgery. Philadelphia: Lippincott-Raven, 2nd ed. 1997:2057–2070, with permission.)

deficits owing to spinal cord compression by pathologic fracture. The prognosis for survival of multiple myeloma patients involving spine, despite all recent advances, still remains poor. Median survival ranges from 11.5 to 32 months (131,134).

### Solitary Plasmacytoma

Solitary plasmacytoma, like multiple myeloma, is also a plasm cell neoplasm. However, these lesions are rare with only 3% of all plasma cell neoplasms (135). Because of the significant different natural history of multiple myeloma and solitary plasmacytoma, these two lesions are considered as two manifestations in a continuum of B-cell lymphoproliferative diseases (19). Spinal lesions,

most in the thoracic spine, constitute 25% to 50% cases (136,137). Overall, men have a higher incidence than women (138).

Clinical manifestations of solitary plasmacytoma may present with back pain and neurologic deficit. Initial radiographs of spine demonstrate a lytic lesion within vertebra, usually first seen in the pedicle then extended to the anterior vertebral body. Vertebral plana and collapse can occur following the progression of lesion. Fifty percent of these lesions may develop to systemic disease and multiple myeloma (139). Like multiple myeloma, bone scan has little value for the diagnosis because of lack of sclerotic bone reaction, whereas bone marrow aspiration and serum and urine protein electrophoresis are necessary. Computed tomography can identify the lesion that can be

not seen on plain radiograph. Magnetic resonance imaging provides useful information for evaluating the location and extent of the lesion.

Radiotherapy is the major treatment for this tumor because of its radiosensitivity (41). Patients with solitary plasmacytoma may have prolonged survival compared with multiple myeloma. It was reported that 5-year survival rates range from 35% to 70% (136,140). Mclain and Weinstein reported that the 5-year disease-free survival in 84 cases of spinal lesions was approximately 60%, with a median survival of 92 months (141).

### Lymphoma

Primary bone lymphoma is an uncommon malignancy. It accounts for less than 5% of the primary bone tumors and 5% of the extranodal non-Hodgkin lymphoma (142,143). It has the same histologic features of other lymphomas arising from the lymphoid and soft tissue. Hodgkin disease rarely presents with bony lesions. Non-Hodgkin lymphoma may occur as a solitary lesion of bone or, more commonly, as systemic disease with associated bony lesions in 20% of patients (143–145). In spine, vertebral body is more commonly involved than posterior elements. Patients are usually in the middle age of life, with a range of 18 to 69 years (146).

Lymphoma has a destructive nature and can cause collapse of the vertebral body with extraosseous extension of the lesion to the paravertebral area and into the spinal canal. The symptoms and signs vary from localized back pain to a partial or complete neurologic deficit (147). The tumor on radiographs is a lytic lesion with an ill-defined margin that gradually expands and breaks through the cortex (147); however, these radiographic features are inclusive and variable. Percutaneous or open biopsy is desirable to clarify the diagnosis (146).

The treatment of choice traditionally is a combination of chemotherapy and radiation therapy. Radiation therapy may be unnecessary for children. Surgery usually is appropriate for patients with neurologic deficits by spinal cord compression owing to pathologic fractures.

### Osteosarcoma

Osteosarcoma is the second most common malignant primary bone tumor after myeloma, constituting 20% of all primary malignant tumors of bone (143,148,149). It usually occurs in the metaphyses of extremity long bones. The peak age of onset is in the second decade. The estimated incidence of this tumor in the United States is approximately 1.7 cases per million per year, representing about 500 to 600 new cases annually (150,151). Primary osteosarcomas of the spine are extremely rare, constituting only 3% of all primary osteosarcomas and 5% primary malignant tumors of the spine (1,152,153). Primary osteosarcomas in the spine tend to occur in patients

in an older age group than does the same tumor in the extremities (152).

Osteosarcoma of spine commonly occurs at the vertebral body. Back pain from the affected vertebra area is the main symptom. Most patients also have variable sensory or motor deficits (152,154). Malignant features on radiographs include osteoblastic and osteolytic changes, cortical destruction, and soft-tissue calcification. The radiographic hallmarks of osteosarcoma in the extremities—Codman triangle of reactive bone and “sunburst” appearance—are not present in spinal lesions. The level of serum alkaline phosphatase is usually elevated in these patients and can be used for differentiation. Computed tomography, MRI, and bone scan are helpful for identifying the extent of tumor and diagnosis. For case with suspected osteosarcoma, biopsy is necessary before initiating chemotherapy (152).

Prognosis for patients with osteosarcoma has traditionally been poor. Before early 1970s, amputation was the primary treatment of osteosarcoma of long bones, with a poor 5-year survival rate of 20% (143,148,150,155–157). During the last 15 to 20 years, since the use of adjuvant and neoadjuvant chemotherapy by eradicating micrometastasis, the survival rate has been improved dramatically, to 50% to 70% (158–161). Like the lesions in the long bones, the survival of patients with osteosarcoma of the spine is also poor, with a median survival of 6 to 10 months (152,162). To improve the prognosis, chemotherapy followed by aggressive surgical excision of lesion is proposed. Anterior and posterior wide excision or complete spondylectomy has been applied in addition to chemotherapy. Postoperative radiotherapy to the primary site in conjunction with postoperative chemotherapy is used to improve the survival rate.

### Chondrosarcoma

Chondrosarcoma is the third most common primary malignant tumor of the bone next to multiple myeloma and osteogenic sarcoma (147). About 4% to 8% of chondrosarcomas occur in the spine (20,163). The basic neoplastic tissue is cartilage without osteoid, formed directly by sarcomatous stroma (143,164). It may occur as a primary lesion or secondary to a preexisting benign tumor. The average of age for chondrosarcomas is 40 years, with a broad range (163,165–168).

Clinically, chondrosarcomas is most common in long bones and pelvis, but it is not unusual for the spine column to be affected, especially the lumbar and sacral region (147). Local discomfort or pain and a slow-growing mass are common manifestations. Lumbar or sacral lesions may result in a large pelvic or intraabdominal mass. Chondrosarcomas are histologically divided into low, intermediate, and high grades. Low-grade tumors seldom metastasize, whereas high-grade lesions have early metastases to the lungs and other areas of the body.

Bony destruction and a growing lobulated mass with calcific mottling are the common signs of chondrosarcomas on radiographs. Computed tomography can clearly demonstrate the location, cortical destruction, and extent of the tumor. Bone scans are positive in most chondrosarcomas (169). Biopsy is usually necessary for final diagnosis.

Radiotherapy and chemotherapy have little value for the treatment of chondrosarcoma. Wide surgical resection is the treatment of choice (164), but this is frequently restrained by spinal structures. The most important factors for patient survival are augmented chromosomal content and tumor size. Kreicbergs et al. found that chondrosarcoma with normal DNA content were associated with a significantly higher 10-year survival rate than those with abnormal chromosome content, 81% versus 21% (170,171).

### Chordoma

Chordomas are rare primary malignant tumors of the axial skeleton, arising from the remnants of embryonic notochord (172,173). These lesions constitute 1% to 4% of primary malignant bone tumors (20,143), yielding an annual incidence of approximately 25 afflicted persons in the United States (173,174). A little more than half of the tumors occur in the sacrum, 35% at the base of skull, and 15% in the spine vertebrae and other areas (20,173,175, 176–179). Although chordomas have been reported in all age groups, they are commonly seen in the fifth through seventh decades of life (104,180–182). Males are more affected than females, with a ratio of 2:1 (20).

Chordomas are slow-growing masses. The symptoms vary from months to several years before patients see the physician. The symptoms and signs of the tumor are related to the location and are usually nonspecific. Pain is the frequent symptom of tumor in the sacral coccygeal region. Most of these tumors extend anterior to the sacrum; therefore, the tumor can grow to a large size before being diagnosed because of the relatively large space available for expansion within the posterior pelvis. Rectal and bladder dysfunction can occur in 20% to 40% of patients and are late features (41,173). A careful rectal examination either with finger or proctoscope is necessary for diagnosis. A firm and fixed presacral mass can be palpated on rectal examination. Neurologic deficits of these tumors at the base of skull, cervical, thoracic, and lumbar regions of spine column are relevant to their location. Although this tumor is aggressive locally, it also can metastasize to other distant sites of the body, such as lymph nodes, lung, liver, and other intraabdominal viscera. Metastases can be discovered as early as 1 year and as late as 10 years after diagnosis of primary tumor, with variable incidence from 5% to 40% (177,179,183).

The characterized radiographic finding in sacral chordomas is a lytic lesion involving several segments of the

sacrum associated with an expansile ballooning soft-tissue mass anterior to it (180,181). Peripheral calcification can be seen in 40% to 80% of tumors (184–186). Tumors involving the true vertebrae usually originate in a single vertebral body and are lytic with surrounding reactive sclerosis (181). Computed tomography can disclose the extent of tumor mass and calcification. Heterogeneous signals and internal septations on T2-weighted MRI are predominant features (186). Bone scans are rarely positive for these lesions. Biopsy can be done for diagnosis.

Although chordomas are considered low-grade malignant lesions and are slow to metastasize, their proximity to the spinal cord and cauda equina and the extent of tumor at time of initial presentation make them extremely difficult to treat effectively (187). Wide surgical resection with adjuvant radiotherapy has been recommended for the treatment of chordoma. Chemotherapy has not proved even modestly effective (104,188). In sacrococcygeal chordomas, the level of lesion significantly affects the mode of treatment. The removal of the S1 vertebra impairs the stability of the pelvic girdle. There is a significant difference in surgical treatment between lesions involving the third sacral segment distally and those involving the more proximal portion of the sacrum. Distal chordoma can be excised posteriorly (104,188). Sphincter control of bowel and bladder is directly related to the number of preserved nerve roots. If the most caudad nerve root preserved is the first sacral nerve, no control can be expected, and the patient may be unable to walk without orthotic assistance. If both second sacral nerve roots are spared, 50% of patients regain at least partial bowel and bladder control. If one third of the sacral nerve root is preserved, most patients regain sphincter control. Stener and Gunterberg have described surgical techniques for high radical sacrectomy, either above or through the anterior foramina of the S1 nerve root. They believe that it is possible to sacrifice all sacral nerve roots unilaterally without significant disturbance of bowel or bladder function (189).

Because the tumor in the vertebral column is usually located at the vertebral body, an anterior approach or a combination of anterior and posterior procedures is carried out to excise the lesion and reconstruct the stability of spine column. Because the recurrence rate and ultimate failure rate are much higher for these tumors, adjuvant proton-beam therapy has been used both for palliation of recurrent tumors and for otherwise inoperable lesions (173,190).

The reported survival rates have been poor in the past. The surgical treatment of spine chordoma is less satisfactory than that of sacrococcygeal lesion. Sundaresan reported the disease-free survival rate is less than 10% (173). However, aggressive excision with adjuvant radiotherapy achieves the best results with a disease-free survival of more than 5 years for 50% to 77% of patients (104,186,191).

## Ewing Sarcoma

Ewing sarcoma of bone was first described in 1921 by James Ewing (192). It accounts for approximately 6% of all malignant primary bone tumors (20). Ewing sarcomas are the second most common primary malignant tumors of bone in childhood and adolescence, with an annual incidence rate in whites of 3 per 1 million children less than 15 years of age. The average age of patients is 15 years, with a range from the first to the fourth decade of life (193,194).

Ewing sarcoma of the spine is rare, representing only about .5% of all primary malignant tumors of bone, and 8% to 10% of all Ewing sarcoma (20,195,196). Primary sites are sacral and vertebra. Pain and neurologic deficits are the most common presenting features. Metastases may occur in patients at the time of diagnosis, commonly involving the lungs or other locations in the spinal column. Many patients have low-grade fever, anemia, leukocytosis, and elevated erythrocyte sedimentation rate.

Plain radiographs reveal a lytic destruction lesion, often with peripheral sclerosis and a soft-tissue mass. Computed tomography and MRI are needed to further identify the location and extent of tumor. Bone scan is used to rule out other metastases. An accurate diagnosis is made by pathology. Showing histopathologically as small blue round cell tumors, Ewing sarcomas show a typical chromosomal rearrangement in more than 95% of cases (197).

Because of the obvious limitations in excising the tumor and achieving adequate margins, standard treatment for local control of the primary lesion, historically, has been chemotherapy and radiation. The overall 5-year survival rate in the past is low, approximately 20% (195,198). Great strides have been made in the diagnosis and treatment of patients with Ewing sarcoma. Currently, surgical resection has become a more effective option in the multidisciplinary treatment of patients with this disease. The response to induction chemotherapy is a strong prognostic factor (199,200). Cotterill and coauthors, by analyzing 975 patients, also found that metastases at diagnosis, primary site, and age are the prognostic factors (201). With the advent of modern chemotherapy, the long-term survival has improved to approximately 50% to 70% (194,197,202).

## CHAPTER 82

# Metastatic Spine Tumors

Stanley D. Gertzbein

---

One million new cases of cancer are diagnosed every year in this country (1). Metastases occur in approximately two thirds of patients, with the skeleton being the most common site for metastatic tumors, after the lung and liver (2). A metastasis of the spine is defined as a malignancy whose cells have been transferred from the primary site of the tumor to the spinal column with continued unchecked growth. The spine is the most common site of spread (3), one third of which are symptomatic (4). Up to 5% of patients are diagnosed with symptomatic spinal cord lesions (2,5).

The highest incidence of metastases in the spine is in the lumbar region, followed by the thoracic and cervical levels (6). Most associated spinal *cord* lesions, however, are located in the thoracic spine, related to the smaller spinal canal size, vascular supply (7), and predisposition of the thoracic spine to kyphotic deformity (8).

### ETIOLOGY, SPREAD, AND GROWTH

Secondary spread of metastatic disease to the skeleton occurs from the following organs in order of frequency: breast, prostate, lung, and kidney. These organs make up approximately 80% of all secondary spread to the spine (4). Of the epidural metastases, the order of frequency is breast, lung, prostate, and kidney (6).

Metastatic lesions are commonly spread by the arterial side of the circulation, particularly from the lung and prostate (9). However, the venous route through Batson plexus may be a source of contamination by tumor cells in the pelvis and abdomen from retrograde spread. The lack of venous valves allows backflow into the vessels of the vertebrae with increased pressure in the abdomen (10). A combination of both of these routes may also be operative (11). Tumors may also spread to the spinal column directly, such as in the mediastinum from lung and from retroperitoneal structures, including the pancreas.

Metastatic lesions enlarge through biochemical and mechanical factors. Osteoclast activating factor (12), col-

lagenase (13), and prostaglandin (14,15) release result in the breakdown of ground substance and collagen, allowing tumor cells to grow and expand. As the mass of the tumor increases, there may be direct pressure on the bony trabeculae, resulting in ischemia and subsequent resorption of bone.

### INSTABILITY

Spinal stability relies on the intact spine. As proposed by Denis (16), there are three structural components of the spine, the anterior, middle, and posterior columns. With tumor spread throughout these columns, there is an

**FIG. 82-1.** Spinal instability. This lateral radiograph demonstrates collapse of a metastatic lesion resulting in a pathologic fracture (*white arrow*) with moderate angulation (*dotted lines*).

increase in the degree of instability. The middle column accounts for approximately 60% of the axial strength (17) so that when this component is compromised, the spine is at risk for collapse with the potential to create a pathologic fracture. Along with flexion forces, a kyphotic deformity may result with further loss of vertebral height. The fulcrum of the spine in each motion segment, located in the middle column, may migrate posteriorly toward the posterior elements as the forces act on the weakened structures with the result that deformity occurs (Fig. 82-1). In some cases, however, there can be an even collapse of the spine, which does not result in kyphosis, although the expansion of tumor and bone into the spinal canal may result in compromise to the spinal canal and neurologic impairment.

## CLINICAL FEATURES

### History

Most patients complain of fatigue, malaise, and weight loss because of their underlying disease. Although many metastatic lesions to the spine are asymptomatic, a significant proportion of patients complain of pain because of involvement of the bony elements by tumor tissue. As the tumor replaces bone, the trabeculae weaken, resulting in microfractures or full pathologic fractures, deformity, and instability. Posterior element involvement leading to instability may be a source of pain as well. Pain is the most common presentation in up to 96% of patients, resulting from these sequelae (18). The deposition of peridural tumor in the spinal canal causes compression of the neural elements, and this may also result in pain (Fig. 82-2) (6,19).

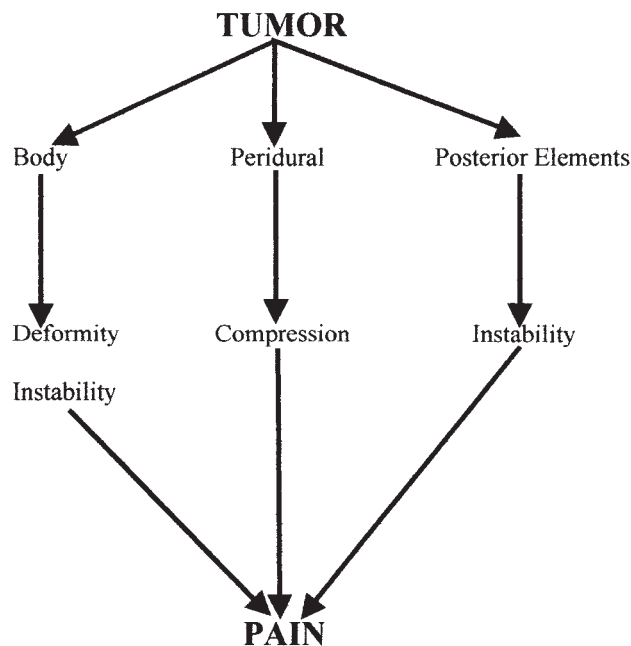

FIG. 82-2. Mechanisms of pain with spinal metastasis.

Neurologic symptoms include weakness, numbness, and paresthesias of the limbs and, with spinal cord involvement, spasms, and bowel and bladder complaints. Neurologic compromise is most common in the thoracic spine, with approximately 70% of all neurologic deficits found in this region, and 15% each in the cervical and lumbar spine (6).

### Physical Examination

Although there may be no deformity, the most common observation of malalignment on inspection is that of kyphosis, where there has been collapse from a pathologic fracture. Local tenderness is often present. Neurologic examination may be normal early but with neural compromise the physical examination elicits features associated with upper motor or lower motor neuron findings, depending on the involvement of the spinal cord, the cauda equina, or the nerve roots. A rectal examination is essential in all neurologically compromised patients to identify bowel or bladder dysfunction.

## INVESTIGATION OF SPINAL METASTASES

### Laboratory Evaluation

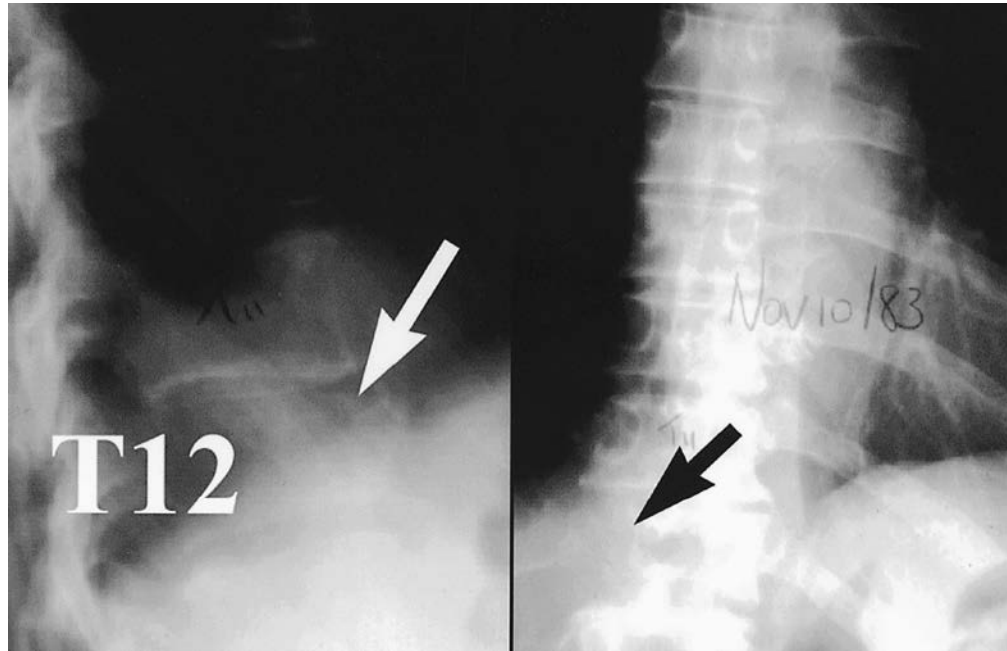

Blood work includes a complete blood count, including a sedimentation rate, electrolytes, blood urea nitrogen, calcium, phosphorus, alkaline phosphatase, serum proteins, and protein electrophoresis. This blood profile may be helpful in determining the extent of systemic involvement but does not identify the primary tumor. The immunologic status can be determined from some of these studies as well. Prostatic-specific antigen is useful for identifying prostatic tumor, and carcinoembryonic antigen may be useful in monitoring the progress of tumor therapy (20).

### Plain Radiographs

It has been estimated that up to 70% of bone mass loss must be present to visualize an osteolytic lesion on normal X-rays (21). Often, a missing pedicle is the first radiographic finding (Fig. 82-3) (22). Destruction of the vertebral body with or without collapse and the presence of prevertebral soft-tissue findings are late signs of involvement. Although most lesions are osteolytic, several are known to be osteosclerotic. The prostate is the most frequently identified osteosclerotic lesion, but a small proportion of the following lesions are also associated with osteoblastic findings on plain radiographs: breast, bladder, thyroid, and gastrointestinal tumors.

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is very useful in not only determining the extent of the lesion within the

**FIG. 82-3.** Antero-posterior (AP) and lateral radiograph of the thoracic spine. The lateral projection demonstrates a pathologic fracture of T12 (*white arrow*). On the AP projection the pedicle is absent because of destruction by the tumor, which is often an early sign of involvement.

spinal canal and its relationship to the spinal cord and cauda equina, but also in helping to differentiate osteoporotic fractures from pathologic fractures caused by tumors of the spine. The distinction is best evaluated on T2-weighted images, where high intensity is seen with

**FIG. 82-4.** Magnetic resonance image. T2-weighted image of a secondary metastasis to the lumbar spine with hyperintensity of the tumor (*white arrow*) clearly identifying the significant encroachment of the lesion into the spinal canal.

tumors as opposed to normal intensity with osteoporotic fractures (Fig. 82-4). Lesions as small as 3 mm can be detected (23). The use of contrast agents when studying T1-weighted images also assists in interpreting metastases, especially when suppressing the fatty component in the marrow (24). Contrast material injected at the time of MRI scanning also may be helpful in following the effectiveness of chemotherapy or radiation over time (25).

#### Computed Tomography Myelogram

Although a computed tomography myelogram (myelo-CT) is useful in some cases to define the extent of a block when tumor tissue is present within the spinal canal, the MRI, for the most part, has superseded the use of this study. The CT scan alone, however, provides excellent detail by defining the extent of osseous involvement of the metastasis (Fig. 82-5). This can be helpful in planning the type of surgery.

#### Bone Scan

Bone scans usually are not helpful in assessing the specific lesion because most secondary tumors demonstrate increased uptake. However, rapid proliferation of some tumors, such as lung, kidney, and myeloproliferative disorders, may not be positive (26). The bone scan, however, is useful in identifying the extent of spread within the spine and other parts of the skeleton and may detect a more accessible lesion to perform a biopsy.

**FIG. 82-5.** Computed tomography scan accurately identifies the extent of bony involvement at T7, indicating lateral infiltration of the vertebral body. This lesion could readily be addressed surgically from a postero-lateral approach.

### Biopsy

Prior to initiating treatment, a biopsy should be performed in all lesions where possible when the diagnosis is deemed necessary. Biopsy can be performed under CT-guided assistance. The entry point of the needle in the skin is 6 to 7 mm lateral to the midline at an angle of about 35°. The success rate in obtaining a tumor specimen is as high as 75% to 95% (27), with an accuracy rate as high as 95% (28,29). The complication rate is low (5), but includes neurologic complications, hemopneumothorax, and excessive bleeding (30,31).

### MANAGEMENT OF METASTATIC TUMORS OF THE SPINE

A team approach is essential in treating patients with metastatic disease. This includes the orthopedic surgeon, neurosurgeon, oncologist or radiotherapist, radiologist, and pathologist.

Variables in determining the type of treatment include the type of tumor and the response of the tumor to non-operative measures. If the tumor is sensitive to chemotherapy or radiotherapy, nonsurgical treatment may be the treatment of choice, especially if the lesions are stable biomechanically and neurologically (32). In cases where there are multiple tumors and widespread involvement of the vertebrae, palliative measures are more appropriate (33). Finally, with patients whose medical status is poor and cannot undergo the trauma of surgery, a less aggressive approach is indicated.

### NONOPERATIVE TREATMENT

#### Chemotherapy

The use of chemotherapeutic drugs will likely have been initiated according to the protocol of the particular

primary tumor before the discovery of the spinal lesion. The various regimens are supervised by the oncologist and are beyond the scope of this chapter.

Steroids have been used to reduce edema and inflammation associated with spinal cord compression. This should be considered as an adjunct to management because significant cord compression requires surgical intervention (20), although some protocols have shown a positive effect in combination with radiotherapy (34).

#### Radiotherapy

Radiation therapy is an effective modality in the treatment of spinal metastases, especially where a painful radiosensitive tumor such as prostate and breast (35) can be treated before there is a major neurologic deficit and before the bony architecture has been significantly destroyed. Although it usually does not return a patient to ambulatory status (33), it is effective in pain control in many instances, especially with multiple site involvement. The dose of radiotherapy to the spinal cord should not exceed 5,000 cGy in 25 fractions over a 5-week period to avoid radiation myelopathy (33,33a). If surgery is performed, adjunctive radiotherapy should be given well before the date of surgery or at least 21 days after the surgery to avoid problems with healing of the soft tissues (36) as well as fusion (37).

#### External Orthoses

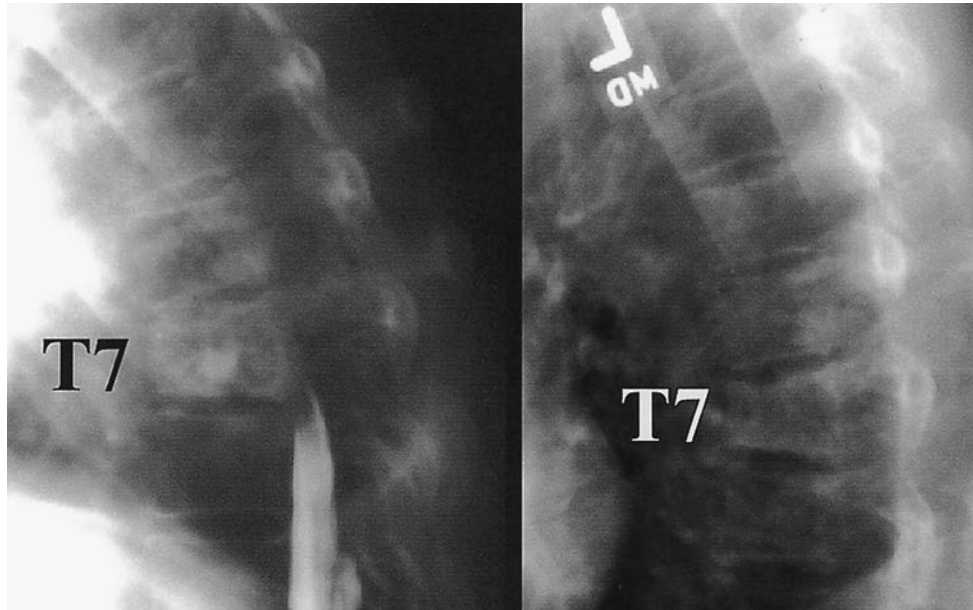

Braces in the thoracolumbar spine are useful during and after treatment for healing and pain control. The halo-vest is similarly effective for patients with cervical lesions (38), but care must be taken in its use because of the concern for skin breakdown in a neurologically or nutritionally compromised patient.

### SURGERY

Before performing surgery, several factors require evaluation, including life expectancy. Life expectancy should be evaluated in terms of the prognosis of the primary tumor. It is clear that some tumors have a short survival time irrespective of spread to the spine, such as gastric carcinoma. Other primary lesions have a longer prognosis, including prostate and breast (39). Surgery, therefore, for the most part, should be directed at prevention of local progression and complications such as neurologic sequelae, deformity, and pain. The exception is a solitary metastasis where total spondylectomy is considered for possible cure (40).

The nutritional (41) and immunologic status (42) of the patient as well as the pulmonary status, especially for anterior surgery (20) must be assessed. If these factors are favorable, or if they can be improved, then surgery can be considered. The goals of surgery include: (a)

**FIG. 82-6.** Nonoperative treatment, antero-posterior and lateral radiographs. This breast metastasis at T7 was associated with a major block to the spinal canal, but with only a minor neurologic deficit. The patient was treated with radiation therapy and bracing with relief of the neurologic deficit. One and a half years later the vertebrae maintained its integrity and no neurologic sequelae were seen.

decompression of the neural tissues, (b) prevention of neural injury by stabilization of the unstable spinal column, or (c) pain control. Those patients with no or mild neural deficit and minimal erosion of bone without collapse of the spine and demonstrate good alignment who are chemosensitive or radiosensitive can be treated with these therapies along with a brace and analgesics, as mentioned in the preceding (Fig. 82-6). The remaining patients require surgery. The principles of surgery include tumor reduction, decompression of the neurologic tissues, and stabilization of the spine. There is some controversy as to whether prophylactic surgery is indicated in patients with less than 50% involvement of the vertebral body (43-45). Patients who progress to greater than 50% often collapse (43,44). It is also known that a significant number of patients with spinal metastases go on to neurologic compromise (2,5). For these reasons, cases with greater than 50% vertebral body collapse, especially where there is imminent involvement of the spinal cord, should be stabilized after clearing of the tumor. When pain is the primary indication for surgery, a good response can be expected from the surgery but the life expectancy remains unaltered (46).

#### STAGING AND CLASSIFICATION OF METASTATIC LESIONS

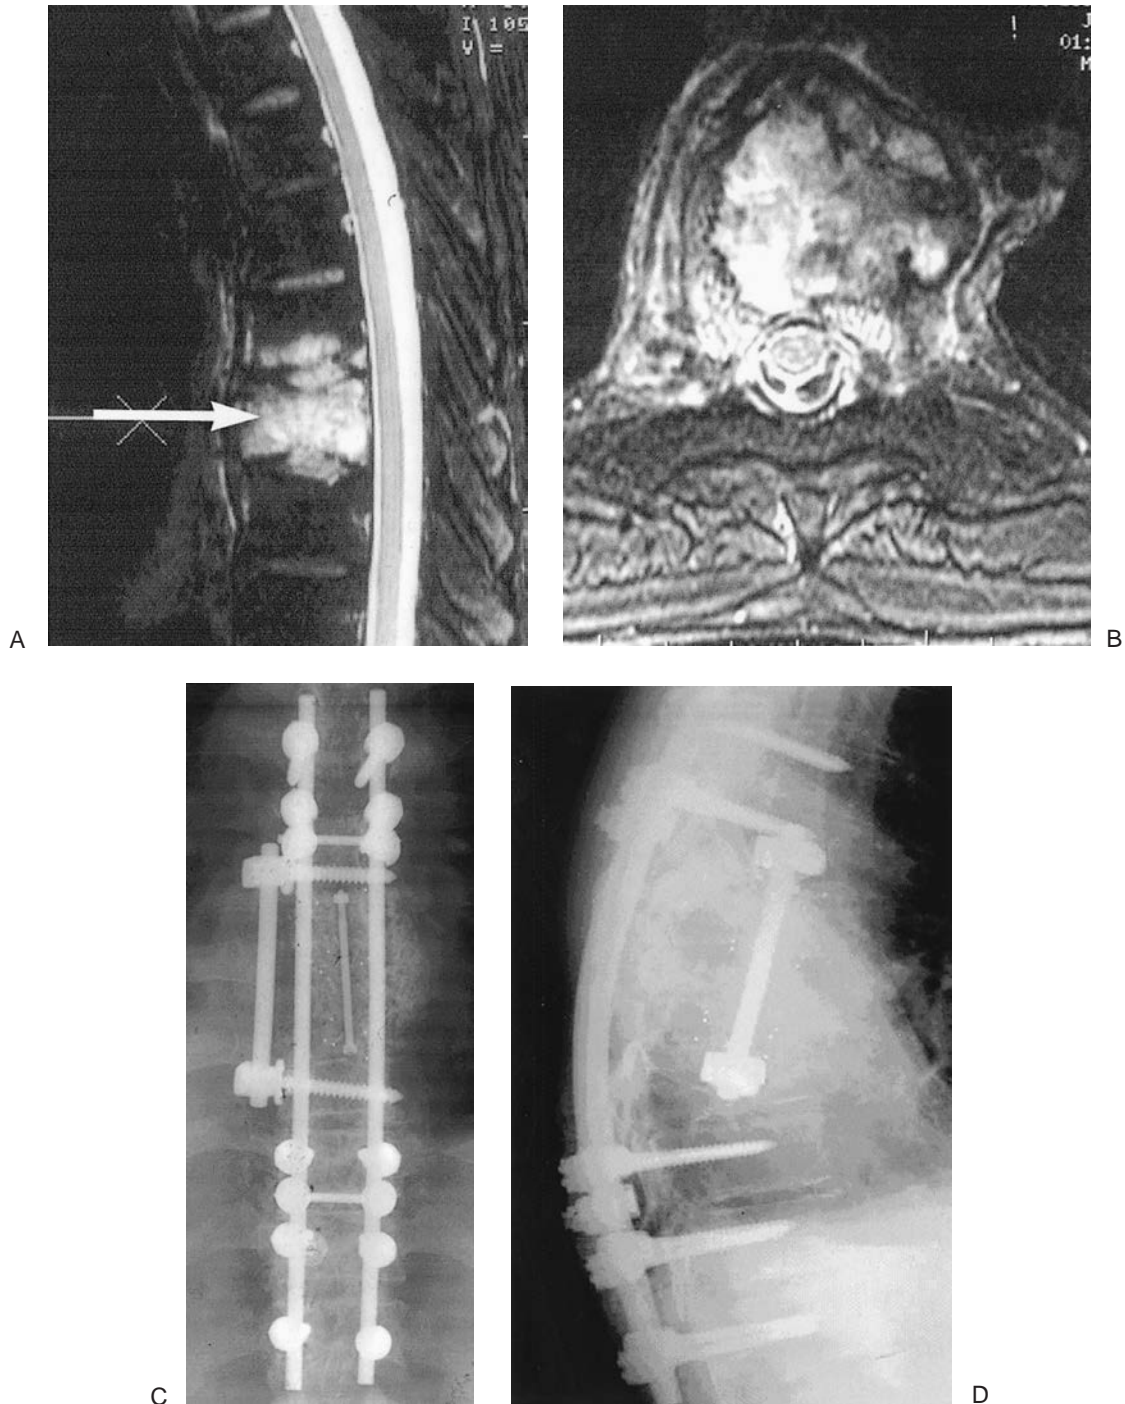

Recent interest in more aggressive surgery for metastatic disease has been spurred on, in part, by improvements in surgical technology. It is now feasible to perform a total

excision of a vertebra and stabilize the segment (40,47-50), depending on the extent of bony involvement (Fig. 82-7).

Scoring systems have been devised that address the important aspects of tumor surgery and include classifications that describe the extent of instability (51), the neurologic involvement along with instability (52), prognostic factors to determine if surgery should be performed (53), and factors that determine the type of surgery to be performed (54,55), specifically whether en bloc surgery is feasible over major excision, palliative surgery, or no surgery. Caution must be exercised in attempting to precisely determine tumor containment because spread can extend beyond tissues commonly held to be natural barriers, such as the posterior longitudinal ligament (46).

In a recent paper on surgical strategy for spinal metastasis (55), an attempt was made to determine the type of surgery necessary based on three prognostic factors: grade of malignancy, visceral metastases, and bony metastases (Fig. 82-8). Points are awarded according to the aggressiveness of the primary tumor and the extent of visceral and bony spread. A low score leads to total excision surgery, whereas a high score does not merit surgery.

The results indicated that the en bloc patients had a survival of 38 months, whereas the intralaminar excision patients survived 22 months. The palliative surgery patients lived 10 months and those without surgical treatment died at 5 months. Satisfactory pain control occurred in 80% of patients and neurologic improvement in 74%. These results suggest that an ordered approach to surgical intervention has merit, although the outcomes are not

**FIG. 82-7.** Vertebrectomy. **A:** Lateral magnetic resonance image of the thoracic spine demonstrating increased intensity of metastasis in T8 with spread into the inferior aspect of T7 and the T8-9 disc. **B:** Computed tomography scan of T8 demonstrating containment of the tumor within the bone without involvement of the spinal canal. **C,D:** Antero-posterior and lateral radiograph postoperatively following complete vertebrectomy of T7 and T8, anterior fixation with methyl methacrylate and rod fixation, and posterior pedicle screw and rod instrumentation. (From Dr. Rex Marco, with permission.)

that much different than earlier surgical series (56–58). Long-term survival is obviously related to the aggressiveness of the primary tumor, but if local extirpation is effective, then local recurrence should not be an issue in the long-term survivors.

As an adjunct to surgery, the use of preoperative embolization of metastatic spinal tumors has been shown to be effective not only in allowing for more extensive removal of the tumor, but also in reducing the intraoperative bleeding significantly with less intraoperative complications (59).

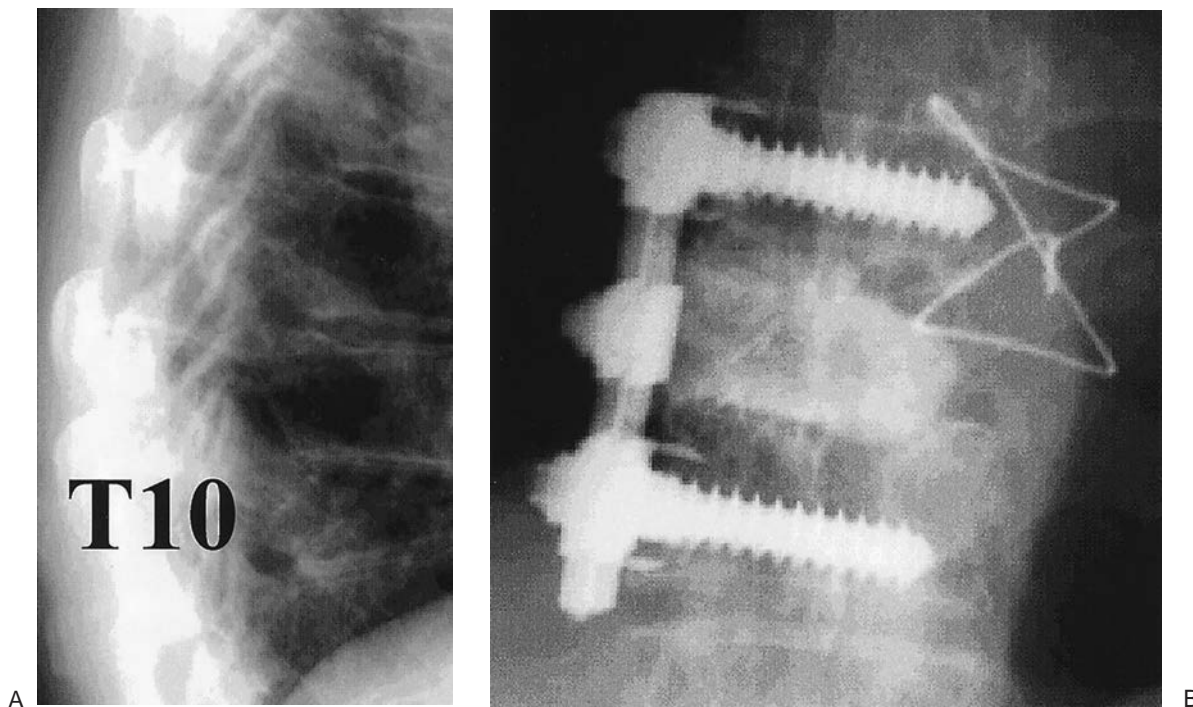

**FIG. 82-8.** Classification of the involvement of metastatic tumors grouped into intracompartmental, extracompartmental, and multiple lesions. (From Tomita K, Kowahara N, Kobayashi T, et al. Surgical strategy for spinal metastases. *Spine* 2001;26(3): 298–306, with permission.)

**THE ANTERIOR APPROACH TO THE SPINE**

When there is a need to reduce the tumor size and decompress the neurologic tissues, the most direct approach is anteriorly because the most common site is in the verte-

bral body, although a posterolateral approach may be performed in some instances (Fig. 82-5) (60,61). Stabilization of the spine also can be performed anteriorly when decompression anteriorly is required (62,63). Methyl methacrylate is a useful material as an anterior spacer (51,58,64,65),

**FIG. 82-9.** Anterior approach. **A:** Lateral radiograph of the thoracic spine demonstrating a pathologic fracture of T10 secondary to lung carcinoma. **B:** Antero-posterior projection following anterior corpectomy and decompression of the tumor with methyl methacrylate and rib strut grafting along with anterior instrumentation T9 to T11.

**FIG. 82-9.** (Continued). **C:** Computed tomography scan outlining the presence of methyl methacrylate and rib strut grafts. There is a complete decompression of the spinal canal (*white arrow*).

especially in patients with a shorter estimated time of survival. The use of mesh cages is also effective when filled with cement or allograft. Anterior iliac strut grafts combined with internal fixation is an option in patients with a longer survival time (Fig. 82-9). Prosthetic devices also have been described but are not widely used (66–69).

### THE POSTERIOR APPROACH TO THE SPINE

Laminectomy alone is not effective in improving neurologic function (70–72). Furthermore, attempting to remove tumor tissue from the anterior spinal canal from the posterior approach, especially at the thoracic and cervical levels, has a high risk of neurologic deterioration (73) and often destabilizes the level, leading to deformity with the potential for additional neurologic impairment. Nevertheless, the posterior approach is more accessible, less hazardous, and effective in the correction of deformity if combined with instrumentation (Fig. 82-10). Seg-

**FIG. 82-10.** Posterior surgery. **A:** Lateral radiographs of a breast carcinoma at T9. The patient had quite significant pain from this pathologic fracture and tumor. **B:** Computed tomography scan demonstrating significant involvement of the vertebral body and encroachment on the spinal canal although she was neurologically intact. **C:** Lateral postoperative radiographs demonstrating fixation of the lesion and bone grafting followed by radiation therapy with good pain relief and no neurologic deterioration.

mental fixation using pedicle screws is often the treatment of choice, although sublaminar wiring may be used as well, particularly if there is multiple segment involvement in an osteoporotic spine (74). For posterior or lateral pathology, particularly at the lower lumbar region, a posterolateral approach often is sufficient.

### COMBINED APPROACH

The combined approach is required for those cases where there is major involvement of the spinal columns both anteriorly and posteriorly. Anterior grafting or spacers along with posterior instrumentation, with either pedicle screw fixation or segmental fixation, is often required to be performed in two stages under one anesthetic or a few days apart. Alternatively, the anterior and posterior procedures can be effectively accomplished through a posterior approach (65,75). If complete vertebrectomy is feasible in an isolated lesion of the vertebra, then stabilization using an anterior bone strut combined with anterior and posterior stabilization is necessary following the vertebrectomy (Fig. 82-7) (40,57,61,76).

### RESULTS OF SURGERY

In most studies, pain relief is significant, as high as 92% (77,51,61). Neurologic deficits following surgery improve by about 80%, especially with anterior surgery (Table 82-1) (56–58,72,76,78–85). Ambulation has been reported to be as high as 93% (86), particularly with anterior surgery.

### COMPLICATIONS

Surgical complications tend to be higher than in other conditions in the spine but with improving surgical and anesthesia techniques, the incidence of major problems should decrease as was observed in a recent review where 75% of patients had no complications (87).

Mortality for the anterior approach or the posterior approach with instrumentation is as high as 8% (88–90). Worsening of neurologic function may occur in up to 5% of patients undergoing an anterior approach and up to 25% for patients treated by laminectomy alone (20). Wound healing can also be a significant problem because of malnutrition and concurrent radiotherapy (91), as high as 32% in one series. Failure of fixation with resulting deformity or recurrence of deformity is less common with the use of pedicle screw fixation and anterior reconstruction techniques, dropping from as high as 79%, to 0% to 4% (60,61,68,92).

### INNOVATIVE AND NEWER TECHNIQUES

Investigative tools are becoming more sophisticated and include performing MRIs with contrast measuring blood perfusion time-intensity curves to distinguish osteoporotic fractures from pathologic fractures secondary to metastases (93). Another imaging study, single photon emission computed tomography has been found useful in distinguishing benign disease from metastases (94). Percutaneous ablation of certain metastatic tumors of the spine is currently performed for unresectable lesions for pain control (95) and endoscopic surgery for removal of metastases at the cervico-thoracic junction (96). These innovative techniques are examples of some of the future directions that will be pursued as technological breakthroughs continue.

### SUMMARY

Although many metastatic lesions can be treated nonoperatively with bracing, analgesics, chemotherapy, or radiotherapy, those cases with instability and loss of vertebral height as well as deformity; those cases in which there is significant neurologic deficit will require operative intervention. The approach should be tailored to fit the lesion employing the anterior approach for decompression surgery and anterior stabilization, whereas the posterior approach with instrumentation should be reserved for patients with minimal neurologic involvement but in whom instability and deformity are of concern. With newer procedures such as bone conductive spacers, combined anterior and posterior surgery techniques and vertebrectomy surgical outcomes will continue to improve with less risk and complications.

# Lumbar Spine Tumors: Posterior Approach

K. Anthony Kim, Babak Kateb, Peter Dyck, Srinath Samudrala

---

Spinal cord tumors account for approximately 15% of central nervous system tumors (1). Metastatic tumors aside, common tumors of the spine can be divided by location into extramedullary (two-thirds of cases) and intramedullary types. Intramedullary tumors include astrocytoma, ependymoma, hemangioblastoma, lymphoma, and primitive neuroectodermal tumors, among others. Aside from drop metastasis, hemangioblastoma of the conus and nerve roots, and ependymomas of the filum terminale, the surgeon is rarely faced with intramedullary tumors in the lumbar spine. Extramedullary tumors of the lumbar region include nerve sheath tumors such as neurofibromas and schwannomas (40%), meningiomas (40%), filum ependymoma (15%), and dermoid and epidermoid tumors, among others (2–7). Tumors in the lumbar spine are discussed in detail in Chapters 81 and 82. In this chapter, we will focus on posterior approaches to these intradural and extradural tumors of the lumbar spine.

## INDICATIONS

As in any spine surgery, decompression of neural elements, correction of orthopedic deformity, and stabilization of acute or glacial instability are the main goals of the posterior approach (8). Posterior surgery is simple, does not require specialized approach surgeons, and allows for three-column stabilization with transpedicular instrumentation in most cases. However, historically, the posterior approach has been limited in terms of total tumor resection simply due to the proclivity of tumors in the anterior column.

Tumor surgery challenges the spine surgeon to develop minimally invasive methods of neural decompression without worsening the existing deformity and instability brought on by the pathologic process. In the past, limitations of three-column stabilization from anterior surgery alone have necessitated two-stage operations. The 360° operations are particularly significant in tumor surgery in

that excision of tumor naturally worsens a pathologic deformity and contributes to the instability of the spine. The anterior column is supported with graft or caging, and supplementation with posterior instrumentation is considered. To compound the issue, extensive tumor involvement of multiple posterior spinal levels may be an impediment for posterior fusion and instrumentation. The least invasive and least destructive operation is often ideal. The patient is often weakened from chemotherapy and may have had radiosurgery, thus being a suboptimal candidate for bony fusion. Anterior transperitoneal or retroperitoneal approaches are not tolerated in some patients, and the surgeon may consider transpedicular approaches to the vertebral column instead. To summarize, in the era of improved instrumentation, innovative fusion material with minimally invasive interventional drug and cement delivery systems and image-guidance, the posterior approach may well afford simple circumferential decompression and stabilization in patients who are unable to undergo long or multiple spine surgeries or cannot tolerate anterior decompression. Although tumor localization in the spine is predominantly in the anterior column, more posterior-directed tumor surgeries go beyond the simple palliative decompression and stabilization in preference for aggressive decompression and *en bloc* spondylectomy (9–11).

The posterior approach is a well-established method for decompression of neural elements involved by intradural tumors, neural foraminal, and spinal bony tumors that mainly involve the posterior column. A translaminar approach with preservation of the facets is sufficient for exposure to ependymomas, hemangioblastomas, and dermoid or epidermoid tumors involving the cauda equina and conus medullaris.

A simple laminectomy can be extended with facetectomy and a transpedicular approach to access the posterior vertebral column with decompression of the ipsilateral anterior extradural space and associated nerve root. *En bloc* tumor resections or limited posterior debulking

can be accomplished by experienced surgeons from the posterior approach alone for metastatic tumor. Hemilaminectomy with facetectomy allows visualization of the neural foramen and the exiting nerve root in the case of a nerve sheath tumor. Posterior fusion and instrumentation follows in the standard manner. Fluoroscopic-, endoscopic-, or navigation-guided delivery of cement, methylmethacrylate, or fusion protein substances (e.g., bone morphogenic protein) may replace the need for some anterior instrumentation surgeries in the future (12–23).

