for the Study of the Lumbar Spine*

# The Lumbar Spine

## Third Edition

*Official Publication of the International Society  
for the Study of the Lumbar Spine*

Edited by

**Harry N. Herkowitz, M.D.**

*Chairman  
Department of Orthopaedic Surgery  
William Beaumont Hospital  
Royal Oak, Michigan*

**Jiri Dvorak, M.D.**

*Professor  
Department of Neurology  
University of Zurich  
Chief  
Department of Neurology, Spine Unit  
Schulthess Clinic  
Zurich, Switzerland*

**Gordon R. Bell, M.D.**

*Vice-Chairman  
Cleveland Clinic Spine Institute  
Vice-Chairman  
Department of Orthopaedic Surgery  
Cleveland Clinic Foundation  
Cleveland, Ohio*

**Margareta Nordin, Dr.Sci., P.T., C.I.E.**

*Research Professor and Director  
Program of Ergonomics and Biomechanics  
Departments of Orthopaedics and Environmental  
Medicine  
New York University School of Medicine  
Director  
Occupational and Industrial Orthopaedic Center  
(OIOC)  
Hospital for Joint Diseases  
Mount Sinai-NYU Health  
New York, New York*

**Dieter Grob, M.D.**

*Professor  
Department of Orthopedics  
University of Zurich  
Chief  
Department of Orthopedics, Spine Unit  
Schulthess Hospital  
Zurich, Switzerland*

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

The International Society for the Study of the Lumbar Spine (ISSLS) is a unique organization. Its membership includes representatives from all the continents who come together yearly to discuss their unique perspectives on all facets of lumbar disease. It is an organization that thrives on discussion and whose members have dedicated their professional lives to advancing the knowledge of spine disease so that people may live active and productive lives. Many of the membership, past and present, were and are “household names” in the spine world who, through their research and teaching, have made significant contributions to our understanding of the spine. Many others who are not “household names” have also contributed to advancing our knowledge through their active participation in the society. This third edition of the ISSLS textbook is dedicated to the following members who have passed on; each of them has contributed through their research, teaching, and discussion that are reflected in the pages of this third edition: Alf Breig, Alexander Brodsky, John Bromley, Ralph Cloward, Stephan Dorhring, George Dommissee, Alan Dwyer, George Ehni, Harry Farfan, Harry Fahrni, William Fielding, Edward Froning, Jacob Graham, Beckett Howorth, Carlyle Hudson, Shunichi Inoue, Bernard Jacobs, Rae Jacobs, Henry LaRocca, Bruno Lassale, Ian MacNab, John McCulloch, James Morris, Philip Newmann, William Park, Homer Pheasant, Frank Raney, Lester Russin, Antonio Martino, David Selby, Lyman Smith, Arthur Thibodeau, Henk Verbiest, Henrik Weber, Thomas Whitecloud.

The Editorial Board on behalf of the ISSLS membership

Contributing Authors .....	xiii
Preface .....	xxv
Acknowledgments .....	xxvii

## SECTION I. BASIC SCIENCE

<b>1</b> Epidemiology and the Economics of Low Back Pain .....	3
<i>Alf Nachemson</i>	
<b>2</b> Pathophysiology of Nerve Root Pain in Disc Herniation and Spinal Stenosis .....	11
<i>Kjell Olmarker, Robert R. Myers, Shinichi Kikuchi, and Björn Rydevik</i>	
<b>3</b> Biomechanical Considerations of Disc Degeneration .....	31
<i>Allison M. Kaigle Holm and Sten H. Holm</i>	
<b>4</b> Morphologic Changes of End Plates in Degenerative Disc Disease .....	46
<i>Robert J. Moore</i>	
<b>5</b> Clinical Spinal Instability Resulting from Injury and Degeneration .....	51
<i>Manohar M. Panjabi, Vijay K. Goel, Allison M. Kaigle Holm, and Malcolm H. Pope</i>	
<b>6</b> Spinal Instrumentation .....	59
<i>Vijay K. Goel, Manohar M. Panjabi, Hiroshi Kuroki, Setti S. Rengachary, D. McGowan, and N. Ebraheim</i>	
<b>7</b> Fracture and Repair of Lumbar Vertebrae .....	85
<i>Tony S. Keller, Victor Kosmopoulos, and Thomas Steffen</i>	
<b>8</b> Genetic Transmission of Common Spinal Disorders .....	98
<i>Michele C. Battié and Tapio Videman</i>	
<b>9</b> Genetic Applications to Lumbar Disc Disease .....	107
<i>Christian Lattermann, Lars G. Gilbertson, and James D. Kang</i>	
<b>10</b> Clinical Neurophysiologic and Electrodiagnostic Testing in Disorders of the Lumbar Spine .....	113
<i>Jiri Dvorak and Scott Haldeman</i>	
<b>11</b> Sensorimotor Control of the Lumbar Spine .....	120
<i>Sten H. Holm and Aage Indahl</i>	
<i>Outcomes Assessment</i>	
<b>12</b> Outcome Assessment: Overview and Specific Tools .....	132
<i>Kevin F. Spratt</i>	

- 13** The Role of Outcomes and How to Integrate Them into Your Practice . . . . . 139  
*Richard A. Deyo*

## SECTION II. ALTERNATIVES TO TRADITIONAL NONOPERATIVE TREATMENT

- 14** Manual Therapy in Patients with Low Back Pain . . . . . 151  
*Jiri Dvorak, Scott Haldeman, and Wolfgang Gilliar*
- 15** Acupuncture and Reflexology . . . . . 158  
*Marianne L. Magnusson and Malcolm H. Pope*

## SECTION III. THE INJURED WORKER

- 16** Returning Workers to Gainful Employment . . . . . 167  
*Margareta Nordin*
- 17** Occupational Ergonomics . . . . . 178  
*William S. Marras*

## SECTION IV. SURGERY

- 18** Preparation for Surgery . . . . . 201  
*Orso L. Osti, Simon Macklin, and Hiroaki Nakamura*

### *Surgical Approaches*

- 19** Surgical Approaches to the Thoracolumbar Spine . . . . . 210  
*Scott D. Daffner and Todd J. Albert*
- 20** Surgical Approaches to the Lumbar Spine: Anterior and Posterior . . . . . 219  
*Anthony P. Dwyer*
- 21** Posterior and Anterior Surgical Approaches to the Lumbosacral Junction . . . . . 228  
*Peter A. Robertson*
- 22** Endoscopic Anterior Lumbar Procedures . . . . . 235  
*Ensor E. Transfeldt and John N. Graber*

### *Bone Graft*

- 23** Biology of Bone Grafting: Autograft and Allograft . . . . . 247  
*Robert Gunzburg and Marek Szpalski*
- 24** Bone Graft Substitutes in Spinal Surgery . . . . . 255  
*Anis O. Mekhail and Gordon R. Bell*

### *Spinal Instrumentation Overview in Lumbar Degenerative Disorders*

- 25** Principles of Spinal Instrumentation in Degenerative Disorders  
of the Lumbar Spine . . . . . 268  
*Ashok Biyani and Howard S. An*
- 26** Spinal Instrumentation Overview in Lumbar Degenerative Disorders: Cages . . . . . 286  
*Kenneth M.C. Cheung and John C.Y. Leong*
- 27** Translaminar Screw Fixation . . . . . 292  
*Dieter Grob*

## SECTION V. SPECIFIC CLINICAL ENTITIES

*Lumbar Disc Disorders*

- 28** Lumbar Disc Disorders ..... 299  
*Mats Grönblad*

*Operative Treatment—Disc Degeneration*

- 29** Facet Joint Denervation: A Minimally Invasive Treatment for Low Back Pain  
in Selected Patients ..... 307  
*David J. Hall*
- 30** Intradiscal Electrothermal Therapy ..... 312  
*Jeffrey A. Saal and Joel S. Saal*
- 31** Operative Management of the Degenerative Disc: Posterior and  
Posterolateral Procedures ..... 317  
*Gunnar B.J. Andersson and Francis H. Shen*
- 32** Posterior Lumbar Interbody Fusion ..... 324  
*Casey K. Lee and Kenneth J. Kopacz*
- 33** Operative Treatment of Anterior Procedures ..... 331  
*Kambiz Hannani and Rick Delamarter*
- 34** Operative Treatment of Anterior and Posterior Fusion ..... 338  
*Björn Strömqvist*
- 35** Degenerative Disc Disease: Fusion Cages and Dowels ..... 342  
*Richard D. Guyer and Donna D. Ohnmeiss*
- 36** Minimally Invasive Procedures for Anterior Column Fusion and Reconstruction ... 352  
*H. Michael Mayer*
- 37** Degenerative Disc Disease: Complications of Surgery ..... 360  
*Scott L. Blumenthal and Donna D. Ohnmeiss*
- 38** Dynamic Stabilization in the Treatment of Low Back Pain  
Due to Degenerative Disorders ..... 373  
*Dilip K. Sengupta*

*Artificial Disc*

- 39** Lumbar Artificial Disc Replacement: Rationale and Biomechanics ..... 384  
*Geoffrey M. McCullen and Hansen A. Yuan*
- 40** Lumbar Disc Replacement: Current Model, Results, and the Future ..... 393  
*Robert D. Fraser*

*Disc Herniation*

- 41** Disc Herniation: Definition and Types ..... 399  
*Tom Bendix*
- 42** Disc Herniation: Imaging ..... 407  
*Josef Assheuer and Klaus-Peter Schulitz*
- 43** Disc Herniation: Nonoperative Treatment ..... 427  
*Kevin P. Singer and Peter J. Fazey*

<b>44</b>	Operative Treatment of Disc Herniation: Natural History and Indications for Surgery <i>Charles G. Greenough</i>	437
<b>45</b>	Operative Treatment of Disc Herniation: Laminotomy . . . . . <i>Charles G. Greenough</i>	443
<b>46</b>	Chymopapain and Chemonucleolysis . . . . . <i>Jeremy Fairbank</i>	447
<b>47</b>	Microscopic Lumbar Discectomy . . . . . <i>Robert Kraemer, Alexander Wild, Holger Haak, Joerg Herdmann, and Juergen Kraemer</i>	453
<i>Spinal Stenosis Without Deformity</i>		
<b>48</b>	Classification, Natural History, and Clinical Evaluation . . . . . <i>Yong Hai</i>	464
<b>49</b>	Imaging of Spinal Stenosis and Degenerative Lumbar Spondylolisthesis with Stenosis <i>Donald L. Renfrew and and Kenneth B. Heithoff</i>	472
<b>50</b>	Spinal Stenosis Without Deformity: Nonoperative Treatment . . . . . <i>Arto Herno</i>	490
<b>51</b>	Indications for Surgery and Laminotomy Procedures . . . . . <i>Franco Postacchini</i>	495
<b>52</b>	Laminectomy for Spinal Stenosis . . . . . <i>Brian J.C. Freeman</i>	501
<b>53</b>	Laminoplasty . . . . . <i>Yoshiharu Kawaguchi and Masahiko Kanamori</i>	509
<i>Degenerative Lumbar Spondylolisthesis with Stenosis</i>		
<b>54</b>	Degenerative Lumbar Spondylolisthesis with Spinal Stenosis: Natural History, Diagnosis, Clinical Presentation, and Nonoperative Treatment . . . . . <i>Mohamed Mostafa Mossaad</i>	514
<b>55</b>	Decompression . . . . . <i>Bo Jönsson</i>	524
<b>56</b>	Decompression with Posterolateral Fusion . . . . . <i>Gianluca Cinotti</i>	528
<b>57</b>	Anterior Lumbar Interbody Fusion . . . . . <i>Mamoru Kawakami and Tetsuya Tamaki</i>	535
<b>58</b>	Decompression with Instrumented Fusion . . . . . <i>Dilip K. Sengupta and Harry N. Herkowitz</i>	540
<i>Spinal Stenosis with Sagittal or Coronal Deformity</i>		
<b>59</b>	Degenerative Lumbar Spinal Stenosis with Scoliosis-Kyphosis: Surgical Techniques, Results, and Complications . . . . . <i>Hirokazu Ishihara and Hisao Matsui</i>	547
<i>Nondegenerative Spondylolisthesis</i>		
<b>60</b>	Nondegenerative Spondylolisthesis: Epidemiology and Natural History, Classification, History and Physical Examination, and Nonoperative Treatment of Adults . . . . . <i>James Rainville</i>	556