## PREOPERATIVE ASSESSMENT

### Minimizing Blood Loss—Erythropoietin and Preoperative Embolization

Patients with malignant tumors frequently present with malnutrition, anorexia, and anemia. Certain patients have already undergone radiation to the tumor bed or chemotherapy. They are in a state of iatrogenic immunocompromise, leukopenia, coagulopathy, and anemia. Preoperative autologous blood donation of 3 units of whole blood may not be possible in these patients. Cell-saver is not optimal in patients with tumor. Lee et al. studied the minimal effective dosage of recombinant human erythropoietin for posterior decompression and instrumentation of the lumbar spine. In a prospective randomized clinical trial of  $n = 45$ , 50 units per kilogram of recombinant human erythropoietin facilitated the build-up of a patient preoperative hematocrit and enabled preoperative autologous blood donation (24).

The goal of preoperative embolization is for reduction of blood loss in patients undergoing surgery for hypervascular spinal tumors (25,26). Prabhu et al. evaluated 51 patients with magnetic resonance (MR) imaging and angiography. MR imaging had a supportive role in predicting the vascularity of a majority of the tumors studied, and arterial embolization was precluded in patients who shared a vascular pedicle between a radiculomedullary artery and the tumor ( $p = .02$ ) (27).

The main predictor of successful preoperative embolization to minimize operative blood loss is not imaging but the tumor pathology itself. Tumors frequently benefiting from preoperative embolization include renal cell carcinoma (11,27,28), aneurysmal bone cyst (29), chordoma (30), hemangiopericytomas (31), multiple myeloma (11), bony sarcoma (11), neuroectodermal tumors, pheochromocytomas, and hepatocellular carcinoma (11).

### Computer-Assisted Navigation

A disadvantage of traditional tumor surgery is that the extension of the tumor is not accurately determinable intraoperatively. The surgeon is often limited in the extent of neural decompression and hemilaminectomy due to

concern for overall spinal stability and unknown extension of tumor into the canal, conus medullaris, and soft tissue structures. Additionally, tumor involvement of the posterior column may impede intraoperative identification of essential anatomy. Tumor margins are often difficult to appreciate intraoperatively and the extent of resection becomes clear only in a delayed fashion with postoperative imaging (32). Posterior instrumentation for stabilization is complicated when landmarks become unclear secondary to tumor erosion, iatrogenic debulking or prior surgery (33–36). Prior application of bone cement, in particular, renders the re-do open surgery extremely difficult (34). Addressing the frustrations of the aforementioned points, navigation with computer-assistance versus intraoperative real-time imaging may allow for improved resection of tumor and safer application of instrumentation (10).

Computer-assisted tomography or MR navigation has received mixed reviews, namely for its cumbersome preoperative planning and intraoperative real-time inaccuracies compared to preoperative imaging. Accuracy of computer-assisted navigation depends on (a) how mobile the spine segments are in relation to the other, (b) the number of registration points available, and (c) size of the target desired, be it pedicle or tumor (37,38). The presence of a fusion mass impedes conventional intraoperative assessment but can aid computer-assisted navigation by limiting local motion (33,34). Austin et al. studied seven embalmed cadaveric spines. The posterior elements of four spines were covered with bone cement. Pedicle screw placement by standard laminoforaminotomy alone resulted in an overall pedicle breach rate of 21.43% in the spines with fusion mass compared to pedicle breach rates of 6% to 10% using standard fluoroscopy. No pedicle breaches were noted in the navigation-guided pedicle insertions in the spines with fusion masses (34). The multifaceted morphology of the posterior column renders itself to increased navigational accuracy compared to the anterior column.

Buchowski et al. studied 26 pedicle and 8 lateral mass screws in human cadavers using two registration techniques. The trajectory accuracy was 2.5 1.0 mm and 2 degrees from T12 to L5. In this study, only the posterior column could be accurately registered, and there was a discrepancy of accuracy at the cervicothoracic and thoracolumbar junction (39). The use of virtual fluoroscopy offers several advantages over conventional fluoroscopy as well. While maintaining a mean trajectory difference of  $2.7^\circ \pm 0.6^\circ$  and a mean probe tip error of less than 1 mm, virtual fluoroscopic navigation marries the benefits of real-time fluoroscopy with those of computer-assistance (35,40).

Clearly, there are limitations that override the benefits with the current computer-assisted navigation systems. Still in its infancy, the future navigation systems will facilitate midlumbar posterior tumor resection and fusion

surgeries. Caution with computer-assistance is advocated in the highly unstable spine and at junctions of the spine.

### Real-Time Navigation

Intraoperative computed tomography (CT) holds great promise for tumor resection and instrumentation with greater accuracy than current intraoperative fluoroscopy alone (35,41). Holly and Foley evaluated the use of isocentric, three-dimensional, C-arm fluoroscopic-guided percutaneous placement of thoracic and lumbar pedicle screws in three cadaveric specimens. They had no pedicle breaches in the lumbar spine and an 8% breach rate of the thoracic spine confirmed by CT (42). Experience at our institution comparing thin-slice CT with the same device confirms that the isocentric three-dimensional C-arm has more of an increased sensitivity to pedicle breaches than conventional CT (in submission).

Real-time intraoperative CT and MR imaging facilitate complete tumor resection, particularly if the tumor is contrast-enhancing. Whereas a low Tesla intraoperative magnet may be suboptimal for low-enhancing tumors such as low-grade gliomas, gadolinium-enhanced MR imaging is the study for choice during resection of a dumbbell schwannoma at the neural foramen. Though still experimental, phosphorus MR spectroscopic analysis of spinal tumors may replace gadolinium dependence in the future (43). Intraoperative imaging eliminates the anterior dural space blind spot when the transpedicular approach is used for extradural circumferential tumor resection such as in anterior meningiomas and metastases. Intraoperative navigation facilitates the delivery of chemotherapy or bone substitution agents to the anterior column in the case of pathologic fracture from a posterior approach, be it transpedicular or percutaneous (12–23).

An example of the fusion properties of osteogenic protein 1 (OP-1) is seen in the work of Grauer et al. These researchers performed single-level, intertransverse process lumbar fusion in rabbits and assessed for fusion by biomechanics and palpation at 5 weeks postoperatively. Experimental arms were divided into those who underwent carrier-alone fusion and carrier-plus-OP-1 fusion. Whereas only five of eight rabbits in the carrier-alone arm evidenced fusion, all eight rabbits in the carrier-plus-OP-1 group demonstrated stable fusion. There was statistically significant loss of multidirectional movement, including flexion, in the carrier-plus-OP-1 group compared to the carrier-alone group. Although fusion rates of OP-1 determined by manual palpation were not significant from autograft fusion rates, biomechanical testing demonstrated OP-1 fusion to be more stable than the time-matched autograft fusion (17). Quicker and stronger fusion through a minimally invasive corridor is precisely the goal in tumor debulking and reconstructive surgery.

Disadvantages of the intraoperative MR imaging for the spine includes a severe limitation in instrumentation

and tools that are MR-compatible, the current lack of availability of high Tesla systems, the price of open MR imaging and its continued need for maintenance, and the restriction of the open MR imaging space (44).

In an ever-growing market of navigational and intraoperative imaging techniques, the patient with difficult anatomy, especially re-do spine cases, will benefit from image guidance.

### Neurophysiologic Monitoring

The goal of intraoperative nerve root monitoring on the lumbosacral spine is to minimize risk to the cauda equina during intradural tumor resection (e.g., ependymoma) and to reduce risk of misplaced pedicle screws. Nerve root injury has been reported to occur in as many as 11% to 15% of operations (45). The goal of intraoperative somatosensory evoked potentials (SEPs), spontaneous electromyographic (EMG) activity, and compound muscle action potential monitoring are to allow for early warning of injury to the cauda equina, spinal cord, and individual nerve roots so that the surgeon is able to correct the issue immediately. Balzer et al. studied 44 patients who underwent lumbosacral spinal decompression and instrumentation for degeneration, trauma, and tumor. Baseline peroneal and tibial SEPs were taken. Quadriceps and biceps femoris, gastrocnemius, and anterior tibialis muscle groups were recorded for spontaneous EMG. Intraoperative pedicle, pedicle screw, and nerve root stimulation were recorded during instrumentation. Most helpful was EMG recording that became aberrant in cases and required decompression of nerve root or redirection of instrumentation. Simultaneous SEP recordings were “falsely negative” as expected (45). In a separate study, Heyde et al. used intraoperative EMG stimulation of 334 implanted pedicle screws which led to corrected redirection of 3.9% of screws (46).

In the setting of lumbosacral tumor resection, EMG monitoring coupled with nerve root stimulation provides ideal monitoring during surgery. Nerve root monitoring and bladder sphincter monitoring is frequently helpful when débriding a conus myxopapillary ependymoma or tethered cord with dermoid tumor. Nerve root monitoring can provide an early warning of pedicle breach during instrumentation, although its sensitivity and specificity are yet to be clarified (47).

## THE POSTERIOR APPROACH

### Standard Laminectomy Approach to Intradural Lesion

The patient is brought to the operating room and intubated in the supine position. EMG and SEP monitoring, including placement of a bladder sphincter monitor around the Foley catheter, occurs during this period. Arte-

**FIG. 83-1.** Illustration of the prone position for the posterior approach to the spine. The patient is on a radiolucent table. Ideally, the patient is intubated with gel-foam protection of the face, gel-rolls on the chest and the iliac crest pressure points, gel-pads on the knees, and pillows around the ankles. The arms are placed at right angles to minimize retraction of the brachial plexus. The abdomen is freed of pressure to minimize intraoperative bleeding. Electromyographic and somatosensory evoked potential recording devices are placed. A fluoroscopic C-arm is placed under or over the abdomen and included in the sterile field for real-time navigation as needed.

rial line access and central access, if needed, are established. The patient is then placed on a radiolucent table in the prone position with adequate gel protection of the head and gel-rolls on the chest and iliac pressure points. The arms are placed at right angles to arrest retraction of the brachial plexus. The knees are padded and the leg and feet elevated with appropriate pillows. Leg squeezers are placed for deep venous thrombosis prophylaxis. The abdomen is noted to be free of pressure as increased intra-abdominal pressure will aggravate intraoperative bleeding. Navigation equipment is placed in the appropriate positions, including real-time fluoroscopy as needed. A preoperative pelvic X-ray may be taken to ascertain the absence of tumor involvement of the pelvis in case autograft from the iliac crest is required (Fig. 83-1).

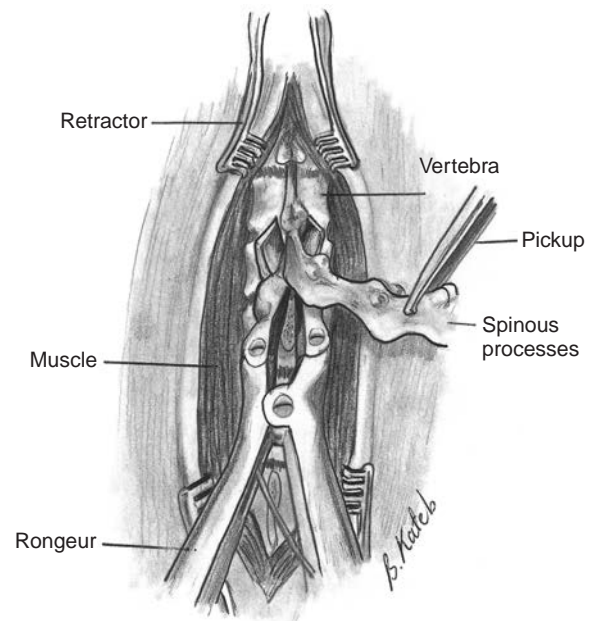

The sterile field is draped to include the medial 10 cm of bilateral iliac crest and extended superiorly as needed for the surgical approach. Frequently, an X-ray is taken with a spinal needle to mark the correct levels of surgery prior to complete field preparation and drape. In the case of sacral chordomas, extensive field draping may be needed in case of muscle flap or plastic reconstructive surgery to follow the tumor debulking.

A standard midline incision is placed and extended down to the supraspinous ligament. The erector spinae muscle is dissected away from the spinous process and laminae. Care is taken not to disrupt the interspinous and intraspinal ligaments during the subperiosteal dissection that is performed with Cobb retractors and monopolar electrocautery. Care is also taken to expose only the levels and structures needed, as additional ligamentous/muscle disruption may add to future glacial instability of the spine.

The spinous process and interspinous ligaments of the involved levels are removed with a double-action rongeur or spinous process cutter (Fig. 83-2). The inferior portion of the superior lamina is drilled down to a thin “eggshell” using a high-speed drill. The remaining lamina is removed with Kerrison rongeurs keeping above the ligamentum flavum as the ligamentum flavum at this level

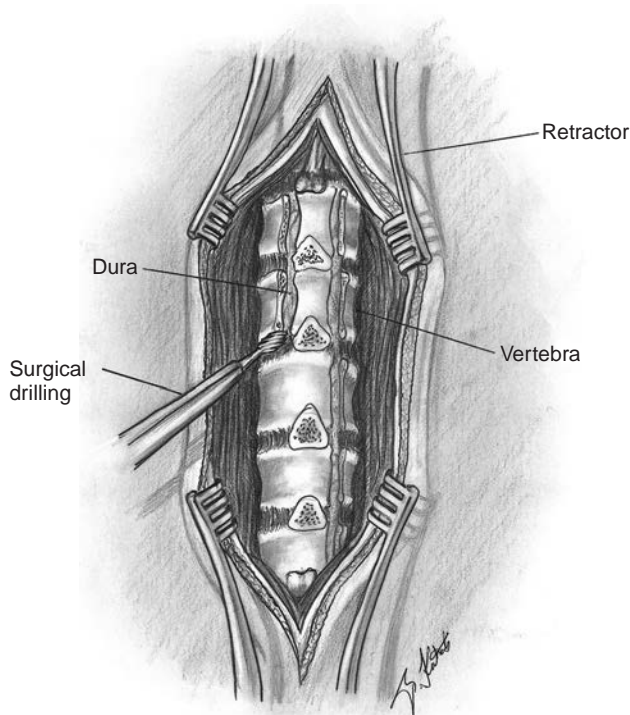

will reduce the risk of inadvertent tearing of the dura. Laminectomy is carried out superiorly and inferiorly once the dura is visualized using the combination of high-speed drilling and Kerrison rongeur technique. Ligamentum flavum is removed with the rongeur to expose the extradural space and dura. Laminectomy is carried out to the laminar-facet border laterally and care is taken not to disrupt the facet joints.

Alternatively, laminectomy may be performed using a 3- to 5-mm burr high-speed drill to drill out troughs or gutters on both sides of the facet-laminar border (Fig. 83-3). At this laminofacet junction, the outer cortical lamina

**FIG. 83-2.** Illustration of a standard approach to lumbar laminectomy. The spinous processes of the involved levels are removed with a spinous process cutter or double-action rongeurs. Care is taken not to remove supraspinous, interspinous ligaments of uninvolved levels to minimize injury to the posterior tension band.

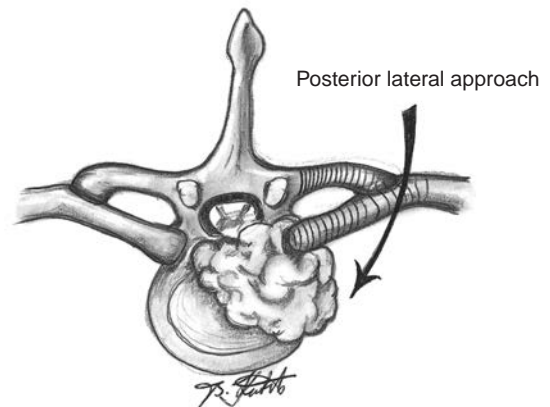

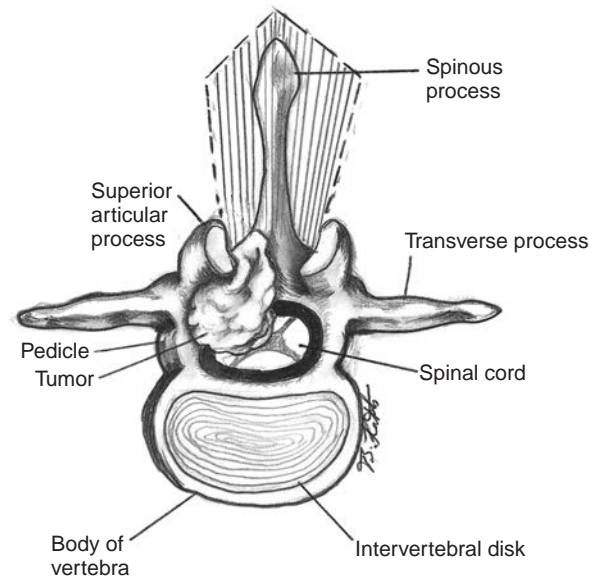

**FIG. 83-3.** Illustration of laminectomy of the lumbar spine. The spinous processes have been removed along with the associated interspinous ligaments. A high-speed drill is used to decorticate the facet-laminar junction while taking great care not to violate the facets. Once the troughs are drilled down to a thin eggshell, they may be removed with Kerrison rongeurs.

is drilled down, leaving a thin rim of bone to the point where Kerrison rongeurs may be used to remove the inner cortex, thereby separating the lamina from the facet complex. The spinous process along with the associated interspinous ligament is removed with a spinous process cutter or double-action rongeur. Essentially, the lamina is de-roofed from the epidural space (Fig. 83-4). In children, the laminectomy may be performed *en bloc* along with the intact spinous process and replaced after surgery with small, absorbable bio-implant material. This laminoplasty method with bone cement, however, is most common in approaches to cervical intramedullary tumors with concern for progressive kyphosis secondary to denervation muscle atrophy in the posterior neck.

Epidural bleeding is arrested with bipolar technique and the use of gel-foam powder. Any remaining ligamentum flavum and epidural fat is removed carefully with Kerrison rongeurs.

The microscope is introduced at this time and the dura is sharply divided at the midline. In the case of a myxopapillary ependymoma, great care is taken to visualize from the conus to the end of the dural sac. Each sleeve of the dura is then gently retracted with several 4-0 stitches to provide optimal visualization of the intradural con-

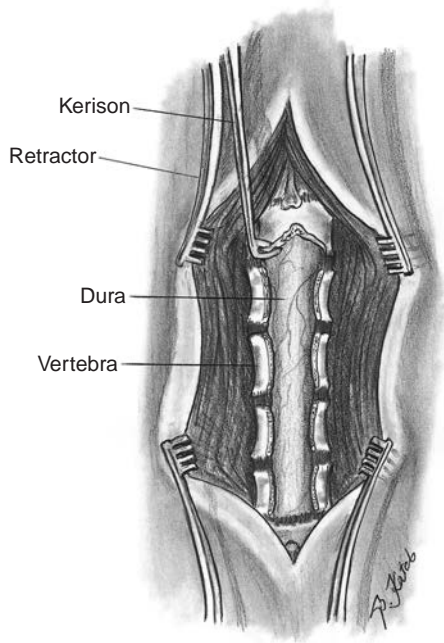

**FIG. 83-4.** Illustration of the spine postlaminectomy. The ligamentum flavum is removed and the borders of the lamina are smoothed out with the Kerrison rongeur. Once again, the facets are preserved. The dura is exposed.

tents. Dural tears are repaired with 5-0 and 6-0 nonabsorbable stitches and fibrin glue. Short long cottonoids provide for protection of nerve root elements during the debulking of the tumor in question. Standard microsurgical technique is followed at this time for tumor debulking. In the case of ependymoma, gentle suction may be sufficient to debulk the tumor from around the nerve roots (Fig. 83-5). The filum terminale can be differentiated from the rest of the nerve roots by intraoperative nerve root stimulation and by the presence of the artery of the filum terminale.

In the case of meningioma, the dura may need to be resected, in which case, bovine pericardium or other dura substitutes are used to perform a duraplasty with a 4-0 nylon stitch. Fibrin glue is placed over the duraplasty edges.

**FIG. 83-5.** Illustration of an intradural neurofibroma of the cauda equina. Often, several neurofibromas may exist in the intradural space regardless of preoperative magnetic resonance imaging findings. Note the dura has been divided and tacked up with 4-0 nylon. Nerve root monitoring and microscope-guided dissection is recommended for this portion of the surgery.

The dura is closed in running non-interlocking fashion with 4-0 nonabsorbable nylon. An intradural lumbar drain is usually not necessary. Valsalva maneuver will detect any unnoticed dural tears. The wound is irrigated and closed in standard fashion.

### Approach to Nerve Sheath Tumors

Prior to approaching a nerve sheath tumor, exact knowledge of the tumor's pathology is helpful. Discussion is held as to what the patient may want done if the tumor is not a benign one or cannot be eggshelled out. In malignant nerve sheath tumors or extensive neurofibromas, the nerve root may need to be excised. Grafting of the nerve root with sural nerve is an option as well.

The combination of hemilaminectomy with limited facet resection may be sufficient for exposure to the lateral recess and neural foramen. A similar approach is used for paramedian microdiscectomy. However, the facet may need to be excised to afford better visualization of the nerve root's path. Discussing with the patient the possibility of unilateral transpedicular screw insertion with rod placement is recommended prior to surgery in the case of a large neural foraminal tumor.

The dissection is carried out with exposure of the transverse process superiorly and, if needed, inferiorly. The surgical window is centered with the neural foramen medially

and the pedicles and transverse processes as the superior and inferior margins. In the case of a schwannoma, the tumor can be debulked from the core outward with a combination of bipolar and suction technique, or "shelled out" with sharp dissectors. Retraction of the nerve root is best minimized and we prefer the debulking from the core outward. Depending on the degree of injury to the bony elements by approach and by the tumor, the surgeon decides on the extent of stabilization instrumentation.

### The Posterolateral Transpedicular Approach

The transpedicular approach is a powerful tool for the treatment of lumbar spine tumors. Aggressive tumor debulking versus limited decompressive laminectomy is often debated and depends to an extent on the patient's life expectancy and comorbid condition. The posterolateral transpedicular approach addresses the controversy of aggressive debulking versus limited laminectomy in that the added debulking can be accomplished in the same procedure without excessively prolonged surgical time or morbidity.

Posterior approach vertebrectomy was first demonstrated as early as 1922 by MacLennan, who performed an apical resection from a posterior-only approach with postoperative casting for severe scoliosis. Since then, posterior approaches to the vertebral column have become increasingly more popular (48,49). Posterior approaches with aggressive decompression and stabilization are now feasible with spondylectomy *en bloc* tumor resection (9,50) or with the transpedicular posterolateral approach (11,51–53). Some variations of the *en bloc* and transpedicular techniques are addressed subsequently.

Through a bi-transpedicular approach with fine thread-wire saws, *en bloc* vertebrectomy was achieved in 14 patients with malignant or benign vertebral tumors by Abe et al. In this study, nerve roots had to be sacrificed in 7 cases with marginal surgical margin achieved in 10 cases. All 14 cases experienced pain relief and ambulation in the immediate postoperative period, with recurrence of tumor in 3 cases at mean 3-year follow-up (9). Bilsky et al. reported a promising 15-month follow-up in 25 patients who underwent a single-stage posterolateral transpedicular approach for spondylectomy, epidural decompression, and circumferential fusion for spinal metastasis. Twelve of these patients had either circumferential or 270° epidural spinal cord compression. Fifteen patients had cerebrospinal fluid (CSF) space obliteration with cord compression. All patients underwent prone position laminofacetectomy with transpedicular excision of tumor. Spine reconstruction is initiated through fluoroscopy-guided placement of methylmethacrylate mixed with tobramycin followed by segmental instrumentation using pedicle screws or hooks as needed. Two patients had progression of neurologic deterioration. Disadvantages of these approaches include the possible need to

sacrifice the nerve root, the need for dura and nerve root retraction (similar to microdiscectomy), the increased risk to nerve root and dura injury through the use of the osteotome or high-speed drill close to the dura, the need for posterior stabilization instrumentation, and the need for some sort of anterior stabilization from the posterior approach (e.g., the methylmethacrylate injection discussed previously) (11). The transpedicular approach has a blind spot roughly at the junction of the lateral recess and anterior dural space. Navigation promises to eliminate this blind spot in the future.

Posterolateral approach to decompression of nerve root and neural elements of the symptomatic side can be stabilized using a single diagonal fusion cage at the surgical bed and supplemented with transpedicular screw and rod instrumentation. A prospective 2-year analysis of 27 patients with degenerative spine disorders who underwent unilateral posterolateral interbody fusion (PLIF) using one diagonal fusion cage PLIF demonstrated radiographic fusion in 25 patients at 1 year (54). Fusion rates will likely be less in patients with malignant tumors, especially those patients undergoing radiation therapy. Novel alternatives, such as the titanium alloy screws connected by elastic synthetic compounds, remain to be better tested prior to standard use (55).

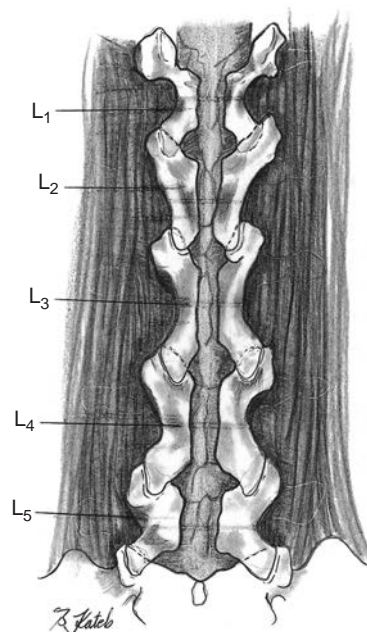

### Technique

Depending on the location of the tumor, either a bilateral transpedicular or a unilateral transpedicular approach is considered. In the thoracic spine, a bilateral approach is frequently necessary for posterior vertebral column resection (56) but a unilateral approach may be sufficient in the lumbar spine (11). The transpedicular approach for removal of a unilateral versus bilateral pedicle and posterior vertebral column mass is a destabilizing procedure. Above and below segment instrumentation is recommended with anterior column grafting.

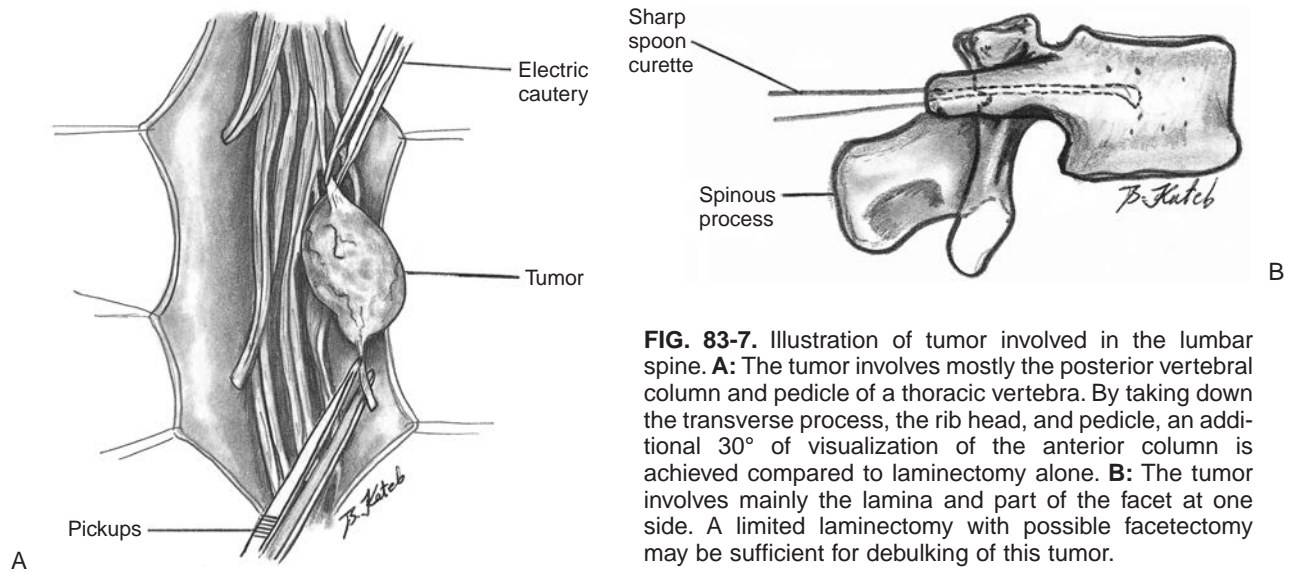

A standard laminectomy is performed over the area of tumor involvement and over the segmental areas that are to be instrumented. The facets of all areas to be fused are removed with double-action rongeurs, and, with the high-speed drill, insertion sites for pedicle screws are prepared with decortication. Decortication is continued at the transverse process and surrounding laminar areas. Discectomy may be performed using sharp dissection of the disc followed by pituitary rongeurs to remove the disc and to prepare the end plate with curettage in the standard fashion for interbody fusion. Pedicle screws are then inserted in all pedicles except for the pedicles that are to be subtracted for the approach. The pedicle that is to be drilled down is identified and the nerve roots beneath it and above it are visualized clearly. For visualization purposes, hemostasis is meticulous with gel-foam powder and microscope- or loupe-resolution is recommended. Using a 3-mm high-speed drill, the center of the pedicle

is drilled down at the angle similar to pedicle screw placement, and the pedicle is eggshelled to the level of the posterior vertebral body (Fig. 83-6). The outer edges ("shells") of the pedicle are removed with small rongeurs. A trough is then created in the posterior vertebral body using the high-speed drill followed by thin osteotomes. At this point, the pedicle will have been removed, exposing a one-inch gap between the two nerve roots. With small osteotomes, the end plate is prepared along with further resection of the posterior body. Real-time fluoroscopy is used to delineate the depth of resection and the nerve roots are carefully spared. The corridor is limited by the dura medially, the nerve roots superiorly and inferiorly, and the anterior longitudinal ligament ventrally. The lateral borders are protected by the fasciae of the psoas and quadratus lumborum muscles. This fascia continues as the transversalis fascia of the abdomen. It is worthwhile to remember that the lumbar plexus resides within the psoas muscle and the psoas muscle and fascia are preserved as much as possible as they hug the vertebral body.

The removal of the pedicle and facet joint enable a 30° corridor of visualization compared to a simple laminectomy (Fig. 83-7A,B). With bilateral pedicle take down, the visualization of the posterior body is almost complete, except for a small piece directly anterior to the dural sac. Down-going Epstein curettes are used to stomp down any small bony or tumor elements compressing the anterior dura. Depending on the extent of the posterior

**FIG. 83-6.** Illustration of a pedicle finder (in this case, curved) inside the pedicle and the posterior vertebral column. In pedicle-subtraction technique, the 1 cm area around the pedicle finder is roughly the bone subtraction desired for access to the posterior vertebral column.

**FIG. 83-7.** Illustration of tumor involved in the lumbar spine. **A:** The tumor involves mostly the posterior vertebral column and pedicle of a thoracic vertebra. By taking down the transverse process, the rib head, and pedicle, an additional 30° of visualization of the anterior column is achieved compared to laminectomy alone. **B:** The tumor involves mainly the lamina and part of the facet at one side. A limited laminectomy with possible facetectomy may be sufficient for debulking of this tumor.

column resection, methylmethacrylate may be used or stackable cages may be placed one on top of the other to complete the anterior column stabilization. Rods are placed in the pedicle screws and placed in compression. The remaining areas are prepared for fusion with decorication. Bone graft is placed in the standard manner, followed by closure.

## COMPLICATIONS

The most common complications following posterior lumbar surgery are wound infections, CSF leak, nerve root injury, and destabilization of the spine. Infections and failed surgery are discussed elsewhere (Chapters 80 and 91, respectively). Wound infections are exceptionally high in patients who are on steroids postirradiation for malignant tumors. Patients should be weaned off steroids as soon as possible. Optimal glucose control and nutrition are important. A patient with spinal headaches in the postoperative period may benefit from 48 hours of flat bed rest. Should there be a CSF leak from the wound, organism-directed antibiotics and placement of a lumbar drain for 3 to 4 days while the leak heals is recommended. The drain is set to remove 10 cc an hour and is clamped on the last day while the patient is mobilized and assessed for CSF leak. Blood or fibrin patch are alternatives to treatment of CSF leak.

# Anterior Procedures

Mark A. Knaub, Douglas S. Won, and Harry N. Herkowitz

---

Neoplastic lesions of the spine may arise from local lesions arising from within the spinal column or surrounding structures or from spread of distant malignancies through hematogenous or lymphatic routes. Local involvement of the spine may result from primary tumors of bone, lesions originating from the neural elements or their coverings, or by direct extension of tumors arising in the paraspinal soft tissues. Metastatic disease to the spine may occur with nearly any solid tumor of the body, with osseous malignancies of the appendicular skeleton, and with lymphoreticular malignancies such as lymphoma and multiple myeloma. The likely diagnosis for any given lesion depends greatly on patient characteristics as well as the location and radiographic appearance of the lesion on imaging studies. Given this information, a physician should be able to generate a reasonable differential diagnosis which will assist in the formulation of a plan for further evaluation and for eventual treatment.

Advances in systemic treatment modalities have increased the life expectancy of patients with malignancies. As a result, the surgical treatment of spinal tumors in these patients has become more common in an attempt to improve their quality of life. The goals of such surgical procedures are to improve the patient's quality of life and to minimize the morbidity and mortality associated with the surgery. Indications for surgical intervention vary depending upon the general health of the patient, the tumor type, and previous treatment rendered. General surgical indications include: (a) an isolated primary or solitary metastatic lesion or a solitary relapse in which the goal of treatment is to cure the patient; (b) pathologic fracture producing neurologic deficit or pain; (c) neurologic deficit arising from direct expansion of the tumor; (d) a tumor that is resistant to the radiation therapy; and (e) segmental instability secondary to bony destruction (1–6). These recommendations assume that the patient is medically stable enough to tolerate an invasive, lengthy surgical procedure and that the expected survival is measured in months or years, not weeks.

Specific goals of surgical intervention in a patient with a spinal tumor are to decompress the neural elements, to provide stability in the setting of preexisting instability or impending pathologic or iatrogenic instability, to decrease or alleviate pain, and in some circumstances to completely excise the tumor. Surgical approaches can be divided into those that provide access to the thecal sac anteriorly (vertebrectomy), posteriorly (laminectomy), laterally (costotransversectomy or posterolateral approach), and combined anterior and posterior access. The choice of surgical approach depends upon the location and extent of neural element compromise, the number of vertebral levels involved, the exact region of the spine affected, the presence of or potential development of spinal instability, and the patient's general medical condition.

The focus of this chapter will be on the anterior approach to tumors in the lumbar spine. Posterior procedures and combined anterior and posterior procedures are covered in detail in other chapters in this book. A brief discussion on the specific surgical indications for an anterior approach will be followed by a description of surgical techniques. A section dealing with the use of anterior instrumentation and various graft options is included to highlight these controversial topics. Finally, complications and results of anterior approaches for lumbar spine tumors are discussed.

### PATIENT EVALUATION

Both primary and malignant tumors can be found in all age groups and at all levels throughout the spine. Metastatic lesions account for a vast majority of all spinal neoplasms and are found more frequently in the thoracic and thoracolumbar spine. These metastatic foci are found most frequently in the vertebral body (7). The etiology of this phenomenon is believed to be related to the vascular supply of the spine, namely the vertebral venous system or the Batson plexus (8). Primary spinal tumors are most commonly found in the thoracic and sacral regions (9).

Primary lesions arising from the posterior elements of the vertebral body are more likely to be benign while those originating in the vertebral body are likely malignant.

The most common presenting complaint of patients with spinal cord neoplasms is pain. More than 75% of all patients diagnosed with a spinal tumor present with back pain, radicular pain, or a combination of both. Fewer than 10% of patients present with isolated motor weakness. Of those who present with back pain, about 50% are also found to have weakness on exam. Pain at night is a common presenting symptom. It is frequently continuous and unrelenting in character. There tends not to be an association with activity as there is with mechanical back pain. When radicular symptoms are present they too tend to be progressive and unrelenting in nature. They are typically not relieved by recumbency or rest as is typical with a disc herniation. Structural deformities may also be associated with spinal neoplasms. Osteoid osteoma and osteoblastoma have been associated with painful scoliosis. The onset and progression of the deformity may be rapid in this situation (10). Deformities associated with neoplasms are usually flexible and easily correctible if treated early but may become rigid and structural if neglected (11).

An algorithmic approach should be used when evaluating a patient with a spinal tumor. A sample algorithm is presented in Figure 84-1. The urgency of this evaluation depends largely on the neurologic status of the patient. After a thorough history and physical examination, initial

imaging should consist of high-quality plain radiographs. Lateral and anteroposterior images of the symptomatic segment are many times sufficient to identify the characteristics of the lesion such as tumor growth and bony destruction. Computed tomography (CT) may be used when suspicion is high and initial radiographs are negative or equivocal. Assessing the amount of actual bony destruction is also best accomplished with CT scans and may be enhanced with the addition of sagittal, coronal, or three-dimensional reconstructions. Bone scans may also be used to evaluate the patient in whom suspicion is high and initial radiographs are normal. Nuclear imaging is also helpful in identifying any skip lesions within the spine and sites of distant metastasis. Magnetic resonance imaging (MRI) has replaced myelography as the “gold standard” for evaluation of epidural metastasis and neural compromise. MRI is noninvasive, safe, and readily available at nearly all centers. It provides greater contrast for soft-tissue evaluation and allows for direct evaluation of the neural structures. Direct tumor extension into the spinal canal and the paravertebral soft tissues can be visualized. Multiplanar images produced by MRI are of superior quality when compared to reconstructions obtained with CT scanning. Identification of multilevel involvement is also possible secondary to the ease of imaging the entire spinal column as well as the sensitivity of MRI at detection of spinal tumors.

Additional evaluation of these patients should include laboratory analysis of blood and urine. Further imaging

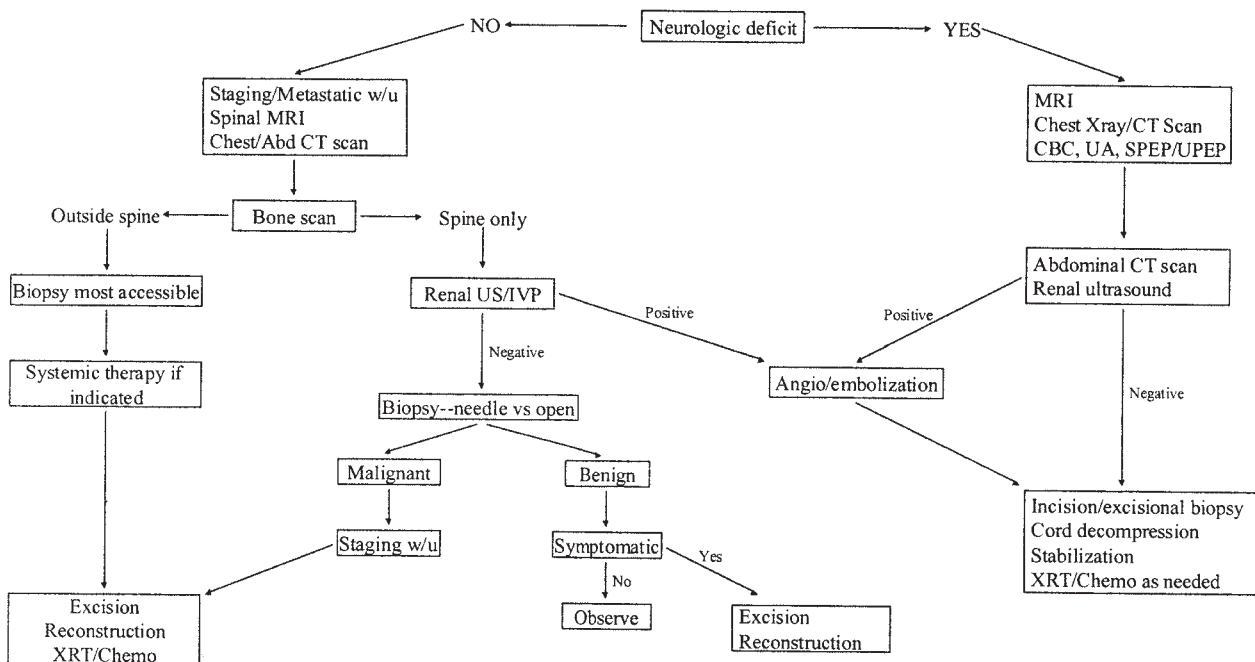

FIG. 84-1. An algorithm for the evaluation and management of a patient with a suspected spinal column neoplasm.

of the chest, abdomen, pelvis, and skeletal system should be performed to assess for other foci of disease or for a primary lesion when one is suspected. The exact nature of the neoplasm must be determined prior to the formulation of a treatment plan. A vertebral body lesion in an older patient with a history of malignancy is likely to be metastatic disease. Tumors in younger patients or those with no known history of malignancy may require a tissue specimen for diagnosis and subsequent treatment. A discussion pertaining to the method of obtaining a tissue sample for pathologic diagnosis is beyond the scope of this chapter. If an incisional biopsy is performed, strict adherence to the principles of oncologic surgery is a necessity.

### SURGICAL INDICATIONS FOR THE ANTERIOR APPROACH

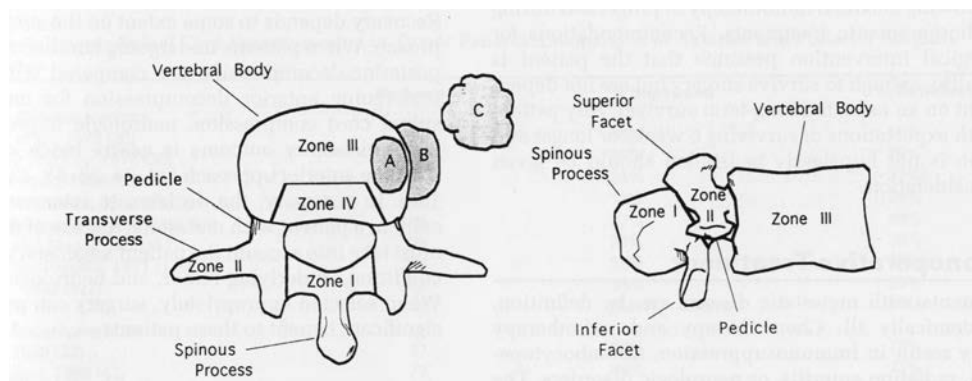

A multidisciplinary effort during the evaluation process will allow for a more global understanding of the ramifications of the patient's disease. The decision to proceed with surgical intervention in these patients should be made only after thorough evaluation of the patient's life expectancy, medical condition, and quality of life before and after any proposed surgical treatment.

When the diagnosis of a primary neoplasm of bone has been made or is suspected from the evaluation, the vertebral body can be divided into four anatomic zones for surgical planning. Tumor extension is designated as intraosseous, extraosseous, and distant tumor spread (12). A graph illustration of this anatomic staging system can be seen in Figure 84-2. Surgical planning not only requires attention to the bony involvement of the vertebral body but also the involvement or extension of the tumor into the surrounding vital structures. Involvement of the spinal cord, aorta, or vena cava likely renders the tumor unresectable.

Obtaining the widest surgical margin possible is essential in malignant and most aggressive benign tumors. The location of the lesion within the vertebral body as well as the extent of soft tissue extension determines the feasibility of wide surgical excision. Wide excision of B-type lesions in the lumbosacral regions may render the patient with a significant neurologic deficit. Lesions in zone I are best approached posteriorly. Lesions in zone II must be approached posterolaterally (13). Lesions in zone IV often require combined anterior and posterior surgical approaches. These scenarios are discussed in detail in other chapters in this text.

Lesions in zone III should be approached anteriorly. Tumors confined to a single vertebral body (type A) can be adequately resected throughout the lumbar spine. Careful scrutiny of type B lesions must be performed preoperatively to assess for invasion into vital surrounding soft-tissue structures. Segmental instability created by removal of large portions of a vertebral body should be addressed with structural bone grafting. The addition of anterior instrumentation may afford sufficient stability to avoid a posterior instrumented fusion. Lesions that require the resection of the fifth lumbar vertebral body are not amenable to an anterior approach alone. While difficult, resection of the vertebral body is feasible, but the addition of instrumentation is nearly impossible secondary to the fact that caudal fixation must be obtained in the anterior portion of the sacrum. Fixation methods available currently are not suited for placement into the anterior sacrum and any instrumentation in this region is dangerous secondary to the proximity to the great vessels. A more thorough discussion on the use of structural grafts and anterior instrumentation in the lumbar spine is included later in this chapter.

Metastatic lesions occurring in the spine are most often found within the vertebral body. As a result, most epidural compression stemming from metastatic tumors

**FIG. 84-2.** An anatomic staging system for spinal tumors. The location of the tumor within the body is described relative to zones I through IV. Extension of the tumor is described as intraosseous (**A**), extraosseous (**B**), or distant metastatic disease (**C**). (From McClain R. Spinal neoplasms. In: An HS, ed. Principles and techniques of spine surgery. Philadelphia: Lippincott Williams & Wilkins, 1998, with permission.)

develops ventral to the thecal sac. Early studies failed to take this fact into consideration when they reported the poor neurologic results when posterior decompression alone was used to treat neurologic deterioration. These studies reported no advantage of laminectomy over radiation therapy alone. As a result, many physicians have been taught that surgical intervention should be used only as a last resort. With recent advances in the understanding of the metastatic disease process and in surgical techniques for canal decompression and the stabilization of spinal instability, surgical intervention has become an accepted treatment modality in the care of patients with metastatic spinal disease.

The overall goals of treatment of patients with symptomatic spinal metastasis are to provide pain relief, to stabilize or prevent neurologic deterioration, to maintain a maximal quality of life, and to prevent the complications of the metastatic disease process. Various treatment modalities are available to treat symptomatic spinal metastasis including hormonal manipulation, chemotherapy, radiation therapy, steroids, and surgical intervention. In patients with acute neurologic deterioration only steroids and surgical decompression have been shown to be effective in stabilizing or reversing neurologic deterioration. An in-depth discussion on the nonoperative treatment of symptomatic spinal metastasis is beyond the scope of this chapter.

Prior to recommending surgical intervention, one must thoroughly evaluate the entire patient. The nutritional, immunologic, and pulmonary status must be considered as should the life expectancy. Patients with bone marrow suppression from systemic chemotherapy or radiation are susceptible to wound sepsis and the profound consequences that accompany it (14,15). No consensus exists as to the required life expectancy to warrant surgical intervention. Some investigators suggest that a predicted survival of 6 months be required to justify surgical intervention while others use a predicted survival of 3 months (16–21). Because of the difficulty in accurate prediction of survivability, the decision to operate on a patient should include consideration of the patient's quality of life, which can be greatly enhanced by timely surgical intervention.

At present, the indications for operative intervention in the treatment of metastatic spinal disease include progressive neurologic deficit before, during, or after radiation therapy (17,18,20,22–31); intractable pain unresponsive to conservative treatment (18,29,31,32); need for histologic diagnosis (25, 33); radioresistant tumors (23–27); and spinal instability or vertebral collapse, with or without neurologic deficit (14,23,34,35). Entering into surgery with well thought out goals will provide an environment for surgical success. Preservation or improvement in neurologic function, alleviation or lessening of the patient's pain, and stabilization of the patient's spine so that the patient can be mobilized are the main objec-

tives of all surgical intervention for symptomatic metastatic spinal disease. Attainment of these goals will require decompression of the neural elements in conjunction with debulking or removal of the tumor mass, correction of any preexisting spinal deformity, and stabilization of the spine.

### **ANTERIOR SURGICAL APPROACH TO THE LUMBAR SPINE**

Standard surgical approaches to the lumbar spine are used in the treatment of tumors of the lumbar spine. The assistance of a general or vascular surgeon is usually recommended for the actual surgical approach. Exposure to the midportion of the lumbar spine is accomplished through a standard retroperitoneal approach. The retroperitoneal space may be accessed either through a standard oblique flank incision or a longitudinal incision made at the lateral border of the rectus sheath. The traditional oblique flank incision allows for a wider exposure and should be used in most situations. In lesions confined to the vertebral body, the left side is used by most surgeons because of the location of the abdominal aorta. Tumors with extension into the paraspinous soft tissues should be approached from the side of the soft-tissue involvement. Approaching the lumbar spine from the right side places the inferior vena cava at greater risk for injury from excessive retraction and misdirected surgical instruments.

An anterior-only approach for lesions arising from the upper lumbar spine (particularly L1) necessitates the exposure of the T12 vertebral body for placement of instrumentation. Detachment of at least the crus of the diaphragm or possibly the entire hemi-diaphragm will be necessary to work at the level of the body of T12. Therefore, a combined thoracoabdominal approach may be used. The 10th or 11th rib is exposed and removed and can be used for bone graft purposes. A transpleural exposure of the lower thoracic spine is then combined with a retroperitoneal approach to the upper lumbar spine after the diaphragm has been released approximately 1 cm from its insertion on the body wall. Some surgeons prefer to avoid violation of the thoracic cavity during the surgical approach to the upper lumbar spine. To accomplish this, the 12th rib is exposed and removed from its bed, taking care to stay extrapleural. The retroperitoneal space is entered in a standard fashion. Because of the small size of the 12th rib it cannot be used for structural grafting.