<b>61</b> Imaging in the Evaluation of Lumbar and Lumbosacral Spondylolysis and Spondylolisthesis . . . . .	565
<i>Stephen L. Gabriel Rothman and Leon L. Wiltse</i>	
<b>62</b> Evaluation and Management of the Athlete with “Pars Fracture” . . . . .	579
<i>Robert Watkins III and Robert G. Watkins IV</i>	
<b>63</b> Indications for Surgery in Spondylolysis and Spondylolisthesis in Adults and Surgery for Low-Grade Spondylolisthesis . . . . .	585
<i>Dahari D. Brooks and Bruce E. Fredrickson</i>	
<b>64</b> Surgery for High-Grade Spondylolisthesis . . . . .	591
<i>Marek Szpalski and Robert Gunzburg</i>	
<b>65</b> High-Grade Spondylolisthesis: Slip Reduction versus <i>in situ</i> Fusion . . . . .	598
<i>William C. Lauerma and Steven C. Scherping</i>	
<i>Deformity (Lumbo/Lumbosacral) Adult</i>	
<b>66</b> Adult Scoliosis . . . . .	604
<i>Yizhar Floman</i>	
<b>67</b> Adult Scoliosis: Indications for Surgery . . . . .	614
<i>James A. Antinnes and Serena S. Hu</i>	
<b>68</b> The Surgical Treatment of Sagittal Plane Deformity . . . . .	628
<i>Thomas J. Errico, Orin Atlas, and Juan Carlos Rodriguez Olaverri</i>	
<b>69</b> Spinopelvic Fixation . . . . .	636
<i>Joseph Y. Margulies and William O. Shaffer</i>	
<b>70</b> Paget Disease of the Spine and Its Management . . . . .	647
<i>Alexander G. Hadjipavlou, Ioannis N. Gaitanis, Pavlos G. Katonis, Michael N. Tzermiadianos, and George M. Tsoukas</i>	
<i>Osteopenia</i>	
<b>71</b> Osteopenia: Basic Science, Magnitude of the Problem, Classification, Clinical Presentation, and Medical Therapy . . . . .	663
<i>Charles W. Cha and Scott D. Boden</i>	
<b>72</b> Surgical Options and Indications: Kyphoplasty and Vertebroplasty . . . . .	672
<i>Christopher M. Bono, Christopher P. Kauffman, and Steven R. Garfin</i>	
<b>73</b> Osteopenia: Vertebrectomy and Fusion . . . . .	683
<i>Manabu Ito and Kiyoshi Kaneda</i>	
<i>Inflammatory Arthritides</i>	
<b>74</b> Inflammatory Spondyloarthropathies . . . . .	690
<i>Philippe Goupille and David Borenstein</i>	
<b>75</b> Psoriatic Arthritis . . . . .	702
<i>Philippe Goupille and David Borenstein</i>	
<i>Ankylosing Spondylitis</i>	
<b>76</b> Ankylosing Spondylitis: Nonoperative Treatment . . . . .	712
<i>Federico Balagué and Jean Dudler</i>	
<b>77</b> Ankylosing Spondylitis: Operative Treatment . . . . .	727
<i>Edward H. Simmons, Edward D. Simmons, and Yinggang Zheng</i>	

*Infection*

- 78** Pyogenic and Fungal Lumbar Spine Infections ..... 739  
*Matthew J. Geck and Frank J. Eismont*
- 79** Tuberculosis ..... 755  
*S. Rajasekaran*
- 80** Postoperative Lumbar Spine Infections ..... 769  
*Eric C. Chamberlin and Edward N. Hanley, Jr.*

*Tumor*

- 81** Primary Spine Tumors ..... 775  
*Edward D. Simmons and Yinggang Zheng*
- 82** Metastatic Spine Tumors ..... 792  
*Stanley D. Gertzbein*
- 83** Lumbar Spine Tumors: Posterior Approach ..... 803  
*K. Anthony Kim, Babak Kateb, Peter Dyck, and Srinath Samudrala*
- 84** Anterior Procedures ..... 812  
*Mark A. Knaub, Douglas S. Won and Harry N. Herkowitz*
- 85** Combined Anterior-Posterior Procedures ..... 824  
*Osamu Shirado, Naoki Takeda, Akio Minami, and Kiyoshi Kaneda*
- 86** Prognosis and Results of Surgery for Primary and Metastatic Tumors ..... 833  
*Jonathan N. Grauer and Alan S. Hilibrand*

*Failed Surgery/Revision Surgery*

- 87** Determining Reasons for Failed Surgery ..... 839  
*Christopher S. Raffo and Sam W. Wiesel*
- 88** Failed Back Surgery Syndrome: Nonoperative Interventional Management Options ..... 848  
*Richard Derby and Connor W. O'Neill*
- 89** Psychological Approaches to the Management of Failed Surgery and  
Revision Surgery ..... 859  
*Robert J. Gatchel and Chris J. Main*
- 90** Surgical Treatment of Symptomatic Recurrent Disc Herniation ..... 867  
*Ragnar Johnsson*
- 91** Management of Failed Lumbar Surgery: Recurrent Stenosis ..... 871  
*Jayesh M. Trivedi and Stephen Eisenstein*
- 92** Failed Surgery and Revision Surgery: Failed Instrumentation ..... 877  
*Frank M. Phillips*
- 93** Management of Failed Surgery: Adjacent Segment to Fusion ..... 884  
*Thomas S. Whitecloud III and Paul Pagano*
- 94** Lumbar Pseudoarthrosis ..... 890  
*S. Govender*
- 95** Management of Failed Surgery: Posttraumatic Spinal Deformity ..... 897  
*Jeff S. Silber and Alexander R. Vaccaro*
- 96** Treatment of the Failed Back Patient: Spinal Cord Stimulation ..... 905  
*Donna D. Ohnmeiss and Ralph F. Rashbaum*

- Subject Index ..... 913

Simmons Orthopaedic and Spine Associates  
Buffalo, New York*

# Preface

---

---

This third edition of the International Society for the Study of the Lumbar Spine textbook represents a complete revision of the prior edition. A significant amount of new information is included— from the basic science of spine disease to surgical management of lumbar disorders. The members of this society who have contributed their excellent work are also the ones whose research has led to the many advances in the care and management of spinal disorders. This is an inclusive textbook emphasizing the basic science behind the clinical problems we face on a daily basis; it is comprehensive and covers all facets of the diseases that affect the lumbar spine. We are grateful to all the members of this society who have contributed chapters in order to make this the authoritative textbook on the lumbar spine.

This book is intended for all physicians and allied personnel who care for patients with low-back disorders. Hopefully, it will answer all the questions that the reader has to better understand the etiology, pathophysiology, clinical diagnosis, and management of lumbar disease.

*Harry N. Herkowitz, M.D.*

*Jiri Dvorak, M.D.*

*Gordon R. Bell, M.D.*

*Margareta Nordin, Dr.Sci., P.T., C.I.E.*

*Dieter Grob, M.D.*

# Acknowledgments

---

---

No textbook makes it to press without the dedication of those behind the scenes. The International Society for the Study of the Lumbar Spine (ISSLS) textbook is no different.

First, I would like to acknowledge Shirley Fitzgerald, our administrator, friend, and the one person who keeps ISSLS on track making sure the business of the society is dealt with in a timely fashion. Many of us have “grown up with her” over the years and her dedication to the well-being of the society cannot be overstated. She is a unique individual who we are lucky to have in ISSLS.

Second, each Editorial Board member has his/her administrative assistant who helps organize the paperwork, correspondence, and chapter reviews. We would like to thank Christine Musich, Susana Kuster, Katrin Knecht, Elisabeth Weiss, and Katherine Habler.

Without their dedication and organization, the fruition of this textbook would have been significantly delayed. We wish to thank each of you for your outstanding effort.

Finally, we are grateful to Robert Hurley, Kerry Barrett, and Karina Mikhli at Lippincott Williams & Wilkins and Ted Huff, the illustrator, for supporting our organization, for being so professional in putting this textbook together, and for seeing it through to publication.

**SECTION I**

---

**Basic Science**

## CHAPTER 1

# Epidemiology and the Economics of Low Back Pain

Alf Nachemson

---

Epidemiology is critical to understanding the scope of a problem and gives information about its magnitude and the demand on medical and social resources. It is extremely important in our industrialized societies and gives information on the natural history, important for patient counseling about prognosis. It can also identify risk factors, both individual and external, which is beyond the scope of this chapter. It is also of importance to demonstrate both the societal burden of the ailment and its severe consequences for the individual quality of life (1).

Most studies in the literature talk about *prevalence* which is the percentage of people in a known population who have the symptom during a specified period. Point prevalence is the percentage who has pain on the day of the interview. One-month or one-year prevalence is the percentage who has pain at sometime within the past month or the past year. Lifetime prevalence is the percentage who can remember pain at sometime in their life. *Incidence* is the percentage of people in a known population who develop new symptoms during a specified period of time. It is commonly applied to those who report injuries or present for health care within a specified period.

Most recent surveys define low back pain as pain occurring between the costal margins and the gluteal folds. Some surveys use a diagram to show pain areas.

Back pain has often been defined differently. Epidemiologic rates for “back symptoms,” “back disability,” or “health care for back pain” respectively can all differ dependent of study sample.

Another major limitation of defining back pain is that surveys depend entirely on individual’s own report of pain and disability, which is open to subjective bias, particularly when one is reporting from a disliked working environment. There may be recall bias: the longer ago the time of back pain is asked about, the more unreliable the

answer. People with more severe trouble may be more likely to include earlier information within the period of the question (2–4) and present pain when questioned increases recall of earlier periods (5). Official statistics may overcome this problem to provide more accurate data about work loss, health care use, sickness verification and benefits, but these usually give lower rates for each of these than self-reports from population surveys (6). For example, a Danish study showed that only 25% of those reporting lower back pain in the past month ever visited a health care practitioner and less than 5% received sickness benefits; i.e., collecting unemployment (7).

There may also be sampling bias. Many surveys study selected group(s) of workers or patients, who may not be representative of the general population.

Raspe (8), Shekelle (9), and Andersson (2) reviewed altogether several hundred epidemiologic studies of low back pain from North America, Great Britain and Europe, in particular the Scandinavian countries. Because many of the surveys do not ask comparable questions, they give different results. Thus, the definition of morbidity chosen for the survey is of importance for the resulting frequency of pain.

The best available evidence on the epidemiology of low back pain is from large, representative, population surveys (2,10–19). Most recent surveys have used similar wording for their questions, and many have asked about pain lasting more than 24 hours, to exclude minor or passing symptoms.

Many international surveys of low back pain report a point prevalence of 15% to 30%, a 1-month prevalence between 19% and 43%, and a lifetime prevalence of about 60% to 80%. The exact figures in different studies appear to depend mainly on the wording of the question rather than any difference in the people studied (Table 1-1). What is clear, however, are the similarities of prevalence at any age, from 10 to 90 years of age.

**TABLE 1-1.** *One-month back pain prevalence at different ages and in different countries*

Age (yr)	Country	Yes (%) <sup>a</sup>
10–15	Sweden	40
12–15	France	50
15–18	Switzerland, Finland	32
25–35	Sweden, Denmark, Great Britain	35
40–50	Great Britain, Germany, Sweden, Finland, Tibet	40
40–60	Austria	68
55–65	Great Britain, Holland	30
70–85	Sweden	45
85+	Sweden	40

<sup>a</sup>Percentage of individuals who responded “yes” to the question, “Have you had any low back pain in the last month?”

The Nuprin Pain Report (17) found that 56% of American adults said they had at least one day of back pain in the last year. Fourteen percent had pain for more than 30 days in the year. Back pain was the second most common pain after headache. Most back pain was mild and short-lived and had very little effect on daily life, but recurrences were common. The most recent larger population study from Canada reported 8% with significant back pain in a 6-month period (20).

Von Korff et al. (18) found that 41% of American adults between the ages of 26 and 44 years had back pain in the last 6 months. Most people had occasional short attacks of pain, but they reported that they had had these attacks over a long period. Their pain was usually mild or moderate and did not limit their activities.

Some British surveys give comparable figures; Mason (21) found point prevalence around 15%, 1-month prevalence of 40%, and lifetime prevalence of 60%. Walsh et al. (19), Mason (21), and Papageorgiou et al. (13) found an almost identical lifetime prevalence of 60%, the same as reported in Belgium (16). In Tibet rural population the point prevalence was 34% and 12-month prevalence was 42% (22).

Population surveys suggest that the age of onset of back pain is spread fairly evenly from the teens to the early 40s. It is uncommon to develop nonspecific low back pain for the first time after the mid-50s. However, several recent studies of children show a higher prevalence of back pain than previously realized (Table 1-1). Brattberg (23,24) carried out a longitudinal study of 471 schoolchildren aged 10, 13, and 15 years in the county of Gävleborg in Sweden. In each year's survey, about 26% of children said they had back pain, but only 9% of the children reported back pain in both surveys in 1989 and 1991. Burton et al. (25) prospectively studied 216 adolescents from 11 through 15 years of age. Only 12% of 11-year-olds said they had ever had back pain, but by age 15 this number rose to 50%. The back pain these children describe was usually recurrent but did not deteriorate

with time. Adolescents appear to have about the same prevalence of back pain as adults, but it is rarely disabling and few seek health care. Burton et al. (25) suggest that most adolescent back trouble should be considered a normal life experience and should not have undue significance attached to it. There is no evidence on whether it predicts low back trouble in adult life. The study by Hellsing (26) of 19-year-old conscripts suggests the same finding when they were followed up to 10 years later.

The General Survey on Living Conditions in Sweden (27) found that neck and back problems are among the most common causes of “chronic sickness.” About 3% to 5% of the population between the ages of 16 and 44 years and 11% to 12% of those between the ages of 45 and 64 years report back problems as a “chronic sickness.” For those between the ages of 65 and 84 years the frequency of back pain is somewhat reduced or 9% to 11%, although Brattberg (28,29) reported a higher prevalence of 45%. Back trouble is the most common cause of chronic sickness in both men and women under age 64 and the second most common cause of sickness for those between the ages of 65 and 74. Only circulatory system problems are more common among those in the 65+ age group. There is a slight increase over time of back pain in the general population according to the General Survey on Living Conditions (27). As an average for the population between 16 and 84 years (men and women), 6.5% reported back pain symptoms in 1985 compared to 8.0% in 1994. Linton et al. (30), in a study covering subjects living in the middle part of Sweden, but limited to subjects 35 to 45 years of age, found even higher prevalence figures, although these were probably dependent on how the questions were asked.

Other Scandinavian studies (3,31–33) have all described point prevalence of around 30%, 1-year prevalence of around 50%, and lifetime prevalence up to 80% or more.

The traditional clinical classification of back pain is acute, recurrent, and chronic, but recent epidemiologic studies show that back pain is usually a recurrent, intermittent, and episodic problem. Croft et al. (12,34) suggest that the most important epidemiologic concept, and also an important clinical concept, is the pattern of back pain over long periods of the individual's life, and that the experience of back pain may be better expressed as the total days of pain over 1 year. Von Korff et al. (18) also described this recurrent trait in back symptoms in the United States, as have others (35,36).

## WORK LOSS DUE TO BACK PAIN

It is difficult to get accurate information on the amount of work loss attributed to back pain. In many countries, including Sweden since 1991, the first 2 weeks of sick pay are paid by employers who hold the data individually and do not return any statistics to any central authority.

Social security data contain claims and benefits paid, which depend on entitlement. The recent monograph by Waddell et al. (37) goes to unsurpassed length to describe this. The back pain absenteeism from no less than 13 countries was compared, demonstrating differences as well as similarities. There is little, if any evidence to suggest any physical basis to the overall level of reported back pain or disability in any of the examined industrialized societies. Instead, cultural, societal, and economic factors seem to play a more important role. According to the Waddell report, "There is now extensive evidence that psychosocial factors are more important than any physical changes in the back for development and maintenance of chronic pain and disability" (37).

In the 1970s, Valkenburg and Haanen (38) conducted a study in Zoetermeer, Netherlands of 6,500 men and women 20 years of age and older and provided data as seen in Table 1-2. These authors performed a physical and X-ray examination that demonstrated increasing "degenerative" changes with age that were not directly related to disability. Many others have since supported these findings.

Andersson (2) found that back problems were the most common cause of activity limitation in adults under age 45 and the fourth most common in those between the ages of 45 to 64. Seven percent of adults reported a disability due to their back or due to both their back and other joint problems that limited their activities for an average of about 23 days each year. These figures suggest that 7% to 14% of U.S. adults have some disability due to back pain for a least 1 day each year, and just over 1% of Americans are permanently disabled by back pain and another 1% are temporarily disabled by back pain at any one time. These figures have been confirmed by Murphy and Volinn (39), with little observable change over the years studied.

Walsh et al. (19) conducted a population survey using clinical measures of low back disability based on eight activities of daily living. The 1-year prevalence of a disability score of 50% or more was 5.4% for men and 4.5% for women, while the lifetime prevalence was 16% and 13%, respectively. The 1-year prevalence of time off work because of back pain was 11% for men and 7% for women, while the lifetime prevalence was 34% and 23%, respectively.

**TABLE 1-2.** *Low back complaints and work disability in the Dutch city of Zoetermeer (38) in the 1970s*

	Men (%)	Relative (%)	Women (%)	Relative (%)
Point-prevalence	22.2		30.2	
Lifetime incidence	51.4		57.8	
>3 months	14.3	28	19.6	34
Unfit for work	24.3	47	19.5	34
Work change	4.2	8	2.4	4

The South Manchester Study (14) found that 8% of adults said they had bed rest for back pain at some time in the past 12 months. However, these figures are again self-reports about what people said they did about back pain, not the treatment they received.

The Clinical Standards Advisory Group (40) estimated that work loss due to back pain in the United Kingdom in 1993 was about 52 million days, while 106 million days' sickness and invalidity benefits were paid for back pain. However, there was only overlap of 7 million days between these two groups. Most of the workers who lost short periods of work were paid by their employers, did not receive any state sickness benefits, and did not appear in the official statistics, while most of the benefits went to people who were not employed (41).

Guo et al. (42) provide the best estimate of work loss due to back pain in the United States, using data on 30,074 workers from the National Health Interview Survey. In 1988, about 22.4 million people, or 17.6% of all U.S. workers, lost an estimated 149 million days of work due to back pain. This can be compared to the very recent figures in Sweden that claim the world record of sickness absence in recent years. Short-term sickness of less than 1 year was registered for a total of 380,000 workers in a population of 4.4 million of working age; and 480,000 subjects were sick more than 1 year or permanently disabled in 2001 (43,44). According to Murphy and Volinn (39), the prevalence of back illness has not changed much in the U.S. since those 1988 rates. Comparison can be made to recent Swedish rates provided in the following paragraphs.

In most studies, about half the total days missed from work due to back pain are accounted for by the 85% of people who are off work for short periods, with a median of less than 7 days (45). The other half is accounted for by the 15% of people who are off work for more than 1 month. This is reflected in the total social costs of back pain. It is widely quoted that 80% to 90% of the health care costs of back pain are for the 10% of patients with chronic low back pain and disability (2,46-48). Watson et al. (49) showed that the same is true for the social costs. In 1994, back pain in the island of Jersey accounted for 11% of all sickness absence. Only 3% of those off work with back pain were off for more than 6 months, but they accounted for 33% of the benefits paid.

## WORK LOSS DUE TO BACK PAIN IN SWEDEN

The city of Gothenburg, with its 450,000 inhabitants, has been a source of much Swedish epidemiologic data through the late 1990s (2,45,47,50-54).

In the studies just mentioned from the 1970s, Svensson and Andersson (50-52) indicated that between 2% and 6% of all people reporting illness in Gothenburg suffered work loss due to back pain. An interesting fact was that one-fourth of the men who said they never had had back pain actually had been off work 1 day or more with that diag-

nosis when insurance data were checked. This illustrates the difficulty in relying on memory in questionnaire surveys. Sweden's workforce of approximately 4.4 million people between the ages of 18 and 65 years of age lost approximately 58 workdays per year on an average due to sickness in 2001. As a comparison, it can be calculated that the annual amount of working days lost among the 125 million people of similar age in the U.S. amounts to 150 million per year (42). In Sweden with 4.4 million people of working age the same work loss due to low back pain was 50 million days (i.e., approximately 8 times higher).