Access to the anterior portion of the lower lumbar spine is more difficult because of the bifurcation of the great vessels. Exposure down to the midportion of the L5 vertebral body can be accomplished with a standard retroperitoneal approach in which the anterior portion of the flank incision is curved parallel to the lateral border of the rectus sheath. Mobilization of the great vessels adjacent to the lower lumbar spine is difficult because of

the tethering effect of the iliolumbar veins. These vessels are especially prone to injury and will bleed profusely if injured. Ligation of the iliolumbar veins is often required for adequate mobilization of the great vessels.

Lesions arising in the L5 vertebral body are best approached directly anterior. A skin incision oriented longitudinally in the midline or just off the midline is used to gain access to the peritoneal cavity for a transperitoneal approach or the retroperitoneum for a retroperitoneal approach. The bifurcation of the aorta anterior to the L4 vertebral body allows for direct anterior access to the lumbosacral junction in the window between the common iliac vessels. Because of the variability in vascular anatomy, preoperative imaging studies such as a CT scan or MRI should be used to determine the exact level of bifurcation prior to proceeding with surgical incision.

Once the anterior portion of the lumbar spine has been exposed and the great vessels retracted, the segmental vessels adjacent to the involved vertebral body as well as the bodies cranial and caudal to it should be ligated. Identification of the involved body is straightforward if a large soft-tissue mass is present or if extensive bony destruction has occurred. In situations where identification of the level of involvement is difficult or impossible, a localizing radiograph should be obtained. The removal of the diseased vertebral body is begun by performing complete discectomies at the adjacent levels. This allows for preparation of the adjacent vertebral end plates and identification of the exact location of the posterior longitudinal ligament and the spinal canal. The diseased vertebral body is removed with a combination of large osteotomes, Leksell rongeurs, and pituitary rongeurs. The anterior portion of the vertebral body is removed first. This creates a cavity into which the material close to the canal can be pulled anteriorly. The addition of distraction will assist in visualization of the posterior vertebral cortex and is especially useful if vertebral collapse and kyphosis are present. This can be accomplished with a large vertebral spreader or distractor. If the posterior cortex is intact, a high-speed burr may be used to thin the bone. Small curettes can then be used to pull the posterior cortex anteriorly, thereby avoiding any posteriorly directed force toward the canal. In situations in which the posterior cortex of the body has been compromised, great care must be exercised to avoid pushing tumor or bone fragments posteriorly into the canal. Penfield dissectors and small curettes may be used to free tumor found in the epidural space from the thecal sac. Care must be taken to avoid injury to the dura. Epidural venous bleeding can be controlled with the use of Gelfoam soaked in thrombin.

After complete decompression of the neural elements and removal of the diseased vertebral body, stabilization must be performed. There are many different choices for both grafting material as well as instrumentation. The details of these are discussed in the next section of this chapter.

## **RECONSTRUCTION OF THE ANTERIOR LUMBAR SPINE: GRAFTING AND INSTRUMENTATION OPTIONS**

Decompression of the neural elements and removal of the pathologic tissue fulfill only two of the goals of the surgical treatment of spinal tumors. Correction of preexisting deformity and preventing future deformity by stabilization of the spine are also paramount to the success of surgical intervention. Tumor removal and decompression of the neural elements results in further destabilization of the already compromised anterior column. Many choices for anterior reconstruction of the lumbar spine exist. The method chosen must be able to withstand the physiologic loads imparted on it and must be able to remain functional for the remainder of the patient's life expectancy.

The defect created by decompression and tumor removal can be reconstructed by both biologic and non-biologic struts. Examples of biologic struts include vascularized and nonvascularized autogenous rib grafts and various allograft struts including fibula, tibia, femur, and humerus. Autogenous nonvascularized rib grafts have been used in anterior reconstruction following resection of metastatic disease in the thoracic spine (36). Concerns about the lack of strength and small cross-sectional area limit their use in anterior lumbar reconstruction. Vascularized rib grafts have been used with success in reconstruction of kyphotic deformities but the limited life expectancy of patients with metastatic disease precludes their use in this situation. The use of fibular strut allografts for anterior column reconstruction has been described (37,38), although late collapse and recurrent deformity have been reported when they were used in metastatic disease (39). Structural rigidity combined with a small cross-sectional diameter predisposes fibular grafts to subsidence into the adjacent vertebral bodies. Concerns over subsidence into the adjacent end plates really preclude their use in this situation although some surgeons have placed two fibula grafts, "double stacking" them side-by-side in the defect. Fibular autografts may also be considered, but the relatively high complication rates from the donor site likely outweigh the benefits of using autograft in this patient population.

Allografts such as tibia, humerus, and femur have larger surface contact area and are composed of cortical bone. Therefore, they are less prone to subside into the adjacent end plates and result in kyphosis. The cortical bone that comprises these grafts allows for sufficient strength for these grafts to withstand the normal physiologic loads they will encounter. An example of anterior reconstruction with an allograft femoral strut combined with anterior instrumentation is shown in Figure 84-3. In patients with long life expectancies, the cylindrical geometry of these allografts allows for placement of additional bone graft material in the center of the graft. Filling the

**FIG. 84-3.** Preoperative lateral radiograph, axial computed tomography scan, and sagittal T2-weighted magnetic resonance image of a patient with a pathologic L3 burst fracture from metastatic adenocarcinoma. The patient presented with an acute increase in low back pain and progressive neurologic deterioration. Anterior decompression through an oblique flank incision, retroperitoneal approach was performed. Anterior column reconstruction was accomplished with an allograft femoral strut and a Kaneda dual rod/screw construct. (Images courtesy of Eeric Truumees, MD, William Beaumont Hospital, Royal Oak, MI.)

center of an allograft with cancellous autograft from the iliac crest many increase fusion rates and decrease time to solid arthrodesis. The use of both bone graft substitutes, including bone morphogenetic proteins may also have beneficial effects on time to arthrodesis and pseudoarthrosis rates.

Various nonbiological struts may also be used for reconstruction of anterior defects created by decompression and tumor removal. Titanium mesh cages (40–42), carbon fiber implants (43), ceramic vertebral body replacements (44,45), and methylmethacrylate (46–48) have been described for anterior column reconstruction following corpectomy. When methylmethacrylate is used alone, it merely functions as an internal splint and will fail in time. Therefore, the role of methylmethacrylate without bone grafting is limited to patients with short life expectancy (48). If polymethylmethacrylate (PMMA) is used, reinforcing it with wires or wire mesh will improve its strength and decrease its bending flexibility. The addition of Steinmann pins to the construct will also increase the bending resistance and can be used to anchor the cement spacer to the adjacent vertebrae. These Steinmann pins are placed through the intact vertebral bodies, spanning the defect, prior to placing liquid cement into the defect (27). Great care must be exercised to avoid thermal

injury to the nearby dural sac and adjacent great vessels. Placement of a sheet of Gelfoam adjacent to the dura and the use of more “doughy” cement, in addition to constant cool saline irrigation, can be helpful in avoiding this complication (6).

Metallic and carbon fiber cage devices initially function as internal splints as well. The long-term function of these implants relies on the development of a solid arthrodesis. Like the long bone allografts mentioned previously, these devices are typically filled with bone graft. The choice of grafting material depends somewhat on the life expectancy of the patient and the preference of the surgeon. Choices for packing of these grafts include autograft cancellous iliac crest, rib autograft, allograft cancellous bone, and various bone graft substitutes/expanders. In the future, the use of bone morphogenetic proteins may eliminate the need for autograft harvest, decrease the time to union, and decrease the rate of pseudoarthrosis and hardware failure.

Anterior strut grafts function to maintain correction of any preexisting deformity by distributing load across the end plates of the adjacent vertebral bodies. Release of distractive forces used for graft insertion results in compression across the strut graft. Despite these compressive forces and the interference fit between the graft and the

adjacent end plate, these struts alone do not provide enough stability to allow for mobilization of the patient and are frequently used in combination with anterior instrumentation. Grafts placed anteriorly without additional support are likely to displace and may do so into the spinal canal with devastating consequences. The addition of anterior instrumentation alone or in combination with posterior instrumentation and fusion will provide adequate stability to protect against graft displacement when the patient is mobilized. Concerns about excessive torque and lateral bending moments in the lumbar spine have resulted in some surgeons advocating the addition of posterior instrumentation and fusion when anterior lumbar vertebrectomy and fusion are performed after tumor resection (49). Combined anterior and posterior procedures are covered elsewhere in this text.

Anterior instrumentation for the thoracic and lumbar spine comes in many forms. Many screw/plate devices and screw/rod devices are available for anterior column reconstruction and stabilization. The use of many of these devices in the lower lumbar spine is difficult because they are not “low profile.” Any hardware placed outside of the confines of the bony spinal column will be adjacent to the great vessels as they descend in the retroperitoneum. Erosion of the implant into the vessel could result in pseudoaneurysm formation or catastrophic bleeding. Screw and rod constructs such as the Kaneda device or the Xia anterior system, are high-profile devices that protrude laterally from the bony spinal column. Their insertion in the lower lumbar spine is challenging secondary to the difficulty in mobilization of the psoas muscle in this area. The close proximity of the vessels to these implants in the lower lumbar spine typically precludes their use. These screw/rod constructs can be used safely in the thoracolumbar and upper lumbar spine. The details of the precise surgical technique for these devices are beyond the scope of this chapter.

Plate/screw devices are also available for anterior reconstruction of the lumbar spine. These devices are lower profile than the screw/rod constructs but they still extend beyond the confines of the vertebral body, therefore, the potential exists for damage to the surrounding soft-tissue structures. Loosening and back-out of the screws can also result in damage to the adjacent structures. These devices are available in many different sizes and may be precontoured to fit the spine (contoured anterior spinal plates, or CASP plates). Multiple-hole designs allow for variable placement of the screws in the intact, adjacent vertebral bodies and the intervening allograft strut. Slots have been added to some systems to allow for the transmission of dynamic compressive forces across the allograft. Locking screws have also been designed to allow these plates to function as fixed angle devices. Hook and distraction rod devices, such as the Knodt distraction rod/hook system and the Rezaian distraction device, do not extend beyond the confines of the verte-

bral bodies, therefore the risk of vascular injury is low. Unfortunately, the stability provided by these devices, even when they are combined with cement augmentation, is insufficient without posterior stabilization.

The existing clinical literature does not support the superiority of one specific structural graft or instrumentation system for reconstruction of the anterior lumbar spine following corpectomy for neoplastic disease. Clinical studies evaluating the use of various anterior instrumentation systems for the treatment of burst fractures have documented varied rates of implant failure and pseudoarthrosis (50–53). Biomechanical studies have been performed in an attempt to determine the optimum construct for anterior spinal reconstruction. Lee et al. used a calf lumbar spine corpectomy model to study the effect of different anterior grafts on the stability of different anterior reconstruction constructs (54). They found that the use of a titanium mesh cage (Harms cage) increased the torsional rigidity when combined with either anterior or posterior instrumentation. They compared the mesh cage to a block of PMMA or a calf tricortical iliac crest graft also combined with anterior or posterior instrumentation. No differences in stability were found in flexion/extension or in lateral bending. The authors hypothesized that improved friction at the graft/bone interface from the serrated edges of the cage resulted in a more rigid construct in torsion.

Biomechanical studies aimed at evaluating anterior instrumentation systems have also been published. Zdeblick et al. reported that the Kaneda anterior rod/screw construct provided greater stability than earlier systems such as the CASP and the Kostuik-Harrington devices (55). In a study by An et al., the Kaneda device, anterior TSRH system, the Z-plate, and the University anterior plating system were all found to restore stability in all loading modes when combined with an interbody graft (56). Lim et al. also evaluated the Kaneda device and the University anterior plating system in an unstable calf spine model. These devices, when combined with an anterior graft, restored the stability of the spine to at least that of the intact state (57). Kotani (57a) used a synthetic spine testing model to evaluate the static and fatigue properties of 12 anterior thoracolumbar instrumentation systems. The instrumentation systems were applied according to manufacturer’s recommendations to two synthetic cylinders that were standardized to represent vertebral bodies. Compressive loading was applied which resulted in lateral bending forces on the implants. The bending strength and fatigue properties are illustrated in Figures 84-4A and 84-4B, respectively.

The authors also included a description of the failure modes for each device. This “worst-case scenario” testing did not include the addition of a strut between the simulated vertebral elements. However, the addition of a biomechanical strut would improve both the bending strength and the fatigue properties of these devices. This study clearly demonstrates the *in vitro* superiority of some of the

**FIG. 84-4. A:** Bending strength (*N*) and **(B)** failure cycles (at 500 N) of 12 different anterior instrumentation systems. SYN, Synthes thoracolumbar locking plate; KSRT, Kaneda SR titanium; UNI, University plate titanium system, ISO, anterior ISOLA; DEW, Dewald-LDI; OLE, Olerud plate; CMS, Cross Medical Synergy; KSRS, Kaneda SR stainless steel; TSR, TSRH system; KAN, Kaneda device; SLO, Slot-Zielke device; ZPL, Z-plate. [From Kotani Y, Cunningham B, Parker L, Kanayama M, et al. Static and fatigue biomechanical properties of anterior thoracolumbar instrumentation systems: a synthetic testing model. *Spine* 1999;24(14):1406, with permission.]

anterior instrumentation systems. Despite this, the authors are careful to point out that most of these devices have been used with reasonable success in clinical situations. This suggests that perhaps strict attention to surgical technique and careful patient selection are the keys to success when performing anterior-only reconstruction after resection of a tumor in the thoracolumbar or lumbar spine.

## RESULTS

The anterior approach to the thoracolumbar and lumbar spine has been used successfully to address spinal

cord compression and instability caused by lesions such as neoplasm, fracture, infection, and deformity. Many studies have documented significant neurologic improvement in patients who underwent anterior decompression. The results of these studies must be carefully evaluated secondary to the variability among studies including surgical indications, timing of operations, methods of defining patient function, definition of surgical complications, and length of follow-up. In addition, extrapolation of these data to the lumbar spine is also difficult because these studies combined surgical treatment of the tumors involving the cervical, thoracic, and lumbar spines.

The vast majority of malignant primary spine tumors and metastatic lesions of the spine occur in the vertebral body. When neurologic compromise does occur it is most likely related to compression of the neural elements from ventral pathology. Retropulsed fragments of bone from a pathologic fracture, direct extension of tumor, epidural metastasis ventral to the thecal sac, and draping of the neural elements over a kyphotic segment created by a fracture can account for compression of the neural structures. Initial studies that documented the results of the surgical treatment of neurologic deterioration in the setting of spinal tumors found that surgical decompression, in the form of a posterior decompression, had no benefit when compared to radiation therapy alone. These studies failed to take into account the fact that neural compression occurs ventrally and therefore, is not directly addressed by posterior decompression.

Several studies have been published that compare anterior and posterior approaches for the treatment of metastatic or primary lesions of the anterior column. Kostuik et al. reviewed 100 consecutive patients with tumors involving the anterior column (2). Metastatic lesions comprised 71% of the patients in this study. The stated indications for the surgical intervention included spinal instability, impending pathologic fracture, and rapid progression of neurologic deficits. Decompression and reconstruction of the thoracic and lumbar spine were performed through anterior, posterior, or combined anterior and posterior approaches. In the group of patients with metastatic disease, 30 of the 41 (73%) patients who underwent an anterior decompression achieved significant neurologic recovery, compared with only 16 (40%) patients who were decompressed with a posterior approach. Siegal compared the neurologic status of patients with primary and metastatic tumors of the spine that underwent anterior decompression versus posterior decompression (24). Eighty percent of patients treated with anterior decompression retained or regained the ability to walk postoperatively, compared to only 40% of those treated with a laminectomy. In addition, 5 of 25 patients who underwent laminectomy experienced neurologic deterioration. In comparison, 12 of 13 patients treated with anterior decompression regained at least one grade in neurological function. McLain performed a review of the literature and reported on 427 cases of anterior decompression. He found that 78% of patients that were decompressed anteriorly had a significant improvement in neurologic function and that a satisfactory outcome was obtained in 80% of the patients. Weinstein reviewed 746 cases of posterior decompression found in the published literature (58). He compared the neurologic and functional outcomes of these patients to those reported by McLain (59). Only 33% of patients that underwent posterior decompression showed neurologic improvement postoperatively. Weinstein also found that only 37% of these patients had satisfactory clinical out-

comes. While these two literature reviews combine studies with great variability, they highlight the fact that patients with neurologic decline secondary to metastatic spinal lesions benefit from anterior decompression of their spinal canal.

A strong correlation has been repeatedly reported between preoperative neurologic status and postoperative outcome, regardless of the surgical approach for decompression. Most studies have found that 60% to 95% of the patients who had the ability to ambulate at the time of diagnosis retained the ability to ambulate postoperatively. Conversely, only 35% to 65% of the patients with paraparesis regained the ability to ambulate after decompression. Those patients with complete paraplegia have less than 30% likelihood of regaining the ability to ambulate (1,2,30,60–64). The rate of progression of neurologic deficit is also an important prognostic factor. Harrington reported that if the neurologic deficit progresses rapidly, in less than 24 hours, the prognosis for neurologic recovery is poor, irrespective of the treatment rendered (3). Slow onset and progression of the neurologic deficit tended to have a much more favorable prognosis.

A review of 36 patients with metastatic disease of thoracic and lumbar spine treated with anterior corpectomy and stabilization was published by Kaneda (65). A majority of these patients presented with pain as their main complaint. Following surgery, only 1 of 36 patients required occasional narcotic pain medication. Nearly 60% of the patients were pain-free while 20% reported only minimal pain. Of the 27 patients with preoperative neurologic deficit, 19 (70.4%) patients improved at least one Frankel grade postoperatively. Of the 14 patients who were bedridden before surgery, 11 became ambulatory and 2 were able to transfer from a bed to a chair. Local recurrence occurred in 5 patients who underwent subtotal corpectomy and 3 patients who underwent total corpectomy. Recurrence occurred at an average of 16 months (7 to 28 months), and all 8 patients had radioresistant tumors.

Harrington also reported on 52 patients with spinal instability secondary to metastatic lesions of the spine (20). These patients underwent anterior decompression and stabilization with methylmethacrylate *in situ*. Of 52 patients, 26 had a metastasis to the cervical spine, 18 to the thoracic spine, 4 to the thoracolumbar spine, and 4 to the lumbar spine. Preoperatively, 40 of the 52 patients had a major neurologic deficit that required spinal cord or nerve root decompression. Of these, 40% had complete neurologic recovery following anterior decompression and stabilization. Twenty-five percent showed significant improvement while five patients remained unchanged. Only one patient deteriorated neurologically after an anterior decompression and stabilization.

Despite the variability in patient characteristics found in published reports on the surgical treatment of primary spine tumors and metastatic lesions of the spine, three major themes have emerged:

1. The presence of a preoperative neurologic deficit correlates with poorer outcomes regardless of the treatment rendered.
2. Rapidly progressive neurologic deterioration is predictive of less likely return of neurologic function after decompression.
3. Because of the anatomic location of most malignant primary and metastatic tumors in the spine, compression of the neural elements occurs ventrally in the vertebral body.

Accordingly, decompression through an anterior approach results in a greater chance of neurologic recovery, greater pain relief, and better clinical outcomes.

## COMPLICATIONS

Complications related to the surgical treatment of spinal tumors are common. Adverse events such as infection, recurrent instability, recurrence of disease, vascular injury, pseudoarthrosis, and medically related complications have been reported in approximately 25% of cases. The occurrence of a new neurologic deficit following anterior decompression for spinal tumors is approximately 2% to 4% (20,24,66). The development of complications in this patient population can be devastating. They may result in multiple return trips to the operating room and prolonged hospitalizations, which negatively affect the quality of life of these patients. As with any procedure, prevention of the complication is the best treatment.

McAfee et al. retrospectively analyzed 24 patients who had major complications after undergoing stabilization with methylmethacrylate. Initial instability was related to metastatic tumor in 9 patients and to a traumatic condition in 15 patients (67). Postoperative neurologic deficit occurred in 11 patients. The authors thought that the recovery of the neurologic function was hindered by cement in 6 of these patients. The most common complication in this group of patients was loosening and loss of fixation. Hardware failure occurred in 12 of 15 of the trauma patients and in 8 of 9 patients with neoplasm. A deep wound infection developed in 6 patients. Based on the findings of this review, the authors recommended combined anterior and posterior procedures for the reconstruction of instability in the setting of tumor. The use of methylmethacrylate alone, without bone grafting, will fail because a solid, bony fusion will not occur. This technique should be reserved for patients with a limited life expectancy. In patients whose long-term prognosis is good, biologic (autograft or allograft) struts should be used to allow for eventual union across the fused segments.

The use of radiation therapy for the treatment of spinal tumors has also been shown to affect complication rates. McLain et al. reported that patients undergoing preoper-

ative radiation therapy accounted for 42% of all complications (68). This group also suffered 70% of the major complications in this study. Wise et al. also reported higher complication rates (40%) in those patients treated with radiation therapy preoperatively (15). In McLain's study, 36% of patients developed transient neurologic deficits in the postoperative period (68). Wound infection and vascular injuries also occurred in 18% of patients. Clinically significant pseudoarthrosis developed in two patients while progression of renal cell carcinoma led to late instability in another two patients. Failure of fixation occurred in four patients and was attributed to inadequate reconstruction of the anterior column that was compromised from tumor involvement.

Wise et al. (15) retrospectively reviewed 80 patients who underwent surgical treatment for metastatic disease of the spine. Mean survival time after the diagnosis of spinal metastasis was 26 months, while mean survival time after surgery was 15.9 months. Twenty (25%) of 80 patients had 35 complications. The authors found a relationship between the Harrington classification and complication rates. Increased rates of complications occurred in those patients with greater neurologic deficits, lower Frankel grades before and after surgery, and those who were treated with radiation preoperatively.

Patients with spine tumors are more likely to be immunosuppressed secondary to their primary disease as well as the treatment of that disease. These patients may also be malnourished because of the systemic effects of their malignancy and its treatment. Both immunosuppression and poor nutritional status have been associated with higher rates of postoperative complications (69–73). The urgency with which many of these patients present many times precludes the optimization of nutritional parameters prior to operative intervention. If elective decompression and stabilization is planned, laboratory studies such as albumin, serum transferrin, and total lymphocyte count may be used to guide preoperative nutritional supplementation. Optimization of the nutritional status of the patient may help to prevent postoperative complications that could negatively affect the patient's quality of life.

# Combined Anterior-Posterior Procedures

Osamu Shirado, Naoki Takeda, Akio Minami, and Kiyoshi Kaneda

---

The survival time of patients with malignant tumors has been increasing, not only because of the advances of adjunctive treatments such as chemotherapy and radiotherapy, but also because of advances in surgical treatments. Thus, raising the quality of life (QOL), as well as lengthening life expectancy, has become another important concern for clinicians who treat patients with malignant tumors.

The surgical treatment of primary malignant and metastatic spine tumors has progressed with the development of surgical techniques and spinal instrumentations. Laminectomy proved to have no advantage over conventional radiation therapy in 1970s (1). Following this evidence, simultaneous laminectomy and stabilization with spinal instrumentation provided better results than laminectomy alone (2). The technique of posterolateral decompression or costotransversectomy (3) in thoracic lesions has also provided much better surgical results for metastatic spinal disease (4). However, the main goals of those surgical procedures were to relieve and prevent deteriorating paralysis, thus those procedures were palliative treatments. As a result, local recurrences inevitably arose if the patients survived for a long enough time after surgery (4,5).

In the modern era, when patients with cancer may experience medium- or long-term survival, we now see patients with spinal metastases who will require more radical and aggressive surgery to decrease the rate of local recurrence. Accordingly, total spondylectomy through combined anterior-posterior procedure or posterior procedure alone is needed and indicated for patients with primary malignant or metastatic spinal tumors who are expected to have a long-term survival (6–9).

Total spondylectomy can be performed using two approaches: the anterior-posterior combined approach (6,7,10) or the posterior approach alone (8,9,11). Our preferred and recommended method is the combined approach. On the other hand, one of the most popular posterior approaches is known as total *en bloc* spondylectomy, or TES (8,9).

From the oncologic standpoint, either approach results in intralesional resection if the tumor has invaded both pedicles. No matter how *en bloc* resection of the involved vertebra with tumors is performed, it is impossible to curatively resect the tumor with a wide margin in such cases. Contamination by the remaining tumor cells is almost inevitable when dissecting the posterior and anterior elements of the vertebra at the pedicle during surgery. However, this procedure is currently recommended as the most aggressive treatment and is likely to have the most successful outcome in patients with primary malignant or metastatic spinal tumors. In this chapter, the surgical indications and techniques for the combined anterior-posterior procedure for resecting spine tumors are described.

### INDICATIONS FOR THE COMBINED ANTERIOR-POSTERIOR PROCEDURE (TABLE 85-1)

A number of different surgical approaches are available to spine surgeons. The surgical approaches for spinal tumors, however, can be divided into three main procedures: anterior, posterior, and the combined anterior-posterior approach. Spine surgeons must consider several factors before determining the most appropriate approach for each case. The most suitable choice of approach for patients with spinal tumors depends upon (a) the patient's life expectancy, (b) the number of vertebrae involved, (c) the location and extent of neural impingement, (d) the presence and degree of spinal instability, and (e) the patient's general medical condition (12). The most appropriate surgical approach is determined only after considering the following factors: the efficacy of adjunctive therapy such as radiotherapy, tumor biology including the grade of malignancy, the extent of tumor, the degree of spinal instability, vertebral involvement, and life expectancy. More basic factors should be taken into account as well such as the patient's immunologic, nutritional, and psychosocial condition.

**TABLE 85.1.** *Indications for the combined anterior and posterior procedure for spinal tumors*

Anticipated life expectancy longer than 6 months
Three-column involvement of the tumor
High-grade instability such as the three-column instability
Involvement of contiguous vertebral bodies
Solitary metastases
Destructive benign tumor such as giant cell tumor

After considering all of the above, indications for combined anterior and posterior procedures in primary malignant and metastatic spinal tumors are as follows (6,7,10): (a) three-column tumor involvement of the spine, (b) high-grade instability such as the three-column instability, (c) involvement of contiguous vertebral bodies, (d) the presence of solitary metastases, (e) anticipated life expectancy longer than 6 months, and (f) destructive benign tumor such as a giant cell tumor. Solitary metastasis limited to the vertebral body may also be an indication for this combined procedure, as TES can be performed more safely using this approach.

From the prognostic point of view, it is very important to predict the patient's life expectancy as exactly as possible. Some prognostic scoring systems are advocated to evaluate the life expectancy in patients with spine tumors, especially metastatic tumors. Tokuhashi et al. (13) proposed an assessment system for the prognosis of metastatic spine tumors. They employed six parameters: (a) the patient's general condition, (b) the number of extraspinal bone metastases, (c) the number of metastases in the vertebral body, (d) the presence of metastases to major internal organs, (e) the primary site of the cancer, and (f) the severity of spinal cord palsy. Each parameter ranged from 0 to 2 points, for a possible total score of 12 points. The more the points the patient receives the better the prognosis. The authors pointed out that the total score is likely to be well correlated with the prognosis in each patient. An excisional operation should be performed on those cases scoring 9 points or above. Tomita et al. (9) proposed a prognostic score using three prognostic factors: grade of malignancy, the presence of both visceral metastases, and bone metastases. Based on the scoring system, they suggested a surgical strategy for spinal metastases. As a result, they recommended that all patients with solitary tumors have the potential for long-term survival, thus justifying a more aggressive strategy.

### SHORT REVIEW OF THE LITERATURE ON THE SURGICAL APPROACHES FOR SPINAL TUMORS

Kaneda and Takeda (6) recommended the anterior procedures for corpectomy when (a) the metastasis is confined to one, or two to three contiguous vertebrae, (b) a metastatic lesion is confined to the vertebral body of a

radioresistant tumor, (c) there is anterior instability (i.e., a vertebral collapse is more than 50% likely), (d) there is epidural expansion in the anterior spinal canal and the main mass is confined to the vertebral body, or (e) the anticipated life expectancy is longer than 6 months.

Simultaneous corpectomy with posterior-element resection of the vertebra (i.e., total spondylectomy) is indicated in solitary metastases to the spine in radioresistant tumors such as those encountered in renal, thyroid, and breast cancers (9,10). There are two types of surgical approaches for total spondylectomy: posterior approach alone and a combined anterior and posterior approach. In 1971, Stener (14,15) removed three vertebrae in a patient with a chondrosarcoma of the spine using the posterior approach alone. He recommended complete spondylectomy of the thoracic and lumbar vertebrae down to the third lumbar vertebra using the posterior approach alone. For complete removal of the fourth lumbar vertebra, however, he advised using both an anterior and posterior approach. There were two reasons for this recommendation: one was the close relationship between the lower lumbar spine and several large vessels; the other was the hindrance caused by the iliac wings when exposing the L5 vertebral body from behind.

Roy-Camille (11) performed a thoracic one-stage total vertebrectomy through a simple posterior approach. However, he pointed out that the psoas and iliac muscle insertions on the vertebral body, as well as the vascular lumbar pedicles, make the posterior-only approach to the lumbar vertebra impossible. A two-stage operation should be recommended in such a case. Magerl and Coscia (16) reported a posterior vertebrectomy of the thoracic and lumbar spine. However, it would be contraindicated to attempt a total vertebrectomy using the posterior procedure alone in a situation of extension of the tumor into the soft tissues surrounding the vertebral body. More recently, Tomita et al. (8) reported a TES that resected the involved vertebra in two major blocs using the posterior approach alone. This technique is the most appropriate surgical procedure for primary vertebral malignancy.

Conversely, Sundaresan et al. (17) recommended that spondylectomy should be carried out as a two-stage operation with stage 1 the posterior phase and stage 2 the anterior phase. They recommended a staged operation in order to minimize the possibility of neurologic deficits resulting from ischemic damage to the nerve tissues. Fidler (18) reported a radical resection of the spine from a posterior approach (the first stage), and then an anterior and posterior combination (the second stage). He concluded that a purely posterior approach was not feasible in some cases, because of lung involvement, extensive adhesions after a previous operation, paravertebral hematoma, and the difficulty of mobilizing and delivering a large tumor through the posterior approach alone. A combined approach enabled radical resection of all the involved tissues allowing direct visualization, and also

permitted the unhindered access to, and control of, the blood supply to the tumor.

### PREOPERATIVE MANAGEMENT

Adjunctive treatment such as radiotherapy and chemotherapy is carefully considered and planned during the preoperative period. Preoperative radiotherapy is often very effective for some radiosensitive malignant tumors such as prostatic and lymphoreticular tumors. In such tumors excellent clinical results can sometimes be obtained by irradiation alone in many patients.

The effectiveness of spine surgery in treating tumor cases is sometimes compromised by excessive bleeding. Metastatic renal cell and thyroid carcinomas can be highly vascular, increasing patients' morbidity and mortality. Angiography with selective embolization of the segmental vessels in the involved vertebra, including the vertebrae above and below, can be an effective way to manage such lesions, and may be safely carried out up to 24 hours prior to surgery. The use of this technique can decrease intraoperative blood loss and perioperative morbidity and mortality. It may also be helpful to identify the origin of the Adamkiewicz artery. We recommend this procedure one day before surgery. Thoracolumbosacral orthosis (TLSO) for postoperative external support should be manufactured preoperatively.

### SURGICAL TECHNIQUES IN THE COMBINED ANTERIOR-POSTERIOR PROCEDURE

The posterior procedure precedes the anterior one. The combined procedure is usually performed under the same anesthesia.

#### Step 1: Posterior Procedure

Resection of the posterior elements (including the spinous process, laminae, articular processes, transverse processes, and the pedicles) is performed first. Patients are positioned prone on the Hall frame in a comfortable fashion without pressure on the thorax or abdomen. The skin is suitably prepared, and is infiltrated only into subcutaneous tissues with a 1:500,000 epinephrine solution. A midline skin incision is made over at least two spinal segments, above and below the involved segment, followed by subperiosteal exposure. Dissection should be extended laterally along the ribs with the thoracic spine and the transverse processes in the lumbar spine. Wide resection is needed to make the total spondylectomy feasible. The ribs of the involved vertebra should then be dissected 3 to 4 cm from the midline. The periosteum should be carefully removed from the ribs to avoid opening the pleura. This posterior procedure should be performed extrapleurally and retroperitoneally.

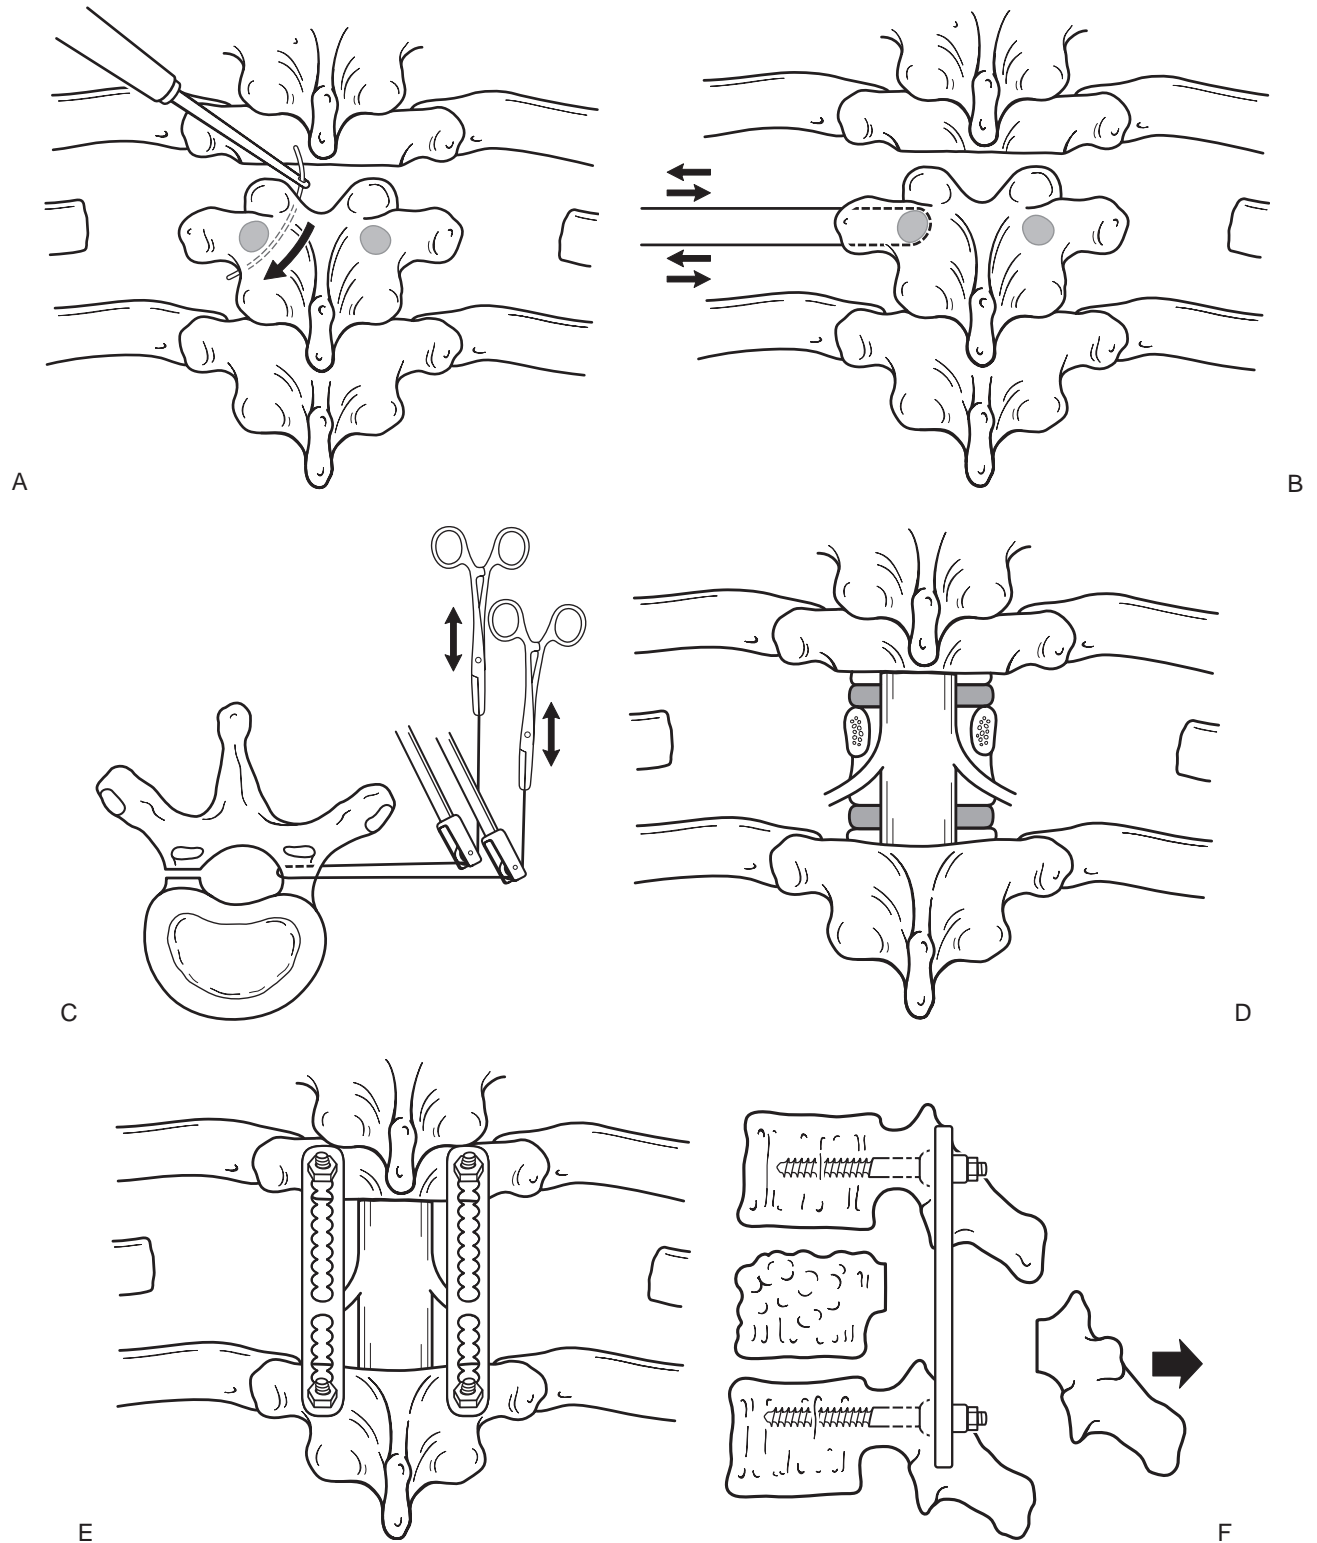

Both costotransverse ligaments are divided, and both rib heads should be carefully removed. Both superior articular facets of the involved vertebra are then exposed by removing the proximal lower laminae and inferior articular processes of the adjacent cranial vertebra. A threadwire saw, or T-saw (a flexible, multifilament device, 0.54 mm in diameter, designed and developed by Tomita), is used to perform *en bloc* resection of the posterior element (8,9). The T-saw is inserted into the epidural space beneath the lamina through a T-saw guide, and is pulled out of the neural foramen (Fig. 85-1A). The T-saw guide should be introduced along the medial cortex of the pedicle so that the spinal cord and the nerve root are not damaged. Both ends of the T-saw are pulled around the pedicle of the involved vertebra with a sawing motion. This maneuver is performed in a lateral direction with the help of a T-saw manipulator and guide (Fig. 85-1B, C).

Thus, both pedicles of the involved vertebra are cut off using the T-saw. Finally, after incising the interspinous ligament, the facet capsules, and ligament flavum, posterior elements of the involved vertebra can be removed *en bloc* (Fig. 85-1D). To maintain spinal stability after resection of the vertebral body for the next step, a temporary spine fixation is performed with a unilateral posterior instrument such as the pedicle screw system (Fig. 85-1E, F). Otherwise, the spine could be completely temporarily destabilized and at even greater risk of neurologic compromise.

The segmental arteries, which lie inferior-lateral to the pedicle, should be identified and tightly, bilaterally ligated. The pleura are pushed aside from the lateral aspect of the body. The segmental arteries and the aorta are carefully dissected from the vertebral body using the fingers. A curved spatula or malleable retractor is inserted to protect and displace the anterior structures. The discs above and below the pathology are carefully identified, and resected posterolaterally from both sides. Great effort should especially be paid to resecting the contralateral sides of the disc from which the anterior approach is performed. With the dura visible, the posterior longitudinal ligament can then be carefully cut with a knife. Following these procedures, the final posterior instrumentation is adjusted, and the spinal deformity or lesion should be corrected appropriately.

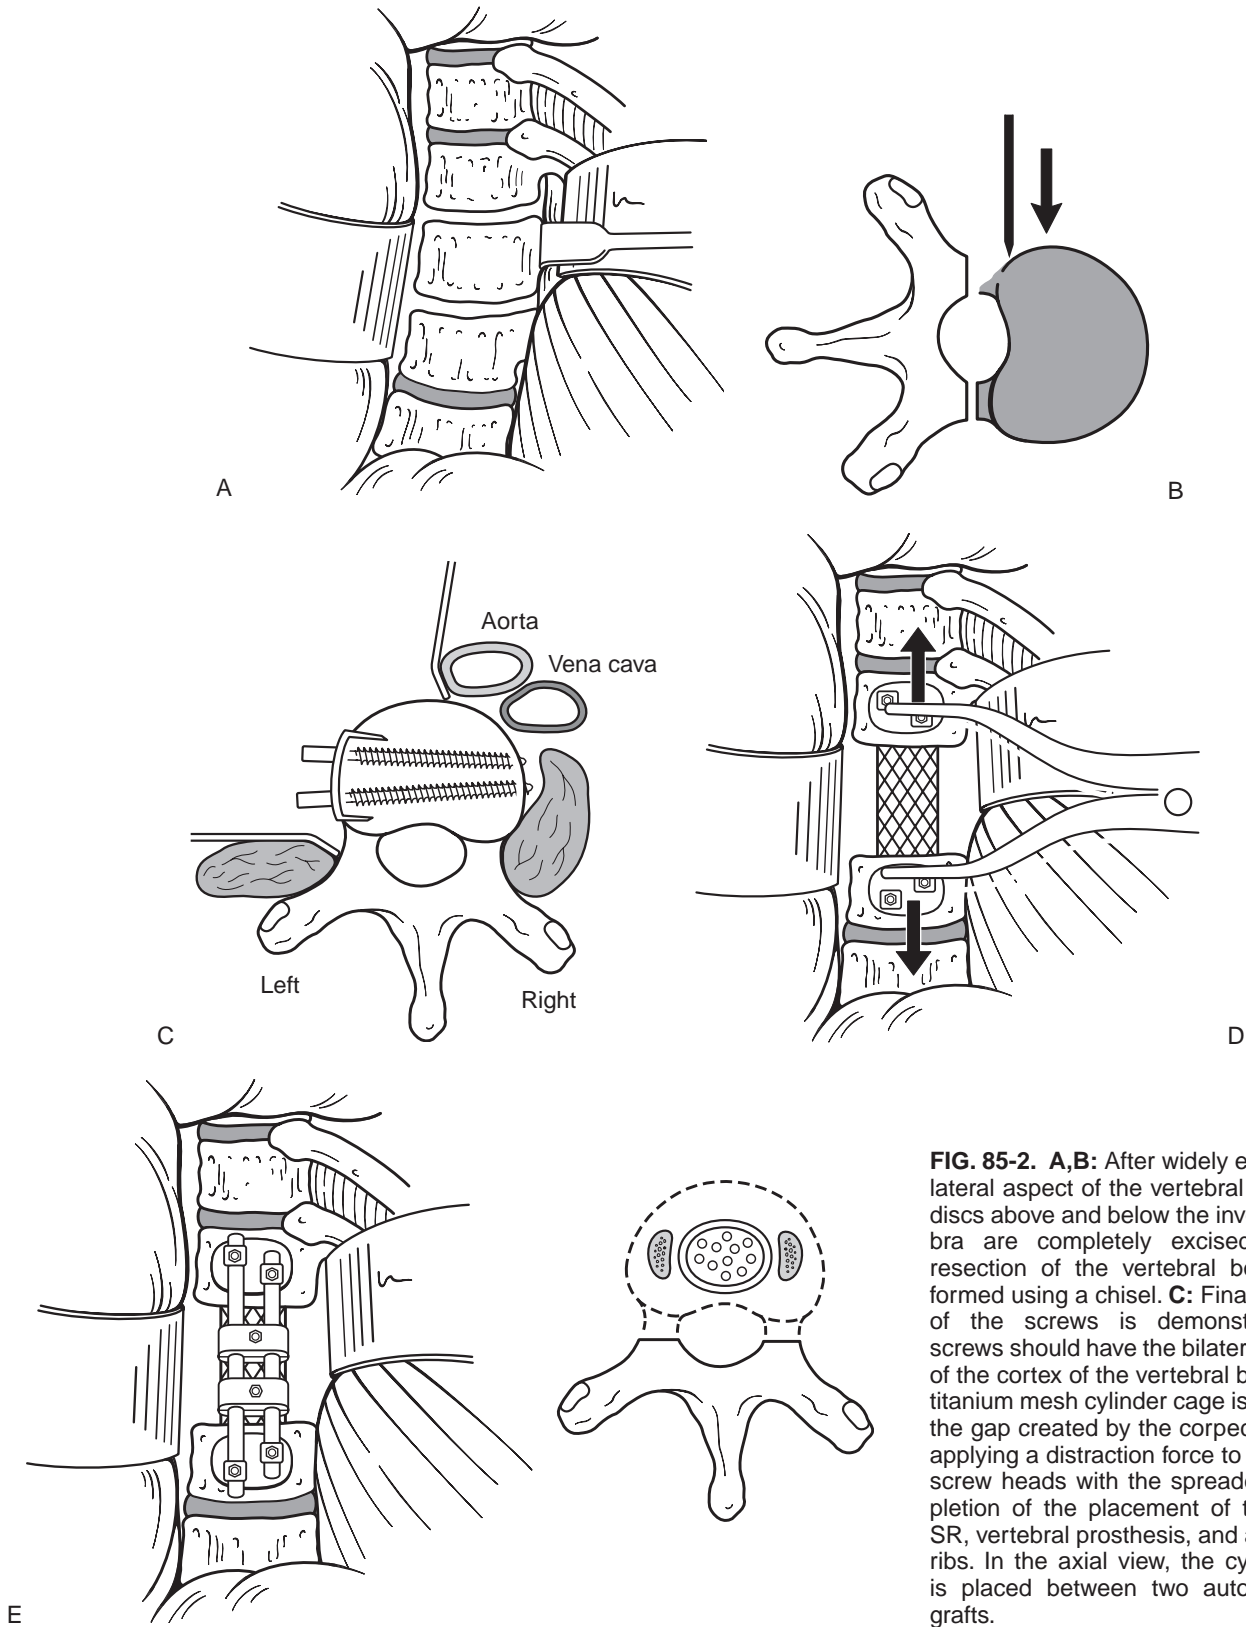

#### Step 2: Anterior Procedure

The involved spine can be approached from either the right or left side, depending upon the location of the pathology. If there is no special consideration regarding the pathology, then our preferred approach to the thoracolumbar and lumbar spine is from the left side. The aorta is located on the left and anterior to the spinal column at this level, and is much easier and safer to manipulate than

**FIG. 85-1.** **A:** After widely exposing the posterior element and resecting the proximal ribs of the involved vertebra, the threadwire saw (T-saw) is introduced into the epidural space under the lamina through a T-saw guide, and is pulled out of the neural foramen. **B,C:** Both ends of the T-saw are pulled around the pedicle of the involved vertebra in a sawing motion. This procedure is carried out in a lateral direction with the T-saw manipulator. **D:** After the resection of the whole posterior element of the involved vertebra, the dural tube, costal nerve, and posterolateral aspect of the anterior element can be directly visualized. **E,F:** To preserve the stability after resection of the vertebral body, the spine is temporally fixed with posterior instrumentation.

**FIG. 85-2.** **A,B:** After widely exposing the lateral aspect of the vertebral bodies, the discs above and below the involved vertebra are completely excised. *En bloc* resection of the vertebral body is performed using a chisel. **C:** Final placement of the screws is demonstrated. The screws should have the bilateral purchase of the cortex of the vertebral body. **D:** The titanium mesh cylinder cage is placed into the gap created by the corpectomy, while applying a distraction force to the anterior screw heads with the spreader. **E:** Completion of the placement of the Kaneda SR, vertebral prosthesis, and autogenous ribs. In the axial view, the cylinder cage is placed between two autogenous rib grafts.

the vena cava. The left-sided approach can usually be performed up to the level of T9 or T10. The thoracic vertebrae above T9 or T10 are approached from the right side, because the aorta at this level is located on the left side of the thoracic spines (6,7).

The thoracolumbar spines (T10-L2) are usually exposed using an extrapleural and retroperitoneal approach by the resection of the 10th or 11th rib. Even for the thoracic spines above the 10th vertebra, surgeons should make every effort to expose the spines extrapleurally. However, thoracotomy is usually needed for the exposure at this level. At the lumbar spine below L2, a retroperitoneal exposure is usually performed.

After exposure of the anterior spine, the involved vertebral body can be carefully dissected from the surrounding organs and soft tissues. The segmental vessels on the three vertebrae, including those above and below the involved vertebrae, are then tightly ligated and cut. The lateral aspect of the vertebral bodies must be adequately exposed for total or subtotal corpectomy, and appropriate application of the anterior spinal instrumentation, such as the Kaneda SR, should be performed. For lesions involving the lumbar spine, the psoas major muscle must be sufficiently retracted posteriorly. After exposing the lateral aspect of the vertebral bodies, the discs above and below the involved vertebra should be completely excised, including the anterior longitudinal ligament. *En bloc* resection of the vertebral body is then easily carried out because the pedicles, posterior longitudinal ligament, and contralateral side of the disc have already been resected in step 1 (Fig. 85-2A, B).

After the resection of the involved vertebra, the anterior spinal instrumentation was applied to secure the unstable vertebra created by the total spondylectomy. The Kaneda SR is our preferred anterior instrumentation, and has proved to be safe and biomechanically rigid enough to reconstruct unstable spines produced by a variety of pathologies such as tumor, trauma, spinal deformity, and degenerative spondylosis (19). First, the spinal plates marked with the letters A (anterior), P (posterior), and C/R (caudal and rostral) are placed on the lateral aspect of the vertebral body. Second, the appropriate screw size is measured with the specially designed vertebral-width gauge. Then, the spinal screws are inserted into the vertebral bodies through the plate holes. The screw tips must penetrate the opposite vertebral cortex by approximately 2 to 3 mm. Screws with blunt tips can alternatively be used if the risk to the major vessels is anticipated due to the presence of these sharp screw tips (Fig. 85-2C).

Third, kyphotic deformity can be corrected by applying a distraction force to the anterior screw heads with the distractive spreader. A vertebral prosthesis such as an allograft and titanium mesh cylinder cage can be

tapped into the gap created by the corpectomy (Fig. 85-2D). The resected autogenous rib taken earlier may be added as a strut-graft material if a secure and rigid bony fusion is required. Fourth, the vertebral prosthesis is securely fixed by applying an appropriate compressive force using the compressor or other compressing device. Then, two rods may be inserted into the screw head holes, and the vertebral prosthesis firmly kept in place by applying the compressive force. Finally, the set screws can be used to fix the rods into the screw head holes that are then firmly tightened, and two rod couplers can then be added between the rods (Fig. 85-2E) (6,7).

## POSTOPERATIVE MANAGEMENT

If the patient is in a stable medical condition after the surgery, he or she can be ambulatory with the TLSO within a week after the operation. The TLSO is usually worn for 12 to 16 weeks. However, it depends upon several factors such as life expectancy, spinal stability, and QOL. Postoperative adjuvant radiotherapy can be attempted when a subtotal spondylectomy instead of a total spondylectomy is performed.

## CONCLUSIONS

As patients with a primary malignant or metastatic tumor may now be expected to live longer, the chance of local recurrence increases. Thus, the life span of cancer patients depends upon how the local recurrence can be controlled. Missenard et al. (5) investigated local tumor recurrence in 58 patients who survived 1 year or more. They highlighted the following results. First, the sensitivity of the primary cancer to adjuvant treatment and correct timing of the critical postoperative radiation therapy seemed to significantly reduce local tumor recurrence. Second, complete excision of the tumor should be indicated when the patient has a tumor that is insensitive to the adjuvant treatment (either radiotherapy or chemotherapy), and when the patient's life expectancy reaches 1 year or more.

Investigators pointed out that the local recurrence rate after corpectomy or total vertebrectomy was 22% (6) and 32% (20), respectively. This rate seems to diminish if *en bloc* total vertebrectomy is performed. As a result, *en bloc* total vertebrectomy should be recommended if the patient has a solitary spinal metastasis from a radioresistant tumor such as that from a renal, thyroid, or breast cancer (Figs. 85-3, 85-4). Combined anterior and posterior procedures described in this chapter are a powerful tool for surgeons who are willing to manage patients in need of a total spondylectomy.

**FIG. 85-3.** Case 1: Metastatic thyroid carcinoma at L1 with intractable low back pain and paraparesis in a 68-year-old woman. After tumor embolization, total en bloc vertebrectomy was performed with the anterior and posterior combined procedure. **A:** A T2-weighted sagittal magnetic resonance (MR) image demonstrated marked collapse of L1 vertebral body and spinal cord compression at L1. **B,C:** A computed tomography-myelogram and a gadolinium-enhanced axial MR image showed the tumor involving the vertebral body and the right pedicle. **D,E:** Plain X-rays 4 years after the operation. En bloc total spondylectomy of L1 was performed through the combined approach. First, the posterior element of L1 was resected, followed by reconstruction with a pedicle screw system from T11 to L3. Second, the vertebral body was resected en bloc, followed by reconstruction with an A-W glass ceramic vertebral prosthesis and the Kaneda SR system. The patient is still ambulatory with no evidence of disease, and solid biologic bony fusion has been obtained. The A-W glass ceramic spacer has now been taken off the market due to the manufacturer's circumstances. **F,G:** Plain radiographs demonstrated the L1 vertebra resected in the en bloc fashion. The vertebra was dissected only at the pedicles with no destruction of the other part.

**FIG. 85-4.** Case 2: Metastatic renal cell carcinoma at T11 and T12 with severe back pain and paraparesis in a 52-year-old man. After tumor embolization, total vertebrectomy was performed with the combined procedure. **A–C:** A sagittal T1- and T2-weighted magnetic resonance (MR) image (**A**) demonstrated collapse of T11 vertebral body and spinal cord compression at T11. The tumor extended into the spinal canal as well as into the paravertebral area. The MRI and computed tomography films also showed that the tumor invaded to the superoposterior portion of T12 vertebral body. **D,E:** The plain X-P films after the surgery. The spine was firmly stabilized, both anteriorly and posteriorly, and the neurologic deficits completely recovered.

# Prognosis and Results of Surgery for Primary and Metastatic Tumors

Jonathan N. Grauer and Alan S. Hilibrand

---

Previous chapters have described the incidence and work-up of primary and metastatic tumors of the spine. Surgical indications and techniques also have been presented. This chapter reviews the prognosis and results of operative treatment for spinal tumors. In general, surgical intervention has been shown to improve outcomes with regard to longevity and quality of life for most benign (1–3) and all malignant (4–8) primary spinal tumors. On the other hand, the role of surgery for metastatic spinal disease is more controversial (9–11).

For most spinal tumors, the extent of resection has been correlated with lower rates of recurrence and improved survivorship (7,8,12). However, the unique anatomy and function of the spine often limit the ability to perform even a wide excision of some tumors. The surgeon must find a balance between attaining adequate surgical margins and preserving vital neurovascular structures.

The potential for postsurgical instability is also an important issue. For example, decompressive laminectomy can be complicated by progressive kyphosis (13). Although the most rigid stabilization can be achieved through a posterior approach, posterior instrumentation can only stabilize the posterior column. Because many surgeons now approach lesions from the column of primary involvement, which is often anterior (9,14,15), there has been a greater emphasis on anterior resections and anterior or circumferential reconstructions. This is discussed in later sections.

Adjuvant therapies have been evolving in parallel with surgical techniques for the treatment of spinal tumors. Radiation can provide local cytotoxicity and reduce neural compression by shrinking tumor mass. However, this effect is limited in field, raises concern for inducing sarcomatous changes, and can compromise future surgical approaches within the radiation field. Chemotherapy affords more systemic cytotoxicity, which can be both

beneficial and limiting. Finally, as reviewed in this chapter, evolution in surgical techniques has led to improvements in prognosis and results of surgery for tumors of the spine. Because it is difficult to generalize about prognosis of spinal tumor surgery, primary benign, primary malignant, and metastatic tumors are discussed separately, and the results of surgery for individual tumor types are reviewed.

### PRIMARY TUMORS

Primary tumors of the spine are relatively uncommon, especially in comparison with metastatic disease. As such, most studies are small and retrospective, with larger series including patients from multiple medical centers or over prolonged periods of time. As a result, there is great variability in surgical techniques and adjuvant therapies within and between study populations. Furthermore, published studies often report outcomes in different forms and with varying lengths of follow up. In this chapter, an emphasis is placed on larger series. Comparable data and outcome measures are presented where available.

#### Benign

The six most common benign tumors of the spine that present for treatment are: osteblastomas, osteoid osteomas, osteochondromas, giant cell tumors, aneurysmal bone cysts, and hemangiomas in order of decreasing frequency. This is as noted in a retrospective review of 31 such tumors by Weinstein and McLain (7). Outcomes were usually good with relatively low long-term morbidity and mortality. The overall recurrence rate was 21%, and the overall 5-year survival rate was 86%.

Osteblastomas and osteoid osteomas are both benign osteoblastic lesions, of which 36% and 10% occur in the

Spine respectively (16). Surgical excision can afford immediate pain relief and facilitate early patient mobilization (3). Recurrence rates for osteoblastomas and osteoid osteomas have been found to be 0% to 10% and 9%, respectively (17,18). Such recurrences have been related to incomplete excisions. In cases of osteoblastoma with poorly defined margins, adjuvant radiation can improve results (17). Alternative treatments, such as high-frequency radiowave ablation, have been tried recently for osteoid osteomas with minimal morbidity and good initial success (19).

Osteochondromas are osteocartilaginous exostoses, of which 1% to 4% occur in the spine as solitary lesions or as manifestations of familial osteochondromatosis (1). In most cases, surgery is indicated only if there is neurologic compromise or secondary scoliosis (2,20). Approximately 90% of patients have been reported to have relief of symptoms (1,2). Recurrences are rare but have been reported (21,22).

Giant cell tumors are locally aggressive lesions of large multinucleated cells, of which 1.8% to 9.3% occur in the spine (23). Because of the locally aggressive nature of giant cell tumors, they do not share the same favorable prognosis as other benign lesions (7). For this reason, radical resection is recommended, if possible (24). Radiation has been found to improve results for patients with incomplete excisions or local recurrences (23). Nevertheless, recurrence rates of 22% to 42% have been reported (23,25), and half of the recurrences reported in the series by Weinstein and McLain were giant cell tumors (7).

Aneurysmal bone cysts are highly vascular lesions of unknown origin, of which 10% to 30% occur in the spine (26,27). With early excision with or without bone grafting or embolization, recurrences have been reported in the 2% to 19% range (12,26,27). Selective arterial embolization has been associated with superior clinical results because of decreased operative bleeding. In fact, some studies have suggested that embolization alone may be sufficient treatment (26); however, others additionally recommend routine curettage and bone grafting (12,27). Radiation has not been found to decrease the rate of recurrence (28).

Hemangiomas often are noted incidentally or never detected. Surgical decompression or excision is considered for those with neurologic symptoms, or when the

structural integrity of a vertebra is compromised. Similar to aneurysmal bone cysts, embolization offers a means to minimize surgical bleeding (29,30). Recurrence was noted in 27% of patients in one surgical series (29). Postoperative radiation thus was recommended to minimize recurrence if subtotal tumor resection is performed. Vertebroplasty (31) or ethanol injections (32) may provide an alternative means of treatment for these tumors, although long-term results of these treatments have not yet been reported.

### Malignant

The six most common primary malignant tumors of the spine are: solitary plasmacytomas, chordomas, chondrosarcomas, lymphomas, Ewing sarcomas, and osteosarcomas, in order of decreasing frequency. This is as noted in a retrospective review of 51 such tumors by Weinstein and McLain (7). Overall 5-year survival rates correlated with tumor type and extent of initial surgical excision (Table 86-1). Survival was greatest for patients with chondrosarcomas and solitary plasmacytomas and was shortest for those with osteosarcomas and primary lymphomas. The overall local recurrence rate was 21%, and metastatic disease developed in 27% of these patients.

Solitary plasmacytomas are treated to prevent local progression and dissemination to multiple myeloma. Although initial treatment often consists of radiation, partial resection or curettage is recommended for progressive neurologic symptoms or cord compression. The role of chemotherapy is controversial (33). The prognosis for plasmacytoma is much better than of multiple myeloma. Five- and 10-year survival rates have been found to be 86% to 100% and 85%, respectively (34,35). Disease-free survival at 5 and 10 years has been found to be 40% to 60% and 0%, respectively (33,35). Recurrence is correlated with the appearance or increase of the M light-chain component (35).

Chordomas are low-grade, locally invasive tumors that are slow to metastasize. The 5-year survival rate for these tumors has been reported to be 58% to 86% (5,36). Achieving tumor-free margins has been shown to be important for preventing local recurrence and improving survival (5,36). Additionally, more proximal lumbosacral

**TABLE 86.1.** 5-Year survival rates for primary malignant tumors of the spine

Primary bone malignancy	5-Year survival rate	References
Solitary plasmacytoma	86%–100%	Meis et al. (34), Delauche-Cavallier et al. (35)
Chordoma	58%–86%	Cheng et al. (36), Ozaki et al. (5)
Chondrosarcoma	55%–72%	Bergh et al. (4), Shives et al. (38), York et al. (8)
Ewing sarcoma	33%	Grubb et al. (13)
Lymphoma	22%–24%	DiMarco et al. (41), Salvati et al. (40)
Osteosarcoma	4%–10%	Barwick et al. (48), Shives et al. (6)

location and initial radiation have been correlated with longer survival (36). Metastases develop in 5% to 40% of patients studied (5), and preservation of the mid-sacral roots has been found to be important for maintaining bowel and bladder function.

Chondrosarcomas are malignant cartilage producing tumors. Approximately 9% of these lesions are in the axial skeleton (Fig. 86-1) (37). Five- and 10-year surgical survival rates have ranged from 40% to 72% (4,8,38). Lower histologic grade (4), wider tumor resection (4,8,37), and younger age (4) have been associated with improved survival. Neither radiation nor chemotherapy has been found to be beneficial (8).

Although some consider an epidural lymphoma primary to the spine only if the original foci are in the spine (38,40), others report all lymphomas presenting with spinal cord compression within this group, irrespective of the presence of other previously undetected neoplastic foci (41,42). Traditionally, these tumors have been treated with decompressive laminectomy and radiation with poor clinical outcomes; one such study reported six of 12 dead within 6 months and the remaining six dead within 4 years (39). With adjuvant chemotherapy and improved surgical techniques, outcomes have improved; 5-year survivals of 22% to 40% are now reported (40–42). Neurologic status was found to be an independent prognostic

**FIG. 86-1.** Case example of a 54-year-old man with a chondrosarcoma arising from the right T11 costovertebral junction. Preoperative plain film (A), computed tomography (B), and magnetic resonance imaging (C) demonstrate the lesion. Postoperative plain films (D,E) show the anterior and posterior reconstruction after resection was performed.

factor for this group of patients (40,42), but tumor histology was not (42).

Ewing sarcomas are malignant tumors of unknown cell origin, of which only 4% to 7% are found in the spinal column (43,44). Early work suggested that spinal involvement was a poor prognostic feature, with 6% survival compared with overall 16% survival (43). With newer regimens of chemotherapy and radiation tailored to this disease process, survival rates of primary spinal Ewing have improved (45). A recent review of 36 cases found the 5-year survival rate to be 33% (13). It has been suggested that sacrococcygeal tumors may have a worse prognosis than those elsewhere in the axial skeleton (46).

Osteosarcomas are malignant osteoid producing tumors, of which 1.5% to 3% occur in the spine (6,47). Reported outcomes have been poor. With or without decompressive laminectomy, attempted excision, radiation, or chemotherapy, all but one patient died of the disease in two series (5-year survival rates of 4% to 10%) (6,48). Furthermore, the mean length of survival was only 6 to 10 months for those who did not survive 5 years.

In summary, primary malignant tumors of the spine pose a significant surgical challenge. Aggressive surgical excision with appropriate adjuvant therapy provides the best chance of preventing local recurrences and distant metastases. However, regardless of the treatment regimen, long-term outcomes are not good for most subtypes.

## METASTATIC TUMORS

The surgical indications for metastatic disease of the spine are less well defined than those for primary tumors.

The risks of significant morbidity in chronically ill patients with limited life spans must be weighed against the potential for pain relief, restoration of quality of life, and prolongation of survival. A clear understanding between surgeons and patients of the variables affecting prognosis and results of surgery aids in the decision-making process.

General indications for surgical management include progressive neurologic deficit, intractable pain, spinal instability, radio-resistant tumors, and the need for histologic diagnosis (Fig. 86-2) (11,49). Radiation with or without chemotherapy is the mainstay of treatment for metastatic disease. Surgery is an adjunct to these primary modalities. Goals of surgery include decompression of neural structures, with debulking the tumor mass, correction of deformity, and stabilization for the relief of pain.

Historically, most resections were done from posterior approaches, despite the fact that the majority of metastatic lesions occur anteriorly, in the vertebral body. Consequently, the results of such procedures were disappointing (50,51), and some authors found no significant difference in outcome between those undergoing decompressive laminectomy and radiation and those receiving radiation alone (52). However, adjuvant stabilization did improve results (53).

Anterior decompression and stabilization has been found to provide significantly better results for patients with anterior disease isolated to one or two continuous segments (Fig. 86-1) (9,14,15,49). In a review of the literature, Weinstein found the average percentage of patients with satisfactory outcome to be 37% after posterior decompression and 80% after anterior decompression.

**FIG. 86-2.** Case example of a 61-year-old woman with metastatic disease of L3. Preoperative plain film (A), preoperative magnetic resonance imaging (B), and postoperative laterals (C) show anterior column reconstruction with femoral allograft and an anterior plate.

sion (15). Patients with more than two segments of continuous disease pose a much greater challenge. If anterior collapse or neural element compression exists, an anterior decompression and posterior stabilization is indicated. A posterior approach may be considered if there is extensive disease over many levels (54), although such extensive disease suggests a poor prognosis and may militate against any significant benefit from operative treatment.

Pretreatment neurologic status, duration of neurologic compromise, and rate of neurologic decline have been identified as prognostic factors in treatment (55,56). For this reason, some have recommended early surgical intervention for spinal metastases once neurologic manifestations are recognized. Significant neurologic improvements have been described after anterior decompression and reconstruction of metastatic tumors. Among patients with neurologic deficits undergoing operative treatment, Harrington described complete recovery in 42% and significant improvement in an additional 26% (9). Kostuik et al. found a significant neurologic return in 40% of posterior decompressions and 71% in anterior decompressions (14). Siegal and Siegal found a 31% increase in patients' ability to walk from pre-decompressive to post-decompressive laminectomy and a 52% increase with anterior decompression (49).

Tumor type also has been found to affect outcome (11,55,56). The most common primary tumors metastatic to bone are tumors of breast and prostate (84%), thyroid (50%), lung (44%), and kidney (37%) (15). As expected, the more aggressive the primary tumor, the worse the long-term prognosis. Wise et al. found postoperative survival rates were the longest for myeloma and soft-tissue sarcomas and the shortest for adenocarcinoma of unknown primary origin and prostate cancer (11).

The decompression site can be reconstructed with autograft, allograft, or methyl methacrylate. The advantage of autograft or allograft is the potential for incorporation and biologic fusion, which can provide long-term stability. However, fusion is often compromised in the tumor patient by local factors such as abnormal tumor biology, local radiation effects, and chemotherapeutics. Some authors have recommended the use of methylmethacrylate if expected survival is limited (generally less than 1 year) (9,14). However, care must be exercised in placing methyl methacrylate in proximity to the neural elements to avoid injury from the exothermic curing process.

Perioperative complications can significantly limit the potential benefits of surgical treatment in this patient population and dramatically alter the postoperative course. The most common complication is postoperative wound infection (11). This can result from impaired wound healing, which is seen in the setting of prior radiation treatment (11), and chronic malnutrition (57,58), both of which are common in this population. These vari-

ables also lead to relative states of immunosuppression by limiting vascular ingrowth and thus further predisposing to local infections.

In summary, surgery for metastatic disease of the spine is indicated for correction of deformity, preservation of neurologic function, and control of intractable pain. Mean survival time after surgery for metastatic disease is only about 11 to 16 months (10,11,14), although this is primarily related to the natural history of the underlying primary tumor. Nevertheless, as surgical techniques and adjuvant therapy regimens are refined, surgical goals are becoming more attainable and outcomes are improving.

## CONCLUSIONS

Neoplastic lesions of the spine pose a significant clinical problem. Most are found in older patients and are the result of metastatic disease. Although the follow-up of such patients treated surgically is limited, the results reviewed in this chapter provide some indication of the relative benefits of surgery for the different tumor subtypes. Adequate tumor resection, appropriate stabilization, and targeted adjuvant therapy are important considerations in all such patients. The past 20 years have seen tremendous strides in the surgical management of all types of spinal tumors—primary and metastatic. In particular, an increased appreciation of the need for direct decompression of the tumor via an anterior approach, followed by anterior column reconstruction and (often) posterior stabilization has extended the benefits of surgery to many more cancer patients. However, more large multicenter studies are needed to prove the efficacy of these more extensive surgical procedures in improving patient quality of the life and survivorship.

# Determining Reasons for Failed Surgery

Christopher S. Raffo and Sam W. Wiesel

---

Surgery on the lumbar spine is not always successful. An estimated 300,000 new laminectomies are performed yearly in the United States and 45,000 of these patients will continue to be disabled (1). The patient who has undergone multiple surgeries with continued or worsening pain and disability is of increasing concern. As lumbar surgeries continue to grow, the problem will continue to expand. With this expansion comes an ever-growing cost of treating these patients, an obvious concern in the era of rigid cost containment. The complexity of a multiply operated patient necessitates a methodical, precise, and cost-efficient evaluation.

It seems obvious, but is worth restating, that the best chance for an excellent outcome from spine surgery is appropriate indications for that surgery. Conversely, surgery with inaccurate or inappropriate indications must be avoided due to its dismal chance for good outcome (2,3). Precise correlation of physical symptoms and findings with the diagnostic imaging studies is essential, owing to the high incidence of clinically false-positive myelograms, discograms, computed tomograms (CT), and magnetic resonance imaging (MRI) (4–6). Exploration of the spine is unacceptable, without well-defined and correctable pathology that matches the data gathered from advanced imaging. Also, due to increasing complexity with each revision operation, the first surgical procedure has the greatest chance for success.

The first decision point in the evaluation of *failed back surgery syndrome (FBSS)*, the term describing the complex problem of the multiply operated and failed spine, is to separate mechanical from nonmechanical pathology. Mechanical pathology includes herniated discs, segmental instability, and spinal stenosis. These conditions often respond favorably to surgical treatment, because they cause direct compression of the neural elements. Nonmechanical causes of lumbar spine pain include scar, discitis, psychosocial conditions, and general medical problems. Nonmechanical conditions will not improve with surgery and, in fact, will probably further deteriorate.

Differentiating between the two is the critical first step in selecting surgical candidates.

The keystone in establishing a good outcome when treating lumbar spine pathology is obtaining an accurate diagnosis. While this seems intuitive, failure to accomplish this primary goal will lead to a treatment course fraught with difficulty.

## EVALUATION

An organized approach to the evaluation of a patient who has undergone multiple low back operations is required to simplify the evaluation and to prevent missing significant details. The history can be quite detailed and complex. Many patients have a desire to relate their entire history of back problems, and it is best to let them do so. After deciphering these often complex stories, three historical points must be gathered.

1. The number of previous spine surgeries correlates with the outcome for future surgeries. The chance for a successful result is dramatically reduced with additional operations. Historically, a second procedure for a given problem has only a 50% success rate and further procedures often worsen the patient's condition (7–9)

2. The length of the pain-free interval must be clearly understood. If the patient awoke from a previous operation with the exact pain that brought him or her to surgery, it is likely that the nerve root was not decompressed completely or the improper nerve root was decompressed. However, if the interval from surgery to the present complaint is 6 months or more, the new pain may be the result of a recurrent disc herniation at the same or different level. If the pain-free interval is only 1 to 6 months, and the new symptoms gradually progressed, scar tissue is suspected (7,10). Both epidural fibrosis and arachnoiditis can cause this pain pattern.

3. The patient's pain pattern must be recorded. If leg pain predominates, a herniated disc or spinal stenosis is likely the diagnosis. Scar tissue may also result predomi-

nantly in leg pain. Back pain, however, is suggestive of infection, instability, tumor, or possibly scar tissue. Having both back and leg pain is suggestive of spinal stenosis or scar tissue.

After a thorough and detailed history, the physical exam is the next most important aspect of evaluation. Objective neurologic findings and the presence of a tension sign, such as the sitting straight-leg raise, must be sought. A dependable presurgical exam is very helpful, as it allows comparison with the current postoperative exam. If the neurologic exam is unchanged from before the surgery, and no tension sign is present, then mechanical compression is unlikely. If a new neurologic deficit is present and a tension sign also is present, then compression on the neural elements is possible. The tension sign is not pathognomonic for neural compression; however, it can also be caused by epidural or perineural fibrosis.

Special attention should be paid to inorganic physical findings. Red flags include nonanatomic pain distributions or distraction signs. Waddell et al. showed that presence of three or more nonorganic signs predicts a poor outcome from repeat lumbar surgery (8). Also, it is essential to identify litigation or secondary gain issues that may influence treatment and outcomes. Multiple authors have shown that unresolved litigation or compensation is a significant risk for poor outcome. While formal testing, such as the Minnesota Multiphasic Personality Inventory, can be useful, it should not replace the surgeon's attempt to identify well-motivated and adjusted patients (11). These patients are most likely to benefit from surgery.

## DIAGNOSIS

Arriving at the correct diagnosis is the primary goal in the evaluation of the patient with the multiply operated back. The lesions most commonly responsible for FBSS include persistent or recurrent disc herniation (12% to 16%), lateral (58%) or central (7% to 14%) stenosis, arachnoiditis (6% to 16%), epidural fibrosis (6% to 8%), and instability (less than 5%) (10,12). To standardize and simplify the approach to treatment of this complex problem, an algorithm has been developed. The aim of the algorithm is to assist by organizing diagnostic criteria, helping identify the correct diagnostic category, and directing treatment principles (Fig. 87-1; Table 87-1).

An important step in the algorithm is identifying nonorthopedic causes for back pain. Important diagnoses to consider are pancreatitis, diabetes, and abdominal aneurysm. All can mimic FBSS and will potentially respond to disease-specific therapy. A general medical evaluation, by an internist or equivalent physician, should be routinely obtained and appropriate treatment initiated. In addition, any psychosocial abnormality should be identified. These include alcoholism, drug dependency,

anxiety, or depression. A psychiatric evaluation is necessary in these cases. Again, it is worth restating that patients with unresolved litigation or compensation issues do not respond to further surgery (13).

Of course, patients with psychiatric disorders may have legitimate orthopedic pathology. It is wise to address the psychiatric diagnoses before proceeding with any further surgery. Hopefully, treatment of the psychiatric condition will eliminate or significantly reduce the somatic back symptoms and disability.

The remaining patients, after eliminating those with medical or psychiatric diagnoses and those motivated by secondary gain, will have either back or leg pain. The goal is to identify which patients have specific mechanical problems that may respond to further surgery from those with symptoms resulting from scar tissue or inflammation.

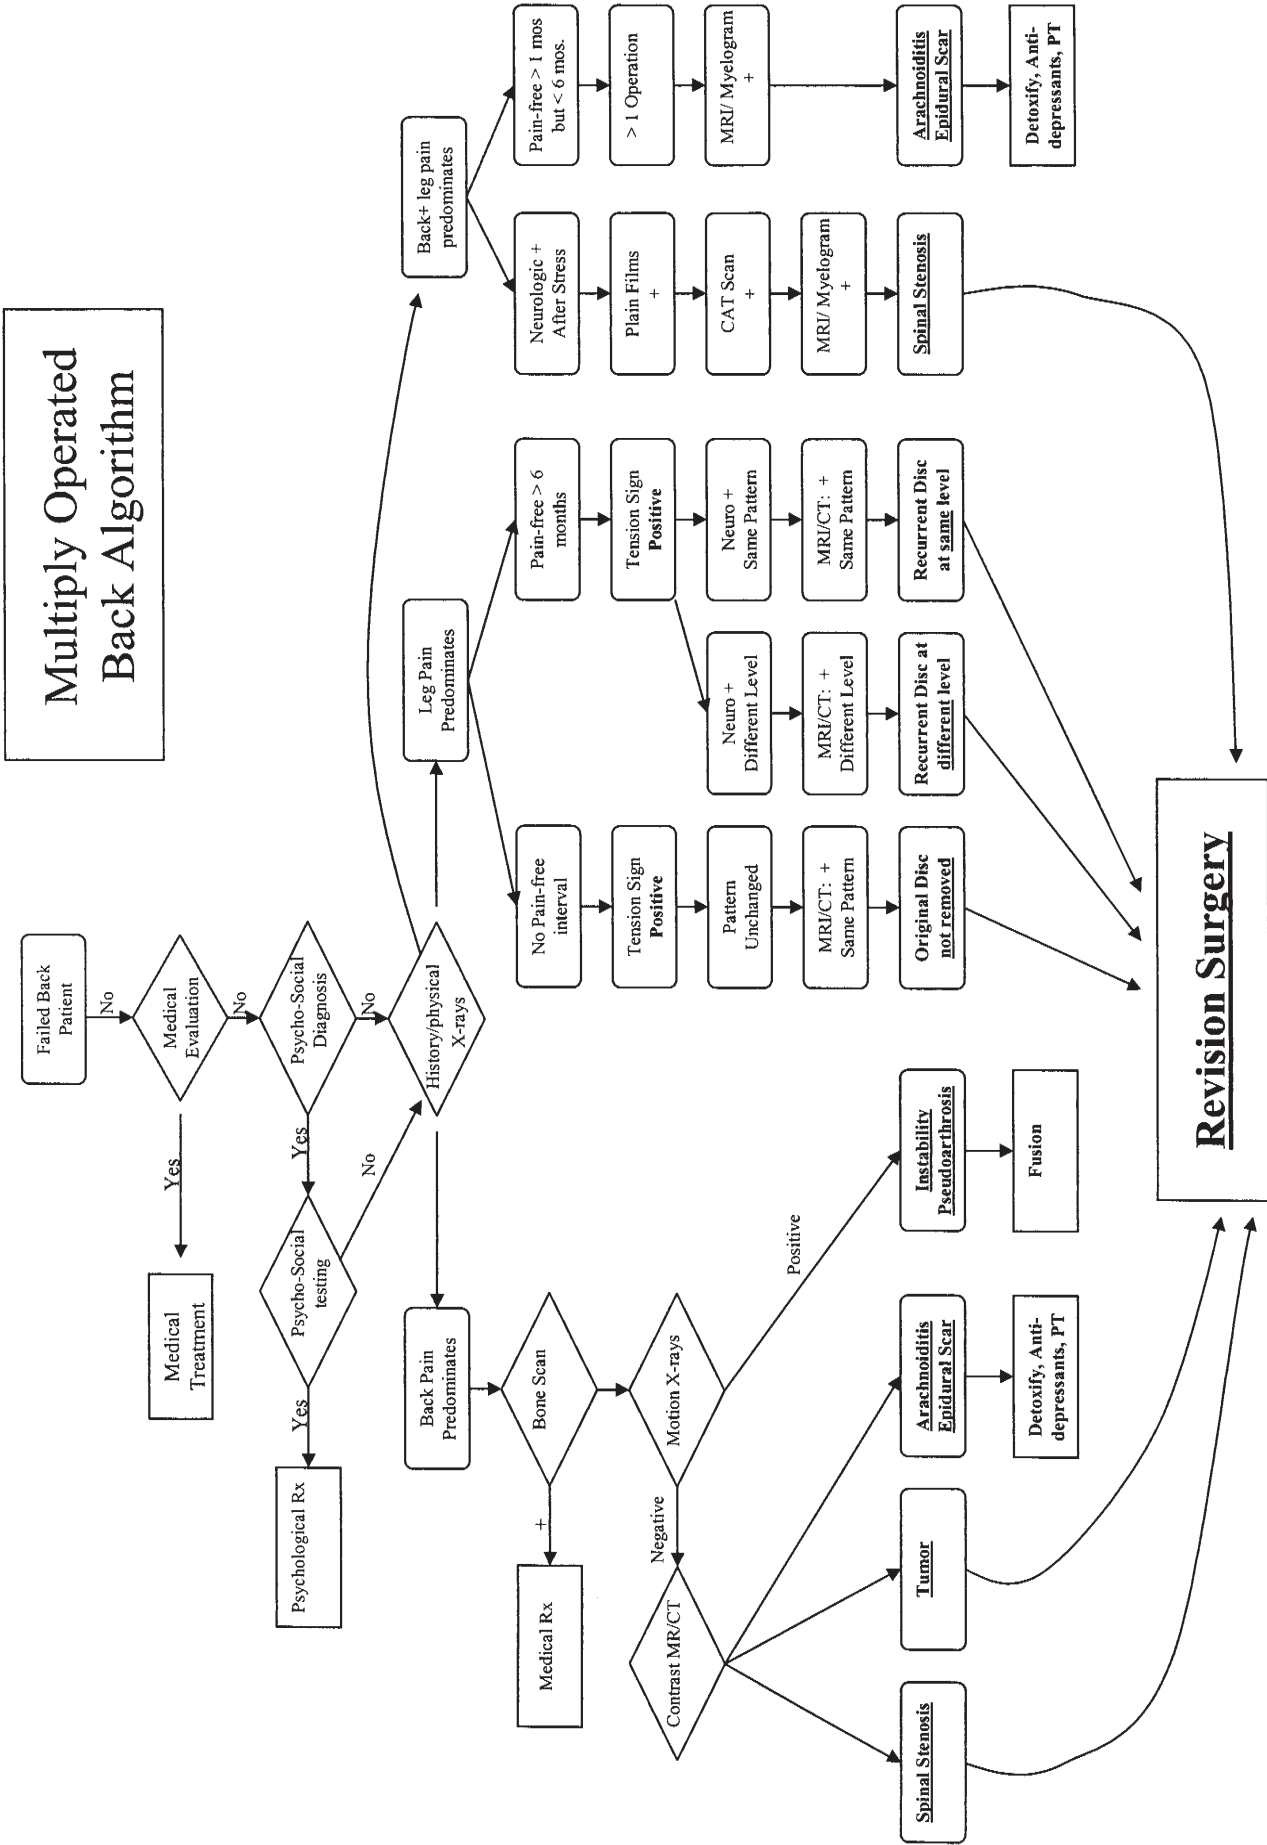

## Mechanical Lesions

### *Herniated Intervertebral Disc*

If the pain of FBSS is from a herniated disc, three possibilities exist. The prior decompression may have been inadequate. This may occur when the correct level was insufficiently decompressed, an incorrect level is decompressed, or disc material is left behind. Typically leg pain predominates and mimics the original symptoms. The pain pattern is identical because the nerve root remains mechanically compressed. The neurologic findings, tension signs, and radiographic pattern will be unchanged from the preoperative findings. The key historical point is the absence of a pain-free interval: the patient awoke in the recovery room with the same pain he or she had preoperatively. Patients in this category will benefit from a proper and complete decompression.

A recurrent herniation may also occur at the previous level, despite an adequate decompression at the index procedure. Typically, the patient awoke in the recovery room pain-free and remained so for at least 6 months. The recurrent disc then irritates and compresses the original nerve root, causing the identical symptoms. If contrast-enhanced CT or gadolinium-enhanced MRI demonstrates herniated disc material, then further decompression is warranted.

Lastly, a different disc may herniate at a new level, causing a different constellation of symptoms. The pain-free interval is typically greater than 6 months, but can be shorter. Leg pain usually predominates, in an anatomic pattern consistent with mechanical compression of a different nerve root. The tension sign should be positive. Again, if contrast-enhanced CT or gadolinium-enhanced MRI demonstrates a disc at a level consistent with the symptoms then the patient will benefit from another decompression.

**FIG. 87-1.** An algorithm for evaluating patients with failed lumbar spine surgery. (Modified from Boden SD, Wiesel SW, Laws ER Jr, et al. The aging spine. Philadelphia: WB Saunders, 1991, with permission.)

**TABLE 87.1.** Table format of algorithm for treatment of failed back surgery syndrome: differential diagnosis of the multiply operated back

History and physical radiographs	Original disc not removed	Recurrent disc at same level	Recurrent disc at different level	Spinal Instability	Spinal Stenosis	Arachnoiditis	Epidural Scar Tissue
No. of previous operations						>1	
Pain-free interval	None	>6 months	>6 months			>1 month but <6 months	>1 month gradual onset
Predominant pain (leg vs. back)	Leg pain	Leg pain	Leg pain	Back pain	Back and leg pain	Back and leg pain	Back and/or leg pain
Tension sign	+	+	+			May be positive	May be positive
Neurologic exam	+ same pattern	+ same pattern	+ different level		+ after stress		
Plain X-rays	+ if wrong level				+		
Lateral motion X-rays				+			
Metrizamide myelogram	+ but unchanged	+ same level	+ different level		+	+	+
CT scan	+	+	+		+		+
MRI	+	+	+		+		+

### ***Lumbar Instability***

Segmental instability is a poorly understood cause of persistent back pain in the FBSS patient. Instability, the abnormal motion between two vertebrae, results from the inability of the spinal motion segments to bear normal physiologic loads. While deformity or neurologic deficits are potential complications of instability, pain is the most frequent finding (14). The cause in the FBSS patient may be related to the underlying disease, or it may be iatrogenic. The common iatrogenic causes are excessive facet resection during surgery or pseudoarthrosis (15).

The pain felt from segmental instability may be episodic. Particular activities, such as rising from a chair or straightening after forward bending, may provoke symptoms. Less commonly, instability can produce dynamic stenosis creating leg pain. The physical exam is often normal, although a characteristic reversal of normal spinal rhythm may be noted on return from forward bending (16).

The key to diagnosis may be the weight-bearing, lateral flexion, and extension radiographs. Relative sagittal translation of 12% or angulation of 11° is considered positive. At L5-S1, a more modest 25% translation or 19° angulation is considered a positive test (17). Progressive scoliosis or listhesis on subsequent radiographs is also indicative of instability.

Radiographic evidence of motion should be interpreted cautiously since not all patients with abnormal motion will be symptomatic. In the absence of another identifiable mechanical cause for pain, patients with both pain and abnormal motion may benefit from fusion of the affected levels (18). Additionally, exploration of a

pseudoarthrosis may be indicated if abnormal motion can be documented. However, without documented motion or a thorough exclusion of other potential causes for the symptoms, surgery for pseudoarthrosis has a low probability of success (19).

### ***Spinal Stenosis***

In all patients, including patient who has experienced multiple back surgeries, lumbar spinal stenosis may produce back and leg pain. The pain may result from progression of an inherent degenerative spinal disorder, a previous incomplete decompression, or by overgrowth of a fusion mass.

The pain-free interval will vary depending on the circumstances. If the previous surgery failed to completely decompress a stenotic canal, there may be no pain-free interval. Alternatively, the patient may be free of symptoms for months to years before the canal becomes sufficiently stenotic to produce symptoms.

In general, the history and physical should be similar to any patient with lumbar spinal stenosis. Back and leg pain are typically present, and leg pain often is exacerbated by exercise, although this is not essential to the diagnosis. The neurologic exam is typically normal, unless neurogenic claudication can be produced during an exercise stress test. Tension signs are generally absent (20,21). It is crucial to differentiate true neurogenic claudication from pain produced by vascular insufficiency.

Plain radiographic findings suggestive of stenosis are facet hypertrophy and degeneration, decreased interpedicular distance, decreased sagittal canal diameter, and degenerated disc spaces. Spondylolisthesis is commonly

associated with central and lateral stenosis. While it occurs most commonly at the L4-L5 level, it can occur at the previous operative level. MRI clearly shows thecal sac narrowing and, following gadolinium injection, can differentiate between compression caused by epidural scar and by hypertrophied normal soft-tissue structures. Postmyelographic CT provides excellent visualization of bony encroachment on the neural elements centrally, as well as in the lateral recesses and foramina. However, CT cannot reliably differentiate scar from hypertrophied soft tissue (22).

If direct evidence of bony encroachment or mechanical pressure from hypertrophied soft tissue can be found on advanced imaging, then the patient will potentially respond well to decompression of the neural elements. Good results can be expected from surgery in at least 70% of properly selected patients. However, if gadolinium-enhanced MRI shows substantial scar tissue is present, the degree of pain relief that may be anticipated is less certain. Perhaps related to this fact, patients who have undergone previous laminectomy and fusion respond less well to repeated surgical decompression (23).

### Nonmechanical Spinal Lesions

Scar tissue and discitis are nonmechanical sources of recurrent pain in the FBSS patient. Although the location and pathology of these entities differ, they are discussed in common because neither improves with further surgery. Postoperative scar formation in the spine is divided into two main types based on anatomic location. Scar tissue that forms within the dura is referred to as *arachnoiditis*. Scar tissue that forms outside the dura is appropriately termed *epidural fibrosis*.

#### *Arachnoiditis*

Arachnoiditis is strictly defined as inflammation of the pia-arachnoid membrane surrounding the spinal cord or cauda equina (12). The extent of scarring may vary from person to person. At its most severe, the subarachnoid space may be obliterated and the flow of cerebrospinal fluid or contrast agents obstructed. While the precise cause is uncertain, previous lumbar spine surgery, intraoperative dural tears, and the injection of oil-based contrast agents are precipitating factors (24). Postoperative infection may also play a role in the pathogenesis of arachnoiditis (25,26).

There is no consistent clinical presentation for arachnoiditis. A typical patient complains of back and leg pain that developed after a brief pain-free interval, between 1 and 6 months. A history of multiple back surgeries is also common. The physical exam is generally not helpful, with any neurologic deficits being attributed to previous pathology or surgery. CT myelography and MRI may confirm the diagnosis.

At present there is no effective treatment for arachnoiditis. Surgery has proved ineffective at relieving pain or reducing scar formation. Combined with much needed encouragement, various nonoperative therapies can be employed (3,12,26,27). The administration of epidural steroids, transcutaneous electrical nerve stimulation, spinal cord stimulation, operant conditioning, bracing and patient education have all been tried, with varying success. None of these therapies cures the condition, but all may provide some relief to some patients for varying periods. Patients should be detoxified of all narcotics, started on amitriptyline hydrochloride (Elavil; Zeneca Pharmaceuticals, Wilmington, DE), and encouraged to be as active as possible. Treating these patients remains a significant challenge, requiring devotion and patience by both the physician and patient, to achieve optimal results.

#### *Epidural Fibrosis*

Formation of scar outside the dura, on the cauda equina or directly on the nerve roots, is unfortunately relatively common (28). The epidural scar tissue acts as a constrictive force on the neural elements and may cause postoperative pain. However, while most postsurgical patients have epidural scar formation to some extent, only an unpredictable few are symptomatic.

Patients with epidural scarring may present with symptoms at any time, from several months to more than a year after surgery. The onset is insidious and patients often report back or leg pain. New neurologic deficits are unexpected but a tension sign may be present due to constriction and scarring around the nerve root. The condition is best differentiated from a recurrent herniated disc with a gadolinium-enhanced MRI.

As with arachnoiditis, there is no definitive treatment for epidural scar formation. Prevention may be the best strategy. In the past, a free fat interpositional graft was used after laminectomy (29). A study comparing the use of Gelfoam (Upjohn; Kalamazoo, MI), interposed free fat, and placebo showed no statistical difference in relieving or exacerbating epidural fibrosis (30). Adcon-L (Gliatech, Inc.; Cleveland, OH), a recently introduced biodegradable gel matrix that was approved by the U.S. Food and Drug Administration for use after single-level laminectomy or laminotomy, reduces epidural scar formation in experimental studies. While its use is attractive in preventing scarring, its clinical efficacy is not entirely proven. Although Adcon-L is now available for patients thought to be high risk for scarring, its routine use should be avoided until further studies show a distinct benefit in outcomes (31).

Once epidural fibrosis has formed, surgical treatment is not beneficial. More scar, in fact, would form from repeated surgical exploration. The treatment program described for arachnoiditis should also be employed for epidural fibrosis.

**Discitis**

Discitis is an uncommon but debilitating complication of lumbar spine surgery. The pathogenesis, although not completely understood, is thought to be direct inoculation of the avascular disc space (32). Severe back pain, usually about one month after surgery, is the usual presentation. Signs on physical exam that may corroborate the diagnosis are fever, presence of a tension sign, and possibly a superficial abscess.

If discitis is suspected, plain radiographs, blood cultures, an erythrocyte sedimentation rate (ESR), and a C-reactive protein (CRP) should be obtained. CRP is more specific than ESR, especially in the early phases of infection. Also, it normalizes more quickly than the ESR, and in other orthopedic infections is commonly used as a marker of response to treatment. The classic plain radiographic findings of disc space narrowing and end-plate erosion may not be present early in the disease. Contrast-enhanced MRI confirms the diagnosis.

The treatment of discitis is controversial (32). Most commonly, the patient is restricted to short-term bed rest and immobilization with a brace or corset. If the patient has progressive pain despite immobilization or has constitutional symptoms, a needle aspiration is recommended. If an organism can be isolated by aspiration, appropriate intravenous antibiotics are administered, usually for 6 weeks. Open disc space biopsy is unnecessary if the patient improves with treatment outlined above. With improvement of symptoms, and normalization of the ESR and CRP, the patient may ambulate as tolerated.

**Instrumentation**

The use of instrumentation as an adjunct to lumbar spinal fusion has become enormously popular in the last 10 years, almost exclusively in the form of pedicle-screw-based implants. This complicates the approach to the FBSS patient. It is our anecdotal experience that more patients are undergoing lumbar spine fusion without objective indications, resulting in a high failure rate. The presence of the implant itself raises several technical considerations relating to possible revision surgery, including the significance of screw breakage, implant loosening, infection, and aberrant screw placement. Finally, because of adverse publicity surrounding the use of these devices, their presence raises legal implications that at times further cloud a complicated clinical picture.

Pedicle screw instrumentation systems are inert orthopedic implants with an exceedingly low incidence of true allergy. Mechanical failure of the implant does not always represent an indication for removal or revision. The most dramatic mode of failure is breakage of the screw, typically at the shank-thread junction, which has been reported at a rate of 0.5% to 2.5% (33,34). Screw failure

was historically quite common, even early in the postoperative period. With advancements in material science and manufacturing, implant failure is now far less common. Furthermore, a broken screw has questionable clinical significance and does not eliminate the possibility of a successful fusion. However, a study by Lonstein et al. reported a correlation between screw breakage and pseudoarthrosis. In this study, 12 of 19 patients who had a fractured screw had a pseudoarthrosis (33). The authors recommended that all symptomatic patients with broken pedicle screws have the implants removed.

Other mechanisms of failure of these systems include screw loosening in the pedicle and vertebral body. This is a more common long-term finding, typically noted as a small zone of lucency above the screw on routine radiographs. Again, no correlation between loosening and symptoms has been reported. Therefore, asymptomatic loosening, in the absence of pseudoarthrosis with instability, warrants observation.

Finally, the risk of infection appears to be increased with the use of these bulky implants and has been reported as high as 5% (35). Although infection in the perioperative period is more readily diagnosed, late developing infection has been reported and may represent a source of recurrent back pain after a pain-free interval. The patient with worsening pain several months or even years after an otherwise successful fusion may be manifesting late infection and should be evaluated accordingly. CT scanning, looking for a fluid collection around the implant, and aspiration of the wound may aid in this diagnosis.

**SURGICAL TECHNIQUES IN THE MULTIPLY OPERATED SPINE**

Operating on the previously operated lumbar spine can be a considerable technical challenge. The actual technique of a repeated laminectomy is different than the initial procedure. There is certainly increased morbidity, with increased risk of damage to the dura and neural elements. The specific technique for repeated laminectomy and repair of a dural tear are presented in the following sections.

**Repeated Decompression**

The goal of decompression in the multiply operated back patient is identical to the goal for any spinal decompression: to safely and completely free the neural elements, without causing excessive hemorrhage. Unfortunately, after prior decompression, the anatomic features are no longer normal, and the presence of scar tissue may complicate exposure and ease of decompression. Thus, several technical aspects of performing a repeated laminectomy are different from those for a primary procedure.

The first difference involves the operative approach. Stripping the paraspinous muscles away with impunity is not possible, because no lamina or ligamentum flavum is present to protect the neural elements at the previously operated sites. This means that the approach begins at a new anatomic level, which is normal and protected. This allows the surgeon to find the correct depth of the cauda equina (neural elements).

The surgeon may also be tempted, after the depth of the neural elements is determined, to remove the extradural scar tissue directly from the dura. Technically, this is difficult, and there is a great deal of hemorrhage and a high possibility of injury to the dura. Even if the scar tissue is successfully removed, there is no good way to prevent its reformation. Therefore, it is recommended that, in most cases, that extradural scar tissue should be left intact. Only tissue that is covering the area of pathologic change should be removed. Otherwise, the operative plane should be developed by elevating the scar (and dura) away from the bone at the lateral margin of the old laminectomy.

Finally, the nerve roots must be visualized laterally and any mechanical pressure on them removed. This is accomplished by extension of the laminectomy from the new level down to the lateral gutters, leaving the central scar tissue intact. Each nerve root is then identified and any bony encroachment or herniated disc material at that level can be easily removed. It is essential not only to visualize the nerve root to the dorsal root ganglion and to enlarge the foramen, but also to ensure that the root is mobile.