There was a reduction in number of subjects on overall sick leave from 1993 to 1997 after which time sick-listing again increased considerably (55) (Fig. 1-1). In addition there has been a steep increase in new permanent disability claims granted, from 45,000 in 1997 to 70,000 in 2002; 20% of which are due to back pain (43,44,54) (Table 1-3). The total number of days lost because of back

**TABLE 1-3.** *New disability pensions granted in Sweden (1996–2002)*

Year	Total no.	No. for back pain
1996	39.245	8.464
1997	41.198	8.673
1998	34.487	5.951
1999	39.506	6.735
2000	49.237	8.458
2001	57.081	10.014
2002 (approx.)	63.000	13.000

disability in Sweden, including both short-term absenteeism and those on permanent disability exceeded 50 million in 2002 (43,44,55). This figure may be somewhat uncertain because the exact diagnosis is not always clear; it is known, however, that 49% of all sick subjects for more than 1 year have a musculoskeletal disorder, and

**FIG. 1-1.** Total number of sick days paid 1992 to 2002 in Sweden (excluding the first 14 days covered by employer), approximately 30% due to low back pain (43–45,54).

70% of this percentage according to the Gothenburg studies (45,54) is back pain, while 25% of permanent disability pensions are granted for back problems.

## SCIATICA

Few surveys use strict criteria for "sciatica." Several reports give a lifetime prevalence of 14% to 40% for leg pain associated with back problems but they do not distinguish true radicular pain from the more common referred leg pain. Deyo and Tsui-Wu (56) estimated the lifetime prevalence of "surgically important disc herniation" to be about 2%. Lawrence (57) reported a prevalence of "sciatica suggesting a herniated lumbar disc" in 3.1% of men and 1.3% of women. Neither of these studies gave diagnostic criteria. Heliovaara et al. (58) in Finland reported the only large population survey with clinical criteria of radicular pain. That study had a lifetime prevalence of back pain of 77% in men and 74% in women, while the lifetime prevalence of any associated leg pain was 35% in men and 45% in women. Applying strict diagnostic criteria for radicular pain, however, the lifetime prevalence of actual "sciatica" was only 5% in men and 4% in women, also later confirmed (59). Svensson and Andersson (50–52) performed cross-sectional studies of two groups of subjects, one consisting of 940 men between the ages 40 and 46 years and 1,760 women between the ages of 38 and 64 years. They found prevalence rates for all back pain between 60% and 70% with a 1-month prevalence of 35%. Sciatica (or any leg pain) was described by around 30%. This is, however, a different symptom than true radiculopathy. In Belgium, such symptoms necessitating surgery amounted to a yearly incidence of 1 per 1,000 population (60).

## WORK-RELATED BACK INJURIES

Back injuries make up almost one-third of all work-related injuries in the U.S., where there are now about 1 million worker compensation claims for back injuries per annum; the percentage in Sweden, with its general insurance system, is considerably less (5% to 6%) and actually not increasing (54). In Sweden, a steep decline by 80% was noted in 1995/1996 when the rules were changed and back pain was no longer regarded as clearly work-related (47,54).

In the U.K. in 1990/1991, the Health and Safety Executive recorded 34,720 nonfatal back injuries causing at least 3 days off work, which accounted for approximately 23% of all work-related injuries (61,62). Most back injuries were less serious "sprains or strains," but these minor back injuries led to longer time off work and to higher health and compensation costs than any other minor injuries. The issues of work-relatedness are dealt with in several recent reviews including those by the U.S. National Research Council (63) and the Sweden Institute

for Working Life (64) as well as large prospective cohort studies (65). There is an association between reported low back pain and low back pain disability with certain taxing work postures, but there is an equally strong association between low back pain disability and psychosocial factors, especially those related to the workplace (37,66,67). The socioeconomic burden of back pain was recently very thoroughly described in a monograph by Waddell et al. (37). The authors describe how the whole problem of disabling low back pain must be looked upon from a wider psychological, social, and political perspective. When the different trends in low back pain disability are related to the ease of getting benefits, as well as the cultural views in different countries, the different percentages of wage replacements of sickness and permanent disability, and subsequently the absence rates are better understood. How a person is looked upon and accepted in society when declaring they are not fit for work is obviously also a factor.

## IS BACK PAIN INCREASING?

An historical review by Allan and Waddell (68) concluded that human beings have had back pain all through history, and it is no more common or severe today than it has always been. Epidemiologic studies show no evidence of any convincing change in the prevalence of back pain. Leboeuf-Yde and Lauritsen (69) found no definite trend in 26 Nordic studies from 1954 through 1992, and apparent differences are probably mainly due to the wording of the questions. Leino et al. (66) in Finland found that the prevalence of back pain remained unchanged from 1978 to 1992 in annual surveys that have used identical questions each year. Murphy and Volinn (39) analyzed U.S. National Health Interview Survey data and found a 22% increase in chronic low back pain (continuous for more than 3 months) and a 35% increase in activity limitation due to back pain between 1987 and 1994, but a reduction thereafter.

Similarly, there is no clear evidence of any increase in the number of work-related back injuries. Data from the U.K. (11,40,62) show no definite trend. Data from the U.S. are conflicting (39,69). The National Council on Compensation Insurance (70) reported a gradual rise in the proportion of worker compensation claims due to back injuries from 1981 to 1990. However, Murphy and Volinn (39), also using data from the Washington State Department of Labor and Industries and a large worker compensation provider covering approximately 10% of the privately insured labor force, estimated that the annual low back pain claim rate actually decreased by 30% between 1987 and 1995. In Norway and the Netherlands, however, low back disability is increasing at a rate similar to Sweden (37,43,44).

Swedish data detailed until 1991 in the The Swedish State Health Technology Board (SBU) report (45) showed

an increase in the incidence and duration of sickness absence due to back pain in the 1970s and 1980s, and a particular increase in the number of people going on long-term disability and early retirement between the mid-1980s and early 1990s; however, since the early 1990s until 1997 there was a definite decrease in sickness absence and early retirement due to back pain followed by a steep increase until 2002 (43). These changes can be partly explained by both increasing loss of jobs and increasing sickness benefits. Data from the U.K. suggest that the annual rate of new Department of Social Services (DSS) claims for invalidity benefit for back pain have changed very little over the past 20 years, but an increasing proportion of people receive benefit for much longer periods so that the total numbers on benefit and the amount and costs of benefit paid are increasing (37,62). Cross-cultural or international comparisons are, however, difficult to make (37,71).

Despite popular belief, there is no clear historical or epidemiologic evidence that the symptom of back pain has changed since the time any recording has been done. There is no evidence of any change in the pathology of the lower back throughout recorded history. The prevalence of low back pain has not changed, at least over the past 30 years. Instead, all the evidence is of an increase in chronic disability attributed to nonspecific low back pain.

### HOW BACK PAIN BECOMES DISABLING

Pain and disability are subjective. Pain per se does not meet the definition of impairment (abnormality), but if activity aggravates pain and the individual avoids or reduces their activities, then pain may lead to disability. However, low back pain and disability depend more on psychosocial factors than on the physical condition of the back, and can best be understood and managed by a biopsychosocial model (37,61), which is more consistent with the latest evidence on the development of chronic pain and disability:

- The symptom of back pain arises from a physical process in the back and ensuing nociception. The key to chronic pain and disability may be failure to recover, rather than the development of a different syndrome.
- As pain becomes chronic (greater than 12 weeks) attitudes and beliefs, distress, and illness behavior play an increasing role in the development of chronicity and disability (34,37,66,67,72–76).

In an attempt to explain the transition from acute to chronic low back pain, Turk (77) stressed that demographic and psychosocial factors, including socioeconomic ones, are better predictors of chronicity than clinical, radiologic, or physical factors. This was reiterated in the same author's argument for more attention to the psychosocial dimension when treating patients with chronic back pain (78). This all occurs within the social context

(varying worldwide), and leads to social interactions with others, including in particular family, coworkers, and health care providers.

It is well known that there are close links between physiological and psychological events (37,54,76). Nonspecific low back pain seems to be mainly a matter of disturbed function or painful musculoskeletal dysfunction. Disability is reduced function (76). It is a matter of what the individual does (or does not do) and of altered performance. Pain behavior or illness behavior is also a matter of what the individual does (or does not do) (76).

Disability due to back pain involves both physical dysfunction and illness behavior, which in a sense are simply two sides of the same coin. Behavior always involves motor and physiologic activity; and physiologic processes always have behavioral expressions (72,73).

Low back pain and disability are clearly related, but they are not the same and the link between them may be much weaker than often assumed. One study (75) found that severity of pain only accounted for about 10% of the variance of low back disability. It is important to make a very clear distinction between pain and disability conceptually, in clinical practice, and as the basis for social security and sickness benefits (76,79). Another example of importance for ratings of disability is the fact that measured reduced mobility of the lower back is not related to pain or overall ability (80).

Pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (81). Pain is a symptom, not a clinical sign, a diagnosis, or a disease. It is not possible to assess pain directly: assessment always depends on the individual's report of their subjective experience, so the report of pain always depends on how the individual thinks and feels about it and communicates it. A disability, on the other hand, is restricted activity. The most comprehensive definition of disability is by the World Health Organization (WHO) (82), which defines a disability as “any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being.” There are a number of assumptions in the WHO definition. It assumes that what is normal is to have no disability or restriction of any kind, which does not allow for the range that is normal by gender and age. It assumes that disability is “due to an impairment,” which implies a physical basis and cause-and-effect relationship that may not be an accurate reflection of disability associated with pain. It is often taken to imply that disability is a health problem, which is not always true. Nevertheless, the core of all the definitions of disability is that it is restricted activity. For the purpose of sickness benefits or compensation, disability is often considered as incapacity for work, although the definition and degree of incapacity varies in different jurisdictions. Clinical assessment of disability usually relies on the patient's own report, so

again the definition is subjective and open to the same influences as the report of pain (83–85).

Fordyce et al. (72) considered further the nature of impairment and disability associated with low back pain from a biopsychosocial perspective. The problem is that it is not possible to assess back pain, but only the person with the pain. Pain, suffering, and pain behavior all confound questions of impairment and disability. The term *disability* may mean either loss of capacity or simply reduced activity, but observation of performance cannot distinguish these. Reduced performance may reflect actual loss of capacity, or the individual may stop before they reach their physical limits, or they may not even attempt the activity. Fordyce (73) further defines a “state of disability as when the person prematurely terminates an activity, under-performs or declines to undertake it.” The concept and measure of disability cannot be independent of performance. It is not possible to separate body and mind. Physical defects affect a person’s beliefs and expectations about their situation. On the other hand, beliefs and expectations help to shape the impact of physical defects on activity. The extent to which psychological and social processes can influence physical activity should not be underestimated, and vice versa. Concepts of impairment and disability must allow for this dynamic interaction. Disability is not only a question of physical impairment, nor is it only functional capacity: it is a question of behavior and performance. Performance depends on anatomical and physiological abilities, but also on psychological and social resources. Performance depends on effort. Testing itself may cause pain and inhibit performance. Capacity may be set by physiological limits; but performance is set by psychological limits. (72,73).