Routine fusion in a multiply operated back patient is not necessary. If there are preoperative signs of instability on the lateral, weight-bearing flexion and extension radiographs, a fusion is indicated. Also, widening the laminectomy so that bilaterally 50% of the facet joints are destroyed at any one level, or the pars interarticularis is thinned, potentially destabilizes the spine. A bilateral, lateral fusion is recommended in these circumstances. The preoperative patient counseling and the surgical planning should reflect this possibility.

The integrity of a previous fusion mass should be checked during all revision surgeries, for the possibility of a pseudoarthrosis. A pseudoarthrosis can be extremely difficult to detect, even by direct visualization during revision surgical procedures. Unless there are objective signs on flexion-extension radiographs of instability with horizontal translation, a nonunited fusion mass can be easily missed. After identifying the fusion mass laterally, use an osteotome to shave off the outer surface. In a solid fusion, the bone is contiguous throughout. If a defect were identified, the area should be decorticated and new bone graft added. However, even determining if a known pseudoarthrosis is responsible for a patient's symptoms can be particularly chal-

lenging. As stated previously, many pseudoarthroses are not symptomatic. Thus, caution should be used when deciding to treat an *apparently* painful pseudoarthrosis with revision surgery and fusion.

### Repair of Dural Tears

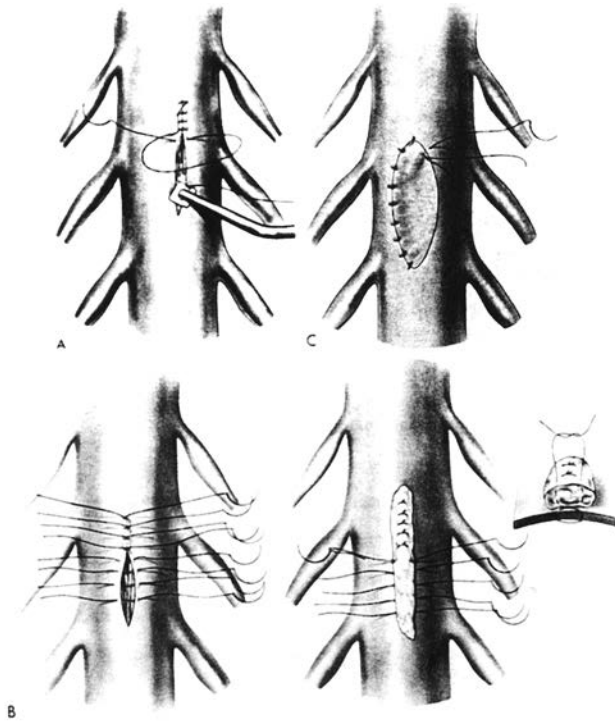

The rate of dural injury or tear is definitely increased in the patient who has undergone multiple back operations. The surgeon must be skilled in handling this complication. Although each dural tear is unique, certain basic principles always should be applied.

A dural tear usually occurs as the surgeon is gaining visualization of the spinal canal. This can result when a bone-biting instrument inadvertently pinches a small fold of the dura. Alternatively, removal of the adherent dura from the undersurface of bone can initiate a tear. When a tear does occur, the wound usually fills quickly with cerebrospinal fluid (CSF), obscuring the extent of the damage. The surgeon's first impulse is to try to see the tear by using suction in the approximate area of the problem. This is a mistake because individual nerve roots may be drawn into the suction tip, causing extensive neurologic damage. Suction should only be applied through a Cottonoid patty (Codman & Shurtleff, Inc.; Raynham, MA) so that no damage is done to the neural elements. After the tear is visualized, the surgeon places a piece of absorbable gelatin sponge (Gelfoam) over the injury site—with a large Cottonoid covering the entire area—and obtains adequate exposure of the tear. The patient's head should be tilted down to decrease the flow of CSF in the wound.

After adequate exposure is obtained, the surgeon's attention can be focused on repairing the tear. The goal is a watertight closure. If this cannot be accomplished, a CSF fistula potentially may form, raising the risk of meningitis or of forming a subarachnoid cyst. A subarachnoid cyst can exert mechanical pressure on the neural elements.

The operative field should be dry, with meticulous hemostasis. Magnification loupes and adequate lighting facilitate the repair. The technique used to close the dura depends on the size and location of the tear. For simple lacerations, 4-0 silk sutures on a tapered, one-half circle needle are used. A running locking suture (Fig. 87-2A) or simple sutures incorporating a free fat graft (Fig. 87-2B) give a watertight closure. If a large tear is present, a graft from the lumbar fascia is obtained and sutured in place with interrupted dural silk sutures (Fig. 87-2C). If the defect is in an inaccessible area, a small tissue plug of muscle or fat is introduced through a second midline durotomy and pulled against a tear from the inside of the dura.

To test the repair, place the patient in the reverse Trendelenburg position and perform the Valsalva maneuver. This maneuver increases intrathecal pressure and stresses

**FIG. 87-2.** Treatment of dural repair. (From Eismont FJ, Wiesel SW, Rothman RH. Treatment of dural tears associated with spinal surgery. *J Bone Joint Surg* 1981;63A:1132–1137, with permission.)

the watertight closure. The fascia is then closed with a heavy nonabsorbable suture to create another watertight barrier to the egress of CSF. Drains should not be used, as drains promote fistula formation. Postoperatively, the patient should be kept flat, on strict bed rest, for at least 3 days. The repair should heal by this time.

Diagnosing a CSF leak in the postoperative period can be challenging. Clear drainage emanating from either the drain site or the wound should raise suspicion for a dural leak. No helpful, noninvasive diagnostic techniques exist at present. The best diagnostic test is a myelogram performed with water-soluble contrast medium; this is recommended if a dural leak is seriously suspected. After the postoperative CSF leak is identified, the patient should be returned quickly to the operating room for dural repair to prevent infection in the CSF.

Closed subarachnoid drainage is a nonoperative alternative treatment for dural leaks (36). A subarachnoid shunt can be placed percutaneously into the lumbar canal, which results in the resolution of some CSF leaks. If a shunt is not quickly successful, the patient should be returned to the operating room for an open dural repair.

Prevention of dural tears is best achieved by excellent visualization and meticulous technique during exposure. Complete hemostasis should always be maintained. If there is any question about the presence of dura in the jaws of a bone-biting instrument, a Cottonoid patty

should be placed between the dura and the bony structures to prevent dural injury. This is an easy and safe preventive measure.

## CONCLUSION

The incidence of FBSS will likely continue to rise with the high rate of lumbar spine surgery in our society. Prevention of FBSS is unquestionably more beneficial to the patient, as out treatment of this condition is limited. Properly selecting candidates for lumbar spine surgery will lead to a high rate of success. Unfortunately, many patients with FBSS were inappropriately selected for their original surgery and further surgery only worsens the patient's condition. When considering revision surgery in these patients, a clear-cut diagnosis of nerve root compression or instability should be present. Consider exhausting nonoperative measures before operating.

The evaluation of patients with FBSS is a critical step in their treatment. The cause of the patient's symptoms must be accurately localized and identified, and a thorough investigation of the patient's psychosocial and general medical status is needed. Critical historical points are the number of previous operations, predominance of back or leg pain, and the duration of the pain-free interval. Neurologic deficits and tension signs are sought on physical exam. All imaging studies available should be thoroughly reviewed to corroborate the history and physical findings. When all the information is integrated, the physician can usually identify patients with correctable mechanical problems from those with epidural fibrosis, arachnoiditis, and discitis.

Physicians involved in the treatment of FBSS should realize there is little likelihood the patient will return to a pain-free state. Some level of permanent pain or disability generally remains. These patients should be counseled and encouraged to resume as functional a role as possible in society.

# Failed Back Surgery Syndrome

## Nonoperative Interventional Management Options

Richard Derby and Connor O'Neill

---

Failed back surgery syndrome (FBSS) is not a diagnosis but a label describing the patient who continues to experience chronic pain following one or more spinal surgeries. Unfortunately, FBSS often connotes psychological pain exaggeration and a centralized self-sustaining pain process in which further diagnostic tests are inappropriate and treatment options directed at a specific structural cause are useless. Although some patients with chronic pain do develop psychological and behavioral problems, in its extreme this condition should be labeled *chronic pain syndrome*, not FBSS. Here FBSS is considered an outmoded phrase for describing patients with persistent intermittent or constant spinal pain following one or more spinal surgeries. Although these patients have an increased likelihood of problematic pain sources such as fibrosis, neuropathic nerve roots, and segmental instability, the diagnostic work-up and treatment options are similar to those of patients without prior surgery.

With more physicians and societies devoted to pain management and musculoskeletal spine and sport medicine, diagnosis and nonoperative treatment algorithms are evolving to include not only pastoral care modalities (e.g., functional restoration, behavioral modification, and psychological counseling), but also algorithms including aggressive pharmacologic pain management and interventional procedures for identifying and treating specific sources of pain. The proliferation of interventional procedures characterizing many nonoperative spine practices has been controversial. Although detractors argue that many of these procedures are dubious, risky, scientifically unproved, and do not lead to long-term functional improvement, they are ubiquitous. Even more procedures are being investigated in both pilot and randomized studies. Some, such as epidural injections have stood the test of time, but others, such as pulsed

radiofrequency treatments are recent concepts that may or may not be in common use in 3 to 5 years. In this chapter, we survey the most common procedures currently in use (1–3).

Most of these interventional procedures are directed at specific peripheral sources of pain originating within the posterior, middle, or anterior columns. However, there is continued doubt that one can identify specific pain sources in chronic low back pain. It has been estimated that using clinical and radiologic data, the source of low back pain can be accurately determined in only 15% to 20% of patients (4) with the exception of imaging (5). Contrary to this view, many spine specialists believe pain sources can be identified using pain reproduction and relief following precise localized and spinal injection techniques (International Spinal Injection Society [ISIS] standards) (6). Based on Schwarzer's studies using precision diagnostic injection as the criterion standard for diagnosis, Bogduk postulated that a definite diagnosis could be made in 70% to 80% of patients (7). Although arriving at a different percentage prevalence of specific pain sources, Manchikanti (3) was able to identify the z-joint, sacroiliac (SI) joint, or disc as the primary source of pain in 68% of patients.

### POSTERIOR COLUMN

The prevalence of specific posterior column pain generators in postsurgical patients is unknown. However, the effects of spinal surgery could increase the likelihood of chronic pain originating from z-joints, SI joints, and muscles or ligaments. Such effects may include increased segmental motion above or below a spinal fusion or increased or abnormal segmental motion owing to partial removal the intervertebral disc.

### Facet Blocks

Attempts to identify a clinical “facet syndrome” have largely been fruitless. Revel (8) has suggested that patients with facet pathology can be reliably identified by clinical criteria. Pain relief following placebo-controlled medial branch blocks is the current standard for diagnosing z-joint pain (9). Using this standard, the prevalence of z-joint pain in younger injured workers with chronic low back pain is approximately 15% and approximately 40% in older rheumatologic patients (10,11). A more recent study found a 40% incidence of facet-related pain in a series of 120 consecutive patients (12).

Relief following local anesthetic denervation does not, however, determine the cause. If pain is caused by inflammation, then injection of corticosteroid into the joint might be expected to give short-term pain relief; if the cause of inflammation is an acute episode, then relief might last until another event causes pain to return. However, in the postsurgical patient persistent z-joint pain is probably more often caused by mechanical strain of facet capsules secondary to abnormal segmental motion, rather than inflammation. Randomized placebo-controlled z-joint treatment trials with chronic low back pain have not shown a significant difference in pain relief between corticosteroid injection and placebo (13,14).

### Medial Branch Neurotomy

Because of the poor long-term results following corticosteroid z-joint injections (15), medial branch blocks have become the standard for diagnosis and treatment of z-joint-related pain. Blocking the medial branches at two consecutive levels temporarily denervates the joints. If pain is caused by the z-joints, pain relief should follow. Studies (16) have shown that lumbar medial branch blocks were target-specific and a valid test of z-joint pain. Carefully diagnosed with controlled diagnostic medial branch blocks, Dreyfuss et al. also showed that 60% of patients obtained at least 90% pain relief at 12 months, and 87% obtained at least 60% relief following radiofrequency medial branch neurotomy (17). In a randomized placebo-controlled study, van Kleef et al. showed that lumbar medial branch neurotomy was not a placebo (18).

However, medial branches do regenerate. In clinical practice the average patient may expect an average of 50% decrease in pain between 6 and 12 months, but the procedure can be repeated with a success rate of approximately 75% (19). In the case of a specific z-joint injury, the purpose of repeat neurotomies is to provide partial pain relief while the injury heals. However, lasting resolution of pain may depend on gradual stabilization of the spinal segment, which may take many years. Over time some patients develop different sources of pain and become unresponsive to further denervation.

### Restorative Injection Therapy of Failed Back Surgery

The medial branches innervate both facet capsules and interspinous ligaments. If pain is caused by chronic ligamentous strain arising from increased or abnormal motion, medial branch neurotomies do not treat the underlying problem. Although there is no evidence to show that multifidus muscle denervation following medial branch neurotomy increases instability, nonsurgical treatments directed at increasing the strength of the ligamentous structures are more appealing.

For many years practitioners of orthopedic medicine have advocated injecting injured connective tissues with proliferative agents (20–22). Theoretically, tissue proliferation could afford increased motion, segment stability, and reduced pain. Although remaining a contentious form of treatment, data showing connective tissue proliferation in animal models has provided some support for this approach (23). In addition, some clinical data have suggested that injection treatments may be of benefit to some FBSS patients. For example, Gedney treated patients with massive degeneration of intervertebral discs by injecting ligaments in the lumbar area and sacroiliac ligament with sclerosing solution (20,21), and Klein et al. (24) successfully treated a group of patients with low back pain, including patients with unsuccessful lumbar fusion.

Despite the continued widespread use of proliferative injections, controlled perspective outcome studies of prolotherapy are few and have not permitted a definitive evaluation. Although Klein et al. (25) showed significantly better results in patients treated by proliferative solution than patients injected with placebo, Dechow (26) failed to show significant differences between patients treated with proliferative solutions and those treated with lidocaine. However, it is significant to note that successful case studies required a period of treatment longer than 6 months and repetition of injections. In the Klein study, treatment included six injections with 1-week intervals between treatments and an exercise program, whereas in the Dechow study patients received only three injections and neither exercise treatment nor manipulations. Follow-up in both studies was 6 months. It is significant that successful case studies required a period of treatment longer than 6 months and injections were repeated. Manipulation and special exercises also were important.

### Intramuscular Botulinum Toxin Injections

Muscle overreactivity resulting in spasms is frequently observed in various pathologic conditions associated with pain (27). It is not clear whether spasm itself causes pain, or is simply a component of a more complex pathologic process. Electromyographic studies have shown that electrical activity of paraspinal muscle is higher in patients with low back pain (28). Although the role of chronic

muscle spasm in chronic back pain is unclear, many physicians believe that overactive paraspinal muscles contribute to chronic spinal pain; this belief has led to the investigation and use of botulinum toxin.

Botulinum toxin's therapeutic efficacy has been established in randomized controlled studies for the treatment of spasticity and dystonia, and there has been an increasing empiric use of botulinum toxin for the diagnosis and treatment of chronic spinal pain.

Intramuscular injection of botulinum toxin causes localized muscle paralysis by inhibiting acetylcholine release from neuromuscular junctions. In a randomized double-blind study pain relief following intramuscular injection of 40 units of botulinum toxin A at each of the five lumbar paravertebral levels was measured relative to placebo (29). At 8 weeks, nine of 15 patients (60%) in the botulinum toxin group and two of 16 (12.5%) of the normal saline group had pain relief exceeding 50% as measured by Visual Analogue Scale (VAS) score. Several possible mechanisms of pain relief using this method were proposed, and include spasm relief mediated via nociceptors, and neuronal innervation of nociceptors or spinal cord neurons.

### Middle Column

Although not the most common sources of spinal pain, recurrent disc herniation, stenosis, instability, and fibrosis are commonly sited structural sources of early or late recurrence of nociceptive pain following lumbar spinal surgery (30). However, even with direct surgical inspection it may be impossible to determine the primary source of axial pain. Many patients may have an undetermined degree of neuropathic symptoms unlikely to resolve following repeated surgical intervention. Many physicians continue to view FBSS as a syndrome characterized by neuropathic pain exacerbated by psychosocial factors (31).

### Epidural Injections

Nociceptive pain unresponsive to oral antiinflammatories and aggravated by inflammatory dural sensitization caused by disc herniations and stenosis is often treated with epidural injections of anesthetic and corticosteroids.

The effectiveness of epidural injections has been evaluated in numerous studies with mixed results (32–34). Performed by nonspecialists without the use of fluoroscopic imaging on patients with an unclear diagnosis current data does not support the application of blind translaminar injections (13). However, the efficacy of transforaminal epidural injections using fluoroscopic verification of targeting is more convincing.

Because of attenuation of the epidural space, postlaminectomy transforaminal injection offers a more selective and reliable method of targeting injectant to the anterior epidural space (35,36). In a randomized study in

patients presenting with lumbosacral radicular pain secondary to herniated disc, Lutze et al. compared the transforaminal injection of local anesthetic and corticosteroid versus trigger point injection (37) and showed an 84% success rate for transforaminal injections versus a 48% success rate for trigger point injections at an average follow-up time of 1.4 years. Subsequent work showed a 50% or greater reduction in pain at an average of 80 weeks following injections (38). In a randomized controlled study of 55 patients requesting surgery for radicular pain, Reiw found that 20 of 28 patients randomized to undergo fluoroscopically guided transforaminal injections with bupivacaine and betamethasone decided not to have an operation at follow-up (13 to 29 months). Among patients receiving betamethasone alone, only nine of 27 decided against surgery. In a prospective evaluation of 30 patients with pain secondary to a foraminal or extraforaminal herniation, Weiner (39) found that 22 of the 28 patients available for long-term follow-up showed sustained relief from their symptoms following transforaminal injection of local anesthetic and corticosteroids.

In a recent randomized controlled trial comparing the effectiveness of transforaminal local anesthetic and corticosteroid injections against a placebo injection of normal saline, Karppinen (40) showed both cost and short-term pain effectiveness for contained lumbar disc protrusions. These benefits were not obtained with disc extrusions.

The efficacy of treating spinal stenosis with transforaminal injections remains understudied. Using computed tomography (CT)-guided transforaminal injections in patients with spinal stenosis showed 72% short- and 28% long-term success rates compared with patients with disc herniations of the lumbar spine, who showed 95% short-term and 69% extended-term success rates.

Although epidural steroid injections are frequently effective for treating middle column inflammation at unoperated levels, the results when treating recurrent herniations and spinal stenosis at operated levels are less predictable. Because the nerve root obtains as much as 50% of its nutrition through cerebral spinal fluid within the dural cuff (41), postsurgical fibrosis may cause nerve root ischemia and neuropathic pain. If this process were responsible for a substantial portion of postoperative pain, epidural steroid injections would not be of significant benefit. However, treatment failure could be of prognostic value by suggesting the presence of irreversible processes unlikely to benefit from further surgery.

Derby et al. retrospectively studied a group of patients undergoing primary and repeat lumbar spinal surgery for extremity pain and determined that greater than 50% relief of extremity pain for more than 1 week following selective epidural block with local anesthetic and corticosteroids correlated with 50% or greater relief of leg pain at 1 year postsurgery. All patients had temporary relief of leg pain for the duration of the local anesthetic. When duration of leg pain was less than 1 year, both steroid

responders and nonresponders had good outcomes. However, when the duration of leg pain exceeded 1 year, patients unresponsive to corticosteroids (two of 13 patients, or 15%) showed a favorable outcome compared with 11 of 13 patients (85%) who responded to corticosteroids. Derby concluded that in patients with leg pain greater than 1 year in duration, not responding to corticosteroids injection, the probability of resolution following surgery was low. The chance of resolution in patients with previous surgery and no significant structural abnormalities was even less likely (42).

Although not specifically addressing the number of injections to perform in situations where the pathology is at an operated level, ISIS guidelines suggest that a series of injections should be limited to no more than four injections at intervals of 7 to 14 days within a 6-month period. Failure to obtain at least 40% relief of pain after any injection is sufficient reason to stop the series unless there is a strong desire to avoid surgery, absence of a surgical lesion, or the patient experienced relief followed by an acute exacerbation of symptoms. The American Academy of Pain Medicine (AAPM) has similar guidelines.

### Lysis of Adhesions

Whether fibrosis is a source of pain remains controversial (43–45). Because fibrosis is often seen in patients with and without continued spinal pain following surgery, some have concluded that continued pain is more psychological than physiologic (46,47–50). Traction on neural structures via fibrous adhesions could theoretically lead to pain; however, coexisting processes (e.g., sensitization because of inflammation, nerve damage, or segmental instability) must be present for pain to be symptomatic.

Surgical neurolysis of adhesions has generally shown poor long-term results (51), although some studies have shown pain relief for 3 to 6 months (52). This apparent short-term surgical relief has prompted the study and use of various percutaneous neurolysis methods.

Although perhaps the simplest method of treating epidural adhesions is the epidural injection of hyaluronidase, local anesthetic and corticosteroid, when Devulder (53) compared the results of transforaminal injection of hyaluronidase, and local anesthetic and a combination of hyaluronidase, local anesthetic, and Depo-Medrol in a randomized study of 60 patients with FBSS owing to fibrosis there was no difference in outcome between the groups at 6 months, although all groups did show a decrease in pain at 1 month. Interestingly only the two groups without corticosteroid showed a statistically significant decreased efficacy at 3 and 6 months.

Another common neurolysis method is the forceful injection of fluid into the caudal epidural space. Using this approach, several randomized comparative studies

have investigated the efficacy of providing pain relief in postoperative patients with back and leg pains without an obvious structural source other than epidural fibrosis. Using fluoroscopic and contrast-verified injections, both Revel (54) and Meadeb (55) compared the efficacy of forced saline injection with or without added corticosteroids versus low-volume corticosteroid alone. Revel showed a 6-month success rate of 45% and 29% for leg pain and back pain, respectively. At 18 months postinjection, there was a statistically significant improvement in patients in back (31%) and leg (39%) compared with the group treated with steroids alone. Meadeb did not follow enough cases to reach statistical significance. However, a modest 15% decrease was seen in 47% of the forceful injection group patients at 1 month following three injections administered at 1-month intervals. No complications were reported.

A more aggressive approach involves fluoroscopically guiding an epidural catheter to the site of fibrosis and using both injected fluid pressure and mechanical disruption by the catheter to lyse adhesions. Racz and Holubec (56) reported the first use of epidural hypertonic saline to facilitate lysis. Originally, Racz followed a 3-day in-hospital protocol using repeat treatments and included, in addition to normal saline and corticosteroids the injection of a hypertonic (10%) saline solution, which presumably decreased edema and attenuated small pain fiber activity. In a randomized comparative study to determine if hyaluronidase or hypertonic saline increased outcome, the Racz group found a 25% or more reduction in VAS scores in 83% of the patients at 1 month, and approximately 50% of the patients at 3, 6, 9, and 12 months. However, there was no difference in the groups, although the groups receiving hypertonic saline with or without hyaluronidase required slightly fewer treatments. More recently, Manchikanti found that a single day protocol using reduced volumes of both normal saline and 10% NaCl achieved similar 50% number of patients who achieved “significant” relief of pain at a 1-year follow-up (57). The use of a catheter directed through the intervertebral foramen also has been advocated as an alternative or perhaps more reliable method of catheter placement when one wants to lyse adhesions within the neural foramen (58).

One recent neurolysis method combines use of fluoroscopy with direct visualization via a fiberoptic endoscope directed through the caudal canal. This approach may facilitate disruption of neural adhesions using injected fluid or the endoscope itself (59). Manchikanti recommends endoscopic neurolysis if neurolysis by catheter technique is ineffective (60).

In addition to pain presumed to be secondary to epidural fibrosis, in a small retrospective study Manchikanti reviewed the charts of 18/239 patients with moderate to severe spinal stenosis who underwent a lysis protocol of 1 to 10 sessions. A 50% or greater reduction

in pain for an average of 10.7 weeks was found (61). Seventeen percent and 11% of patients maintained relief at 1 and 2 years, respectively.

Epidural injection of corticosteroids and hyaluronidase is relatively safe (62–64). However, use of hypertonic saline may significantly increase the risk of complications if the solution inadvertently enters the subarachnoid space. Most reported complications, however, have resulted from pressure following injections of relatively large volumes of fluid.

### Thermal Treatment

In theory, treatment of nociceptive pain by reducing or modifying small fiber input through dorsal root ganglions or dorsal horns is attractive. Surgical interruptions (dorsal root entry zone [DREZ] lesions), however, have not shown an acceptable long term success rate (65).

Since the early 1980s Sluijter has pioneered percutaneous treatment procedures directed at the dorsal root ganglion (DRG) (66). One approach involves a 67°C “cool burn” applied by a radiofrequency (RF) needle positioned close to the DRG after the pain source has been identified via local anesthetic relief. Data suggest that RF heating of the dorsal root ganglion is more effective than placebo in chronic cervicobrachialgia (67,68). Use of this technique for lumbosacral pain, however, is limited. In a retrospective analysis of 279 patients undergoing RF treatment of the DRG, 59% of patients reported satisfactory pain relief at 2 months postprocedure, with a mean duration of 3.7 years (69). Wright reported successful treatment of low back pain via RF directed at the L2 DRG (70). The concept that cooler temperatures permit selective destruction of small fibers has recently been questioned (71).

Although this technique continues to be practiced, it is worth noting that procedures that reduce input into the dorsal horns in neuropathies afford abnormal synaptic connections. In many cases in which chronic extremity pain following surgical intervention, central, neuropathic, and nociceptive pain are present in variable degrees. As Sluijter points out, “when for reasons we do not fully understand the dorsal horn may become permanently altered in its capacity to respond to normal peripheral input, pain centralization and therefore neuroablative procedures are doomed to failure and have the potential of creating additional neuropathic pain.” (72).

### Pulsed Radiofrequency Treatment

When radiofrequency treatment does not depend on neuroablation, but derives its effect from exposure of the DRG to electrical fields created by the RF probe, some problems associated with thermal injury may be eliminated. One approach involves use of a pulsed field. Slapendel et al. (73) found that pulsed RF treatment of the cervical DRG at 40°C and 67°C showed an equal 3

month significant reduction in pain in approximately 50% of both groups. This approaches again the idea of Sluijter, who in his own preliminary studies feels that he can achieve a similar favorable outcome. His preliminary results, theory, experimental data, treatment guidelines, and techniques are presented in his latest book (72).

Because of its low potential for adverse outcome and promotion by medical device manufactures, use of this technique is widespread. However, published outcome studies are lacking. Anecdotally, pain management physicians appear divided on the benefits of this technique.

### Spinal Cord Stimulation

As discussed elsewhere in this volume, neuropathic extremity pain refractory to oral medication is commonly treated with a spinal cord stimulator. In the United States, FBSS is the most common reason for application of spinal cord stimulation therapy (74). The analgesic efficacy ranges from 52% to 72%. A recent analysis of the national Italian register of implantable systems found that 81% of the patients reported a positive assessment for pain control, with a reduction in drug needs reported by 71% of positive responders (75). Some consider spinal cord stimulation a first-choice treatment in FBSS caused by lumbosacral fibrosis (76).

### ANTERIOR COLUMN

The primary structure in the anterior column responsible for continued or recurrent pain after lumbar surgery is the intervertebral disc. In the unoperated spine, the prevalence of pain owing to an internally disrupted disc is at least 39% (77). The prevalence of failed surgery because of continued pain from an intervertebral disc is unknown. Nevertheless, it is known that the surgical failure rate (unrelated to recurrent herniations) is significantly higher when discectomies alone are performed for smaller disc protrusions (78) and significantly higher when posterior reconstructive surgeries without anterior fusions are performed in patients with a low-pressure positive discography (79).

Because of nerve ingrowth in the degenerative, injured, or postoperative disc, continued pain from remaining disc tissue may be responsible for ongoing symptoms (80,81). Although the existence of discogenic pain is now well accepted, use of discography for identifying a painful disc remains controversial because of recent studies showing pain provocation during disc injection in asymptomatic subjects. If one excludes patients with somatization, applying more precise criteria for determining a positive level and use of a manometric grading scale (described by Derby et al. and recently adapted by the International Association for the Study of Pain and International Spinal Injection Society), the specificity of lumbar discography becomes 80% to 100% (82). In previously operated discs, however, the false-positive rate may be higher (83).

A more rational stepwise approach to patients with axial and referred extremity pain owing to an internally disrupted disc is evolving. Of particular interest are patients with lesser degrees of internal disruption, maintained disc heights, and pain provocation during discography at pressures less than 15 psi above opening pressure. Consistent with our current understanding of peripheral sensitization, there may be significant chemical sensitization causing increased pain response relative to the degree of structural pathology (79). Identifying these patients before surgical intervention and offering less invasive treatment options is a focus of current clinical investigations. Whether newer microinvasive techniques will be successful in previously operated discs or discs above or below spinal fusions is uncertain.

### **Intradiscal Injections**

A logical first step might be use of intradiscal corticosteroid injections either during discography or as a series. Although many discographers inject corticosteroid into painful discs at the time of discography, and others consider intradiscal steroid injection a treatment option, the outcome is often unrewarding (84). Outcome studies on the use of intradiscal corticosteroids have, however, included a heterogeneous mixture of disc pathologies. Injected agents may benefit patients with chemically sensitized discs (85).

There is a growing interest in intradiscal solutions that could promote healing of an injured annulus. Animal studies suggest growth factors may modulate repair of the nucleus and transition zone. A single injection of tumor growth factor- $\beta$  has been shown to induce 3 weeks of proteoglycan synthesis and healing of full-thickness cartilage lesions, indicating that continuous exposure to growth factors may not be necessary for healing to occur. Intradiscal injection of a solution of glucosamine, chondroitin sulfate, and hypertonic dextrose is currently being studied. When injected into a disrupted intervertebral disc, these agents could upregulate the biosynthesis of proteoglycans directly and indirectly through the release of endogenous growth factors. In a recent study, a group of 30 patients with chronic low back pain, including five patients with previous lumbar surgery and positive monometric controlled discograms, underwent a series of one to three injections at 2-month intervals. The investigators found 25 of the 30 patients achieved a 50% average decrease in pain and disability scores (24,86). Pain reduction has been postulated to occur because of improvement in the intradiscal chemical environment.

### **Thermal Treatment**

If pain following disc injury arises in part from ingrowth and the subsequent sensitization of nociceptive fibers within annular fissures, pain reduction may occur

by reducing or eliminating nociceptive input by destroying pain sensitive fibers with heat. Percutaneous intradiscal heating treatment was first introduced in 1993 by Sluijter (87) using a standard radiofrequency needle inserted into the center of the disc and heated 90 seconds at 70°. Although this original did not survive a randomized controlled study, better methods have been developed. Currently available methods involve either a resistive thermal coil threaded circumferentially around the annulus (Oratec SpineCath) or an ionic heating catheter threaded across the posterior annulus (Tyco-Radionics Disc Trode). Outcome data on the former method has shown an approximate 60% success rate in selected patients (88–91). Patients best suited are those with maintained disc heights and more limited degrees of disruption with a chemically sensitized outer annulus. Although animal and human data suggest annular temperatures above 45°C are required to destroy nociceptive fibers, the mechanism of pain relief is unclear. A combination of processes including thermal fiber destruction, collagen modification, and perhaps even biochemical modification of the inflammatory process may be involved

### **Coblation**

Other alternative microinvasive intradiscal treatment techniques are emerging. One technique is the use of a microinvasive decompressive procedure using coblation technology. In this approach energy capable of breaking chemical bonds in tissue is generated via a highly focused plasma field. Using this technique an approximate 10% volumetric reduction in nuclear tissue is observed. The resulting decrease in intradiscal pressure is thought to be responsible for pain reduction. Because this is a new method, relatively few outcome studies have been completed. In one study using this method, nucleoplasty gave an overall 79% success rate with a 67% success rate in a group of patients with previous surgery (92). Similar to other decompressive techniques, the procedure is designed to treat patients with extremity pain owing to smaller disc protrusions. There is a growing trend to perform both nuclear decompression and a heating treatment in the same session (Fig. 88-1) (3).

### **Central Pain**

Neuropathic pain is caused by the hyperexcitability of neurons in the peripheral and central nervous system (93). The experience of chronic constant pain may have a primary or secondary component of sympathetic neuropathic pain. That is why even when the primary source of the pain is exterminated, particularly after spine surgery, patients can continue to perceive pain owing to the continued excitation of neurons that are responsible for pain sensation. The mechanism by which this occurs is not fully understood. The normal neurologic pathway in

**FIG. 88-1.** Nucleoplasty intradiscal electrothermal therapy (IDET) combined procedure. Patient with painful internally disrupted disc successfully treated with combined nucleoplasty/IDET. Figure shows nucleoplasty needle and electrode in L5-S disc. Following nucleoplasty, IDET catheter is passed through introducer needle and heated using 85° protocol.

response to and injury travels along the A- $\delta$  and C fibers through peripheral nerves to enter the spinal cord through the dorsal root and synapse on the dorsal horn with interneurons carrying the impulses to ascending tracts, the anterior horn, and intermediolateral cell column, where the painful message is relayed to the sympathetic nerve cell bodies. A sympathetic reflex is activated by efferent sympathetic impulses sent out of the spinal cord through the ventral roots to a ramus communicans albus and then into the sympathetic chain to synapse in a sympathetic ganglion. The postganglionic sympathetic fiber leaves the ganglia, where it travels with the peripheral nerve producing vasoconstriction. If this sympathetic reflex arc does not shut down but continues to function and accelerate, a sympathetic hyperdynamic state ensues. This results in increased vasoconstriction and tissue ischemia, causing more pain and thus increasing the barrage of afferent pain impulses traveling in the spinal cord and reactivating the sympathetic reflex. Hypothetically, repeated sympathetic blocks could be used to treat pain perpetuated or enhanced by this overactive sympathetic state (94). Prospective controlled study has not, however, confirmed effectiveness of this treatment in patients with failed back surgery syndrome (95).

Another cause of neuropathic pain after spine surgery may be direct injury during the procedure, scar tissue, damage to small peripheral nerves of the soft tissues and skin with retraction instruments, insertion of venous catheters, or superficial skin irritants.

Several classes of medications have been shown to be effective in the treatment of neuropathic pain by dampen-

ing the threshold to excitation in the postganglionic sympathetic neurons. Tricyclic antidepressants act as balanced inhibitors of reuptake of both norepinephrine and serotonin at the sympathetic junction that act to suppress pain transmission, resulting in the prolongation of serotonin activity at the receptor (96). It was shown (97) that tricyclic antidepressants via L-tryptophan were effective in the treatment of postoperative pain.

Calcium channel blockers reduce nerve conductivity and excitability (98). Neurolytics such as Gabapentin (Neurontin) act by blocking Ca<sup>+</sup> voltage-dependent channels in the neuron membrane, and thus reducing excitability (99). It is effective in the treatment of intractable neuropathic pain (100) or is used as an adjuvant treatment (101,102). Case studies have demonstrated gabapentin to be effective in the treatment of failed back surgery syndrome caused by epidural fibrosis (103).

Other classes of medications currently being used as adjuvant therapies include *N*-methyl-D-aspartate (NMDA) inhibitors,  $\alpha$ -blockers, and topical anesthetics.

Large groups of medications act as opioid receptor agonists. Analgesic opioids have been used for pain alleviation for ages, and remain to this day the most controversial solution. Cases of iatrogenic addiction owing to the use of opioid analgesics date back the 19th century. Physicians hesitate to prescribe them for fear of their potential addictive qualities. The use of opioids for patients suffering from malignant terminal cancer pain has found wide-ranging acceptance in medical practice. However, in patients suffering with profound pain from

nonmalignant sources such as failed back surgery syndrome where long-term survival is expected, physicians hesitate, assuming the potential for addiction is high. However, the rate of addiction is 0.8% with the use of long-acting medication formulations now on the market (104). The medical literature is fraught with contradictory reports showing the abuse rate in this same population as high as 24% (105). Schofferman (106) found no psychological, psychophysiologic, or clinical characteristics predicting the probability of addiction. This same study demonstrated that opioid analgesics could provide significant improvement in quality of life for patients suffering with chronic low back pain following failed back surgery who had no other treatment alternatives.

Although most patients exposed to opioid analgesics for an extended period develop some degree of physical dependence (107), psychologically their dependence differs from that in drug-addicted individuals seeking euphoria (108). Drug addicts use drugs purely for the euphoric effects despite it destroying their normal life, causing them to withdraw from family and society as well as endangering their health. In contrast, patients suffering from chronic pain take opioid medications in order to restore normal life, relations, and participation with family, and to return to work (109). Another problem that is mostly associated with short-acting analgesics is the development of tolerance to opioids. This occurs because of the upregulation of opioid receptors on the cell membrane, requiring higher doses of the drug to create the same perceived analgesic effect (110). It has been shown in patients without chronic pain who received methadone for opioid dependence that the analgesic effect for both methadone and morphine was diminished. Higher doses were necessary to reach the same analgesic effect (111,112). Studies have shown that chronic pain patients who are being managed on long-acting opioid preparations are able to maintain stable analgesic doses for years (106). It was suggested that chronic pain itself could activate analgesic tolerance (110). Some adjuvant medications can inhibit cellular mechanisms responsible for analgesic tolerance. Namely it has been shown that NMDA blocks opioid receptors, restoring opioid analgesic capacity to both reduce not only tolerance but also allows for dose reduction (113).

Common adverse side effects of oral opioid administration include constipation, sedation, cognitive impairment, pruritus, nausea, and vomiting (114). Usually these complications take place at the beginning of treatment and resolve in a few weeks.

However, in a selected group of patients these adverse reactions do not diminish in time even in the face of adequate pain control. They find that the adverse side effects from the opioids cause even greater levels of disability and diminished functional status. For these select patients alternative methods of administration of the medications via indwelling epidural catheters are now possible. By

delivering the opioid medication directly into the epidural space a fraction of the per oral dose can be used to obtain the same degree of pain control without the medication's systemic adverse side effects.

Implantable self-infusion pump systems are being used in selected cases for the treatment of severe chronic pain in patients with failed back surgery (115). It has been shown that intrathecal morphine pumps are effective in the management of failed back syndrome in more than 60% of patients who had been unresponsive to oral therapy who had been suffering for 5 years or longer (116). Despite the high cost of surgical pump implantation, in long-term prospective studies (11 months and longer) intrathecal morphine therapy is more cost effective than traditional oral opiate therapy (117). Even though this system of opioid delivery solves many of the problems associated with oral administration, some of the same adverse side effects are still possible and do occur with the implantable systems, such as nausea, pruritus, constipation, and urinary retention. These symptoms usually can be controlled with antiemetics, antihistamines, and stool softeners with stimulants (116). In patients where these adverse effects become intolerable and resistant to medical management or in the case of drug tolerance or pump failure, these systems eventually are removed (117).

Physicians should consider long-term opioids as the last option in the treatment of failed back surgery (109,116,118). Psychological evaluation of a patient's potential for addiction is highly recommended before considering the use long term opioid management of chronic failed back syndrome (106). In the case of intrathecal pump placement a 3-day trial in an inpatient setting of intermittent intrathecal opioid administration through a temporary catheter allows for the adjustment of individual dosing with proper analgesic response and diminished adverse side effects (116).

## SUMMARY

This chapter discusses interventional procedures commonly used for the treatment of chronic spinal pain. Many of these procedures are controversial and lack definitive evidence-based medical support. On the other hand, there is a growing use of these procedures both as supplementary optional methods of pain control and as methods to help confirm that a specific structure is a source of pain.

Although the treatment ideally should be directed at the source of pain, in many cases of FBSS either the source of pain is elusive or there are multiple pain sources. In these cases, the more "benign" and least invasive procedures should be tried first. Several different procedures can be performed in the same session (Fig. 88-2).

Interventional procedures used to treat painful posterior column structures include percutaneous medial

**FIG. 88-2.** Combined neurotomy and transforaminal epidural block. The patient 4 years post L4-S1 intertransverse fusion with continued unilateral low back and leg pain. Back pain is reduced by more than 50% following L2 and L3 (shown above) medial branch neurotomies performed at 6- to 12-month intervals. The patient's leg pain, which is secondary to L4 foraminal stenosis, is reduced following transforaminal epidural injections. The patient continues to work and does not want another surgery.

branch neurotomies to denervate the z-joints and intramuscular botulinum toxin injections to temporarily paralyze the paravertebral muscles. Both procedures are relatively benign, have an approximate duration of action of 6 and 3 months, respectively, and can be repeated. In those patients thought to have increased or abnormal segmental movement, a series of three to six injections of hypertonic solutions into the posterior compartment ligaments at 1- to 4-week intervals might be of benefit in increasing stability by promoting a proliferation of connective tissue.

In the middle column, transforaminal epidural blocks may help reduce inflammation and edema secondary to recurrent disc protrusions and spinal stenosis and thereby provide short-term pain reduction. Repeat sessions to mechanically lysis epidural adhesions using a fluoroscopically directed epidural catheter with or without direct visualization may help reduce pain in selected patients but is only weakly validated by a few authors. Pulsed radiofrequency treatments of the dorsal root ganglion is newly proposed and relatively benign method that theoretically reduces pain by exposing the dorsal root ganglion to an electrical field rather than radiofrequency-generated heat, but outcome studies are yet to be published. In contrast, “cool burns” of the dorsal root ganglion, although effective for some patients, carry a significant potential to amplify neuropathic pain and should be undertaken with caution.

Continued discogenic pain at the same or adjacent levels of surgery is a common source of early or late recurrence of anterior column pain. Surgical removal of the

entire disc with interbody fusion is the definitive treatment option. Newer less invasive treatment options, including intradiscal heating, nucleoplasty, or both, may be considered when either the patient does not want another surgery or the number of adjacent painful levels would require excessive surgery. However, these procedures are more likely to be successful before surgical intervention and when the painful disc has limited annular disruption and a preserved disc height.

Pharmacologic management is the first step in treating central neuropathic pain. When medications are either ineffective or cause unacceptable side effects, implantable systems are available. Spinal cord stimulation is commonly performed to reduce neuropathic extremity pain, but reduction in axial pain is more difficult to achieve. Intrathecal implantable drug delivery systems are a last resort.

## ACKNOWLEDGMENTS

We are very grateful to Janine Talty for her valuable suggestions for improving the chapter. We also thank Marina Kurgansky and Todd Bellicci, who worked on the text and prepared the manuscript for submission.

# Psychological Approaches to the Management of Failed Surgery and Revision Surgery

Robert J. Gatchel and Chris J. Main

---

^Today, low back pain (LBP) is a pervasive medical problem in industrialized countries. In addition to the pain and emotional suffering that LBP patients experience, LBP presents enormous costs to society. Such costs include lost earnings, decreased productivity, and increased health care utilization expenses in disability benefits. For example, studies have calculated the annual cost of chronic LBP in the United States alone to be between \$20 and \$60 billion when measures such as lost productivity and social disability insurance benefits were calculated, along with treatment costs (1). Gevirtz et al. (2) have indicated that 80% of Americans suffer back pain at some point in their lives, and about 18% develop chronic LBP disability. Indeed, chronic LBP is the chief cause of disability in people under age 45. Moreover, following an initial episode of LBP, relapses are reported to be 30% to 70% of patients sampled (3).

Thus, as is apparent, the costs of LBP can be viewed in terms of costs to the individual and society. As far as the individual is concerned, costs include both pain-associated suffering and limitations. Suffering can range from mild discomfort to associated distress triggering suicidal ideation, and (rarely) suicide. Pain-associated limitations can include impact on activities of daily living, personal relationships, and work. Most LBP resolves spontaneously or with early focused interventions such as manipulation. Most such treatment, or indeed the passage of time, is successful, although recurrences are to be expected. In the presence of red flags (4), early surgery should be considered; but unless there are clear and equivocal surgical indications, surgery is usually considered only after failed conservative treatment. The problem then may become chronic, and carry with it the psychosocial “baggage” characteristic of the chronic pain patient. Of course, sometimes surgery is successful, but sometimes it is not so, and the costs of failed low back

surgery is considerable to both the individual patient and society as a whole.

Spine surgery is the next line of medical care when conservative treatment for LBP fails. Of course, whenever surgery is performed, there is always the possibility of complications or failure. Fortunately, necessary spine surgery is often successful when performed by an experienced spine surgeon. However, spine surgery has become a controversial area because of the high cost, frequent use, and some research suggesting limited effectiveness. For example, earlier studies focused attention on the complications and perceived poor outcomes of spine fusion surgery, particularly in the lumbar region (5,6). Discectomy, which is usually performed earlier than fusion after symptom onset, is often viewed to be less invasive or controversial. However, although short-term pain relief and improvement in vocational status appear to be supported, reoperations are often common, with rates as high as 17% to 20% reported in early studies (7,8). Nevertheless, more recent studies have suggested that spine surgery is cost effective, and it can lead to significant improvement in lifestyle. For example, Atlas et al. (9) conducted a 4-year follow-up study of patients with lumbar spinal stenosis and found that those treated surgically (primarily with a decompression laminectomy) had significantly less back and leg pain and greater satisfaction than those treated nonsurgically. Moreover, Malter et al. (10) reported that quality of life for patients with herniated lumbar discs, operated on with discectomy, were significantly greater than that of patients treated conservatively for up to 5 years. In addition, the cost effectiveness of the discectomy was found in this study to be significantly greater than that for such procedures as coronary artery bypass grafting for single-artery disease, and greater than medical therapy for moderate hypertension.

### PREVALENCE OF LOW BACK SURGERY

There are wide differences in surgery rates for LBP among countries. It has been estimated by Waddell (11), derived from data by Cherkin et al. (12), that surgical rates in Europe and Australia (in comparison with the United States) are between one third and two thirds (although there is a fivefold difference between the United Kingdom and the United States). This is seen most clearly in a direct comparison of rates of spinal fusion (13). The reasons for this are not entirely clear, because presumably there are not major differences in surgically remediable pathology. The fact that there are even greater differences in back surgery rates *within* the United States suggests that differences are probably influenced also by a range of factors such as access to surgery (in terms of third-party coverage), differences in selection for surgery, and willingness to undergo surgery. A clear majority of patients appear to be satisfied with surgery (14). Early studies (15,16) estimated a success rate for surgery of 65% to 75%; even though later studies have been somewhat optimistic, they estimated an average failure rate of only 15% (17) and 10% (18). Given that approximately 192,000 patients with chronic intractable back pain undergo spinal fusion each year (19), there are still a significant number of surgical failures, with a reoperation rate of 10% for discectomy (15), and 23% for spinal fusion (16). Surgical enthusiasts argue that improvements in surgical technique (including instrumentation) permit a wider range of surgical options and, indeed, surgical rates are increasing; but this increase in surgical intervention does not appear to have been matched by a corresponding improvement in surgical outcome (20).

Poor surgical outcome is costly not only to the individual and his or her family, but also to society. In all studies of LBP, 10% to 15% of patients account for 80% to 90% of the total health care consumption and costs for spinal disorders, and the 1% to 2% who undergo surgery are the most expensive group (21). Furthermore, a recent comparison of societal costs of LBP in various countries has shown that *indirect* costs, in terms of sickness benefits and lost productivity, were considerably greater than *direct* health care costs (22). Clearly it is important, therefore, to consider the determinants of poor surgical outcome. In attempting to address this problem, it is necessary to appraise the evidence concerning the predictors of surgical outcome in general and of poor surgical outcome in particular.

### CONSEQUENCES OF FAILED SURGERY

Of course, spine surgery is certainly not a panacea for all patients. In a comprehensive review of all lumbar discectomies conducted up to the time of their publication, Hoffman et al. (15) reported that the mean success rate

was 67%. Likewise, in reviewing all research on spinal fusion, Turner et al. (16) reported a successful clinical outcome obtained in 65% to 75% of patients, with success rates lower the more levels fused, and generally the more invasive the procedure. Subsequently, Franklin et al. (23) reported that 68% of workers compensation patients who underwent lumbar fusion, were work disabled and 23% required additional lumbar spine surgery 2 years postfusion. These results, therefore, highlight the fact that spine surgical success is not guaranteed. It should also be kept in mind that the way one determines surgical success or failure can be quite variable. We discuss this issue later in this chapter. Nevertheless, spinal surgeons are quite aware of the consequences of FBSS.

Oaklander and North (24) define FBSS as persistent or recurrent chronic pain after one or more surgical procedures on the lumbosacral spine. Unfortunately, as noted, this syndrome is much more common than desired. The surgeon many times becomes "wedded" to these failed back surgery patients. Some of the frustrations and demands subsequently encountered by the surgeon include the following:

- The patient may make increasing demands on the surgeon for pain relief. The surgeon, in turn, feels a strong sense of responsibility to provide relief when the surgery has been ineffective.
- The patient may become increasingly angry with the surgeon because of the failed surgery and, perhaps, litigious.
- Pain medication use by the patient often escalates, thus increasing chances of dependence or addiction. Patients often overuse medication and demand refills before the designated time.
- In an attempt to provide relief, the surgeon may order additional conservative treatments that have little chance of success, thereby increasing length and cost of the case. Moreover, patients may decide to additionally undergo increasingly invasive surgery, with subsequent opportunities for infection, instrumentation failure, or other iatrogenic complications. Unfortunately, the probability of successful outcome significantly decreases with each spine surgery.
- The probability of reducing pain and returning the patient back to work decreases as length of disability increases. Because failed back surgery lengthens the period of disability, these patients are less likely to ever recover. Thus, the total cost of the initial injury dramatically increases because of direct treatment and surgeries plus resultant disability income benefits.
- Finally, there may be financial incentives to remain disabled that far outweigh incentives for recovery.

Thus, the spine surgeon is often faced with a conundrum. The surgeon feels obligated to the patient but, at the same time, becomes frustrated and the target of the patient's distress. The intervention subsequently proposed

often becomes more invasive, but the outcomes are less satisfactory. For example, a failed simple laminectomy or discectomy is frequently followed by a much more extensive fusion (perhaps with instrumentation), leading to greater opportunity for failure. Indeed, many studies concur with the conclusion made by Waddell (25) that the probability of a successful spine surgery outcome leading to pain relief decreases significantly with each successive procedure. For example, in an early study, Pheasant et al. (26) reported that patients who had multiple surgeries had a lower probability of obtaining a good outcome than did patients who only had a single surgery. North et al. (27) also suggest that the long-term success rate in reoperated patients is approximately one third. The only solution to this conundrum is better methods to prescreen patients before surgery in order to eliminate those who have a poor probability of success.

### HOW DOES ONE DETERMINE SURGICAL SUCCESS OR FAILURE?

It should be kept in mind that when one talks about surgical outcome, its assessment is not a straightforward matter. Of course, the most straightforward fashion to determine surgical success is the determination of whether the identified pathology was corrected. Unfortunately, however, patients frequently fail to experience or report any symptomatic improvement despite excellent surgical correction because of the biopsychosocial nature of pain. Therefore, a determination of surgical success requires the evaluation of major areas in which the back pain patient's life is affected, such as activities of daily living and socioeconomic outcomes such as return to work and decrease in health care use. In the past, the great majority of studies on spine surgery have used some variation of the criteria proposed by Stauffer and Coventry (28) to assess outcome. These criteria evaluate outcome in terms of reduced pain sensation, job impairment, use of narcotic medications, and improvement in functional activity. For example, Trief et al. (29) evaluated the percent of patients reporting improvement in back and leg pain, the percent working, and functional disability status using the Dallas Back Pain Questionnaire. More recently, Klekamp et al. (30) have suggested a modification of the original Stauffer and Coventry (28) outcome criteria, which is somewhat more comprehensive in nature. These criteria are listed in Table 89-1.

As can be seen, these criteria appear to capture the major life areas affected by chronic pain. However, there are many gray areas in terms of ratings. For example, what is the precise definition of "infrequent" use of analgesics? Moreover, under the good outcome category, what if a patient meets three of the four criteria? Thus, as can be seen, there may not be any definitive and totally objective criteria that are generic enough to capture success or failure in all patients. In appreciation of the difficulties involved in defining success or failure, it should be kept in mind that, whenever evaluating spine surgical outcome results, no totally accepted criteria are consistently used across all studies.

### Problems in Evaluation of Outcome

The nature of pain, chronic pain in particular, is complex. Surgery is directed primarily at the correction or remediation of some sort of surgical lesion. According to Waddell (11), much current orthopedic practice derives from the discovery of the "ruptured disc" as a cause for sciatica by Mixter and Barr (31), and apparently the first surgeons made the diagnosis on hard neurologic signs; although, their successors came to rely much more on symptoms, and the diagnosis of discogenic back pain became established. It was argued further that, if sciatica was caused by disc prolapse, then LBP might be caused by disc degeneration. Surgery such as lumbar fusion was offered for LBP, and outcome was evaluated in terms of the technical success of the procedure, such as stabilizing the spine and avoidance of complications. It was assumed that surgical intervention would improve (if not abolish) pain, restore function, and facilitate return to work. It became clear that, in a number of patients, not only did surgical success not guarantee improvement in pain, function, and work compromise, but also that evaluation of success simply in terms of surgical parameters was inadequate as a single outcome measure.

Evaluation of success or failure is made difficult also because there are various stake holders. Prior to the advent of managed care and outcome-related funding, outcome was evaluated primarily by the success of the surgery in correction (or amelioration) of structural abnormality, and the avoidance of complications thereafter. Outcome was determined primarily, therefore, by the surgeon's appraisal of the technical success of the operation. However, the move to patient-centered out-

TABLE 89.1. *Criteria for spine surgery outcome*

	Pain relief	Employment	Activities	Analgesics
<b>Good</b>	Most (76%–100%)	No limits	No limits	Infrequently
<b>Fair</b>	Partial (26%–75%)	Lighter work	Limited	Occasionally
<b>Poor</b>	Little to none	Disabled	Greatly limited	Frequently

Source: Adapted from Klekamp J, McCarty E, Spengler D. Results of elective lumbar discectomy for patients involved in the workers' compensation system. *J Spin Disord* 1998;11:277–282, with permission.

come in terms of pain and function complicated the picture, because technical success was not always accompanied by commensurate improvement in pain and function. The advent of managed care and outcome-related health care funding has led to the incorporation of economic and occupational outcomes (e.g., change in benefit status or rate of return to work), thus complicating the picture still further. The issue is of more than academic importance. Rates of success or failure of surgery can only be accurately compared where there are a clear assessment of indication of surgery, a clear description of the surgical intervention, and comparable outcome measures.

### Types of Outcome Assessment

There are two principal types of outcome appraisal: clinical appraisal of the individual and aggregated data on efficacy of treatment (usually for audit or research purposes). The principal domains are shown in Table 89-2.

Implicit in the surgical view of intervention is the assumption that correction of the physical abnormality will produce a commensurate improvement in pain and function. There are undoubtedly many patients in whom global improvement is achieved; however, in a significant minority of patients there is a residual degree of pain or pain-associated incapacity despite surgical "success." The lack of a direct correspondence between physical impairment and pain severity requires a broadening of the discogenic model of pain. Indeed, there is a similar dis-

cordance among pain, functional disability, and work loss (11). Explaining outcome necessitates an understanding of its determinants and, as far as functional disability and work are concerned, a broader model of illness is required than the narrow pathology-based model. The biopsychosocial model of LBP disability (32), drawing inspiration from Loeser's earlier pain model (33), and its several later derivatives (25,34), offers a different way of understanding pain-associated disability. If indeed pain-associated disability is multifactorial, then so perhaps are the determinants of disability and (conversely) the obstacles to successful recovery. A wider perspective on outcome is needed.

### Outcome Assessment

The need for a variety of outcome measures has been increasingly recognized. According to Bombardier (35): "Clinical success in the treatment of spinal disorders has traditionally been measured in terms of morbidity, physiologic changes (e.g., nerve conduction) or improvement in physical findings (e.g. weakness). More recently, outcome measures have been introduced that take into account the patients' self-report of their physical function and health" (p. 3,097). She points out that the use of outcome measures is relatively new, and that "several areas still remain controversial such as the need for and choice of utility measures, which concept of satisfaction should be used, or how to measure reduced work-productivity" (p. 3,098). She offers a set of key questions to ask about an outcome measure, as presented in Table 89-3.

**TABLE 89.2.** *Outcome evaluation: examples of important domains*

Posttreatment clinical domains
Surgical: technical success
Surgical: absence of complications
Pain
Self-rated interference
Self-reported disability
Clinical appraisal
Behavioral observation
Psychological
Beliefs and fears
Emotional responses
Coping strategies
Patient satisfaction
Maintenance and follow-up
Relapse
Length of follow-up
Occupational domains
Time to return to work
Work performance
Further sick leave
Cost-effectiveness
Costs of treatment
Further health care use
Disability/benefit saving
Reduction in presenteeism
Reduction in absenteeism

**TABLE 89.3.** *Key questions to ask about an outcome measure*

Content, population/setting, purpose
Which outcomes do you want to measure?
Which population will you be studying and in what setting?
What is the purpose of your study: to describe, or predict or to measure change?
Content validity
What domains and items are included? Are there important omissions or inappropriate conclusions?
Face validity
Is each question phrased in a suitable way?
Are the response categories appropriate?
Is there an overall score summarizing across questions?
How is it calculated?
Feasibility
Is it easy to understand?
Is it easy to use (i.e., clear instruction manual)?
Is it acceptable?
What format is available (self-administered, telephone, interviewer-administered)?
How long does it take to administer?

### Implications of the Need for Broad-Based Outcomes

Consideration of outcomes from a wide range of perspectives has a number of implications for clinical practice in general, and the evaluation of surgery in particular. There are important implications for clinical decision making. As has been stated, a majority of patients appear to be satisfied with surgery. Nonetheless, there is a significant minority dissatisfied to a greater or lesser extent, and outcome of surgery is coming under increasing scrutiny (36). It used to be argued that surgical intervention is designed to correct a physical abnormality, and that all that can reasonably be asked from a surgical intervention is correction of that abnormality. Outcome assessment was confined to evaluation of technical success (e.g., in stability of fusion or whether or not complications such as instability or infection resulted). Outcome evaluation in terms of physical signs seems to be relatively straightforward, at least from the conceptual point of view. However, most patients seek treatment as a consequence of painful symptoms or pain-associated limitations in function and, unfortunately, technical surgical success guarantees neither cure of pain, complete restoration of function, work retention, nor return to work, even in the treatment of sciatica, which usually is considered to be a better bet for surgery for low back pain (37). Such considerations have important implications for clinical decision making, and require reconsideration of the nature of pain-associated disability and outcome of treatment. Of the many factors that have been examined, psychological factors appear to be particularly important.

### Influence of Psychosocial Factors on Outcome

A number of studies have demonstrated a relationship between psychosocial factors and outcome of surgery. The influence of preexisting or coexisting psychological vulnerability was investigated in a number of early studies (38–40). More recently, in a series of related Scandinavian papers, Graver et al. demonstrated a positive relationship between preoperative psychological distress after lumbar disc surgery, both at 1- and 7-year follow-up (41,42). The precise psychological mechanisms, however, are not entirely clear. Psychological variables influence postoperative anxiety and physical complaints (43). The results concerning postoperative functional disability are inconsistent. Some studies (29,44) have found a positive association between psychological factors and functional disability at outcome, whereas others (18) have failed to demonstrate an association. This may be a consequence of differences in patient selection, whether in terms of screening out patients with positive psychological features, or in terms of better physical indications for surgery (45). A clear association has been found between psychological factors and return to work (29,46). In one of the few predictive studies attempting to disentangle the vari-

ous sorts of psychological factors on return to work after surgery, Schade et al. (46) found that return to work 2 years after surgery was influenced not by clinical findings, such as magnetic resonance imaging (MRI)-identified abnormalities, but by depression and psychosocial aspects of work. This finding is consistent with recent primary care perspectives on secondary prevention of back pain disability, in which early attention to the psychosocial aspects of pain-associated disability is recommended (47). More recent consideration of obstacles to recovery, with differentiation of these yellow flags, focuses on patients' beliefs about pain, disability and treatment, and occupationally focused blue and black flags (48). The blue flags have their origin in the stress literature. They are perceived features of work that generally are associated with higher rates of symptoms, ill health, and work loss (49), which, in the context of injury, may delay recovery or constitute a major obstacle to it. They are characterized by features such as high demand or low control, unhelpful management style, poor social support from colleagues, perceived time pressure, and lack of job satisfaction. Individual workers may differ in their perception of the same working environment. According to Bigos et al. (50), perception may be more important than the objective characteristics because, "Once an individual is off work, perception about symptoms, about the safety of return to work, and about impact of return to work on one's personal life can affect recovery even in the most well-meaning worker" (50). It should be emphasized that blue flags incorporate not only issues related to the perception of job characteristics such as job demand, but also perception of social interactions (whether with management or fellow workers). Black flags are *not* a matter of perception, and affect all workers equally. They include both nationally established policy concerning conditions of employment and sickness policy, and working conditions specific to a particular organization.

Because psychosocial factors seem to have such a powerful influence on outcome, appraisal of such features needs to become an integral aspect of patient evaluation. Many clinics now undertake some sort of presurgical screening or psychological evaluation prior to surgery.

### PRESURGICAL SCREENING

Presurgical psychological evaluation is carried out for a number of reasons, illustrated in Table 89-4.

**TABLE 89.4.** *Purposes of presurgical psychological evaluation*

Identifying contraindications; consider legitimacy and ethics of this
For prior psychological intervention
For conjoint psychological therapy
To flag for postsurgical psychological management

### Identification of Contraindications to Surgery

The costs of surgical failure are considerable, both in terms of financial cost and human suffering. Factors such as distress, unrealistic expectations of outcome, and maladaptive coping strategies are all associated with poor outcome, and a case could be made for simply denying surgery to any patients demonstrating such features. Certainly, such a strategy would improve overall surgical success rates. However, there are two major ethical concerns. First, although adverse psychological factors have been demonstrated among groups of patients, the strength of the relationships with outcome is not sufficiently strong to enable accurate prediction in the individual case. Second, denial of surgery in the presence of good *surgical* indications is regarded by some as an abrogation of clinical responsibility. It might reasonably be argued that surgery is a necessary but not sufficient intervention to produce satisfactory outcome in such patients.

### Prior Psychological Intervention

Coping with surgery requires a certain degree of resilience and, in some patients, a degree of prior psychological preparation may be necessary, with therapy focused on emotional support, the establishment of appropriate and realistic expectations, and the development of effective coping strategies both before and after surgery. Block et al. (44) have presented methods for providing the following.

#### *Conjoint Psychological Therapy*

The opportunity for conjoint psychological therapy clearly is limited, but additional emotional support immediately before surgery or at the time of postsurgical recovery in patients who demonstrate high levels of anxiety about surgery itself or the anticipated sequelae is important.

#### *Flag for Postsurgical Psychological Management*

Patients with a nervous disposition, or poor pain coping skills and low pain tolerance prior to surgery, may not be psychologically oriented for postsurgical management and rehabilitation. Furthermore, it could be argued that *all* failed surgery patients should be considered for psychologically oriented pain management, if not individualized psychological therapy.

### Nature of Screening Tools

Psychological screening, for whatever purpose, usually has involved administration of a self-report questionnaire, ranging from full-scale personality inventories (51)

to fairly simple measures of distress (52). Recently, however, Block et al. (44) developed a specific screening tool, the Psychological Screening Scorecard (PPS), incorporating interview-based assessment of medical and psychological risk factors derived from the Minnesota Multiphasic Personality Inventory (MMPI) and the Coping Strategies Questionnaire (53). The instrument is imaginative and potentially useful, but requires further methodologic development, because the cutoffs for decision making are still not completely quantitative, and the actual sensitivity and specificity in terms of different sorts of outcomes (for whatever purpose) needs to be demonstrated. However, screening does not constitute a comprehensive clinical assessment, and should not be confused with such.

### RISK FACTORS AND OBSTACLES TO RECOVERY

Main (48) has recommended a conceptual shift from *risks* to *obstacles to recovery*. It is possible to take a narrow or a broad view of obstacles to recovery. It may be helpful to base prevention not on risk as such, but to refocus attention on obstacles to recovery, which can be considered either in terms of contraindications to surgery, potential targets for adjunctive psychologically oriented pain management (54), or a functional rehabilitation approach (55). Because surgery is directed first and foremost at correction of physical abnormality, it is perhaps not surprising that good surgical outcome is associated with better surgical indications (45). However, according to Mayer et al. (55): "poor surgical outcomes may result from outmoded postoperative methods, rather than failures of patient selection or surgical technique"; and, according to Polatin et al. (56), "surgery may correct the anatomic dysfunction, but subsequent recovery and return to productivity will be governed by non-surgical factors." Again, Block et al. (44) reviewed the importance of postsurgical rehabilitation in producing good clinical outcomes.

### SOME PRELIMINARY CONCLUSIONS

In designing a successful clinical intervention in the context of failed surgery, we need to be mindful of lessons learned about the nature of pain-associated disability in terms of its development and prevention. The advent of third-party professional practice audits requires a broader perspective on outcomes. In the case of the failed surgery patient, consideration of further treatment needs to incorporate a biopsychosocial rather than a biomedical perspective. The need for a systems approach, involving all key stake holders, is now recognized, particularly in connection with intended occupational outcomes. However, even good clinical outcome does not

guarantee return to work. Comprehensive pain management programs and functional restoration programs include an occupational component. However, certain aspects of work can only be tackled in the actual work place. Successful occupation outcomes may require specific work place interventions, such as phased return to work or transient work adaptations.

In patients who have already failed surgery, iatrogenic misunderstanding and distress may be particularly important features in their overall clinical presentation. Therefore, if the patient is considered to require both surgery and pain management, it is necessary to establish a clinically led systems approach involving all key stakeholders in planning the scheduling of different treatment components, and in enlisting the patient's full understanding and cooperation.

### CONCLUDING REFLECTIONS (KEY POINTS)

1. Outcome of surgery is dependent both on the nature of the physical indications for surgery and the patient's psychological reaction to pain and pain-associated limitation in function. This is true for first-time surgery and probably even more so for repeat surgery.
2. Outcome can be considered from a number of perspectives.
3. There may be a lack of concordance between different sorts of outcomes and among different stakeholders.
4. Patients with poor outcome of surgery are likely to require psychologically oriented pain management. Consideration may have to be given to presurgical preparatory pain management as well as psychologically oriented postsurgical rehabilitation.
5. Arguably, surgery represents the most powerful example of the "bio" part of biopsychosocial intervention. Achieving optimal outcome requires not only clear surgical indications, but also addressing the psychosocial aspects of the patient's pain and pain-associated disability, both at the time of initial assessment and in the entire treatment that may be necessary to achieve satisfactory outcome.
6. Although such methodologic considerations are a critical component in research design, often a more pragmatic approach to outcome has been adopted, and the issue of choosing outcomes becomes the prime focus of concern. A focus group of spinal researchers (57) recommended five key domains for outcome assessment in spinal disorders:
  - Back-specific function
  - Generic health status
  - Pain
  - Work disability
  - Satisfaction (back-specific)

## CHAPTER 90

# Surgical Treatment of Symptomatic Recurrent Disc Herniation

Ragnar Johnsson

---

The crucial watershed for surgical treatment of recurrent disc herniation (DH) is the extent of clinical symptoms, as it is for first-time disc herniation. The combination of the relatively high frequency of asymptomatic lumbar disc herniations of various degree in adults (1), and the potentially confounding effect of a prior disc herniation episode with surgical treatment warrant increased attention to the interpretation of clinical symptoms and signs and spine morphology on imagery. The risk for symptomatic recurrent DH has been estimated to be 5% to 10% after first time discectomy in the lower lumbar spine (2–4), the majority on the same side of the disc (ipsilateral recurrent DH) and the minority on the opposite side (contralateral recurrent DH). In ipsilateral recurrent DH epidural or periradicular fibrosis after the primary discectomy can confound the clinical and imaging evaluation, which normally is not the case for recurrent DH on the nonoperated contralateral side. However, the primary discectomy might have weakened the annulus in general, which could be a predisposing factor for recurrent DH on both sides of the disc.

This chapter proposes guidelines for surgical treatment of symptomatic ipsilateral or contralateral recurrent DH at a previously operated disc level based on basic clinical evaluation, preoperative imaging studies, surgical principles, known surgical results, and functional outcome.

### DIAGNOSTIC PROCEDURES

#### Clinical Evaluation

##### *Ipsilateral Radiating Leg Pain*

The clinical symptoms and signs can indicate to a certain degree whether radiating leg pain is caused by an ipsilateral recurrent DH or another cause as epidural or

periradicular fibrosis after the primary discectomy, disc herniation at another disc level, spinal stenosis, or any other cause. A pain-free period of at least several months after the prior discectomy, severely reduced walking capacity, present radicular pain distribution consistent with the previously operated disc level, radiating leg pain on cough, and straight leg raising test positive at less than 30° increase the likelihood for true symptomatic ipsilateral recurrent DH (5). If there has been no substantial pain-free period of at least some months, the case should be regarded as a failure of the prior discectomy rather than a possible recurrent DH (6).

##### *Contralateral Radiating Leg Pain*

Because normally no surgery has been performed on the contralateral side of the disc, the clinical picture of a contralateral recurrent DH resembles symptomatic first-time disc herniation.

#### Imaging Studies

Magnetic resonance imaging (MRI) is the imaging method of choice to study recurrent DH (7). By comparing T1-weighted images of the previously operated disc level before and after intravenous injection of the contrast medium gadolinium, which enhances vascularized soft-tissue structures, including postoperative scar formations, a recurrent DH with or without sequester and neural structures often can be distinguished from postoperative epidural or periradicular fibrosis (Figs. 90-1 to 90-4). Further, conventional T1- and T2-weighted images yield good information on disc herniation at another disc level, spinal stenosis, or any other lumbar cause that might explain the radiating leg pain.

**FIG. 90-1.** T1-weighted axial magnetic resonance images without (A) and with (B) contrast. With contrast, minimal epidural or periradicular fibrosis (*f*) is distinguished between dura (*d*) and recurrent disc herniation or sequester (*D*).

**FIG. 90-2.** T1-weighted axial magnetic resonance images without (A) and with (B) contrast. With contrast, epidural or periradicular fibrosis (*f*) is distinguished from dura (*d*) but no recurrent disc herniation is present.

**FIG. 90-3.** T1-weighted axial magnetic resonance images without (A) and with (B) contrast. With contrast, epidural or periradicular fibrosis (*f*) is distinguished from dura (*d*), S1 nerve root (*r*), and disc sequester (*D*).

**FIG. 90-4.** T1-weighted axial magnetic resonance images without (A) and with (B) contrast. With contrast, epidural or periradicular fibrosis (*f*) is distinguished from dura (*d*) and S1 nerve root (*r*), but no recurrent disc herniation is present.

### RATIONALES FOR SURGERY

Our knowledge of the natural history and effectiveness of nonoperative treatment of symptomatic recurrent DH is limited (6). Because the intraspinal morphology has been altered with various degrees of epidural or periradicular fibrosis on the side of the primary discectomy and postoperative alteration of the disc tissue has occurred, it is rational to assume a somewhat worse or at best the same course of events as for primary disc herniation. It is also rational to assume that ipsilateral recurrent DH with epidural or periradicular fibrosis, which might trigger radicular pain by itself and limit the mobility of the affected nerve root, behaves less like primary disc herniation than does contralateral recurrent DH without fibrosis. Thus, the rationale for surgery of both types of recurrent DH are similar to primary disc herniation; that is, absolute indication for early discectomy in the rare cases with cauda equina syndrome and relative indication for discectomy in declining order in cases with progressive and severe pain and neurologic deterioration, intractable radicular pain, and long-standing disturbing radicular pain not responding to a trial of adequate nonoperative treatment. Epidural or periradicular fibrosis by itself, however, is not an indication for surgery, because excision of fibrosis and neurolysis without concomitant recurrent DH or any other nerve root compromise does not yield substantial long-lasting pain relief (8).

It has been argued that the occurrence of a symptomatic recurrent DH is a sign of a more severe disc pathology, which should be addressed with combined discectomy and fusion to treat and prevent both radicular leg pain and discogenic back pain. To date, no data support this addition of a fusion to the surgical strategy as a solution for the vast majority of patients with symptomatic

recurrent DH (2,3,8,9). In the few cases with symptomatic recurrent DH and pronounced disc degeneration with intractable presumably discogenic back pain; however, combined discectomy and fusion ought to be considered. This surgical combination also might be contemplated in the rare case of multiple symptomatic recurrent DH at the same disc level, preferably as combined extensive discectomy and interbody fusion.

### SURGICAL TECHNIQUE

A somewhat wider surgical exposure in ipsilateral recurrent DH than at the primary discectomy is usually needed to clear postoperative extraspinal fibrosis. The prior laminotomy or partial laminectomy is increased as much as needed in a facet joint-saving fashion to get a proper exposure of the transition zones between postoperative epidural or periradicular fibrosis, dura, nerve root, and herniated disc material. Magnification of the visual field should be used to optimize this soft-tissue distinction and thereby decrease the risk for damage of the dura or nerve root. The choice of operating microscope or magnification glasses is up to the surgeon, but the microscope improves the educational facility and illumination of the deep surgical field. Enough epidural or periradicular fibrosis is cleared to facilitate the identification and excision of the herniated disc material without compromising the dura or the nerve root. Concomitant lateral stenosis of the nerve root is removed. To decrease the risk for new postoperative fibrosis, the neural structures can be covered with an anti-adhesion barrier gel (10) or a free fat autograft (11), although the effect of both methods on future radicular symptoms is questioned (11,12). The surgical technique for contralateral recurrent DH is similar to primary discectomy.

## SURGICAL COMPLICATIONS

Intraoperative undue handling of the intraspinal soft-tissue structures can easily cause a dural tear and associated leakage of cerebrospinal fluid (CSF). The standard treatment of a dural tear is to suture the defect and then cover the suture line with a fibrin sealant. To ensure proper early healing of the dural defect preventing leakage of CSF with associated postural cerebral symptoms, pseudocyst or fistula, postoperative bed rest in a strict horizontal position minimizing the intradural pressure for 2 days is advised. A systemic prophylactic antibiotic is given to prevent postoperative meningitis. A superficial nerve root lesion is left unattended and superficial epineural sutures are used to approach the nerve root endings in the rare case of complete nerve root lesion. The use of an anti-adhesion barrier gel might induce late symptomatic dural defects according to recent reports (13,14). A too-large free fat autograft can be pressed into the spinal canal and cause a cauda equina syndrome. These risks of an anti-adhesion barrier gel and a free fat autograft, and the questioned effect of both methods on future radicular symptoms (11,12) should be kept in mind when reflecting on covering the neural structures with either gel or fat.

## POSTOPERATIVE MANAGEMENT

The aim of the patient is to attain the normal level of physical and functional activities as quickly as possible. It has been shown that immediately after primary discectomy all activity restrictions can be lifted as soon as the specific domestic, recreational, and occupational activities can be tolerated by the patient without increasing the risk for complications (15). This also probably can be the guiding principle after discectomy of recurrent DH. The rehabilitation process can be further enhanced by adding specific physical exercises 1 month postoperatively to strengthen back and abdominal muscles (16–18).

## RESULTS AND FUNCTIONAL OUTCOME

There is a general expectation of worse results after repeat surgery at a previously operated level in the lumbar spine. The chance for a satisfactory result after discectomy of a recurrent DH is good, however, providing that high-quality pain relief also has been obtained after surgery of the primary disc herniation. The scientific documentation on the results of discectomy in recurrent DH, both ipsilateral and contralateral, implies similar

improvement of radicular leg pain, back pain, and functional outcome during the first years postoperatively as after primary discectomy (2,3,8,9). Documentation on long-term results is still lacking. The risk for another recurrent DH at the same level is unknown and there are no specific preventive measures except combined extensive discectomy and interbody fusion. However, this is not a fruitful surgical option for the vast majority of patients with symptomatic recurrent DH (2,3,8,9).

## CHAPTER 91

# Management of Failed Lumbar Surgery: Recurrent Stenosis

Jayesh Trivedi and Stephen Eisenstein

---

---

Lumbar spinal stenosis is a disabling syndrome affecting older patients. Surgical decompression forms the mainstay of operative treatment. However, the beneficial results of surgical decompression may deteriorate with time, resulting in recurrence of symptoms or development of new symptoms. The purpose of this chapter is to discuss the causes of poor results after surgical decompression for lumbar stenosis and offer management options.

Lumbar stenosis is caused by constriction in the dimensions of the spinal canal or intervertebral foramen. Degenerative stenosis, the most common form, is characterized pathologically by degenerative hypertrophy of the facet joints and vertebral body margins, thickening of the ligamentum flavum, and narrowing of the intervertebral discs (1). The combined effect of these changes is a narrowing of the spinal canal and reduction in the space available to the cauda and exiting nerve roots. Clinically it is characterized by lower limb pain and paraesthesias, varying degree of back pain, and a limitation of walking distance in the presence of good peripheral circulation. The lower limb pain is relieved by stooping or sitting, which increases the spinal canal capacity. This constellation of symptoms constitutes neurogenic claudication (Table 91-1).

Anatomically, the stenosis is classified as “central” when the compression affects mainly the thecal sac, or “lateral” when it affects the nerve roots in the nerve root canals (Figs. 91-1, 91-2) (2). Etiologically, Arnoldi et al. classified stenosis into congenital or developmental, acquired (including degenerative, iatrogenic, and post-traumatic), or combined varieties (3).

The incidence of degenerative lumbar stenosis is 1.7% to 8% (4,5). Symptoms usually develop after the fifth decade of life. The initial management is symptomatic, consisting of analgesics including nonsteroidal antiinflammatory drugs (NSAIDs), epidural injections, physical therapy, and lifestyle modification. Johnsson et al. studied the natural history of 32 patients with lumbar stenosis who did not undergo surgical decompression (6). Seventy percent of the patients were symptomatically unchanged at follow-up. In the remainder, half were better and the other half were worse. At 1 year, the Maine Lumbar Spine Study reported that the patients treated nonoperatively were symptomatically stable, although there was no clinical improvement (7). Other authors have reported a similar success rate with aggressive nonoperative treatment (8,9,10)

**TABLE 91.1.** Comparison between vascular and spinal claudication

Signs and symptoms	Vascular	Neurogenic
Claudication distance	Fixed	Variable
Relief on cessation of walking	Immediate	Lingering symptoms
Effect of posture on pain relief	Standing relieves pain	Flexion of spine and sitting relieves pain
Back pain	Infrequent	Frequent
Walking up hill	Painful	Not painful
Bicycle riding	Painful	Not painful
Peripheral pulses	Absent	Present

**FIG. 91-1.** Magnetic resonance imaging scan axial cuts showing central and lateral stenosis. **A:** Lateral recess. **B:** Central canal.

### SURGERY AND ITS OUTCOME

Surgery for patients with lumbar stenosis is that of decompression with or without concomitant fusion. A variety of techniques to decompress the spine have been reported in literature. These include laminectomy, laminotomies (11,12), and distraction laminoplasty (13). Successful outcomes from surgical decompression have varied from 57% to 95% (14–18), depending on the duration of the follow-up. In most studies the outcome deteriorated with the length of follow-up. Jonsson et al. prospectively studied 140 patients treated surgically, and reported an average improvement of 82% in leg pain and 71% in back pain at 3 years (19). Herron et al. reported satisfactory results in 67% patients at 2 years after surgery that deteriorated to 52% at 5-year follow-up (20). Katz et al., reporting on 88 consecutive patients undergoing laminectomy, found that the initial 89% relief of pain deteriorated to 57% at 4 years after surgery (15). At 7 to

10 years follow-up after surgery, they found that 23% of patients had received repeat surgery, with 33% complaining of severe back or buttock pain. Postacchini reported a 67% satisfactory result in 64 patients followed up to 8.2 years after surgery (21). Meta-analysis has shown a similar outcome in patients with a long-term follow-up (22). Thus, the initial good results after surgery may deteriorate with time but this does not necessarily mean a failure of the initial index procedure.

### FAILED SURGERY FOR STENOSIS

The incidence of unsatisfactory results after surgery for lumbar stenosis is not known. The incidence of failed lumbar surgery syndrome is reported to be 15% to 40% (22–24). The rate of repeat operation in lumbar stenosis has been reported to be 5% to 13% in some studies (13,25). Failed lumbar stenosis surgery may pose a prob-

**FIG. 91-2.** Magnetic resonance imaging scan axial cuts demonstrating facet hypertrophy and lateral stenosis.

lem in diagnostic evaluation and management for the spinal surgeon. Furthermore, the likelihood of obtaining a successful outcome after repeat surgery in this situation may be limited. Unsatisfactory results after surgery for lumbar stenosis may result from: (a) wrong diagnosis, (b) presence of comorbidity, (c) inadequate decompression, (d) recurrent stenosis either at the same level or previously noninvolved levels, or (e) new or increased back pain resulting from iatrogenic mechanical instability owing to surgery or spondylosis, and spondylolisthesis present before surgery and not addressed at surgery.

### WRONG DIAGNOSIS

Distinguishing spinal claudication from vascular claudication is important (Table 91-1). The age for spinal claudication is also an age when peripheral arterial disease is common.

Clinical examination in these patients should include palpation for the presence of pulses in the dorsalis pedis and posterior tibial arteries. A Doppler study in a clinic setting is indicated if the latter are not felt. Absent pulses represent an indication for referral to the vascular surgeon for further investigations to rule out peripheral vessel pathology.

Confirmation of diagnosis with appropriate imaging is essential in patients presenting with symptoms typical of spinal claudication. The authors' preference is for all patients to undergo a magnetic resonance imaging (MRI) scan. Magnetic resonance imaging is reported to have 75% to 85% accuracy in diagnosing stenosis (26). A myelography-computed tomography (myelo-CT) is the investigation of choice if the MRI scan is inconclusive or for patients who can not undergo an MRI.

The use of nerve root sheath injections may be diagnostic and even therapeutic in patients with symptoms predominantly suggestive of a lateral stenosis. These may be combined with electrophysiologic studies of nerve conduction. In patients who have had previous surgery in the lumbar area, the use of contrast-enhanced MRI is essential to estimate the extent of postoperative fibrosis. This involves the intravenous administration of gadolinium (Gd-DPTA). T1-weighted images obtained immediately after the administration of Gd-DPTA demonstrate increased signal intensity in perithecal fibrosis.

### COMORBID FACTORS

Katz et al., reporting on the long-term results of patients undergoing decompression for lumbar stenosis, found that an unsatisfactory long-term outcome is associated with the presence of comorbid medical conditions and laminectomy confined to a single level (15). Preexisting cardiovascular disease, rheumatoid or osteoarthritis, and chronic pulmonary disease were found to influence the long-term results following decompression. The effect of these factors was found to be additive.

Oldridge et al. reported on 34,148 patients with average age of 71 years and undergoing lumbar surgery; they found the mortality rate to be 0.5% (27). They reported that patients older than 80 years had increased mortality. Smith and Hanigan reported that patients with three or more comorbidities had a higher rate of complications when undergoing lumbar surgery (28). Benz et al., in a retrospective review of 68 patients older than 70 years and undergoing decompression, found that serious complications occurred in 12% with an early mortality of 1.4% (29). They were unable to show a significant relationship between comorbidities and postoperative complications.

It is likely that the presence of comorbidities may affect the patient's perception or tolerance to pain and thus influence outcome after decompression.

### Recurrent Stenosis

Postacchini reviewed 40 patients treated surgically for lumbar stenosis and found varying degrees of bony regrowth of the resected posterior arches in 35 of the 40 patients (30). These patients were evaluated at an average of 8.6 years after operation. Two types of bony regrowth were identified. There was either a gradual regrowth of the laminae and the articular surfaces resected at surgery or a coalescence of islets of bone tissue within a fibrous sheet filling the laminectomy defect. Complete resection of the inferior articular processes was found to be preventive against this regrowth. Furthermore, the wider the initial decompression, the less likelihood there was of this regrowth. Patients with degenerative spondylolisthesis were more likely to have regrowth if they had not been fused at the time of the index operation. The clinical outcome was found to be satisfactory in patients with little or no bony regrowth. In patients with moderate or marked bony regrowth, the proportion of satisfactory results was 55% and 40%, respectively. There are other reports of bony regrowth after surgery (31,32). We have not encountered bony regrowth so far in our practice.

Stenosis at previously uninvolved levels may also contribute to recurrence of symptoms. Katz et al., in a long-term review of surgically treated patients with stenosis, found that a single level laminectomy was associated with poor results (15). Degenerative changes and stenosis can occur throughout the lumbar spine so that previously uninvolved levels may become stenotic with time.

### Inadequate Decompression

Inadequate decompression is probably the most common cause of failed surgery in spinal stenosis and persisting symptoms after surgery. Scrutiny of preoperative imaging to ascertain where the compression is, and knowledge of spinal anatomy at decompression is important. Degenerative lumbar stenosis is usually circumfer-

entail and multifactorial in terms of structures that intrude into the space intended for neural anatomy. Therefore, decompression should deal with bone, joint (facet), ligamentum flavum, and disc at all relevant levels if subsequent failure is to be avoided. The surgical technique should address the central canal and lateral recesses. Decompression of the latter should as a rule involve undercutting of the medial aspects of the hypertrophic superior facets of the caudad vertebra. The adequacy of decompression may be assessed by the free passage of a probe along the path of the nerve.

### Stenosis and Low Back Pain

Mechanical low back pain may coexist with stenosis in some patients. It may also be iatrogenic after surgery for spinal stenosis.

Degenerative spondylolisthesis is a radiographic finding often associated with stenosis. It is commonly seen at the L4-5 level and tends to be more common in women. Satomi et al. reported on 41 patients treated surgically with decompression (33). Twenty-seven patients had anterior interbody fusion, whereas 14 patients had decompression alone. The fusion group had 93% good to excellent results as opposed to 72% in the nonfused group. Nasca also reported a better outcome in patients who had concomitant fusion and decompression compared to decompression alone (34). Herkowitz and Kurz published a controlled prospective study of patients with stenosis and degenerative spondylolisthesis who were randomized to either decompression alone or decompression with *in situ* intertransverse fusion (35). A better outcome was reported in the group that underwent concomitant fusion. Other authors have reported similar findings (36,37).

Iatrogenic radiographic instability may result from a radical decompression in which more than 50% of each facet joint has been sacrificed. In this situation flexion-extension lateral radiographs of the patient may detect segmental instability. If these radiographs demonstrate either a 4-mm translational movement or greater than 10° angulation between vertebrae, “instability” is present and fusion may be indicated (38).

We (39) recommend concomitant fusion in the presence of the following: significant low back pain, spondylolisthesis, and radical decompression. Relative contraindications to fusion include age more than 75 years and the presence of comorbidities, including diabetes or cardiopulmonary disease. Our preference is for intertransverse fusion with pedicular screw fixation, the latter depending on adequate bone quality.

## MANAGEMENT

### Nonoperative Treatment

Not all patients with recurrence of symptoms after surgical decompression for stenosis require a repeat opera-

tion. In a retrospective review of 317 patients, Herno et al. found that patients undergoing repeat surgery were less likely to have a successful outcome following surgery (40). In their study excellent to good results were obtained in 67% of the singly operated patients as opposed to 46% in the repeat surgery group. Coexisting disease and surgery within 18 months after the index procedure was associated with poor outcome after repeat surgery. Echeverria and Lockwood in a comparative study of 17 patients undergoing surgery with 10 patients who had undergone previous spinal surgery found excellent to good outcomes in 76% in the former and 50% in the latter group (41). Although other studies have disputed a poorer outcome in revision spinal surgery, it is clear that the outcome in revision surgery is still controversial. Furthermore, there may be no correlation between postoperative radiological findings and the patients' symptoms. This has been shown to be the case by Herno, Finnegan and other authors (40,42,43). Nonsteroidal antiinflammatory drugs, activity modification, use of mobility aids such as trolleys or wheelchairs and epidural steroids are all reasonable options for patients who have failed to have a satisfactory result from previous surgery.

### Surgery: Indications and Technique

Failure to respond to nonoperative treatment, inadequate decompression demonstrable on radiologic imaging, spinal “instability” with intractable back pain not addressed at initial surgery are all indications for further surgery. The patient should be fit to undergo further spinal surgery. The presence of advanced cardiopulmonary disease forms a contraindication for revision surgery. Previously listed causes for recurrence of symptoms should be diligently addressed at repeat surgery to ensure a satisfactory outcome. The technique of surgery is tailored to the patient but concomitant fusion is considered for those demonstrating instability or where radical decompression is deemed necessary.

Repeat decompression surgery presents a daunting prospect, with every expectation of dural injury, neural injury, and unsatisfactory symptom response. Many patients present an anesthetic challenge at the first surgery, by virtue of the intercurrent afflictions of advanced years on all systems. Apart from the difficulties of revision surgery, patients may be disqualified from revision surgery because it presents too great a risk to life.

The fact remains that careful technique can produce a gratifying result in those rare instances where revision decompression is deemed appropriate and possible (44). The surgery can be much simplified by the routine application of one of the commercial polysaccharide pastes to all exposed dural surfaces at the completion of the original operation. These products are expensive

but useful in leaving a plane of cleavage between dura and surrounding bone, annulus, and ligament. The authors have a small but gratifying experience of revision surgery in these circumstances, and use such a product routinely in decompression surgery in the lumbar spine.

Once the dorsal aspects of the relevant segments have been exposed, careful further dissection reveals the junction between the residual lateral or laminar bone margin, and the scar of previous dissection. A sharp elevator separates the scar from bone and usually allows re-entry into the spinal canal without mishap. Careful probing in directions away from the scar ensures a plane between bone and unscarred dura.

A margin of the bony surround is then removed, allowing a leisurely approach from fresh anatomy back toward the previous battleground. Postoperative scar densely adherent to dura is left in place: Too much striving for its removal is unnecessary and dangerous. The elements most likely responsible for persistent or recurrent neural symptoms are new facet joint osteophytes, stenosis of entry to the nerve root foramen, or a new disc prolapse. With patience, care, and persistence, these areas can be reached eventually without major injury, and the intruding tissue excised. All levels demonstrated to be stenotic on imaging should be addressed.

Where recurrence of stenosis is found to be the development of spondylolisthesis since the original surgery, the options are distinctly unattractive. Ideally, revision decompression should be accompanied by fusion, in order to halt further vertebral shift. The difficulty then is that most patients have bone too soft and weak to hold fixation implants. Bone grafting has to be protected by old-fashioned external bracing of some kind for an extended period, probably beyond the tolerance and capability of many elderly patients.

The ancient recommendation that the need for revision surgery is better prevented than that revision surgery is skillfully executed sounds insufferably sanctimonious. It remains true, however, that stenosis surgery over several segments is tedious, tiring, and somewhat frightening, if performed with thoroughness and attending to all elements circumferentially, centrally, and laterally.

## SUMMARY

Management of failed surgery involves a thorough attempt to establish the cause for failure in the index procedure and addressing this at repeat surgery. Development of stenosis at previously unaffected levels may also account for a recurrence of symptoms. The presence of comorbid factors plays an important role in influencing surgical outcome. The technique of revision surgery is tailored to the individual patient, but a satisfactory outcome can be obtained with proper preoperative evaluation and meticulous surgical technique.

# Failed Surgery and Revision Surgery: Failed Instrumentation

Frank M. Phillips

---

The role of spinal instrumentation is to obtain and maintain spinal alignment and stabilize the spine until fusion occurs. Failure of instrumentation is typically the result of a surgeon applying the instrumentation in a situation where the deforming forces exceed the ability of the instrumentation to stabilize the spine. To reduce the likelihood of failure, the surgeon must understand the capabilities of the instrumentation as well as the biomechanical environment across which the instrumentation is applied.

Posterior instrumentation comprising pedicle screws attached to a longitudinal plate or rod is frequently applied in the lumbar spine. Hooks, wires, or cables are alternate posterior techniques for achieving spinal fixation that are less frequently used in the lumbar spine. Anterior instrumentation includes threaded intradiscal devices, vertical cages, or struts and rod or plate-screw constructs. Failure of instrumentation most frequently involves loosening or less commonly breakage of the implant, implying failure of fusion and often associated with a loss of correction of spinal deformity.

When instrumentation fails by implant breakage or screw pullout, plain radiographs usually confirm the diagnosis. In some instances, subtle instrumentation failure, such as screw loosening, may be less obvious on radiographs. Lucencies visualized around the screws should raise concern for ongoing spinal motion, implying failure of fusion. Failure of fusion is difficult to identify radiographically and additional studies such as computed tomography (CT) scans or bone scans may be helpful in the work-up of these patients (1,2). Computed tomography scans are also helpful for assessing the architecture of the pedicle if revision fixation is being considered. The quality of bone, as well as the pedicle diameter and screw length within the vertebral body, can be determined from CT scans.

Instrumentation failure in and of itself may not cause symptoms, and identifying failed instrumentation should prompt a diligent search for the source of the patient's symptoms. Instrumentation failure may alert the physician to a pseudarthrosis that may be the source of the patient's symptoms. Failure of instrumentation may also lead to the development of spinal deformity that requires further surgery. Even in the presence of failed instrumentation, unless a well-defined source of the patient's symptoms is identified, surgery directed toward revising or removing the instrumentation is unlikely to provide relief of symptoms (3).

### POSTERIOR INSTRUMENTATION FAILURE

Posterior constructs secured to the spine via screws placed through the pedicle and into the vertebral body have been popularized over the last decade. Pedicle screw instrumentation allows for segmental control of all three columns of the spine from a posterior approach. The rigidity achieved with these implants may reduce the number of fixation points necessary for stability, thereby reducing the number of levels that are fused. Early pedicle screw fixation systems used an unconstrained linkage of the screws to the rod or plate spanning the involved levels. These systems had high failure rates in terms of implant loosening, breakage, and pseudarthrosis (4) and have been superseded by systems with rigid, constrained connections between the screws and the longitudinal rod or plate. Pedicle screw systems have been shown to provide significant stabilization to the treated motion segment and improve lumbar fusion rates (5–7).

It is uncommon for contemporary pedicle screw systems to fail by breakage or screw-connector disengagement (8,9). These implants are extremely strong and rigid and are more likely to fail by loss of fixation of the

screws to the spine. Posterior instrumentation failures typically occur when the implant is placed in an environment in which the bending loads produced by forces acting eccentrically to the implant's neutral axis exceed the load-bearing capabilities of the implant.

Posterior instrumentation failure may occur:

1. When pseudarthrosis develops, subjecting the instrumentation to continuing bending moments until fatigue failure of the device occurs
2. With anterior column deficiencies, such as might occur with vertebral body tumors or unstable vertebral fractures
3. With spinal deformities, such as advanced spondylolisthesis or kyphosis
4. When the bony anchorage of the screw to the spine is insufficient often because of osteoporosis, and screw loosening or pullout occurs (10)

### Pseudarthrosis

Instrumentation failure often heralds the presence of a pseudarthrosis (3,4,11). If the pseudarthrosis is thought to be symptomatic, revision arthrodesis may be considered. In general, repeat arthrodesis should be performed in the anatomic location where the most favorable environment for fusion exists. If an initial postero-lateral instrumented fusion was attempted, success of repeat postero-lateral arthrodesis may be compromised by the devascularized and scarred "fusion bed." This should prompt the surgeon to consider performing an interbody arthrodesis. Advantages of the interbody technique for arthrodesis include the large surface area available for achieving fusion and the favorable biomechanical environment for fusion (12–14). Autograft bone remains the gold standard for achieving lumbar fusion. The detailed treatment of pseudarthrosis is discussed elsewhere in this volume.

### Anterior Column Deficiencies

Anterior spinal column deficiencies may occur with vertebral body destruction caused by tumor, infection, or trauma (Figs. 92-1 to 92-5). Approximately 80% of the spinal load is transmitted through the anterior column so that deficiencies of this column place large bending stresses on posterior instrumentation constructs (15). McLain et al. (16) reported a 60% rate of instrumentation failure when comminuted vertebral body thoracolumbar fractures were treated with posterior pedicle-based instrumentation extended to the level above and below the fractured level. Furthermore, *in situ* contouring of the rods predisposed to failure. Similarly, Kramer et al. (17) reported that four of 11 patients with thoracolumbar fractures treated with short-segment transpedicular instrumentation had breakage or disengagement of the caudal screw. The kyphosis across the operated levels increased

**FIG. 92-1.** A 60 year-old man with metastatic renal carcinoma to L3 that was treated by anterior decompression and instrumented L2-4 antero-posterior fusion. Radiograph 5 years after initial surgery, when the patient presented with destruction of the L2 vertebral body by tumor, resulting in loss of fixation of the posterior instrumentation and anterior Kaneda device breakage with cage migration, leading to gross spinal instability.

**FIG. 92-2.** The patient was treated with initial posterior stabilization to restore stability and spinal alignment. The antero-posterior radiograph is shown.

**FIG. 92-3.** The patient was treated with initial posterior stabilization to restore stability and spinal alignment. The lateral radiograph is shown.

**FIG. 92-5.** One year later, the patient presented with further anterior column destruction as a result of tumor growth, resulting in fibular dislodgement and posterior instrumentation failure with rod breakage.

**FIG. 92-4.** The patient then underwent anterior instrumentation removal and placement of a fibular strut graft spanning L1 to L4. (Extensive scarring and resulting inability to safely mobilize vessels prevented a more extensive anterior reconstruction.)

by 12.9° postoperatively. Posterior instrumentation may be inadequate in situations in which the anterior column is deficient, and supplemental anterior column support is advisable.

When posterior instrumentation fails in the face of anterior column deficiency, reconstructive strategies should include restoring anterior structural support. This is typically accomplished with placement of a strut or cage to reinforce the anterior column. If interbody support is required, this can be accomplished through either an anterior or posterior approach to the disc space. If vertebral body re-enforcement or replacement is required, a separate anterior approach to the lumbar spine usually is required. In addition to the anterior column reconstruction, revision of the failed posterior instrumentation to enhance stability typically is required. This may be accomplished by using wider-diameter or longer pedicle screws or obtaining additional points of fixation to the spine by incorporating additional levels in the instrumentation construct. The choice to extend the instrumented fusion to improve stability of the construct must be balanced against the increased morbidity associated with the additional level surgery.