## ACKNOWLEDGMENT

Special thanks to Anders Norlund, PhD, and Gordon Waddell, MD, FRCS, for valuable help with important facts and figures.

## CHAPTER 2

# Pathophysiology of Nerve Root Pain in Disc Herniation and Spinal Stenosis

Kjell Olmarker, Robert R. Myers, Shinichi Kikuchi, and Björn Rydevik

---

Lumbosacral nerve roots are known to be intimately involved in the pathophysiology of disc herniation and spinal stenosis (1). During the last decade there has been an increasing interest in this topic, and recent research has aimed at defining basic pathophysiologic events at the cellular or subcellular level responsible for the pathophysiology of nerve root pain. In this chapter, the current knowledge about these mechanisms is reviewed and discussed in relation to the clinical features of lumbar disc herniation and spinal stenosis.

### **SYMPTOMATOLOGY OF NERVE ROOT INVOLVEMENT**

The symptoms of nerve root pathophysiology may be divided into two main categories: pain and nerve dysfunction (2). Nerve root pain is typically radiating in nature, and is usually related to a specific nerve root or roots innervating tissue below the knee. Nerve dysfunction may be present in both motor and sensory modalities, thus producing both motor weakness and sensory disturbances. One may assume that pain and nerve dysfunction result from different pathophysiologic events, but they usually coincide, indicating that nerve root pathophysiology is very complex.

### **PATHOPHYSIOLOGIC MECHANISMS**

Two specific mechanisms at the “tissue level” may be defined: mechanical deformation of the nerve roots and biologic or biochemical activity of the disc tissue with effects on the roots. The mechanical deformation theory is the oldest concept of nerve root injury induced by herniated disc tissue and dates back to the turn of the last century with some clinical observations on injuries in the lumbosacral junction with subsequent leg pain, and more

recently to Mixter and Barr’s seminal observations (1–5). The theory that biologic activity of the disc tissue may injure the nerve roots recently was confirmed experimentally (6). The experimental knowledge regarding these two mechanisms is discussed separately.

### **MECHANICAL EFFECTS**

The spinal nerve roots are relatively well protected from external trauma because they are enclosed by the vertebral bones (Fig. 2-1). However, the nerve roots do not possess the same amounts and organization of protective connective tissue sheaths as do the peripheral nerves (Fig. 2-2). Therefore, the spinal nerve roots may be particularly sensitive to mechanical deformation resulting from intraspinal disorders such as disc herniations or protrusions, spinal stenosis, degenerative disorders, and tumors (7–9). There has been moderate interest in studying nerve root compression in experimental models. Gelfan and Tarlov in 1956 and Sharpless in 1975 performed initial experiments on the effects of compression on nerve impulse conduction (10,11). Although no calibration was performed of the compression devices used, both papers indicated that nerve roots were more susceptible to compression than peripheral nerves. During recent years, however, the interest in nerve root pathophysiology has increased considerably. A number of studies are reviewed in the following.

### **Experimental Nerve Root Compression**

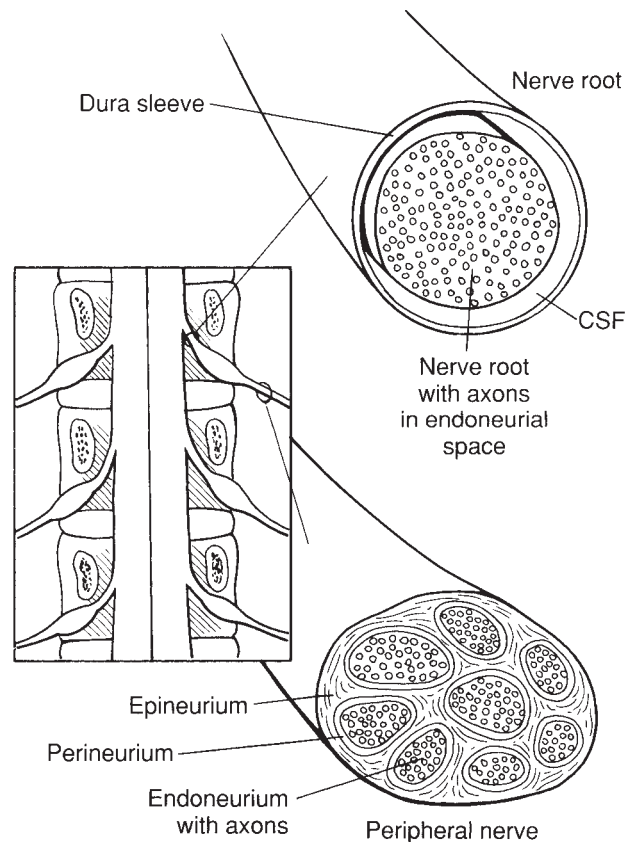

Some years ago, a model was presented for evaluation of the effects of compression of the cauda equina in pigs that allowed for experimental, graded compression of cauda equina nerve roots at known pressure levels for the first time (7,8). In this model, the cauda equina was

**FIG. 2-1.** Drawing of the intraspinal course of a human lumbar spinal nerve root segment. The vertebral arches have been removed by cutting the pedicles (1), and the opened spinal canal can be viewed from behind. The ventral (2) and dorsal (3) nerve roots leave the spinal cord as small rootlets (4) that caudally converge into a common nerve root trunk. Just prior to leaving the spinal canal, there is a swelling of the dorsal nerve root called the dorsal root ganglion (5). Caudal to the dorsal root ganglion, the ventral and dorsal nerve roots mix and form the spinal nerve (6). The spinal dura encloses the nerve roots both as a central cylindrical sac (7), and as separate extensions called root sleeves (8). (From Olmarker K. Spinal nerve root compression. Thesis. Göteborg, Sweden: Göteborg University, 1990, with permission).

compressed by an inflatable balloon that was fixed to the spine (Fig. 2-3). The cauda equina could be observed through the translucent balloon also. This model made it possible to study the flow in the intrinsic nerve root blood vessels at various pressure levels (12). The experiment was designed in a way that the pressure in the compression balloon was increased by 5 mm Hg every 20 seconds. The blood flow and vessel diameters of the intrinsic vessels could be observed simultaneously through the balloon using a vital microscope. The average occlusion pressure for the arterioles was found to be slightly below and directly related to the systolic blood pressure. The blood flow in the capillary networks was intimately dependent on the blood flow of the adjacent venules. This corroborates the assumption that venular stasis may induce capillary stasis and thus changes in the microcirculation of the nerve tissue, which has been suggested as one mechanism in carpal tunnel syndrome (13). The mean occlusion pressures for the venules demonstrated large variations; however, a pressure of 5 to 10 mm Hg was sufficient to induce

**FIG. 2-2.** The nerve root and the peripheral nerve differ in their microscopic anatomy. The axons of the nerve root are located in the endoneurial space and covered by cerebrospinal fluid and the dura sleeve. The axons of the peripheral nerves are located in the endoneurium of the fascicles that are enclosed by the perineurium. These fascicles are all enclosed by the epineurium that is formed by loose connective tissue. (From Weinstein JN, Rydevik BL, Sonntag VKH, eds. *Essentials of the spine*. New York: Raven Press, 1995, with permission.)

venular occlusion. It is assumed that the capillary blood flow also is affected in such situations because of retrograde stasis.

In the same experimental setup, the effects of gradual decompression were studied after initial acute compression for a short while (14). The average pressure for starting the blood flow was slightly lower at decompression than at compression for arterioles, capillaries, and venules. However, it was found that there was not a full restoration of the blood flow until the compression was lowered from 5 to 0 mm Hg. This observation further stressed the previous impression that vascular impairment is present even at low-pressure levels.

Compression-induced impairment of the vasculature may be one mechanism for nerve root dysfunction because the nutrition of the nerve root is affected. However, the nerve roots also have a considerable nutritional supply via diffusion from the cerebrospinal fluid (CSF) (15). To assess the compression-induced effects on the

**FIG. 2-3.** Schematic drawing of experimental nerve root compression model. The cauda equina (A) is compressed by an inflatable balloon (B) that is fixed to the spine by two L-shaped pins (C) and a Plexiglas plate (D). (From Olmarker K, Holm S, Rosenqvist AL, et al. Experimental nerve root compression. A model of acute, graded compression of the porcine cauda equina and an analysis of neural and vascular anatomy. *Spine* 1991;16(1):61–69, with permission.)

total contribution to the nerve roots, an experiment was designed where  $^3\text{H}$ -labeled methylglucose was allowed to be transported to the nerve tissue in the compressed segment both via the blood vessels and via the CSF diffusion after systemic injection (16). The results showed that no compensatory mechanism from CSF diffusion could be expected at the low-pressure levels. On the contrary, 10 mm Hg compression was sufficient to induce a 20% to 30% reduction of the transport of methylglucose to the nerve roots as compared to control.

It is known from experimental studies on peripheral nerves that compression also may induce an increase in the vascular permeability, leading to intraneural edema formation (17). Such edema may increase the endoneurial fluid pressure, which in turn may impair the endoneurial capillary blood flow and in such a way jeopardize the nutrition of the nerve roots (18–21). Because the edema usually persists for some time after the removal of a compressive agent, edema may negatively affect the nerve root for a longer period than the compression itself. The presence of an intraneural edema is related also to subsequent formation of intraneural fibrosis (22), and may contribute to the slow recovery of some patients with nerve compression disorders. To determine if intraneural edema may form in nerve roots because of compression, the distribution of Evan's blue albumin (EBA) in the nerve tissue was analyzed after compression at various pressures and durations (23). The study showed that edema formed even at low-pressure levels, predominantly at the edges of the compression zone.

The function of the nerve roots has been studied by direct electrical stimulation and recordings either on the nerve itself or in the corresponding muscular segments (24–27). During a 2-hour compression period, a critical pressure level for inducing a reduction of Monophasic action potential (MAP) amplitude seems to be located between 50 and 75 mm Hg. Higher pressure levels (100 to 200 mm Hg) may induce a total conduction block with varying degrees of recovery after compression release. To study the effects of compression on sensory nerve fibers, the electrodes in the sacrum were used to record a compound nerve action potential after stimulating the sensory nerves in the tail (i.e., distal to the compression zone). The results showed that the sensory fibers are slightly more susceptible to compression than the motor fibers (26,27). Also, the nerve roots are more susceptible to compression injury if the blood pressure is lowered pharmacologically (25). This further implies the importance of the blood supply to maintain the functional properties of the nerve roots.

### Onset Rate of Compression

One factor that has not been fully recognized in compression trauma of nerve tissue is the onset rate of the compression. The onset rate (i.e., the time from start to full compression) may vary clinically from fractions of seconds in traumatic conditions to months or years in degenerative processes. There may be a wide variation even in clinically rapid onset rates. With the presented model it was possible to vary the onset time of the applied compression. Two onset rates have been investigated. Either the pressure is preset and compression is started by flipping the switch of the compressed air system used to inflate the balloon, or the compression pressure is slowly increased over 20 seconds. The first onset rate was 0.05 to 0.1 seconds, which provided a rapid inflation of the balloon and a rapid compression onset.