### Deformity

Angular and translational deformities of the lumbar spine are frequently addressed with posterior instru-

mented arthrodesis. With advanced degrees of spondylolisthesis or kyphosis, posterior instrumentation may be inadequate to immobilize the involved motion segment and fusion may be less likely. Furthermore, if reduction of the deformity is attempted, large forces are placed on posterior instrumentation that can lead to instrumentation failure or recurrence of the deformity.

With advanced degrees of spondylolisthesis, posterior instrumentation may fail by implant breakage or pullout of the screws. In these situations, revision surgery usually includes the addition of anterior column support as well as posterior implant revision that may require including additional levels in the construct. When lumbosacral arthrodesis is performed, the sacrum is typically the least secure point of fixation of the construct (18). If instrumentation placed into the sacrum has failed, the surgeon might consider improving distal fixation by placing multiple sacral screws such as medial and laterally directed screws at S1, supplemental S2 pedicle screws, placing screws or rods into the ileum, or adding interbody structural support (19,20).

### Osteoporosis

As larger reconstructive spine surgeries are performed on older patients, the ability of the osteoporotic spine to support spinal implants must be considered. Posterior instrumentation failure has been shown to correlate with bone mineral density (BMD) (21–23). In the osteoporotic spine the weak link in the instrumentation construct is the implant–bone interface, and the majority of instrumentation failures involve screw loosening and pullout that may lead to failure of fusion or the development of recurrent or *de novo* deformity.

At the time of pedicle screw insertion, the surgeon may recognize the poor screw purchase in osteoporotic bone. This is usually a result of the surgeon noticing the low insertion torque required to advance the screw. Insertion torque has been correlated with BMD and screw pullout, and may predict early screw failure (18,24,25). If poor screw purchase is recognized intraoperatively, the surgeon should attempt to salvage the situation rather than relying on inadequate fixation to achieve the goals of instrumentation.

The surgeon may consider increasing the length or diameter of the pedicle screw placed in an attempt to improve the screw purchase in bone. Increasing screw length does increase screw pullout strength, although this effect may be less pronounced in osteoporotic bone (26,27). The inability to accurately gage the anterior vertebral body cortex intraoperatively may affect the surgeon's ability to safely place longer screws, because screws extending beyond the anterior vertebral body may predispose to vascular injury. At the sacrum, bicortical purchase may be safely accomplished with medially directed pedicle screws with a low risk of vascular injury. Increasing screw diameter also increases pullout strength

(27–30); however, the dimensions of the pedicle being cannulated limit the screw diameter.

Another strategy to improve reliability of the pedicle screw construct in osteoporotic bone is to increase the number of points of fixation to the spine by including additional levels in the construct. This approach must be weighed against the added immediate morbidity of the additional level surgery as well as the potential long-term consequences of a fusion spanning additional levels. The bone–screw interface also may be improved by injecting bone cement (polymethylmethacrylate) into the pedicle. A twofold to threefold increase in screw pullout has been demonstrated with the use of bone cement injected into the vertebral body through a cannulated pedicle (22,26). Other cements, such as hydroxyapatite cement, calcium phosphate, and carbonated apatite, also have been shown to enhance the screw–bone interface and increase pedicle screw pullout strength (30–32). Possible risks of these techniques include cement extravasation outside of the vertebra, with potential for leakage into the spinal canal or neural foramina. The surgeon also may augment the pedicle screw construct with offset sublaminar hooks that are well suited for use in the osteoporotic spine by relying on the relatively spared cortical laminar bone for fixation (21,33).

Revision surgery after instrumentation failure in elderly osteoporotic patients is often a large undertaking with significant risks. Nonsurgical treatment may be attempted, and bracing may be helpful if early instrumentation failure is suspected. Failure of posterior instrumentation in the osteoporotic spine usually occurs as the result of loss of fixation of the screws, with screw toggling, loosening, and eventual pullout. In osteoporotic bone, this often results in a relatively large void around the screw that precludes reusing the same pedicle for revision screw fixation. If revision surgery is considered, the previously mentioned strategies for enhancing posterior fixation should be considered. In addition, strong consideration should be given to anterior column structural support and fusion as part of the revision strategy. The anterior vertebral end plates provide a wide surface area that is advantageous for promoting fusion and also for load bearing of structural struts (13,14). Anterior column support also helps to reduce flexion-bending moments on the posteriorly placed instrumentation reducing risks of instrumentation failure.

### ANTERIOR INSTRUMENTATION FAILURE

Anterior approaches to the lumbar spine may be preferred in patients with neurologic deficit resulting from anterior pathologies, for anterior release with deformity, and to allow for short segment fixation. Anterior arthrodesis allows for reconstruction of both the anterior and middle spinal columns as well as for placement of bone graft under compression, which provides a favorable mechanical environment for fusion (13,14).

Anterior plate and rod-screw fixation is frequently used for anterior column reconstruction at the thoracolumbar junction and in the upper lumbar spine. These implants are customarily applied to the lateral aspect of the vertebral body and may be less suited for use in the lower lumbar spine because of the vascular anatomy (iliac artery and vein) and because the pelvis may prevent achieving an appropriate trajectory for screw placement. Anterior instrumentation is designed to be load sharing and is typically used in combination with a longitudinally orientated bone graft, strut, or cage to re-enforce the deficient anterior column. The use of anterior instrumentation may allow for fusion of fewer mobile segments than might be required with posterior fixation.

Anterior construct failure typically occurs with implant loosening or with subsidence of the strut or cage into the cancellous bone of the adjacent vertebral body, both of which may lead to failure of fusion and recurrence of deformity. Intravertebral screws may loosen if fixation is poor, as is common in osteoporotic bone. Fixation can be improved by obtaining bicortical purchase of the vertebral body with wide diameter screws (34). Care also must be taken not to penetrate an unfused disc space with the screws. The risk of construct failure as a result of settling of the longitudinal strut or cage into the adjacent vertebral bodies may be reduced by maintaining the integrity of the vertebral end plates during their preparation (35). In addition, small-diameter struts or cages should be avoided, because these tend to cut into the vertebral end plates and piston into the vertebral body. If the surgeon is concerned about the stability of the anterior reconstruction, the construct should be supplemented with posterior instrumentation.

If anterior instrumentation fails with implant loosening or settling of the construct, salvage with posterior instrumentation and fusion to stabilize the involved motion segments may be adequate. However, if the anterior device has lost its structural integrity or has migrated toward adjacent vascular or visceral structures, anterior device removal or revision will be required in addition to the posterior surgery. If the anterior strut has telescoped into the adjacent vertebral body or screw failure has created voids in the vertebral body, additional levels often need to be incorporated in any revision construct so as to obtain fixation to healthy bone. A repeat anterior approach to the previously operated spine may be extremely difficult because of the adherent vessels in close proximity to the spine. If the vascular anatomy precludes safely revising the anterior instrumentation, the surgeon might consider removing the failed anterior construct and then placing a strut only anteriorly, and supplementing this with posterior instrumentation.

### INTERBODY DEVICE FAILURE

Interbody devices may be placed by anterior, posterior, or lateral approaches to the disc (36–40) and include both

impacted implants that rest on the vertebral end plates, and threaded implants whose threads engage the vertebral end plates. Biomechanical studies have shown that interbody devices significantly stabilize the motion segment in all directions except for extension (13,41). Annular tension achieved by disc space distraction is thought to be important for the stability of these devices.

Although early studies reported high clinical and radiographic success with interbody devices used without posterior fixation, it became apparent that with widespread use these results were not necessarily reproduced (14,37,38). Many cases of so-called “failed interbody devices” actually represent failures of patient selection by the surgeon rather than any failure of the device. In addition, poor surgical technique in applying these devices is a common reason for failure (38). Undersized devices may lead to inadequate motion segment stability and ultimately failure of fusion. To achieve successful results with an interbody device, the surgeon must understand both the biomechanics of the device and of the treated motion segment. Situations in which a “stand-alone” interbody device may not be ideal and supplemental posterior fixation should be considered include: (a) interbody device insertion through a posterior approach that necessitates significant bony resection, (b) multilevel constructs, (c) significant instability (e.g., advanced degrees of spondylolisthesis), (d) loss of posterior stabilizers such as may occur with wide laminectomy, (e) poor fixation of the interbody device in osteoporotic bone, and (f) tall disc without a stabilization response.

The more common “implant failures” with the use of an interbody device include failure of fusion, device loosening and migration, and malpositioned devices. Immediate radiographic imaging and work-up is prudent if a patient presents with neurologic symptoms after interbody arthrodesis surgery. If the interbody device is identified as causing neural compression, it should be removed and, where possible, revised. If the revised interbody construct does not restore stability, posterior instrumentation should be added. Alternatively, if a patient presents with back pain after interbody surgery, a prolonged period of observation and conservative treatment is in order before considering further surgical solutions.

Removal or revision of an interbody device is technically challenging with risks of neural or vascular injury with a posterior or anterior approach to the disc space, respectively. If the goal of revision surgery is to address a pseudarthrosis after a previously placed stand-alone interbody implant, often this can be accomplished by performing a postero-lateral instrumented arthrodesis without the need for interbody implant revision. Unless the interbody device is malpositioned and causing symptoms or is posing a risk to neurovascular or visceral structures, the risks of device removal likely outweigh the potential advantages of device revision. When interbody implant revision surgery is necessary, the decision as to the opti-

mal surgical approach must take into account the added morbidity of a new approach to the spine and weigh this against the difficulties of repeat surgery through the previous surgical field. In general, if interbody device revision is performed in the early postoperative period, this usually can be accomplished through the same surgical approach to the disc as was used for device insertion.

If late interbody device removal is required, the approach to the disc space depends on the location of the implant within the disc space, the extent of access required for device extraction, and local vascular and neural anatomy. After late interbody device removal, it is unlikely that adequate stabilization will be achieved with placement of another (larger) interbody device alone, and adding posterior instrumentation is advisable. If interbody device removal requires extensive bony resection or if peri-implant bone deficiency has developed as a result of settling of a nonintegrated implant, a more extensive anterior column reconstruction is required. In this situation, the reconstruction usually includes an anterior strut with supplemental posterior stabilization to ensure stability and prevent settling and subsidence.

## CONCLUSION

When confronted with a patient with failed instrumentation the surgeon should determine the likely reason for failure of the instrumentation. The surgeon must also elucidate the source of the patient's symptoms and any relationship of these to the finding of failed instrumentation. If revision surgery is contemplated, the surgery should be primarily directed to the likely symptom generator. If revision reconstruction of the spine is undertaken, any implants applied must be able to withstand the forces acting across the instrumented spinal segments. Revision surgery often involves posterior instrumentation as well as establishing anterior column support.

# Management of Failed Surgery: Adjacent Segment to Fusion

Thomas S. Whitecloud III and Paul Pagano

---

*Adjacent segment degeneration* describes disc degeneration above or below previously fused spinal segments, also called *transitional syndrome*. The reported incidence of transition zone degeneration by radiographic criteria is approximately 25% to 40%. Not all such patients are symptomatic. Some may benefit from further surgery if nonoperative management has failed (1–4).

The pathophysiology of transitional syndrome merits discussion. One generally accepted hypothesis is that fusion of a spinal segment causes hypermobility, and therefore increased stress, at adjacent mobile segments. However, is transitional syndrome simply a natural progression of disc deterioration? In other words, would the observed radiographic changes and symptoms have occurred if no surgery had been performed? Several *in vitro* biomechanical studies have been published that indicate increased stress and alteration of motion segment biomechanics (5–12).

Panjabi, using an *in vitro* sheep model, showed alteration in spinal segment function above and below a disc injury. The injury was to the annulus either with or without nuclear removal. These asymmetric injuries altered the kinematics of the functional spinal units above and below the traumatized disc segment. Similar changes could lead to a degenerative cascade in an *in vivo* situation (13).

Is adjacent segment degeneration accelerated by spinal fusion? In another *in vitro* study, the effects of instrumentation on adjacent segment intradiscal pressures were reported by Weinhoffer et al. Transducers placed into the disc above a stabilized motion segment showed a greater than normal increase in pressure with flexion. This change in pressure increased with increasing motion (12).

Does the type of fusion (antero-posterior, instrumented, or circumferential) accelerate this disease process? Lee compared stability and adjacent segment

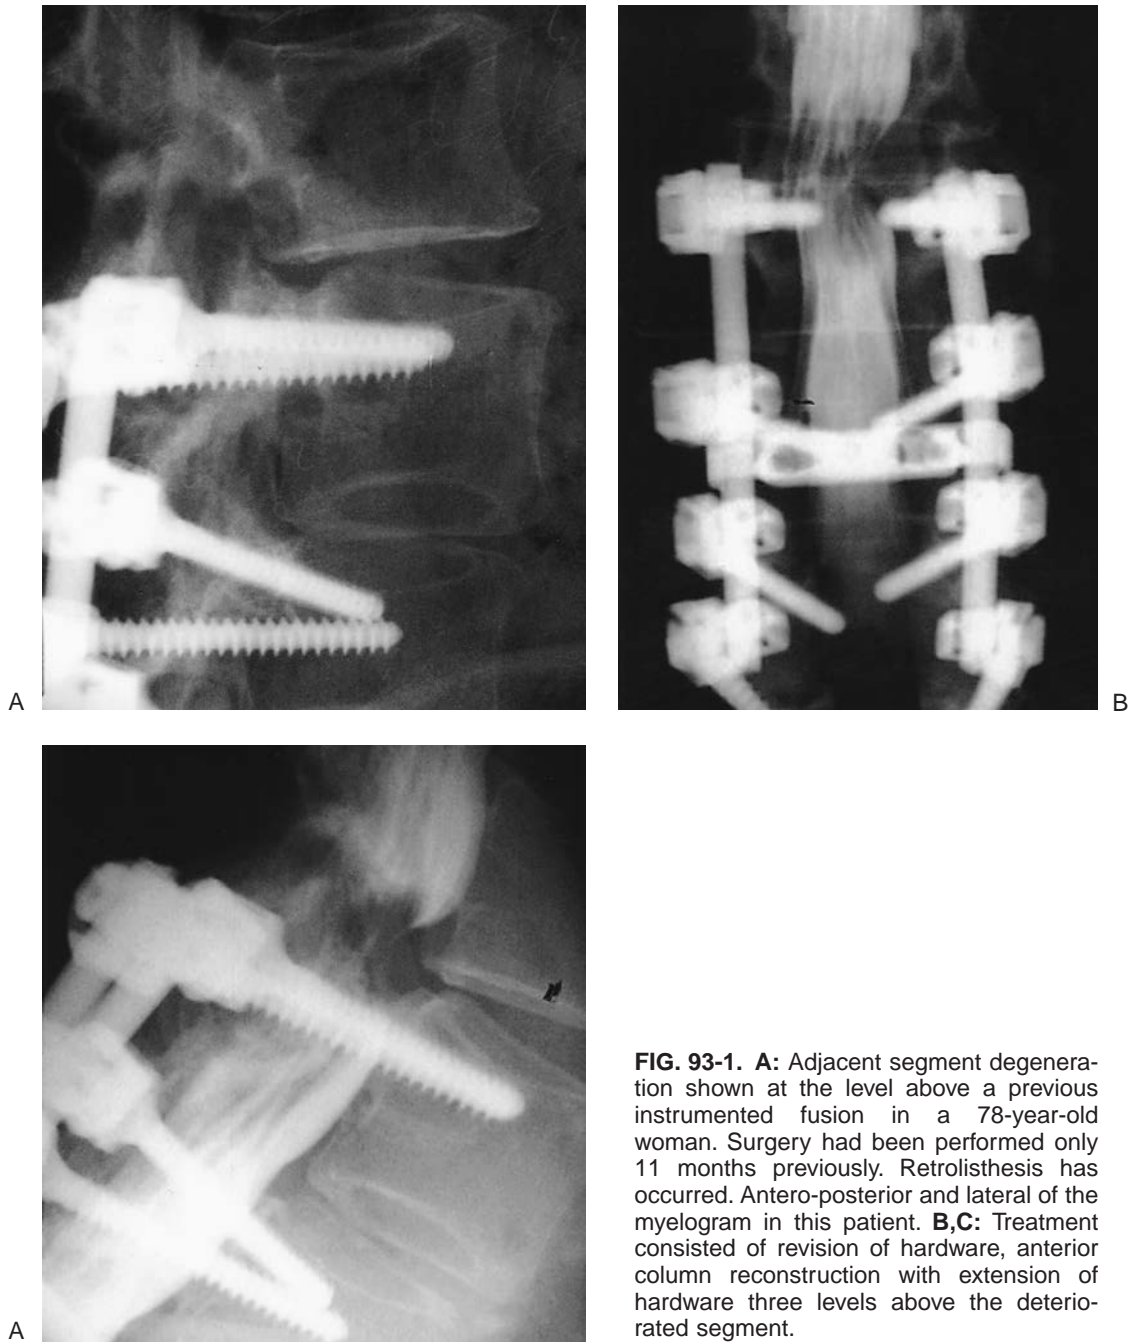

effects of posterior, posterolateral, and anterior lumbo-sacral fusions in a cadaver model. All types of fusion produced increased stress on the adjacent spinal segment, with the facet joints above the stabilized segment demonstrating the highest amount of stress (9).

Several other publications indicate that stabilizing a motion segment does adversely affect the biomechanics of the segment above (5–12). These *in vitro* studies indicate there are mechanical changes above a simulated fusion. They cannot account for functioning muscle mass, bone density, and so on, or take into account load transfers to other adjacent segments of the spine (7).

The patient with transitional syndrome experiences low back pain. In most instances, a cascade of events has already occurred, initiated by disc deterioration, followed by any combination of facet arthrosis, degenerative spondylolisthesis, retrolisthesis, acquired spondylolisthesis, or associated osteoporosis (Fig. 93-1) (2,7,14–17). Several clinical studies discuss the incidence of this problem (1–4). Few address optimum surgical treatment (1,14,16–18).

Lehmann et al. (2) evaluated 62 patients who had undergone lumbar fusion at L3 or lower. The median follow-up was 33 years. Thirty-three of these patients had follow-up roentgenographic studies. The incidence of segmental instability above the previous fusions was 45%. Although approximately 50% of the patients had lower back symptoms, none were considered surgical candidates.

Forty-two patients, each having undergone a posterolateral fusion of the lumbar spine approximately 20 years earlier, were evaluated thoroughly by Hambly et al. (14) A variety of degenerative changes in the transitional zone above the fused segments were found. The intervertebral disc space two levels above the fusion developed abnormalities as frequently as the disc space immediately

**FIG. 93-1.** **A:** Adjacent segment degeneration shown at the level above a previous instrumented fusion in a 78-year-old woman. Surgery had been performed only 11 months previously. Retrolisthesis has occurred. Antero-posterior and lateral of the myelogram in this patient. **B,C:** Treatment consisted of revision of hardware, anterior column reconstruction with extension of hardware three levels above the deteriorated segment.

above the fusion. This finding was also noted by Penta (3). Despite the abnormalities noted in roentgenographic evaluation, 76% of the patients studied reported good to excellent results. No surgery was recommended.

Possible accelerated degeneration of adjacent segments *in vivo* was reported by Rahm (4). Forty-nine patients who had undergone an instrumented lumbar fusion were evaluated. Twenty-five of these patients also had received a posterior lumbar interbody fusion. The time of follow-up varied, but minimally was 2 years. The average was 5.1 years. Thirty-five percent of the patients showed

degenerative changes above the fused segment per X-ray evaluation. A logistic regression model demonstrated that older patients who underwent circumferential fusion with instrumentation were more likely to have deterioration with time. Eight of these patients underwent further surgery. Four of these had poor results, two had insufficient follow-up to be reported, and two were classified as good. A trend to have a pseudoarthrosis in the segments below was noted in the patients who did not show transitional zone changes. I did not feel, because of the variables involved, that there was an increased incidence of

adjacent segment degeneration when compared to postoperative fusion alone.

Aota suggested in 1995 that age is the most significant predictor for developing adjacent segment deterioration in instrumented fusion. Patients over the age of 55 had an incidence of 37%, whereas the incidence of patients under this age was 12%. Posterior translation was the most common finding. The average follow-up time was 39 months. The number of patients evaluated was 65. Overall, the incidence of postfusion instability was 24.6%. Older patients appear to be more susceptible, and failure to correct sagittal and coronal balance accelerates the process (1).

Hypolordosis across the instrumented segments may accelerate adjacent segment degeneration by causing compensatory hyperlordosis in the adjacent mobile segments. Biomechanically, a significant load increase in the adjacent hyperlordotic segments has been described (11).

Spinal surgeons recognize adjacent segment degeneration as a cause of failed back syndrome. However, surgical management of patients with adjacent segment degeneration, if unresponsive to nonoperative management, has not been precisely defined. The literature provides few guidelines as to optimal operative intervention for this diagnosis. Generally, surgical treatment when required is usually decompression, decompression with fusion with or without instrumentation, or additionally with anterior column reconstruction.

In 1994, I presented a small series of patients undergoing surgery for adjacent segment degeneration (17). There were 14 patients in this series, and 12 had undergone more than one previous lumbar procedure. Average time from the first fusion to the adjacent segment degeneration requiring surgery was 11.5 years. All these patients were stenotic with instability either primarily or secondarily following decompression. All had extension of their fusion, five without instrumentation, and nine with pedicle fixation. Without instrumentation, only one patient obtained arthrodesis, resulting in an unacceptable 80% pseudoarthrosis rate for the patient series. Because of this, pedicle instrumentation was used primarily in the next nine patients. Three of the five patients who had not been instrumented, subsequently were revised with pedicle fixation. With instrumentation use, primarily or for revision, the pseudoarthrosis rate was 17%. The authors concluded that pedicle instrumentation is generally needed for stabilization of adjacent segment degeneration. However, the clinical results in this series were not outstanding. The authors felt that this reflected chronicity of patients' symptoms and the salvage nature of the procedure. Because there continued to be a greater than 15% pseudoarthrosis rate using instrumentation, I have been adding anterior column reconstruction with titanium surgical mesh for this condition since 1994.

Other authors subsequently recommended that pedicle fixation be used for adjacent segment degeneration. Chen

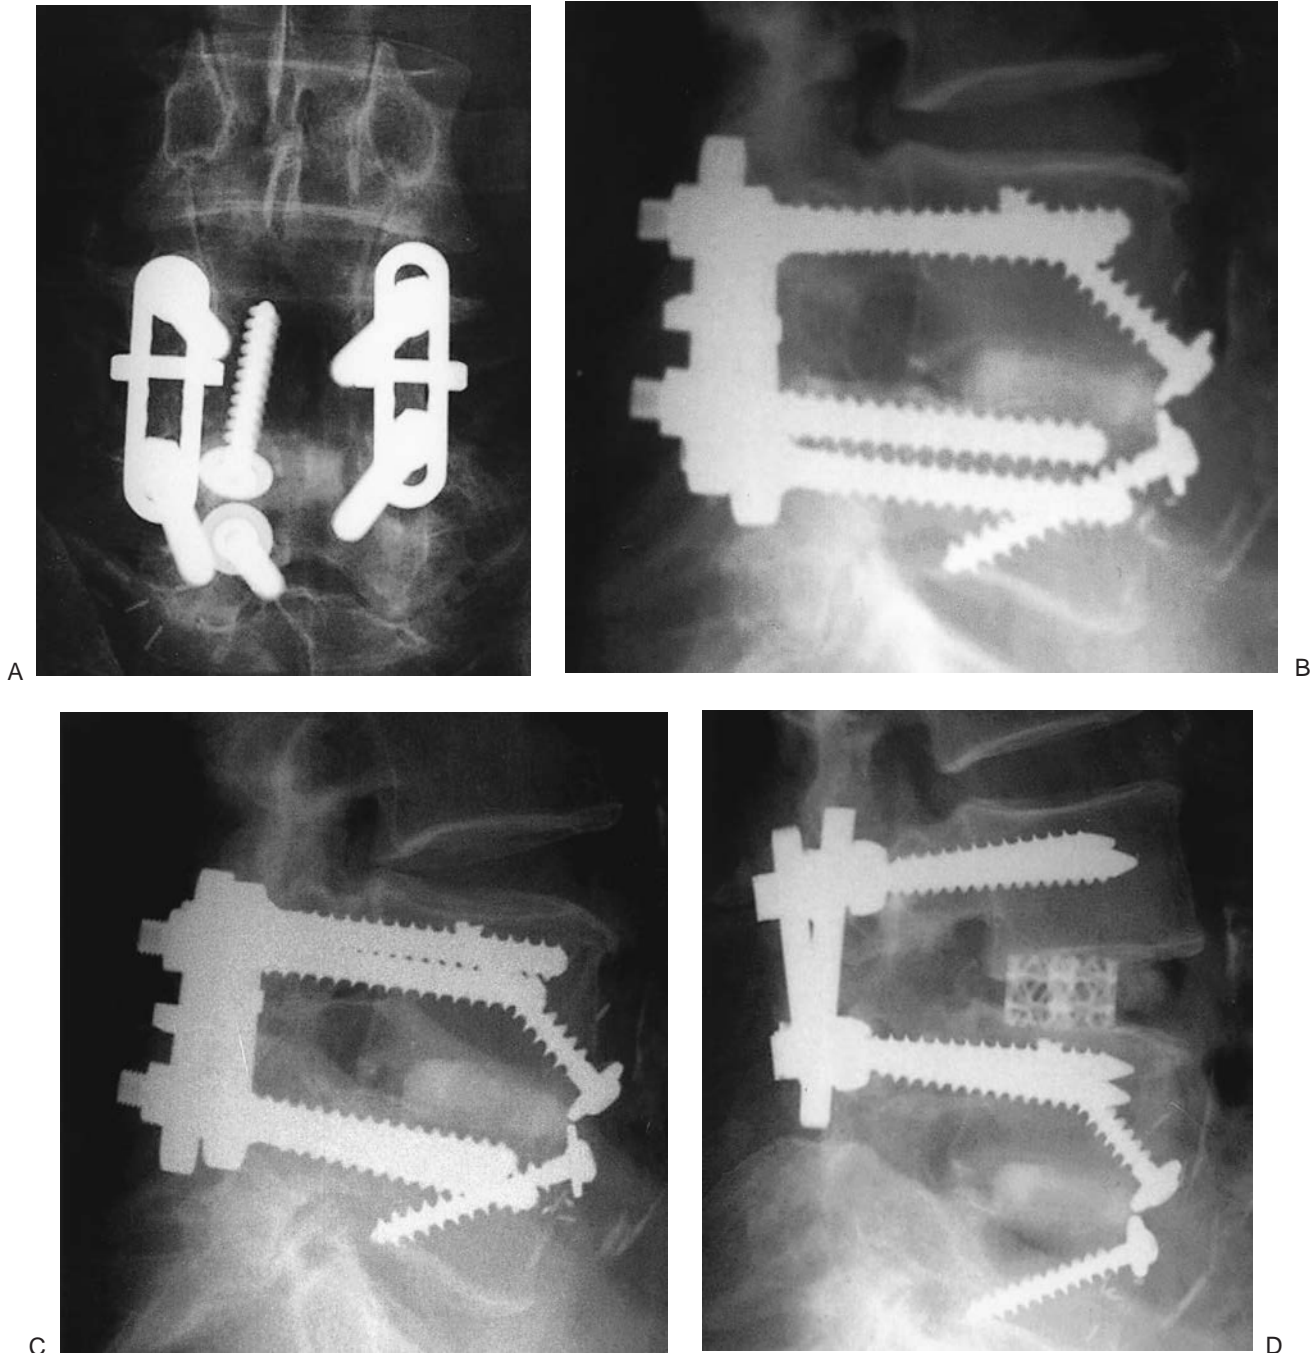

et al. reported on 39 patients who had undergone decompression and instrumented fusion for degenerative spondylolisthesis with stenosis, who then developed lumbar instability with stenosis (18). All underwent a decompression and instrumented fusion at the adjacent segment. The average interval from the index procedure to the second operation was 5.2 years. Follow-up after the second procedure was 62 months. The rate of arthrodesis was 37 of 39 patients, or 95%. Clinical results were satisfactory in 77% of the patients. Five patients subsequently developed a segmental breakdown above the second fused area. These patients had poor results. Pedicle fixation provided immediate segmental stability, and we felt its use contributed to the exceptional rate of fusion and patient satisfaction.

Schlegal (16) reported on 58 patients who had undergone a fusion procedure for a variety of conditions. Their symptom-free period averaged 13 years from the time of their first surgery. A return of symptoms led to operative intervention at adjacent segments. Thirty-seven patients were then followed for at least 2 years. It was noted that segmental deterioration was as likely to occur in the segment two levels above the fusion as at the one at the level adjacent to the fusion. Diagnosis leading to further surgery was spinal stenosis, disc prolapse, or instability witholisthesis. Of the 37 patients with 2-year follow-up, 23 were decompressed without fusion, and 14 decompressed and fused. Three of those patients decompressed without fusion were subsequently stabilized, two of them underwent fusion revision, and two had hardware removal. At 2 years, nine patients were rated as excellent, 17 as good, eight as fair, and two as poor. We concluded that adjacent segment deterioration may simply represent a natural progression of a disease process, and fusion is often necessary if an adjacent segment requires decompression.

The series with the longest patient follow-up following adjacent segment surgery was reported on in 2000 (15). Bohlman performed decompression for spinal stenosis at symptomatic adjacent segments in 39 patients who had undergone lumbar fusion. The patients had been asymptomatic for approximately 7 years following their first procedure. Twenty-six were followed for an average of 5 years. Of the 26 patients, 22 then underwent extension of their posterolateral fusion following decompression. The four patients who were not fused appeared early in the series when we did not appreciate that decompression could destabilize the adjacent segment. Fifteen patients reported satisfactory results, six were neutral about the operative procedure, and five were dissatisfied. Overall, the surgery performed was most effective in relieving leg discomfort in most patients; most patients continued to have some back discomfort. Of the 26 patients studied, six had further lumbar surgery during the follow-up period. Two fusions were revised with instrumentation. One patient had a herniated disc above the fused segment

and three required further decompression for stenosis above the adjacent segment surgery. Five of these six requiring further surgery had poor results. Again, this may reflect the salvage nature of the subsequent procedures in patients with failed back syndrome.

We feel that both surgeon and patient should have realistic expectations about surgery for adjacent segment degeneration. Older individuals are more prone to the condition, possibly because of osteoporosis. Certainly, coronal or sagittal malalignment in the older person

**FIG. 93-2.** **A,B:** Antero-posterior and lateral of circumferential fusion performed in a 42-year-old man. Symptoms were relieved for approximately 5 years until the patient began developing back pain and symptoms of spinal stenosis. **C:** Further deterioration of the segment immediately above the spinal arthrodesis. **D:** Lateral X-ray following circumferential reconstruction by a unilateral transforaminal approach. Autogenous bone was placed in the anterior disc space followed by two titanium surgical mesh cages packed with bone. The patient's symptoms have been improved by the operative intervention.

**FIG. 93-3.** **A,B:** Antero-posterior and lateral X-ray of a 67-year-old woman who had previously undergone a decompression and stabilization for spinal stenosis. **C,D:** Within 2 years, the segment above the adjacent segment had deteriorated with retrolisthesis with return of symptoms. Antero-posterior and lateral X-ray of reconstruction performed in this patient. At the time of surgery, it was found that the lower fusion was not solid. The patient was osteoporotic and she was revised with expandable screws in the previous fusion mass. A transforaminal approach was made to insert titanium surgical mesh at the collapsed L1-2 inner space. Because of the osteoporosis, the segmental instrumentation was carried three levels above the area of concern. L1-2 was also decompressed. The patient's symptoms have been relieved by the procedure.

rapidly leads to adjacent segment degeneration. Surgery for back pain only, without instability, should be avoided.

The pathology that often leads to surgical intervention is segmental instability and spinal stenosis. This condition requires decompression of neural elements followed by stabilization. Decompression alone simply destabilizes the motion segment to a greater degree than it was before operative intervention. Stabilization without instrumentation results in an unacceptable pseudoarthrosis rate. With instrumentation, the anterior column is often deficient and reconstruction should be considered. Reduction also should be attempted if possible.

In the patient younger than 55 who presents with adjacent segment degeneration and a previous fusion of one or two levels, decompression and extension of the fusion over the involved segment generally is sufficient. With a degenerative slip at the involved segment, a circumferential fusion should be considered (Fig. 93-2).

The most challenging patients are often older with a longer original construct, associated sagittal or coronal imbalance, and osteoporosis. These patients require correction of their spinal imbalance, decompression of the involved segments, with selective anterior column reconstruction. A longer pedicle screw construct should extend above the area of pathology (Fig. 93-3).

Adjacent segment degeneration is a common cause of failed back syndrome. Nonoperative management should be used whenever possible. If both the patient and surgeon recognize that operative intervention will likely not be as successful as the index procedure, surgery can be considered. Careful preoperative planning is required. It must be realized that continued progression at the next adjacent segment is possible after further extension of a previous fusion.

# Lumbar Pseudoarthrosis

S. Govender

---

Lumbar arthrodesis has been well established for the treatment of infections, deformity, and trauma (1–8). The introduction of spinal instrumentation, advances in imaging and refinement of surgical techniques have led to the expansion of surgical indications for lumbar spine fusion in patients with instability, back pain owing to mechanical degeneration of the intervertebral disc, and neurologic deficit (9–20). Stauffer and Coventry defined radiographic fusion as “a pattern of continuous trabeculae traversing the grafted region and the adjacent vertebral bodies with no evidence of motion when the patient was bending” (21). The diagnosis of pseudoarthrosis cannot be confirmed with certainty until a year after surgery, although it may be suspected within 6 months of the primary procedure (22). A pseudoarthrosis rate of more than 30% has been reported when lumbar spine fusion of three or more levels was undertaken (23–28). Patients with documented asymptomatic pseudoarthrosis have been observed to develop symptoms when followed for longer periods of time (29,30).

### INCIDENCE OF LUMBAR PSEUDOARTHROSIS

Steinman and Herkowitz reported that the incidence of lumbar pseudoarthrosis ranged from 0% to 68% and depended on the technique of fusion, indications for fusion, and the methods used to detect pseudoarthrosis (31). A pseudoarthrosis of 20% after posterior spinal fusion and 10% following posterolateral fusion was reported by Cleveland et al. (26). In their series failure of fusion was identified on plain radiographs in 11% of the patients; this increased to 21% when flexion-extension radiographs were used to detect pseudoarthrosis. McNabb and Dall found that following two-segment intertransverse fusions (L4-S1), the pseudoarthrosis was lower (7%) when compared with anterior interbody (30%) and posterior (17%) fusions (32). The reasons for the low incidence of pseudoarthrosis following intertransverse fusions were

attributed to an extensive uninterrupted vascular graft bed extending from the zygo-apophysial joints, the lateral aspects of the superior articular facets to the transverse process.

Brodsky et al. found that posterolateral fusions without instrumentation led to 31.5% rate of pseudoarthrosis and only 13% pseudoarthrosis with instrumentation (33). Similar results were reported by Zdeblick, who reported pseudoarthrosis in 5% of patients with instrumentation compared with 35% without instrumentation (20). Following posterolateral fusion for degenerative spondylolisthesis Fischgrund et al. reported 18% pseudoarthrosis in instrumented fusions and 55% for uninstrumented fusions (10).

### CAUSES OF LUMBAR PSEUDOARTHROSIS

De Palma and Rothman stated that lumbar pseudoarthrosis was iatrogenic after inadequate surgical technique and failure to immobilize the spine with appropriate instrumentation or external immobilization (27). Fusion masses that are subjected to increased shear or tensile stresses and abnormal motion following inadequate immobilization develop a higher incidence of pseudoarthrosis. Thorough decortication of the transverse processes and end plate preparation are essential in promoting vascular ingrowth (26,34–36). A pseudoarthrosis will develop if these local factors are inadequate.

Pseudoarthrosis also has been reported in patients who have undergone multiple operations, in those who are nutritionally depleted as a result of chronic granulomatous disease, steroid use, diabetes, osteoporosis, drug abuse, smoking, peripheral vascular disease, following postoperative wound infection, workers' compensation cases, and pending litigation (8,37–48). Corticosteroids decrease the synthesis of major components of bone matrix necessary for bone healing (37,47,49). Nonsteroidal antiinflammatory drugs (NSAIDs) suppress the

inflammatory response and may inhibit bone repair. Deguchi et al. reported lower fusion rates in patients who were on NSAIDs for the first 3 months after surgery and have concluded that NSAIDs inhibited osteoclastic bone resorption in the trabecular area (50). Multiple spinal operations result in increased scar tissue, which in turn result in poor functional outcomes. It has been suggested that individuals undergoing multiple operations are in poor physical condition at surgery, thus impeding rehabilitation efforts and early return to work (51,52). Failure to restore sagittal plane balance and inadequate bone graft surface area after multiple operations predisposes to recurrent deformity and pseudarthrosis (43).

Pseudarthrosis in smokers after spinal fusion has been noted to be three to four times higher than in nonsmokers (37,39,46,47,49). Studies also have shown the influence of smoking on bone mineral loss, especially in postmenopausal women who smoke (38,47). Tobacco smoke extracts have been reported to induce calcitonin resistance and interfere with osteoblastic formation. Deguchi et al. showed a significantly higher rate of pseudarthrosis in patients who continued to smoke after surgery (50). Brown et al. noted significantly lower blood gas levels in smokers as a result of increased carbon monoxide levels and reported a pseudarthrosis of 40% in smokers and 8% in nonsmokers following posterolateral lumbar fusion (39). In smokers, Carpenter et al. found a negative linear association between the outcome scores and the number of pack years (25). Cessation of smoking prior to the operation positively affected the outcome including return to full-time work.

Lower fusion rates have been reported in patients with a postoperative hematocrit of less than 30%, shoulder pain, headaches, educational level of less than 12 years, sciatica, and a family member who had back surgery (47). Narcotic use and neurologic deficit increased the incidence of pseudarthrosis. Between 75% and 100% of the patients with failure outcomes reported severe pain, were out of work, used narcotics on a regular or addictive basis, and could not walk several blocks (53).

Pseudarthrosis may occur following postoperative wound infections (8,37,48). Keller and Pappas postulated that the lack of spinal stability following early removal of instrumentation in the management of sepsis, in addition to septic involvement of the graft, played a major role in the development of a pseudarthrosis (44). The modification of the inflammatory response resulting from the degradation of the bacteria as well as the host enzymatic lysosomal activity are thought to play a role in the diminution of differentiation and activity of osteoprogenitor cells (44). They recommended that it was essential not to remove spinal instrumentation after postoperative infection because it provides the necessary stability to allow for the eradication of infection and improve the potential for fusion.

## **CLASSIFICATION OF LUMBAR PSEUDOARTHROSIS**

Heggeness and Esses classified pseudarthrosis of the lumbar spine following surgical exploration (54). The most common form of pseudarthrosis in their series was a horizontal or transverse defect within the remodeled bone fusion. The shingle type is a defect in the fusion mass that passes obliquely through the sagittal plane and may create an onion skin impression of the fusion mass. A complex pseudarthrosis results from defects in the fusion mass at multiple levels; a different type of pseudarthrosis may be noted on each side. The atrophic variety reveals resorption of the graft and is associated with an intact facet joint in 89.5% of cases. They postulated that in atrophic pseudarthrosis an intact facet joint may provide stress shielding to bone graft placed in the intertransverse area. Sixty-one percent of patients fused with metal ware developed atrophic pseudarthrosis, whereas only 38% without instrumentation developed an atrophic pseudarthrosis. Transverse, shingle, and complex pseudarthrosis are caused by excessive movement of the affected levels despite adequate stress stimulation. Asymptomatic pseudarthrosis (shingle, transverse, and complex) may provide sufficient stability to a previously painful lumbar spine despite the absence of a solid fusion.

## **CORRELATION BETWEEN LUMBAR PSEUDOARTHROSIS AND FUNCTIONAL OUTCOME**

The correlation between bony fusion and clinical outcome is controversial. Achieving a successful fusion does not necessarily lead to improvement of preoperative pain or disability (22,25,53,55). De Palma and Rothman studied 448 patients who had lumbar intertransverse spinal fusions (27). Thirty-nine (9%) patients developed pseudarthrosis, which was demonstrated on flexion and extension views. They compared these patients to 39 patients who had a solid fusion and found no difference in the ability to return to work or activity levels. The authors noted that the back pain and sciatica improved in patients with a solid fusion, but the difference was not marked when compared to the pseudarthrosis group. Similar results were reported by Bragg and Watkins and Bosworth, who reported 43% of lumbar pseudarthrosis being asymptomatic (23,24). O'Beirne et al. reviewed 81 patients following posterior spinal fusion for low back pain and 74% were satisfied with the outcome, although 34% had a pseudarthrosis (56). There was no clear relationship between the integrity of the fusion and clinical success.

Greenough et al. and Flynn and Hoque found no correlation between anterior interbody lumbar fusion and

clinical outcome (11,13). The association between fusion and clinical outcome in compensation and litigation patients was intriguing. Greenough et al. found that the noncompensation patients mobilized more actively inducing axial stresses that promoted union (13). Penta and Fraser reported that the clinical outcome using the low back outcome score was not affected by the presence of radiologic fusion at a minimum 10-year follow-up (57). Greenough et al. reviewed the results of posterolateral lumbar arthrodesis with instrumentation in 135 patients and compared these outcomes with outcomes reported by Penta and Fraser, who performed anterior interbody arthrodesis in 108 patients (13,57). Overall there was a twofold difference in the low back outcome scores, with anterior interbody arthrodesis yielding better results regardless of the patient's workers' compensation status.

Lauerman et al. noted a significantly improved functional outcome in patients in whom a solid fusion was obtained and in those who had undergone only one prior surgery on the lumbar spine (55). Deguchi et al. found a strong positive correlation between radiologic fusion and clinical success following posterolateral fusion for isthmic spondylolisthesis in adults (50). In multiple-operated symptomatic back patients several studies have reported an increased number of poor results in patients who underwent repair of pseudarthrosis and good results in those who had mechanical decompression, although the differences were not statistically significant (7,22,31,52,55,58).

When comparing these series, one should take into account that patient demographic variables and the clinical and radiographic assessment may have been different with regard to known risk factors. The clinical outcomes should be evaluated with a reproducible method of scoring the outcome to facilitate elucidation of the role of confounding factors, such as compensation status and preoperative psychological disturbance.

## DIAGNOSIS

The physical findings generally are nonspecific and include tenderness and restriction of motion. Objective neurologic deficit may be present depending on the initial diagnosis. The development of new neurologic symptoms and objective signs more likely are indicative new pathologic changes on a surgical complication (22,59).

The ability to diagnose pseudarthrosis is important if one accepts the premise that the presence of a pseudarthrosis is potentially the cause of pain, deformity, and instability. No highly specific or sensitive noninvasive method has been developed to detect pseudarthrosis. Plain radiography is certainly the most widely used in many centers and reported in scientific articles, although they judge the structural integrity and not the functional integrity (9,33,60). Rigid internal fixation is unlikely to

be of benefit in judging the functional integrity of the fusion mass unless there is obvious loosening, displacement, or breakage of the metal ware (61). The associated findings with late symptomatic pseudarthrosis (i.e., pain, loss of correction, and failure of instrumentation) do not pose a diagnostic challenge. Surgical exploration is the most accurate means of detecting pseudarthrosis in a symptomatic patient but this is not always practical and cost effective (9,14,33,54,60,62). Therefore, the detection of pseudarthrosis rests to a great extent on the surgeon's ability to interpret the antero-posterior, lateral, and oblique radiographs to assess fusion. A continuous trabecular pattern transversing the grafted segments denotes a solid fusion. Flexion-extension radiographs that demonstrate gross motion may be insensitive when subtle motion, muscle guarding, or both are present, and following transpedicular fixation (14,61,63). Blumenthal and Gill found that the overall agreement between radiographic assessment of fusion and actual surgical results was 69% in patients stabilized with rigid internal fixation (60). Preoperatively the assessment of fusion from anteroposterior and lateral radiographs was undertaken by two spinal surgeons and two musculoskeletal radiologists. Intraoperatively the fusion was explored bilaterally to determine the presence or absence of fusion. In addition a mechanical stress test of the motion segment was performed with a Kocher clamp and observations were recorded. The authors concluded that plain radiographs can predict the presence or absence of pseudarthrosis in approximately two thirds of patients.

Rothman and Glenn found reformatted computed tomography (CT) scan very useful in the evaluation of patients with pseudarthrosis although CT scan does not provide a measure of motion but only the integrity of the fusion (64). Lang et al. reported that three-dimensional (3D) sagittal planar and coronal reformations were more reliable than any other imaging method to detect instability following spinal fusion (62). The understanding and interpretation of 3D-reformatted image is essential in the diagnosis of pseudarthrosis. In the assessment of fusion integrity with 3D the cleft in the fusion may be obscured from view by overlying unattached shards of bone that blend with the underlying bone into one solid-appearing fusion mass. Clefts less than 1 mm were generally not detected in 3D surface cuts. Undulations in the fusion mass may produce fictitious clefts in the 3D image of a solid fusion. However, the amount and position of previously grafted bone can be determined. Larsen et al. performed a prospective study comparing plain radiographs, flexion-extension views, CT scanning and bone scintigraphy with operative findings in the assessment of pseudarthrosis in pedicle screw fusion (61). The combination of the results of plain radiography, CT, and bone scintigraphy did not predict pseudarthrosis or fusion at a statistically significant level. Similarly, Brodsky et al.

noted a poor correlation of the preoperative radiologic assessment (plain X-rays, bending films, tomography, and CT scan) of pseudarthrosis with surgical exploration (33). Albert et al. analyzed the efficacy of single photon emission computed tomography (SPECT) in pseudarthrosis and found that it was sensitive in only 50% and specific in 58% when comparing the results of the blind readings with surgical exploration (53). In the instrumented fusions the sensitivity (.42) and specificity (.56) was lower, which may result from the SPECT scan interpretation. Single photon emission computed tomography scanning may be more useful in diagnosing pseudarthrosis in the noninstrumented spine (65). Bohnsack et al. evaluated planar bone scintigraphic scan ( $^{99m}\text{Tc}$ ) to detect bone union after posterior spinal fusion in cases clinically and radiologically suggestive of pseudarthrosis (66). The sensitivity and positive predictive value of bone scintigraphy were low to detect pseudarthrosis after spinal fusion. Pape et al. found that surgical exploration confirmed the adequacy of roentgen stereophotogrammetric analysis (RSA) as a reliable *in vivo* method to evaluate lumbosacral stability after anteroposterior fusion (16). Roentgen stereophotogrammetric analysis was used to study vertebral motions after posterolateral fusion with transpedicular fixation and proved to be able to differentiate between patients with and without fusion (14,63).

Interbody fusion cage devices that provide axial load-bearing capability in the anterior column interfere with surgeons' ability to interpret the status of the fusion. Anterior fusion (extra cage) was noted in 81% of patients with interbody cage by independent observers following the use of structural titanium mesh cages (67–69).

## TREATMENT

Pseudarthrosis has been identified as one of the causes of failure following lumbar spine surgery (10,23–25, 29,37,42,51,53). The patient with a failure after lumbar spine surgery may present with evidence of one or more of these entities and the contribution of each to the patients' pain pattern as well as the likely response of a given pathology to surgical treatment need to be determined. Nonoperative care should be attempted initially in the majority of patients with symptomatic pseudarthrosis because of a high failure rate at surgical attempts to repair pseudarthrosis (7). If symptoms persist despite prolonged rehabilitation a meticulous selection of patients is essential in achieving acceptable results. The timing of revision fusion should not be considered before 1 year to allow fusion to consolidate unless there is progressive instability or increasing neurologic deficit and pain (70). A thorough clinical evaluation should localize the anatomic source of pain. The evaluation of pseudarthrosis repair in patients who initially had no indication for fusion must be carefully taken into consideration before surgery. The

rationale for previous surgical treatment must be reviewed, including review of all imaging studies. The technical details of the prior procedure should be evaluated. It is also possible that a new pathologic condition has risen since the last procedure and is responsible for the patient's current symptoms (25,53,55).

Low back pain is uniquely personal and invariably has a physical basis (58). The psychological ramifications are universal and usually become more important after failed or multiple surgery and should be given due consideration before any decision is taken to operate. Social factors may contribute to disability and the social consequences of disability are unavoidable. The presence of compensation undoubtedly alters these psychological and social aspects (25,53,55). Depression; conversion mechanisms; and economic, legal, and work-related factors can affect a patient's response to treatment. These extenuating factors, which are frequently overlooked, must be evaluated before considering further surgery. The clinician should refer patients with identifiable psychological stress to trained professionals and community resources including counselors and self-help groups. Patients in whom clear operative indications are lacking, may benefit from programs incorporating cognitive therapy with physical, vocational training, and disability management (25,41,42,51,53,57). In addition prior to surgery other factors to be excluded include infection, adjacent segment degeneration, and inadequate rehabilitation or incorrect diagnosis.

Waddell et al. analyzed the results of repeat back surgery for degenerative disc disease in 103 Workmen's Compensation Board patients (7,58). The authors found that the results were better when the preceding operation provided pain relief for greater than 6 months, when sciatica was worse than back pain and when a recurrent disc herniation was noted. Pseudarthrosis, previous infection, scarring, and adverse psychological factors precluded a good result. They recommended rigorous patient selection, including a psychological assessment prior to repeat surgery.