Such a rapid onset rate has been found to induce more pronounced effects on edema formation (23), methylglucose transport (16), and impulse propagation (24) than the slow onset rate. Regarding methylglucose transport, the results show that the levels within the compression zone are more pronounced at the rapid than at the slow onset rate at corresponding pressure levels. There was also a striking difference between the two onset rates when considering the segments outside the compression zones. The levels approached baseline values closer to the compression zone in the slow rather than the rapid onset series. This may indicate the presence of a more pronounced edge zone edema in the rapid onset series, with a subsequent reduction of the nutritional transport also in the nerve tissue adjacent to the compression zone.

For the rapid onset compression, which is likely to be more closely related to spine trauma or disc herniation than to spinal stenosis, a pressure of 600 mm Hg main-

tained only for 1 second is sufficient to induce a gradual impairment of nerve conduction during the 2 hours studied after the compression was ended (28). Overall, the mechanisms for these pronounced differences between the different onset rates are not clear, but may be related to differences in displacement rates of the compressed nerve tissue toward the uncompressed parts because of the viscoelastic properties of the nerve tissue (9). Such phenomena may lead not only to structural damage of the nerve fibers, but also to structural changes in the blood vessels with subsequent edema formation. The gradual formation of intraneural edema also may be closely related to the described observations of a gradually increasing difference in nerve conduction impairment between the two onset rates (23,24).

### Multiple Levels of Nerve Root Compression

Patients with double or multiple levels of spinal stenosis seem to have more pronounced symptoms than patients with stenosis only at one level (29). The presented model was modified to address this interesting clinical issue. Using two balloons at two adjacent disc levels, which resulted in a 10-mm uncompressed nerve segment between the balloons, induced a much more pronounced impairment of nerve impulse conduction than had been previously found at corresponding pressure levels (30). For instance, a pressure of 10 mm Hg in two balloons induced a 60% reduction of nerve impulse amplitude during 2 hours of compression, whereas 50 mm Hg in one balloon showed no reduction.

The mechanism for the difference between single and double compression may not simply be because the nerve impulses have to pass more than one compression zone at double level compression. There also may be a mechanism based on the local vascular anatomy of the nerve roots. Unlike for peripheral nerves, there are no regional nutritive arteries from surrounding structures to the intraneural vascular system in spinal nerve roots (7,31–34). Therefore, compression at two levels might induce a nutritionally impaired region between the two compression sites. In this way, the segment affected by the compression would be widened from one balloon diameter (10 mm) to two balloon diameters, including the interjacent nerve segment (30 mm). This hypothesis was partly confirmed in an experiment on continuous analyses of the total blood flow in the uncompressed nerve segment located between two compression balloons. The results showed that a 64% reduction of total blood flow in the uncompressed segment was induced when both balloons were inflated to 10 mm Hg (35). There was complete ischemia in the nerve segment at a pressure close to the systemic blood pressure. Data from a study on the nutritional transport to the nerve tissue at double level compression demonstrated that there is a reduction of this transport to the uncompressed nerve segment located

between the two compression balloons similar to that within the two compression sites (36). Thus, there is experimental evidence that the nutrition to the nerve segment located between two compression sites in nerve roots is severely impaired, although the nerve segment itself is uncompressed.

Also, it was evident that the effects of nerve conduction were enhanced if the distance between the compression balloons was increased from one to two vertebral segments (30). However, this was not the case in the nutritional transport study where the methylglucose levels in the compression zones and the uncompressed intermediate segment were similar between double compression over one and two vertebral segments (36). This indicates that the nutrition to the uncompressed nerve segment located between two compression sites is affected almost to the same extent as at the compression sites, regardless of the distance between the compression sites, but that functional impairment may be directly related to the distance between the two compression sites. The impairment of the nutrition to the nerve segment between the two compression balloons thus seems to be more important than the fact that the nerve impulses have to overcome two compression sites in double-level compression.

Double-level compression of pig cauda equina with electrical nerve root stimulation to simulate a walking situation showed that an initial short-term increase in cauda equina blood flow rapidly decreased (37). Such observations further support the pathophysiologic significance of double-level cauda equina compression in spinal stenosis.

### Chronic Experimental Nerve Root Compression

The discussion of compression-induced effects on nerve roots has dealt with acute compression so far (i.e., compression that lasts for some hours and with no survival of the animal). To better mimic various clinical situations, compression must be applied over longer periods. Probably many changes in the nerve tissue, such as adaptation of axons and vasculature, occur in patients but cannot be studied in experimental models using only 1 to 6 hours of compression. Another important factor in this context is the onset rate, which was discussed in the preceding text. In clinical syndromes with nerve root compression, the onset time probably is quite slow. For instance, a gradual remodeling of the vertebrae to induce spinal stenosis leads to an onset time of many years. Of course, it is difficult to mimic such a situation in an experimental model. Also, it is impossible to have absolute control over the pressure acting on the nerve roots in chronic models because of the remodeling and adaptation of the nerve tissue to the applied pressure. However, knowledge of the exact pressures is probably less important in chronic than acute compression situations. Instead, chronic models should induce a controlled compression with a slow onset time that is eas-

ily reproducible. Such models may be well suited for studies on pathophysiologic events as well as intervention by surgery or drugs. Some attempts have been made to induce such compression.

Delamarter et al. presented a model on the dog cauda equina in which they applied a constricting plastic band (38). The band was tightened around the thecal sac to induce a 25%, 50%, or 75% reduction of the cross-sectional area. The band was left in place for various lengths of time. Analyses were performed and showed both structural and functional changes that were proportional to the degree of constriction.

To induce a slower onset and more controlled compression, Cornefjord and collaborators used a constrictor to compress the nerve roots in the pig (39). The constrictor initially was intended to induce vascular occlusion in experimental ischemic conditions in dogs. The constrictor consists of an outer metal shell that is covered on the inside with a material called amaroid that expands when in contact with fluids. Because of the metal shell, the amaroid expands inward with a maximum expansion after 2 weeks, resulting in compression of a nerve root placed in the central opening of the constrictor. Compression of the first sacral nerve root in the pig resulted in a significant reduction of nerve conduction velocity and axonal injuries using a constrictor with a defined original diameter (39). Also, it was found that there is an increase in substance P in the nerve root and dorsal root ganglion following such compression (40). Substance P is a neurotransmitter related to pain transmission. Thus, the study may provide experimental evidence that nerve root compression produces pain. The constrictor model also has been used to study blood flow changes in the nerve root vasculature (41). It could then be observed that the blood flow is not reduced just outside the compression zone, but significantly reduced in parts of the nerve roots located inside the constrictor.

One important aspect in clinical nerve root compression conditions is that the compression level is probably not stable but varies as the result of changes in posture and movements (42,43). Konno and collaborators recently introduced a model where the pressure could be changed after some time of initial chronic compression (44). An inflatable balloon was introduced under the lamina of the seventh lumbar vertebra in the dog. The normal anatomy and the effects of acute compression using compressed air were first evaluated in previous studies (45). By inflating the balloon at a known pressure slowly over 1 hour with a viscous substance that would harden in the balloon, a compression of the cauda equina could be induced with a known initial pressure level. The compression was verified by myelography. Because the balloon under the lamina comprised a twin set of balloons, the second balloon component could be connected to compressed air and could be used to add compression to the already chronically compressed cauda equina.

In conclusion, acute nerve root compression experiments have established critical pressure levels for interference with various physiologic parameters in the spinal nerve roots. However, studies on chronic compression may provide knowledge more applicable to the clinical situation.

### Spinal Stenosis: Experimental–Clinical Correlation

There is substantial knowledge about critical levels of pressure for inducing changes in nerve root nutrition and function. These critical levels are of interest in understanding the basic pathophysiologic mechanisms of compression-induced changes in nerve roots. However, such absolute pressure levels may be of relatively less significance in chronic situations. When nerve tissue is compressed, there is a gradual displacement of the nerve tissue from the compressed to the uncompressed segments (46,47). If the pressure is of an extremely low onset rate (e.g., spinal stenosis), there may be an adaptation of the nerve tissue to the applied pressure. In cadaver experiments, Schönström et al. found that when a hose clamp was tightened around a human cadaver cauda equina specimen, there was a critical cross-sectional area of the dural sac when the first signs of pressure increase among nerve roots were recorded by a catheter placed in the compression zone (48). This cross-sectional area was approximately 75 mm<sup>2</sup>, which was found also to correlate with a corresponding measurement on CT scans in spinal stenosis patients (49). The pressure increased when the hose clamp was further tightened. However, pressure dropped with time because of creep phenomena in the nerve tissue. When the pressure did not normalize within 10 minutes, the “sustained size” was registered and was found to be in the range of 45 to 50 mm<sup>2</sup> (48). This indicates that even in acute compression, there is an adaptation of the nerve tissue to the applied pressure. In a longer perspective, this probably means that the nerve also may be reorganized in its microstructural elements, which results in a nerve with a smaller diameter. Under such circumstances, with gradually decreasing nerve diameter, the nerve pressure acting on the nerve is reduced to some degree.

Despite these important aspects regarding chronic changes in compressed spinal nerve roots, it is interesting to note the correlation between the animal experimental observations regarding critical pressures for functional and nutritional changes in nerve roots under compression on one side, and the measurements of pressure levels among nerve roots in human cadaver lumbar spines following experimental constriction of the dural sac. Acute pressure increase among cauda equina nerve roots to 50 mm Hg was induced when the cross-sectional area of the dural sac was reduced to 63 mm<sup>2</sup>, and a pressure of 100 mm Hg was induced at a cross-sectional of 57 mm<sup>2</sup> (50). Such pressure levels correlate with *in vivo* observations

regarding physiologic changes in cauda equina nerve roots following experimental compression (7,12,23).

Epidural pressure measurements have been performed, evaluating for example the relationship between epidural pressure and posture (43). It was found that the local epidural pressure at the stenotic level was low in lying and sitting postures, and high in standing postures. Pressure was increased with extension but decreased with flexion of the spine. The highest epidural pressure, 117 mm Hg, was found in standing with extension. Measurements also have been reported regarding changes in epidural pressure during walking in patients with lumbar spinal stenosis (51). It was found that the pressure changed during walking with a wave pattern of increase and decrease. Such observations correlate with the previously mentioned experimental observations regarding intermittent cauda equina compression (42).

### Mechanical Deformation and Pain

There are some experimental observations that indicate that mechanical nerve deformation per se may induce impulses that could be interpreted as pain by the central nervous system. Howe and collaborators found that mechanical stimulation of nerve roots or peripheral nerves resulted in nerve impulses of short duration, and that these impulses were prolonged if the nerve tissue had been exposed to mechanical irritation by a chronic gut ligature for 2 to 4 weeks (52). The same results were obtained in an *in vitro* system using rabbit nerve roots (53). However, in this setup it was also evident that the dorsal root ganglion was more susceptible to mechanical stimulation than the nerve roots. The dorsal root ganglion has drawn a special interest in this regard, and an increase in the level of neurotransmitters related to pain transmission has been found in the dorsal root ganglion in response to whole body vibration of rabbits (54). A similar increase also has been seen in the dorsal root ganglion and nerve root after local constriction of the same nerve root (40). *In vivo* models of pain behavior have demonstrated that a severe mechanical deformation, such as ligation, of the nerve root generally is not painful (55–57). However, it seems that if chronic gut sutures are used, the additional irritation makes the mechanical compression painful. Recent studies have shown that disc incision with leakage of nucleus pulposus into the epidural space or a light mechanical deformation and slight medial displacement of the nerve root, does not produce pain behavior in a rat model, whereas the combination of the two factors produces pain (58–60). This is discussed in the following.

Interesting observations have been made regarding contact pressure between the nerve root and the disc in patients with lumbar disc herniation (61). Nerve root pressure before discectomy varied from 7 to 256 mm Hg (mean, 53 mm Hg). The magnitude of nerve root pressure

correlates with the severity of neurologic deficits, but not with the degree of straight leg rising.

### Neuropathology and Pain

There is a considerable body of work on the relationship of pain to neuropathologic changes that has been reviewed recently (62). In fact, much of what is known has been studied in relationship to mechanical and inflammatory injury of the sciatic nerve in the rat. Entrapment of a peripheral nerve produces pathologic change in proportion to the degree of compression and its duration (63), as is known to be the case for nerve root compression. In an electron microscopic study (63), minor degrees of nerve compression were associated with ischemic injury to Schwann cells, resulting in their necrosis and in demyelination. Severe nerve compression was associated with injury to the axon resulting in Wallerian degeneration. Subsequent experiments established the relationship of pain to these forms of neuropathologic change (64). These studies established that mild levels of ischemia producing demyelination generally were not painful, whereas severe ischemia producing Wallerian degeneration resulted in hyperalgesia. In fact, the pathology of the chronic constriction injury model of neuropathic pain is based on this relationship and the added insult of inflammation caused by the chronic gut ligatures used to compress the nerve (65). It is now recognized that the cytokine-driven processes of Wallerian degeneration are the dominant neuropathologic factors linking nerve injury and pain (64,66,67) and that the degree and extent of wallerian degeneration relates directly to the magnitude and duration of hyperalgesia (68).

### BIOLOGIC AND BIOCHEMICAL EFFECTS

The clinical picture of sciatica with a characteristic distribution of pain and nerve dysfunction, but in the absence of herniated disc material both at radiologic examination and at surgery, has indicated that the mechanical component is not the only factor that may be responsible for sciatic pain. Therefore, it has been suggested that the disc tissue per se may have injurious properties that may be of pathophysiologic significance (9). However, not until recently was it confirmed in an experimental setup that local, epidural application of autologous nucleus pulposus in the pig with no mechanical deformation, induces significant changes in both structure and function of the adjacent nerve roots (6). This finding has opened up a new field of research, which is reviewed in the following.

#### Biologic Effects of Disc Tissue (Nucleus Pulposus)

No changes in nerve function or structure were observed after placing autologous nucleus pulposus,

obtained from a lumbar disc in the same animal, onto the tibial nerve in a rabbit (69). However, there are certain differences in microscopic anatomy and vascular permeability between peripheral nerves and nerve roots that make the extrapolation from peripheral nerve experiments to spinal conditions difficult. McCarron and collaborators applied autologous nucleus pulposus from discs of the dog's tail in the epidural space of the animal (70). They observed that an epidural inflammatory reaction did not occur when saline was injected as control. However, the nerve tissue was not assessed in this study.

Olmarker and collaborators presented a study that demonstrated that autologous nucleus pulposus might induce a reduction in nerve conduction velocity and light microscopic structural changes in a pig cauda equina model of nerve root injury (Fig. 2-4) (6). However, these axonal changes had a focal distribution and the quantity of injured axons was too low to be responsible for the significant neurophysiologic dysfunction observed. A follow-up study of areas of the nerve roots exposed to nucleus pulposus that appeared to be normal by light microscopy, revealed that there were significant injuries of the Schwann cells with vacuolization and disintegration of the Schmidt-Lanterman incisures (Fig. 2-5) (71). Schmidt-Lanterman incisures are essential for the normal exchange of ions between the axon and surrounding tissues. Therefore, an injury to this structure would be likely to interfere with the normal impulse conduction properties of the axons. However, the distribution of changes was too limited to fully explain the neurophysiologic dysfunction observed. For instance, a recent study that demonstrated that freezing of the nucleus pulposus prevented the reduction in nerve conduction velocity also demonstrated these characteristic changes histologically in spite of normal nerve conduction (72). However, the potency of the nucleus pulposus was further emphasized in an experiment using a dog model where it was seen

that a surgical incision of the annulus fibrosus, with minimal leakage of nucleus pulposus, was enough to induce significant changes in structure and function of the adjacent nerve root (73).

Because there is no structural correlate to the functional changes, continued studies have assessed the potential effects of nucleus pulposus on the nerve root nutrition. Epidural application of autologous nucleus pulposus within 2 hours induces an intraneural edema (74,75) that leads to a reduction of the intraneural blood flow (75). Histologic changes of the nerve roots are present after 3 hours (76), and a subsequent reduction of the nerve conduction velocity starts 3 to 24 hours after application (6,76).

From these initial experiments, it could be concluded that nucleus pulposus has significant properties to injure the nerve roots by its mere presence. However, the mechanisms for the nucleus pulposus-induced nerve root injury are not yet fully understood. These studies indicated that inflammatory reactions were present, at least epidurally. This initiated a study where a potent anti-inflammatory agent, methylprednisolone, was administered at different times intravenously after nucleus pulposus application (77). The results showed clearly that the nucleus pulposus-induced reduction in nerve conduction velocity was eliminated if methylprednisolone was administered within 24 hours of application. If methylprednisolone was administered within 48 hours the effect was not eliminated but significantly lower than if no drug was used. This observation indicates that the negative effect does not occur immediately but develops during the first 24 hours after application. However, if methylprednisolone is administered within 24 hours, some areas in the nerve roots demonstrate normal impulse conduction properties with light microscopic axonal changes in the same magnitude as in the previous study (6). This further corroborates the impression that the structural nerve

**FIG. 2-4:** **A:** A nerve root exposed to fat for seven days. There are no apparent changes. **B:** A nerve root exposed to autologous nucleus pulposus for seven days. There is pronounced axonal degeneration and the normal architecture of the endoneurial space has been markedly changed.

**FIG. 2-5.** Seven days after the application of nucleus pulposus. Myelinated nerve fiber with prominent vesicular swelling of a Schmidt-Lanterman incisure (SL). Note the mononuclear cell (M) in close contact with the nerve fiber. A, Well-preserved axon; M, myelin sheath; S, outer Schwann cell cytoplasm; Arrowheads, Myelin sheath layers outside the Schmidt-Lanterman incisure. (Bar: 2.5  $\mu$ m) (From Olmarker K, Nordborg C, Larsson K, et al. Ultrastructural changes in spinal nerve roots induced by autologous nucleus pulposus. *Spine* 1996;21(4):411–414, with permission.)

injury inducing nerve dysfunction may not be found at the light microscopic level but must be sought for at the subcellular or molecular level.

Although methylprednisolone may intervene with the pathophysiologic events of the nucleus pulposus-induced nerve root injury, it was not clear if this resulted from the anti-inflammatory properties of the methylprednisolone or something else. To establish if the presence of autologous nucleus pulposus could initiate a leukotactic response from the surrounding tissues, a study was initiated that assessed the potential inflammatory properties of the nucleus pulposus (78). Autologous nucleus pulposus and autologous retroperitoneal fat were placed in separate perforated titanium chambers and placed subcutaneously with a sham chamber in the pig. Seven days later, the number of leukocytes was assessed for the chambers. The number of leukocytes was the same between the fat and the sham chambers. However, the nucleus pulposus-containing chambers had a number of leukocytes that exceeded the two others by 250%. In another experiment, autologous nucleus pulposus and muscle were placed in Gore-Tex (W. L. Gore & Associates, Inc., Flagstaff, AZ) tubes subcutaneously in rabbits (79). After 2 weeks, there was an accumulation of T-helper and T-suppressor cells in the tube with nucleus pulposus that persisted the full observation time of 4 weeks.

Nucleus pulposus may also interfere with the nutrition to the intraspinal nerve tissue. Following application to

the dorsal root ganglion, the intraneural blood flow was dramatically decreased and there was a simultaneous increase of the tissue fluid pressure (75). The authors suggested that this might indicate that the nucleus pulposus induced intraneural edema because of the increased vascular permeability of the intraneural capillaries.

Kawakami et al. recently showed that neuropathic pain in an experimental setting seems to be mediated by infiltrating leukocytes (80), a finding consistent with the observations of neuroimmune inflammatory changes and pain (81). In rats made leukopenic by nitrogen mustard, the pain response was absent after application of nucleus pulposus, whereas normal rats with nucleus pulposus application displayed a pathologic response to stimulation. The same group also demonstrated that inhibition of cox-2 might reduce nucleus pulposus-induced pain behavior (82). Taken together, this further supports the idea that autologous nucleus pulposus may elicit inflammatory reactions when outside the intervertebral disc space and that such reactions may not necessarily be restricted to resorption of the herniated tissue but be intimately involved in the pathophysiology of sciatica.

### Nucleus Pulposus and Sciatic Pain

Pain is much more difficult to assess than nerve conduction in controlled experimental studies for obvious reasons. The available literature indicates that pain may be induced by both mechanical and nucleus pulposus-mediated factors. The role of the nucleus pulposus in this context is interesting although uncommon in patients with obvious symptoms of disc herniation but no visible herniation at radiologic examination or surgery (19,83). The existing data suggest that communication between the intradiscal and epidural space is sufficient for inducing effects on the nerve roots, indicating that annular disruption with a discrete leakage of nucleus pulposus material into the spinal canal, with no visible herniation, could be enough to induce symptoms. The potential of nucleus pulposus material to induce pain was indicated in clinical studies that showed that noncontained herniations (where the nucleus pulposus is in contact with the epidural space) are much more painful and have a more pronounced straight leg-raising (SLR) than contained herniations (84–86).