Although efforts are made to ensure a solid fusion is achieved, a partially failed fusion or pseudarthrosis is not detrimental. Pseudarthrosis may well be desirable because patients whose fusions develop pseudarthrosis might be less susceptible to subsequent adjacent-segment degeneration (71). Attempted repair of a pseudarthrosis is based on a doubtful rationale because there appears to be no correlation between the presence of a pseudarthrosis and persisting back pain. Operative repair of a pseudarthrosis is a salvage procedure in a patient who has already had at least one previous attempt at spinal arthrodesis (25). The use of bone growth factors (bone morphogenetic proteins, basic fibroblast growth factor) may be helpful in preventing nonunions, particularly in conditions of impaired vascularization, such as smoking, diabetes, spinal instability, and insufficient bone graft (38,72,73). However, there are few reports on the func-

tional outcome in these patients. In a multicenter pilot study 14 patients underwent anterior interbody fusion at L5-S1 with titanium fusion cages. Eleven patients had fusion cages filled with rhBMP-2/carrier and three controls had autogenous iliac graft filled in the cages. At 6 months and 1 year 100% of patients with rhBMP-2 had solid fusion and only two patients with autograft had fused (72).

Repair of a pseudarthrosis is challenging in terms of the technical difficulties, approach, and selection of patients. It is frequently difficult to decide which patients require a combined procedure versus either an anterior or posterior operation alone for symptomatic pseudarthrosis (53). Most techniques of pseudarthrosis repair have reported on posterior fusion without instrumentation, posterior fusion, with instrumentation or anterior fusion alone (21,26,51,55,59). The poor vascularity and scar tissue following revision posterior surgery and loss of sagittal alignment of the lumbar spine have been suggested as reasons for low success rates of pseudarthrosis repair (6,7,55,74). Anterior interbody fusion may be more appropriate in patients who had multiple posterior operations resulting in inadequate bone stock for fusion or insertion of posterior instrumentation. In addition the graft is placed closer to the center of vertebral motion, theoretically achieving greater stiffness when fusion has occurred. The intervertebral height may be restored and a smaller volume of bone graft may be used compared with that required for posterior techniques (36,42). An anterior interbody fusion with tricortical iliac crest autograft and more recently femoral ring allografts packed with autograft have been recommended (34,35,75,76). The increased vascularity of the vertebral body, superior biomechanical environment, and large surface area of contact offer an optimal environment for a fusion. Structural iliac crest grafts have several limitations (i.e., donor site morbidity, limited amount of graft available for multiple-level fusion, and graft subsidence). Femoral ring allografts take a longer time to incorporate but there is less graft subsidence and loss of correction when compared with iliac crest grafts. In addition, femoral ring allografts can be used at multiple levels without subjecting the patient to significant donor site morbidity. Thorough preparation of the vertebral end plate is essential to promote fusion. Cohen et al. obtained a 100% anterior fusion rate with femoral ring allografts and anterior instrumentation (35). The Bridwell-Lenke grading scale (34) was used to evaluate the anterior fusion; they noted no difference in the return to work between patients involved in litigation and those not involved in litigation. In addition, they found no significant difference in the fusion rate or long-term functional outcome when using iliac crest allograft and femoral cortical allografts. However, graft site morbidity was not evaluated in their study. Interbody fusion cages have been approved only for limited investigational applications in humans because the long-term

effects are not yet known (68,74). The most reliable radiographic indication of fusion is the sentinel sign or the presence of bridging bone anterior to the fusion cage. High rates of fusion (greater than 90%) following anterior interbody arthrodesis have been reported with the BAK and Ray cages at 2-year follow-up. The 5-year functional outcomes are currently in progress (67–69).

Several studies have reported that despite a solid fusion the functional results have not been uniformly satisfactory (25,28,43,51,57,77–79). Kozak and O'Brien obtained 85% fusion rate for repair of pseudarthrosis but only 30% of their patients had good clinical results (77). Similarly, Kostuik et al. reported 91% fusion rate but only 43% of patients returned to work (6). Others have noted that a successful fusion was important in predicting a satisfactory outcome (21,37,55). Kim and Michelsen reported 81% of patients who had a successful fusion following pseudarthrosis repair had a satisfactory outcome, whereas 95% who had a poor functional outcome did not achieve a fusion (52).

Albert et al. achieved 90% fusion rate following repair of pseudarthrosis with a combined anterior and posterior approach (53). The advantages of the circumferential fusion include elimination of all potential sources of pain both anteriorly and posteriorly as well as maximization of stability with resulting increase in the rate of fusion (18,19,25). This hypothesis is supported by reports of back pain that persisted despite solid posterior fusion but was subsequently relieved after the addition of anterior discectomy and interbody arthrodesis (80). A functional failure of 31% was noted despite a successful fusion. The authors identified functional failures in those patients using two or more doses of narcotic medication per day prior to surgery and those with abnormal neurologic findings, compensation, or legal claims were at more than twice the risk for functional failure after pseudarthrosis repair (53). The association of perineural fibrosis emphasizes the difficulty in obtaining a good functional outcome in patients who had multiple surgery and nerve root injury.

## CONCLUSION

Prevention of pseudarthrosis is the most successful treatment that entails appropriate patient selection, meticulous surgical technique, and well-managed postoperative rehabilitation. Clearly, not every patient with pseudarthrosis after lumbar spine fusion requires repeat surgery. Nonoperative treatment is an option in patients who had multiple attempts at fusion and have associated risk factors. Successful pseudarthrosis repair leads to a successful surgical result if the rationale for the original procedure was sound. It is equally important to exclude other potential pathologic conditions responsible for the pain. The expectations of revision surgery must be explained to the patient.

## CHAPTER 95

# Management of Failed Surgery

## Posttraumatic Spinal Deformity

Jeff S. Silber and Alexander R. Vaccaro

---

Each year in the United States there are more than 1 million acute injuries to the spine, with approximately 50,000 of these resulting in fractures to the bony spinal column (1). Although there are 7,000 to 10,000 new cases of spinal cord injury each year, for the most part, the majority of spinal injuries are minor and without long-term consequence (2). The majority of spinal injuries often only involve the paraspinal soft tissues and do not require surgical stabilization or even prolonged orthotic immobilization.

The vast majority of unstable spinal injuries are recognized early and managed appropriately, either nonoperatively or operatively. In rare cases requiring surgery, the operative management may have been inadequate, either in alleviating neural compression or in achieving adequate spinal stability. In clinical scenarios in which inadequate biomechanical stability is achieved, continued unrelenting exposure to physiologic stresses may result in a gradual posttraumatic deformity, further impeding the functional and emotional recovery of the trauma patient.

The management of failed surgery for traumatic injuries of the thoracolumbar spine leading to posttraumatic deformity can be extremely challenging. Various clinical situations may be responsible for a failed surgical posttraumatic deformity. These include:

1. Inadequate selection of fusion levels
2. Inadequate placement of instrumentation
3. Pseudoarthrosis or nonunion
4. Junctional breakdown above or below the fusion segment. The development of a Charcot or neuropathic spinal deformity may be considered under this category
5. Implant failure

A careful history and examination of all initial presurgical imaging studies is necessary to determine the

appropriate classification of the initial injury and to determine if the index procedure was biomechanically sufficient as a treatment alternative. During the consultant's evaluation, up to date imaging studies are obtained to get an understanding of the patient's global balance. Dynamic plain radiographs are also obtained to evaluate for any objective evidence of instability.

### SYMPTOMS

#### Pain

Usually the first and most common symptom after a failed surgical procedure for thoracolumbar trauma is increasing pain. This may be secondary to iatrogenic spinal imbalance in the coronal or sagittal plane, failed instrumentation leading to a progressive deformity, or the result of a symptomatic pseudoarthrosis. Typically, patients initially complain of a constant aching discomfort most commonly located in the apical segment of the deformity. The complaints of pain are exacerbated with activity such as bending, walking, lifting, and twisting but also can be aggravated with prolonged sitting or standing (3). This pain is caused by spinal column imbalance and resultant abnormal forces placed on the soft-tissue structures, leading to gradual soft-tissue fatigue and pain. Furthermore, pain also may be a consequence of premature degenerative changes associated with the spinal deformity.

#### Neurologic Dysfunction

A minority of patients with a failed surgical procedure leading to posttraumatic spinal deformity may manifest symptoms of neurologic deterioration (Fig. 95-1).

**FIG. 95-1.** Lateral radiograph after an anterior decompression and strut grafting followed by posterior segmental instrumentation. The neural elements were decompressed and the sagittal alignment re-established, resulting in functional improvement and decreased pain.

Recently, it has been reported that patients developing a posttraumatic kyphosis of less than  $15^\circ$  or canal stenosis of less than 25% had a 50% less likely chance of developing a hydromelia (spinal cord cyst) than patients developing a greater deformity (4). Neurologic dysfunction without spinal cord cystic degeneration has been shown to result from progressive kyphosis, stenosis, instability, arachnoiditis, and cord tethering (4). It is important not to underestimate the potential for progressive myelopathy in the setting of a static long-term kyphotic deformity, which may manifest neurologically only with activity. In this setting, patients may present with no obvious pathologic findings on physical examination but give a clear history of lower extremity weakness, incoordination, and loss of balance with ambulation. This is attributed the active tethering of the scarred neural elements (spinal cord) over the prominent vertebral fracture fragment or deformity during ambulation.

Neurologic worsening following initial neural improvement or plateauing may result from the development of an intracord or intramedullary cyst or cavity known as either a posttraumatic syringomyelia or progressive posttraumatic cystic myelopathy. Because of the wide availability of advanced imaging studies such as magnetic resonance imaging, these processes can be rec-

ognized and diagnosed early in patients with complaints of neural deterioration. The prevalence of this abnormality has been reported to be 3.2% to 40% (3,5). There are many causes of intracord or intramedullary cyst or cavity development. These include spinal cord tethering, microcystic cord degeneration, arachnoiditis, and spinal column instability resulting in spinal cord compression. The pathoanatomy of posttraumatic syringomyelia consists of a confluent cyst within the spinal cord parenchyma. When the presence of numerous microcysts exists in the absence of a large cyst, it is referred to as posttraumatic myelomalacic myelopathy (6). Surgical intervention for this syndrome consists of cyst shunting or fenestration and releasing any existing tether. Unfortunately, shunting of the cyst alone has resulted in disappointing long-term improvement with shunt revisions frequently needed (7).

## CAUSES OF FAILED SURGERY

### Pseudoarthrosis (Bone Union Failure)

A postoperative pseudoarthrosis or nonunion may result in a progressive spinal deformity. This may occur in the presence of a previously well-performed spinal reconstructive procedure, but is more common in the setting of inadequate fusion level selection or inadequate instrumentation. The concomitant use of nicotine products or pharmacologic agents that retard osteoblast function may also contribute to bony nonhealing. Patients with a symptomatic nonunion often present with increasing pain, with or without activity localized to the operative site. Pain intensity usually heightens approximately 6 to 9 months after the index procedure and may plateau or worsen gradually, depending on the integrity of the spinal instrumentation. Patients or their relatives may also notice a change in the patient's posture over time. Radiographic examination may reveal evidence of instrumentation loosening or failure, and bone nonhealing. It is imperative to exclude the possibility of an occult deep infection when a symptomatic nonunion is identified. Fortunately, the vast majority of nonhealed spinal fusions are asymptomatic and do not result in a progressive spinal deformity.

### Instrumentation Failure

As mentioned, implant loosening or failure may result in a pseudoarthrosis and deformity progression. This is the most common reported complication resulting in a posttraumatic deformity. In some series, it has been reported in up to 16% of patients following a posterior instrumented stand-alone fusion procedure. Often, a mistake in judgment in selecting appropriate fusion levels or the extent of stabilization, or an error in technique is the etiologic factor for posterior-only instrumentation failure. Instrumentation failure in this setting eventually results

from excessive forces at the implant bone junction leading to migration, displacement, or breakage. Revision stabilization often is required when early failure of instrumentation occurs.

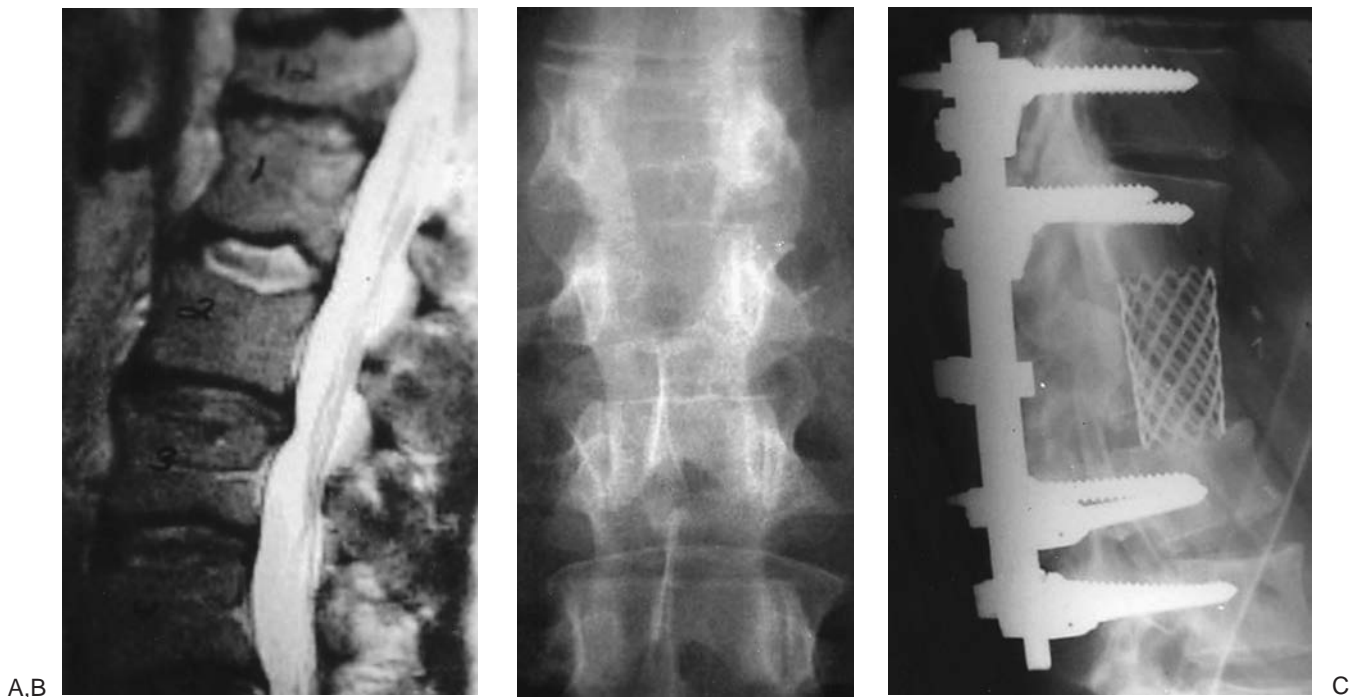

### Inadequate Biomechanical Stability

This cause of surgical failure is closely related to the causes of instrumentation failure. Postsurgical deformity progression may occur in the setting of inadequate restoration of spinal stability. This is commonly encountered following anterior or posterior-alone procedures in which significant incompetence exists in the nonsurgically treated spinal columns. Additionally, fusion procedures of inadequate length may not adequately stabilize a three-column spinal injury leading to a gradual spinal deformity. Keene reported on 106 patients who underwent operative stabilization for unstable thoracolumbar fractures. Sixteen patients (15%) eventually required additional surgery for chronic instability and deformity progression 4 months to 16 years after the index procedure. The authors reported on several risk factors responsible for the posttraumatic deformity progression. These included the presence of a laminectomy or a short fusion segment (Fig. 95-2). The authors found that long-term adequate spinal alignment without significant progres-

sion of deformity was observed when at least five levels or more were incorporated posteriorly into the fusion segment (Fig. 95-3). They also reported the same observations when a posterior laminectomy was not performed at the initial surgery (8).

### Charcot Spine

Charcot spine is a rare neuropathic spinal deformity, which often leads to a significant posttraumatic deformity in active young patients with a complete spinal cord injury. The pathophysiology of a neuropathic spine involves abnormal motion between vertebrae, resulting in cartilage and ligament breakdown, end plate fracture, and failure of subchondral bone ultimately leading to vertebral collapse. The end stage of this destructive process is a massive pseudoarthrosis. Although this process is initiated in the environment of insensate vertebral segments, patients commonly complain of worsening back pain, increased lower extremity spasticity, palpable and audible crepitans with increased motion at the Charcot segment, and a progressive gibbus formation with loss of sitting balance. If pronounced, decubitus ulcers may develop over the acute kyphotic segment (9,10). In the early stages, radiographic examination demonstrates hypertrophic bone formation. This is seen in vertebral seg-

**FIG. 95-2.** **A:** Sagittal magnetic resonance image 12 months after a T12 burst fracture managed with a posterior decompressive procedure alone. A focal kyphotic deformity developed, producing increased pain and neural dysfunction. **B:** Antero-posterior radiograph revealing the decompressive laminectomy defect. **C:** Postoperative lateral radiograph of an anterior T12 corpectomy and strut grafting followed by a posterior stabilization procedure. Note the improvement in sagittal spinal alignment.

**FIG. 95-3.** Lateral radiograph showing a failed short-segment posterior instrumented fusion in the management of an L1 burst fracture. The patient developed an increased kyphotic deformity with posterior skin breakdown.

ments adjacent to and below the level of the spinal cord lesion. This hypertrophic bone formation also may develop immediately below a previous fusion segment (9,11). Further progression of the process results in fragmentation of the intervertebral disc space and end plates. The final stage of this process is massive hypertrophic periosteal bone formation and a giant pseudoarthrosis, resulting in an audible and palpable crepitans with spinal motion (11). In order to prevent the development of a rapid spinal deformity with this disorder, early detection through physical and radiographic evaluation is necessary (12,13).

### SURGICAL CONSIDERATIONS

The combination of all imaging data along with a history defining the impact of the present deformity on the functional status of the patient determines if revision surgical intervention is necessary. Revision surgical intervention may be considered if:

1. The spinal deformity is progressive.
2. There is a static or progressive neurologic deficit.
3. The deformity is considered responsible for unremitting back pain or functional disability recalcitrant to conservative management.

Various surgical options can be employed to treat a failed surgery resulting in a posttraumatic spinal defor-

mity. These include a posterior- or anterior-only approach or any variation of a combined anterior and posterior procedure. It has been shown that in most cases of failed surgery resulting in a posttraumatic deformity, a posterior-only revision approach is often inadequate for optimal deformity correction and stabilization.

The long-term outcome following surgical management of failed surgery leading to posttraumatic deformity has been satisfactory. The earlier intervention is provided to the patient, the better the overall outcome. There is an increased risk of operative complications seen in this difficult group of patients, including wound breakdown or infection, neurologic worsening, or fusion nonhealing. The most feared complication, neurologic worsening, is often the consequence of the existing kyphotic spinal deformity resulting in the draping, scarring, or tethering of the neural elements over the posterior aspect of the anterior vertebral elements. Often the patient in this setting has a baseline neurologic deficit; any neural manipulation, especially a subtle tension force, may result in progressive neural dysfunction.

### OPERATIVE APPROACHES

Many surgical strategies are available in the setting of a radiographically identified spinal deformity following failed surgery. The goal of surgical intervention includes relief of symptomatic neurologic compression, correction of spinal malalignment and spinal stabilization, and hopefully, the alleviation of pain. The surgical approach may be a posterior- or anterior-only approach or any variation of a combined anterior and posterior procedure. It has been shown that in the management of a late posttraumatic thoracolumbar kyphotic deformity, a posterior stabilization procedure alone, unless an adequate posterior column shortening osteotomy is performed, is often insufficient to achieve both optimal spinal alignment correction and long-term stabilization. An obvious biomechanical disadvantage exists in a posterior-only fusion in the presence of an existing kyphotic deformity owing to the considerable tension placed on the posterior instrumentation and bone graft. These stresses often exist regardless of the adequacy of sagittal plane correction and result from the large bending moments challenging the corrective forces needed to obtain adequate spinal alignment provided by the instrumentation. This assumes an osteotomy was not used to obtain the desired sagittal correction. To improve on the biomechanical integrity of a posterior-only revision procedure, a sagittal plane osteotomy often is required to balance the C7 vertebral body over the sacral elements. Recently, the posterior transforaminal interbody approach has gained increased popularity in reconstructing the anterior lumbosacral column when significant deformity is not present. This technique has the advantage of allowing for anterior graft placement without excessive retraction of the neural ele-

ments. Polly et al. have reported the usefulness of the bilateral transforaminal approach. They report on the biomechanical advantage of anterior structural graft placement that functions as a pivot point of rotation followed by posterior compressive forces. The combination of anterior strut grafting and posterior compressive force helps to restore sagittal (lumbar lordosis) alignment. This approach allows for an indirect circumferential fusion and is extremely useful, especially in patients where an anterior approach is undesirable (14).

An alternative revision strategy that has proved to provide long-term stability involves either an initial anterior release or decompressive procedure and grafting followed by a posterior segmental stabilization procedure. This strategy provides a favorable biomechanical environment, allowing significant manipulation and restoration of spinal alignment. Furthermore, improved fusion success is seen when anterior column reconstruction is accomplished. An anterior-alone approach has been shown to provide good long-term stability in the setting of a native fracture and correctable sagittal plane deformity with a stable posterior spinal column (15). This is rarely the clinical situation in the setting of a failed surgical procedure resulting in a posttraumatic spinal deformity.

When a fixed lumbar kyphotic deformity (flat back) is present, the surgeon may select one of several surgical strategies. These include a combined anterior and posterior approach or a posterior-alone approach involving a pedicle subtraction, eggshell, or Smith-Peterson osteotomy. As much as 35° of focal sagittal plane correction may be achieved with a closing wedge osteotomy (14).

Kostuik et al. reported on 54 patients managed with a combined anterior opening wedge osteotomy and instrumentation followed by a posterior closing extension osteotomy with instrumentation for a fixed iatrogenic flat back deformity. The average increase in lumbar lordosis went from a preoperative measurement of 21.5° to 49° postoperatively. They also reported significant postoperative pain reduction in over 90% of the patients (16). The back-front-back procedure popularized by Shufflebarger consists of an initial posterior release with removal of existing instrumentation, the performance of necessary osteotomies and facetectomies, followed by an anterior release and reconstruction. Posterior placement of instrumentation is then performed to restore the posterior spinal element tension band (17).

## OSTEOTOMY TECHNIQUES

Two commonly performed posterior extension osteotomy techniques used in the correction of flat back (kyphotic) deformities include the Smith-Peterson osteotomy and the pedicle subtraction osteotomy (PSO) (18). The Smith-Peterson osteotomy removes a predetermined V-shaped wedge of bone from the posterior elements in

order to rebalance sagittal alignment (18,19). The amount of bone resected is determined preoperatively and is determined by the degree of sagittal deformity present. With a Smith-Peterson osteotomy, approximately 1° of sagittal correction is usually achieved for each millimeter of bone resected. If 20-mm of bone is resected, this will achieve 20° of sagittal plane correction. It is usually easy to close an osteotomy defect that is up to 15 mm in height without additionally releasing the anterior intervertebral disc. If needed, multilevel osteotomies can be performed or a thorough release of the anterior annulus and removal of the disc may be performed to achieve greater sagittal plane correction. All posterior bone removed is kept for subsequent grafting. A V-shaped osteotomy is created often beginning superiorly below the L2 or L3 pedicle. This is well above the iliac vessel bifurcation and below the rib cage. A symmetric amount of bone is removed from both sides leading to the removal of the pars interarticularis bilaterally. A V-shaped osteotomy is chosen so as to prevent the possibility of rotation once the osteotomy is closed. In the presence of a coronal plane deformity, the symmetry of posterior bone removal may be adjusted depending on the degree of coronal alignment correction necessary. The decompression exposes the pedicles above and below the level of bone resection. The remaining lamina is undercut in order to avoid dural impingement when the osteoclasis is performed. Once the osteotomy is completed, the hips are gradually extended as the surgeon applies an anterior to posterior force to close down the osteotomy site (Fig. 95-4) (18,19).

A pedicle subtraction osteotomy involves the posterior removal of the pedicles at the desired level followed by the planned decancellation of the vertebral body up to, but not involving, the anterior vertebral cortex. The bone anterior to the pedicles may be removed in a V-shaped fashion with the base of the triangle being the posterior vertebral cortex, or the entire vertebrae may be decancelled. Using this technique at one level, usually at L2 or L3, often achieves 30° to 35° of sagittal correction. A variation of this technique involves the removal of the pedicles bilaterally along with the superior vertebral body in a posterior inferior to anterior superior direction including removal of the cephalad intervertebral disc. Fluoroscopic guidance may be used with this technique. The outer margins of the pedicles may be removed last as the pedicles are cannulized in order to protect the neural elements medially and inferiorly at the pedicle level. Once the pedicles are cannulated, curettes are inserted through the pedicle on one side to perform the decancellation as pituitary rongeurs aid in the removal of loose bone through the opposite pedicle (Fig. 95-5). The anterior vertebral body cortex is left intact to act as a fulcrum for subsequent osteoclasis. Once adequate bone is removed within the vertebral body, the posterior vertebral body cortex is tamped into the vacant vertebral body cavity. The pedicles then are removed and the osteotomy is

complete. Extension of the hips along with anterior directed force applied at the osteotomy site closes down the created posterior defect. All neural structures are carefully inspected during the osteotomy reduction (Fig. 95-6). Before the completion of the osteotomy, a temporary rod is placed on one side and locked so as to prevent

inadvertent premature catastrophic translation at the working site. This rod is allowed to glide through the spinal anchors when the reduction force is subsequently applied. An intraoperative lateral radiograph or fluoroscopic views then are obtained to assess the adequacy of the reduction.

## COMPLICATIONS

The potential for neurologic injury in the surgical management of a failed surgery resulting in posttraumatic spinal deformity is significantly increased over the index procedure because of the complexity of the deformity, the anterior draping of the neural elements over the anterior vertebral elements, and the presence of neural scarring. The incidence is significantly higher in the surgical management of failed spinal surgery and posttraumatic deformity. The presence of preexisting spinal cord injury with associated spinal cord tethering, vascular ischemia, and scarring also sensitizes the neural elements to the potential for stretch injury from manipulation. New onset or progressive neurologic injury is reported to be approximately 1% following all spinal surgery. Intraoperative spinal monitoring should be used during deformity correction as an aid to detect early changes in neurologic function during surgical manipulation and hardware placement (1). If any neurologic changes are noted during spinal manipulation or hardware placement, the decision of releasing the correction or removal of hardware must be seriously considered.

## SUMMARY

The long-term outcomes following the surgical management of postoperative deformity or posttraumatic instability are influenced by many factors. These include patient age and medical status, the type or mechanism of initial injury, the time period between the initial injury and surgical deformity correction, the quality and availability of bone stock for hardware placement, and most important, the experience of the surgical team. Trauma to the spinal cord and column is a devastating injury that may be fraught with many complications, including posttraumatic deformity. Certainly the best treatment is prevention of initial spinal deformity through adherence to biomechanical principles and close follow-up with early intervention if needed. Once failure of the index proce-

dures presents itself, treatment of the posttraumatic deformity follows basic principles consisting of neural decompression and re-establishment of the integrity of the compromised spinal columns. This may involve an anterior, posterior, or combined surgical approach. Great care must be given when manipulating the sagittal profile of the spinal column so as not to over-lengthen the neural elements, which is poorly tolerated, especially in the setting of a pre-existing spinal cord injury. The surgical management of posttraumatic deformity is a challenging problem. The treating physician must pay strict attention to the biomechanics of the entire spinal column and be cognizant of the response of the neural elements to any form of manipulation. Hopefully, this will allow a successful surgical and functional outcome.

# Management of the Failed Back Patient

## Spinal Cord Stimulation

Donna D. Ohnmeiss and Ralph F. Rashbaum

---

Spinal cord stimulation (SCS) has been used for decades in the treatment of chronic, intractable pain. The concept of stimulation for decreasing pain may initially appear paradoxical. The exact mechanism by which SCS provides relief is not fully understood. However, it is thought to be rooted in the gate control theory of Melzack and Wall (1). They theorized that one could modulate pain by stimulating low-threshold, large-diameter, afferent A- $\delta$  fibers responsible for inhibiting impulses from the small unmyelinated C-fibers associated with pain sensation. Therefore, SCS is thought to produce a pain-relieving effect by stimulating the inhibition of pain signals. It does not directly address the source of the pain. The first article on spinal cord stimulation for pain control was published by Shealy in 1967 (2). Since that time it has been used to treat a broad range of painful conditions, including angina, spinal cord injury, ischemic limb pain, peripheral vascular disease, failed back syndrome, tumors, phantom limb pain, and brachial plexus injuries. Since the early days of SCS there have been continual developments of the stimulators including the leads, batteries, transmitters, and programming units. Dual lead systems are now available as well. The literature related to SCS is difficult to synthesize because of the wide variety of devices used, differences in study methodology, variation in surgical technique, and the fact that many studies deal with mixed diagnostic groups. In the past, some have viewed SCS as a treatment of last resort. It was thought to be applicable to patients in whom no clear pathology related to their ongoing pain complaints could be identified, or for patients whose pain was related to problems such as arachnoiditis that was not likely to respond to other treatments. Added to the fact that many SCS patients have concomitant health problems or failed surgery at least once, this created a very difficult popula-

tion of patients to treat. With time, indications for SCS have been better defined in failed back surgery (FBSS) patients; at the same time the role of SCS has expanded. In this chapter, we review the literature on SCS primarily for the treatment of FBSS. The discussion of complications focuses primarily on recent literature because this better reflects the problems encountered with modern stimulation systems.

### PREOPERATIVE PLANNING AND EVALUATION

#### Patient Education

As part of screening candidates for SCS, prospective recipients need to be evaluated to determine that they can understand the operation of the external programming unit. At our facility, a nurse educator spends time with each patient, and preferably a family member, explaining the trial procedure, implant procedure, and basic operation of the device. After the implant procedure, patients receive more detailed education about the operation of the programming device they will use.

#### Realistic Expectations

It is imperative that realistic expectations be set by the patient, family, insurer, and physician before the surgery. Spinal cord stimulation for FBSS, like any other treatment for this condition, is not likely to yield complete pain relief. Realistic goals must be discussed. Typically these are reduced pain and increased function. For some patients, return to work is realistic, for many it is not. Another issue to address is fluctuations in pain. This can be related to weather, increased activity, and psychological factors, particularly those related to increased stress

and depression. There are technical reasons for failure of SCS. The most obvious of these is getting the correct lead placement. Only if the leads are positioned to achieve coverage of the symptomatic areas can a good result be achieved. At some point, many SCS patients require repositioning of their leads to regain optimal coverage in the areas needed. Rarely is there a device failure. One difficulty we have observed with SCS patients is changing expectations. One problem is the degree of pain relief, and the other item is pain location. Some patients initially report great satisfaction and good pain relief. With time the pain relief is the same, but they are less satisfied because they want more. Many times before surgery patients indicate that pain in one particular region is the primary problem they want to address. Postoperatively, with this pain under control, they return with different complaints, or more likely want relief of pain that was present but was not their primary concern at the time of SCS implantation.

### Role of the Psychologist

Teaming with a psychologist in the treatment of SCS and FBSS patients is essential. The psychologist can provide comprehensive preoperative screening. The screening typically consists of an interview and formal psychological testing including the MMPI (Minnesota Multiphasic Personality Inventory). Based on the results, some patients who are at risk of having a poor outcome can be identified and SCS not undertaken. The psychologist also can provide treatment strategies for improving coping skills, relaxation, and stress reduction. He or she also may play a role in determining if the patient has realistic expectations or in setting these. At our facility, the psychologist who performs the patient screening is in the operating room during the SCS trial to keep the patient relaxed and at ease during the procedure.

### SURGICAL PROCEDURE

There are several variations in surgical procedures for SCS implantation. Presented here is an overview of the procedure that has been used in our facility for several years and has been described in detail elsewhere (3). The procedure is performed under local anesthesia and the patient is only lightly sedated. The psychologist who performed the preoperative evaluation and screening is in the operating room to help keep the patient distracted and relaxed. It is essential that the patient be awake during the placement and testing of the leads in order to provide feedback concerning which areas are being stimulated. After preparing the operative area in the usual sterile manner, imaging is used to identify the spinal levels. At the T12 or L1 level the skin is anesthetized and a stab wound is made midline or slightly off-midline depending on the location of the patient's symptoms. A Touhy nee-

dle is progressed caudally into the epidural space. A lead is introduced and progressed into the thoracic region. Imaging is used to check the position of the lead. Trial stimulation is initiated after the lead is introduced. Various stimulation settings are used, with the patient providing feedback for each concerning how well coverage is being achieved in the target symptomatic regions. Also, any stimulation in undesirable regions, such as into the chest or abdomen, is noted. The lead may be repositioned to gain optimal coverage. If coverage of all target symptomatic regions cannot be achieved with one lead, a second lead can be introduced and the trial continued. After satisfactory coverage is achieved with no undesirable stimulation, the trial is over. The extension wires to the leads are brought through the skin at a location away from the implant site. These wires are connected to an external screening unit that powers the leads. The patient then uses the device for a period of several days to determine the degree of pain relief during daily activities. Typically, the system is implanted if the patient achieves 50% or greater pain relief during this trial period. Spinal cord stimulation had an advantage over many procedures in that it can be undertaken in steps and is reversible. That is, if the patient fails the trial period, there is no procedure to implant the battery or internal receiver. The percutaneously placed leads are easily removed.

It should be noted that there are two primarily types of SCS systems. One is totally implantable, including the battery. The other has a receiver that is implanted and is powered by a radiofrequency transmitter that is powered by a common 9-volt battery worn externally. With either system, the patient has a programming unit that can be used to turn the device on and off and to change the intensity of the stimulation.

### REPORTED RESULTS

In one of the older studies involving FBSS patients that was published in 1975, Long and Erickson reported that 29% of patients had a good result (4). They noted that they changed their patient selection criteria based on their experience. Initially they had used SCS in some patients with poor psychological profiles. They also noted that another reason for some patients having poor results was that coverage was not achieved in their symptomatic areas. This is related to the fact that the system was implanted while the patient was anesthetized. During SCS it is important that the patient be awake and be able to provide feedback concerning coverage of the stimulation with regard to the painful body regions. This is the only way to optimize the lead placement for pain relief. Although the overall results were not impressive, the authors noted that some patients had remarkable pain relief from the SCS.

Racz et al. reported on their experience with SCS in a group of 26 patients with chronic pain following multiple

prior spine interventions (5). The follow-up was 21.2 months. The results were encouraging with 68% of patients having good to excellent pain relief, 84% reduced or eliminated narcotic use, and 72% with lifestyle improvement. In the early 1990s the results of two studies, each with 23 patients, were published (6,7). Both studies reported good or good to excellent results in 74% of patients. The study by LeDoux and Langford also noted a reduction in narcotics use (7).

North et al. reported the long-term follow-up, averaging 7.1 years, in a group of 171 patients (8). With regard to results, 52% of patients reported 50% or greater pain relief and 60% indicated that they would undergo the procedure again for the same result. Although this study had the strength of involving a large number of patients and a long follow-up, it did include a mix of stimulator types used over the long period needed to accumulate such a large number of patients.

In 1996, two prospective studies on SCS were published (9,10). Burchiel et al. reported a 1-year follow-up on 70 patients enrolled in a multicenter study (9). They found that 56% of patients had 50% or greater pain relief. They noted there was no significant change in medication use. In a prospective study involving a group of 40 FBSS patients who underwent SCS for primary complaints of the lower extremity, both functional testing and questionnaires were used to assess outcome at various time periods up to 24 months (10). There was a significant improvement in pain as assessed by Visual Analogue Scales (VAS). However, 50% or greater pain relief was noted in 53% of patients at 6 months and in only 26% of patients at the longer follow-up periods. At 12- and 24-month follow-up, at least 65.6% of patients had reduced or eliminated narcotic use. Bilateral isometric extremity function was assessed. Significant functional improvement was noted at 6 weeks and remained improved throughout the 24-month study period. A worse case analysis was performed in which a negative response was assigned for any patients lost to follow-up. With this method, 70% of patients indicated that the procedure had helped them and they would recommend it to someone with similar problems.

North et al. collected follow-up data on a group of 45 patients who underwent SCS for FBSS (11). The mean follow-up was 5 years. Success was defined as 50% or greater pain relief and the patient indicated that he or she would undergo the procedure again for the same result. At a mean follow-up of 2 years, 53% of patients had a successful result. At the mean follow-up of 5 years, 47% of patients were classified as a success. At both follow-up periods, another 7% of patients experienced 50% or greater pain relief, but would not undergo the procedure again. At follow-up the majority of patients were not taking analgesics. Before SCS, 74% of patients were taking narcotic medication. After SCS this figure reduced to 12%, and one half of these patients were using a reduced dosage.

In 1995, Turner et al. published the results of a review on the use of SCS for FBSS (12). They found that when synthesizing the data from the various studies, 59% of patients experienced 50% or greater pain relief and 75% received 50% or greater relief of leg pain.

For many years SCS was used in FBSS patients with no other operative option. Patients with diagnoses such as symptomatic pseudoarthrosis, recurrent disc herniation, and so on, were not generally considered for SCS. North et al. reported the results of a prospective randomized study comparing SCS to conventional reoperation (13). Patients had what was described as "surgically remediable disease." The study excluded patients with neural compression, primary complaints of back pain, and those with significant psychological problems. At 6 months follow-up, patients were allowed to decide if they wanted to cross over to receive the unassigned treatment. Twenty-seven patients reached the 6-month follow-up. Two of 12 patients (17%) in the SCS group chose to cross over to traditional reoperation. Among the 15 patients who underwent reoperation after being assigned to that group, 10 patients (67%) opted to cross over and undergo SCS. These studies support that SCS may be a viable treatment alternative in patients who may otherwise undergo much more invasive surgery.

### Arachnoiditis

Arachnoiditis is difficult to treat. A few studies have focused on the use of SCS for its treatment and have reported favorable results (14–17). In 1982, Siegfried et al. reported on a series of 191 patients with this condition who underwent a trial for SCS (17). Eighty-nine patients passed the trial stimulation and progressed to implantation of the system. At 1-year follow-up, 71% of patients had a successful outcome. This figure decreased to 61% at 4- to 8-year follow-up. However, considering the difficult population being addressed and the long follow-up duration, these results are quite good. The authors noted that the results were decreased among patients with significant psychological problems. A year later another study dealing with SCS specifically for the treatment of arachnoiditis was published (14). Their study involved 38 patients with a mean of 3.5 previous surgeries. The mean follow-up was 38.5 months. There was a 60% improvement in pain, and 40% of patients substantially reduced their use of pain medication. In 1995 Fiume et al. reported on a group of 36 patients who underwent SCS for pain related to arachnoiditis (15). They reported that 56% of patients had 50% or greater pain relief a mean of 55 months after the SCS surgery. They noted that the results were better in female patients and those who had primarily radicular, rather than axial pain.

Probst reported good results from SCS for pain related to epi-/intradural fibrosis in a group of 112 patients with a mean follow-up of 54 months (16). He reported that

patients in whom the electrodes were implanted epidurally had a better outcome than did patients in whom the electrodes were placed endodurally (67% versus 45%). Analgesic use was reduced or eliminated in 40% of patients.

### Case Report

Presented here is a case report of a 36-year-old man who had worked in his family's iron-working business since a young age. He first underwent a discectomy at age 16. In his twenties, he reinjured his back and eventually underwent a series of lumbar surgeries including a repeat discectomy combined with a Harrington rod fusion from L3-4 to the sacrum. The rods were later removed and this was followed by an infection requiring débridement. He was able to work only sporadically during these years because of pain. Upon presentation to our clinic the patient reported back pain rated as 10 of 10 in intensity and equally severe leg pain. He was obese at 5'8" tall and 250 pounds. The patient was also a two-pack-a-day smoker. He had been disabled from work for the previous 3 years. As seen in Figure 96-1, the patient had severe arachnoiditis. The patient underwent SCS implantation. He reported being significantly improved at his 2-week postoperative follow-up office appointment. At his most recent office visit, approximately 4 years after SCS implantation, his ambulation improved and he had lost more than 40 pounds. With regard to activity, the patient reported that he had been able to go on a vacation with his

family and that he had returned to full-time employment in the iron-working business. The patient is still using some analgesic medication. There was one reoperation to replace his depleted battery.

### Low Back Pain

Among FBSS patients, SCS was traditionally indicated for patients with primary complaints of leg pain. With the development of dual lead systems, the indications for SCS expanded to include patients with primary complaints of back pain as well. There have been two studies published recently that dealt specifically with patients having primarily complaints of low back pain. Ohnmeiss and Rashbaum published the results in a group of 41 patients, 38 of whom were diagnosed with FBSS (3). The length of follow-up ranged from 5.5 to 19 months. A negative response to a patient follow-up questionnaire was assigned for the four patients who had the device removed. Also, a worst-case analysis was performed in which a negative response was assigned for patients lost to follow-up or who elected not to respond to a question. At follow-up (the number in parentheses is the worst-case analysis figure), patient responses to questionnaires indicates that 79% (72%) of patients would recommend the treatment, 70% (58%) were satisfied, 76% (69%) would do it again, and 60% considered themselves improved.

Barolat et al. reported on a group of 41 patients in whom SCS was used to treat chronic back pain (18). The authors reported excellent results at 1 year, with 88% of

**FIG. 96-1.** Myelogram (A) and axial myelogram-computed tomography (B) showing severe arachnoiditis.

patients having excellent relief of leg pain, 69% excellent relief of back pain, and 88% satisfaction with their outcome. However, results of this study must be read with caution. The 12-month follow-up included only 17 of the original 41 patients. Patients in whom the device was removed, who were lost to follow-up, or who were removed from the study for unexplained reasons, were not included in the 12-month data. It is likely that at least some of these patients had a poor outcome that was not reflected in the reported results.

### Factors Related to Outcome

Burchiel et al. investigated possible prognostic factors for SCS treatment outcome in a group of primarily FBSS patients (19). They found that the best prognostic factors with regard to change in the VAS scales were patient age and the depression score on the MMPI. Factors not related to outcome were gender, educational level, pain location, compensation, pain duration, Oswestry scores, Beck Depression Inventory, McGill Pain Questionnaire, Sickness Impact Profile, and the other scales of the MMPI. However, the stepwise linear regression analysis that was used to generate the predictive equation included the depression scale, age, and the McGill Pain Questionnaire. The analysis revealed that 54% of variation in the preoperative to postoperative VAS could be explained by these three variables. One significant drawback to this study was the inclusion of only 34 patients with a 3-month follow-up. With so few patients, prognostic factors are difficult to evaluate. However, this study indicates that more work involving a larger number of patients is warranted.

### COMPLICATIONS

This review of complications is limited to newer SCS devices and to those studies dealing specifically with FBSS or back pain patients. Complications of SCS are not infrequent, but fortunately they are generally not serious. North et al. reported on complications in a series of patients with a mean 7.1-year follow-up (8). Clinical data were available for 171 patients, and 298 patients were available for analysis of device-related problems. They reported no cases of spinal cord injury, bacterial meningitis, or life-threatening infection. There was a 5% rate of wound infections. These were all treated successfully by removal of the SCS system and a course of antibiotics. After the infection was addressed, the SCS unit was reimplanted. The authors reported that electrode and lead assembly failed because of fatigue fracture of the conductors or insulation failure occurred in 7% of cases. The radiofrequency receiver failed in 5% of systems. The authors did not provide the number of patients who underwent reoperation for revision of migrated leads.

In the review of SCS literature, Turner reported that across multiple studies, on average 42% of patients had a

complication, ranging from 20% to 75% (12). Infection occurred in 5% of patients, and what was termed a biological complication other than infection was reported in 9% of patients. Thirty percent of patients had a stimulator complication, ranging from 0% to 75% in the various studies. Problems with the electrodes were noted in 24% of patients, problems with the lead wires occurred in 7%, and 2% of patients had a problem with the pulse generator. The authors noted that although the complication rate was rather high at 42%, the complications were minor and few if any resulted in permanent neurologic damage or death. It should be noted that the review included studies dating back to the 1970s and included a variety of devices.

In more recent studies, the most frequently occurring complication related to SCS is migration of the lead(s) requiring reoperation (3,7,10). This has been reported in up to 43% of patients in various studies (7). Lead migration typically presents as patients who have done well suddenly report that they no longer have coverage in their painful regions. One can take radiographs to compare the current location of the leads to that seen on earlier radiographs. One can try reprogramming the leads to restore coverage. If this does not adequately address the problem, the patient is scheduled for a procedure to reposition the leads. Hopefully, with new developments in the technology, an anchoring system is incorporated into the design that reduces the problem with lead migration, without increasing the risk of injury to the dura or nerve roots.

Several studies have reported that about 10% of patients have the SCS system removed because it has ceased to provide them relief (3,10,19,20). Another study reported a greater rate of removal, at 26% of patients (7). Another problem noted early in a series of patients was the need to relocate the stimulator to a more comfortable position after initially placing it under the patient's belt line (10). In another study the authors reported a 17% incidence of patients reported pain at the receiver implant site (7). A few other miscellaneous complications have been reported, including unpleasant sensations at the lead or generator (5.7%), shorting-out (2.8%), muscle spasm (1.4%), urinary hesitancy (1.4%), and lead fracture (1.4%) (9).

### POSTOPERATIVE REHABILITATION

Spinal cord stimulation patients are typically a group who have experienced pain for many months and in most cases several years. During that time, many have undergone and failed surgical intervention. Because of pain, they have significantly reduced their activity level and are typically deconditioned. These patients need to be encouraged to initiate an exercise program. The patients need to start slowly with activities and gently progress. They need to be aware that there may well be a flare up in pain particular related to increased activity. When this

occurs, simply reduce activities for a brief time and then more gradually progress.

## DISCUSSION

Patients who have failed to gain acceptable pain relief, or who report new severe pain following spine surgery represent a difficult to treat patient population. In patient with well-defined pain origins such as pseudoarthrosis, neural compression, recurrent disc herniation, adjacent segment breakdown, or instability, further traditional surgery may be indicated and many surgeons are comfortable addressing these problems. However, patients in whom pain is related to arachnoiditis, scarring around the nerve roots, or in whom the source of symptoms is not well defined represent a very difficult to treat population. In either group of FBSS patients, one must be acutely aware of the potential for psychological problems in this group of patients. This may be part of the reason for the initial failed surgery or may have developed after failing one or more surgeries.

In the early use of SCS, there was a tendency to use it in patients for whom no other treatment option was available. As discussed, some of the early reported results for SCS were likely compromised because patients were included who were poor psychological risks for an operative intervention. As with spine surgery in chronic pain patients in general, there has been a growing appreciation for the importance of psychological screening for SCS patients. Also, results of some of these earlier studies were compromised because the leads were placed with the patient anesthetized. Unless the patient is awake, there is no way to determine if the lead is positioned to provide optimal pain relief.

In recent years, several studies have indicated that the role of SCS is expanding in the treatment of FBSS patients. Traditionally, it was reserved for patients with primary complaints of lower extremity pain and for those who were not considered candidates for traditional spine surgery intervention. Advances in stimulator technology have now broadened the use for FBSS patients with primary complaints of low back pain rather than axial pain. Two recent studies have reported good results for this application (3,18). Based on the randomized study by North et al., it appears that SCS is a viable alternative to traditional reoperation in FBSS patients (13). More studies on this application are warranted. Spinal cord stimulation may provide a treatment to allow patients to avoid more invasive traditional intervention and may be a viable option for patients who are otherwise poor operative candidates owing to general health problems. However, as with other spine surgery procedures, one should not pursue using SCS simply because the surgeon feels obligated to do something.

Surgeons and patients must understand that the treatment of SCS patients is an ongoing process. The leads

may need to be repositioned, the system may need reprogramming, implanted batteries need to be replaced, there may be fluctuation in pain that needs attention, and pain medication needs to be refilled.

As with many spine surgery procedures, the reported results of SCS vary. Overall, the results of SCS have been good, particularly considering the population being treated. Several studies defined success as 50% or greater pain relief. This is a more stringent criterion than used in many studies dealing with other forms of operative intervention for back pain. In the study by Ohnmeiss et al. (10) based on the VAS, only 26% of patients met this rigid criterion at the 24-month follow-up. However, even in the worst-case analysis 70% of patients reported benefit from the procedure and would have it again for the same result. Also in that study, patients reduced narcotic use and significantly improved lower extremity function and maintained these improvements throughout the 24-month follow-up period.

As seen in this review of some of the SCS literature, the results generally have improved over time. This is likely because of improvements in the technology, better definition of selection criteria, and improved operative technique using fluoroscopic imaging to check lead placement and performing the procedure with the patient awake and able to provide feedback concerning pain relief with various lead placements and device settings. The development of SCS technology will continue. The primary problem with SCS systems is migration of the leads. Hopefully, new developments in the design of the leads will address this problem. Based on the literature, it appears that the role of SCS is increasing to include patients with primary complaints of back pain. Of importance, based on the work of North et al., SCS appears to have a role in a broad spectrum of FBSS patients. Further investigation is needed to confirm its efficacious role in FBSS rather than performing traditional surgery. Spinal cord stimulation can be an effective treatment for many patients with chronic pain. However, physicians using this treatment must be carefully trained in patient selection, operative technique, and dealing with the long-term treatment of these chronic pain patients.