Recent studies on rats, using pain behavior assessment, have indicated that nucleus pulposus may well be involved in pain production. Pain behavior in this context refers to response thresholds to thermal and mechanical stimulation. Kawakami et al. showed that a three-level laminectomy and an application of homologous nucleus pulposus or annulus fibrosus taken from three intervertebral discs in another rat, applied at three nerve roots, produced pain behavior (57); whereas Olmarker and Myers showed that facetectomy with incision of the disc and transfer of the autologous nucleus pulposus to the adja-

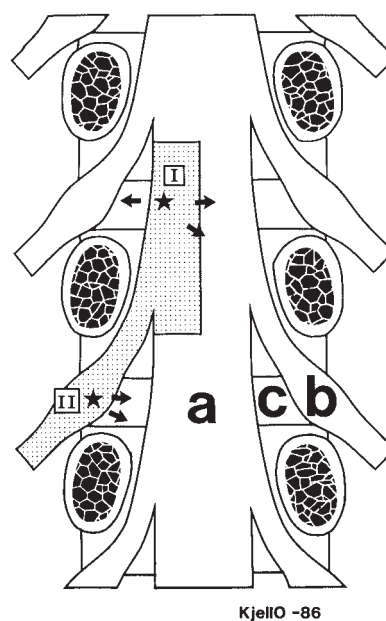

cent nerve root or dorsal root ganglion did not produce pain behavior (58). This indicates that there may be a dose-response curve between pain behavior and the amount of nucleus pulposus material in the epidural space. However, in Olmarker's model, pain behavior was present when the disc incision was combined with a slight medial displacement of the nerve root or dorsal root ganglion (DRG), and induced a mild mechanical deformation; whereas the displacement per se was found not to produce pain behavior (58). This observation is consistent with the neuropathologic understanding of pain and the consequences of combined mechanical and inflammatory injury to nerve fibers that are superimposed to increase the number of fibers injured and the corresponding increase in proinflammatory cytokines (67,68). The same pathophysiologic response was observed in a study assessing walking patterns, in which it was seen that the combination of displacement and disc incision produced detectable changes (60). A pain behavior study assessing changes in spontaneous behavior showed that the combined action of displacement and disc incision produced changes, whereas displacement or disc incision alone did not produce changes (87).

These experimental studies on pain behavior may indicate that the presence of nucleus pulposus has sensitized the nerve tissue to become sensitive to mechanical deformation. It is known that compression of peripheral nerves is not painful and that touching of a normal nerve root during local anesthesia is not painful (88). However, touching of a nerve root exposed to a disc herniation often reproduces sciatic pain (88). This clinical observation and the experimental finding that nucleus pulposus sensitizes the nerve root relates very well. It may be assumed that, in the pathophysiology of sciatica, except for inducing nerve dysfunction, nucleus pulposus can sensitize the nerve tissue to produce pain when exposed to mechanical stimulation.

Although the combination of a mechanical component and the presence of nucleus pulposus seems to be a prerequisite to produce changes in the *in vivo* situation, neurophysiologic studies have demonstrated that the mere application of nucleus pulposus may induce increased neuronal pain transmission (89). This may indicate that pain behavior assessment is a gross instrument to detect pain and that nucleus pulposus may induce pain in the absence of a mechanical component as well.

Theoretically, one may hypothesize two different mechanisms by which mechanical or biologic factors may induce pain; either by direct stimulation of nerves or innervated structures, or by neuroischemia. A vascular impairment of the nerve tissue with a nutritional deficit that results in ischemia of the nerve seems to be a likely pain mechanism, and could be induced by both mechanical and biologic factors. In studies where pain was suspected to result from direct stimulation of the nerve roots, the nucleus pulposus material primarily was in contact with the surrounding meninges, not the axons (56–58,60,84,

87,90). Also, in a study where locally anesthetized patients re-experienced their sciatic pain after local stimulation of the nerve root, the meninges might have been the actual tissue of stimulation (88). The spinal dura mater is known to contain nerve endings, and stimulation of the dura has been suggested as a mechanism for sciatic pain (9,91,92). Irritation or stimulation of the dura as an important factor for sciatica could explain many clinical features. The dura is segmentally innervated, as indicated in Figure 2-6; the sensory nerves travel in a caudal-lateral direction and are drained to the corresponding nerve root by the nerve of Luschka (93–96). Stimulation of the dura at a point where the dorsolateral herniations appear (Fig. 2-6I) should be recorded by the corresponding nerve root (97). However, the irritation may spread medially to the contralateral segment at this location, producing bilateral symptoms; or laterally, producing symptoms from levels above. Similarly, a lateral disc herniation (Fig. 2-6II) could produce symptoms in the lower level. If the pain of the straight leg raising test is the result of dura irritation caused by friction to the herniated mass, one may consider the phenomenon of “crossed SLR” to be based on simultaneous stimulation of the contralateral dura. Such a “radiculitis” or “local meningitis” could be regarded as similar to peritonitis. In peritonitis, a reflector muscle contraction usually is present

**FIG. 2-6.** Suggested area of innervation by one recurrent sinuvertebral nerve (nerve of Luschka). Disc herniation at location I may be recorded by the same nerve and also by the nearby innervation areas, laterally and contralaterally, as indicated by the arrows. At location II, a lateral disc herniation of the disc one level below may affect the same nerve root but also the root one level below, located medial to this root, as indicated by the arrows. (From Olmarker K. The experimental basis of sciatica. *J Orthop Sci* 1996;1:230–242, with permission.)

over the affected area. An analog for this local meningitis could be the reflector ipsilateral contraction of the spinal muscles, producing “sciatic scoliosis,” or lateral bending of the spine at the level of herniation.

To speculate further, one could elaborate that the deep visceral pain presented earlier as referred pain may be related to painful conditions in the nerve (e.g., neuroischemia), and that the sharp, distinct pain presented as radicular pain may be related to dura irritation. However, although these proposed mechanisms are subject to speculation, the view of spinal pain may change dramatically in coming years based on new ideas and concepts as well as rapidly increasing knowledge about the molecular events active in the pathophysiology of sciatica.

### Mechanisms and Transport Routes

When considering various pathophysiologic mechanisms below the tissue level, three mechanisms seem reasonable: (a) a direct neurotoxic effect on the nerve tissue; (b) a vascular impairment; and (c) inflammatory or immunologic reactions.

It is difficult to relate the observed histologic changes of nerve tissue as induced by nucleus pulposus to direct neurotoxic effects or ischemia. There is always reason to assume that there are neurotoxic substances acting on the axons present in the nucleus pulposus. However, histologic observations indicate that the changes are focal and mainly found in the center of the nerve roots, resembling a mononeuritis simplex induced by nerve infarction caused by embolism of the intraneural vessels (6,71,98). Particularly in view of the work of Jayson et al. that indicate an impairment of the venous outflow from the nerve roots owing to periradicular vascular changes, one must consider vascular impairment as a highly interesting factor (99–102). Even relatively large molecules deposited in the epidural space may be found in the intraneural vessels of the adjacent nerve roots within seconds after application (103). Considering the possibility of epidurally placed substances to penetrate the relatively impermeable dura, cross over the CSF, and then diffuse through the root sheath and into the axons, this vascular route may seem more relevant. As mentioned, nucleus pulposus seems to have certain inflammatory properties (6,78–80,104). Because many inflammatory mediators are involved in vascular and rheologic phenomena such as coagulation, one may suspect that vascular impairment of the nerve root may result from vascular embolism. In fact, it was observed in a vital microscopic study that the presence of nucleus pulposus may induce thrombus formation in microvessels (78). Inflammatory mediators might also exert a direct effect on the myelin sheaths, as indicated by an electron microscopic study of nerve roots exposed to autologous nucleus pulposus in the pig (71). There were significant injuries of Schwann cells with vacuolization and disintegration of the Schmidt-Lanterman incisures, which closely resembles the

injury pattern of inflammatory nerve disease (105,106). As described, results from recent studies have indicated that epidural application of nucleus pulposus induces an increase of the vascular permeability and a subsequent reduction of the blood flow in the adjacent nerve roots, which suggests that vascular impairment is pathophysiologically important.

It has been suggested also that because the nucleus pulposus is avascular and thus “hidden” from the systemic circulation, presentation of the nucleus pulposus could result in an autoimmune reaction directed to antigens present in the nucleus pulposus, and that bioactive substances from this reaction could injure the nerve tissue (107–113). Also, there could be autoimmune reactions, not only in the disc, but also in components from the nerve tissue that are released as the result of injury, such as basic myelin protein. It is not clear if such immunologic reactions occur, but ongoing research has demonstrated immunoreactivity in some patients at the time of surgery. An interesting study assessed the possible presence of immune complexes in herniated disc tissue obtained at surgery as an indicator of immunoactivation (114). It was found that there was IgG in close relation to the disc cells in herniated disc material. However, no IgG was found in the residual disc evacuated at the time of surgery. Neither immune complex was found in control disc material obtained at spine surgery for causes other than pain. Although inconclusive, this study might indicate that immunologic activation may be present in some cases of sciatica.

### Components of the Nucleus Pulposus of the Intervertebral Discs

The nucleus pulposus mainly comprises proteoglycans, collagen, and cells (115,116). Therefore, the observed effects as induced by the nucleus pulposus at local application probably should be contributed to one or more of these components. The proteoglycans have gained most attention; and are suggested to have a direct irritating effect on the nerve tissue (113,117,118). Neither the collagen nor the cells previously were suggested to be of pathophysiologic importance. However, recent studies of the cells of the nucleus pulposus showed that these cells are capable of producing metalloproteases such as collagenase or gelatinase, as well as interleukin-6 and prostaglandin E<sub>2</sub>, and do so spontaneously in culture (104). Using the same pig model as described, the possible role of the nucleus pulposus cells for the nucleus pulposus-induced nerve injury has been assessed (72). In a blind fashion, autologous nucleus pulposus was subjected to 24 hours of freezing at -20°C and digestion by hyaluronidase or a heating box at 37°C for 24 hours. The treated nucleus pulposus was reapplied after 24 hours and analyses were performed 7 days later. It was evident that there were no changes in nerve conduction velocity in animals where the nucleus pulposus

had been frozen and the cells killed, whereas in the other two series the results were similar to application of unaltered nucleus pulposus. Therefore, it seems reasonable that the cells are responsible in some way for inducing the nerve injury and that the structural molecules are of less importance. This assumption was further supported by a study using the same model, which showed that application of cultured pig disc cells to the cauda equina reproduced the reduction in nerve conduction velocity (119). However, application of disc cell membranes also reproduced this reduction, indicating that the responsible substances probably are membrane bound.

Substances such as IgG, hydrogen ions, NO, and PLA2 might be responsible for the pathophysiologic reactions (113,120–124). Another substance produced by the disc cells that has similar pathophysiologic effects as nucleus pulposus is tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (125). The possible involvement of TNF and other related cytokines in the pathophysiology of sciatica is discussed in the following.

### **Cytokines as Mediators of Nerve Dysfunction and Pain**

Tumor necrosis factor is known to be a regulatory proinflammatory cytokine that has both specific biologic effects as well as the ability to up-regulate and act synergistically with other cytokines, such as IL-1B and IL-6 (126–131). Immediately after nerve injury, TNF is released and up-regulated by Schwann cells at the site of nerve injury (132). This is followed by the release and up-regulation of TNF in many other endoneurial cells, including endothelial cells, fibroblasts, and mast cells. Tumor necrosis factor also is produced by chondrocytes and disc cells (125, 133–136). The local production of TNF is the stimulus that results in macrophage attraction to the injury site (66), which then contributes massively to the concentration of proinflammatory cytokines in the injured tissue. Several studies have clearly shown that blocking TNF production or delaying the invasion of macrophages to the site of nerve injury results in reduced or delayed neuropathologic change and reduced hyperalgesia (81,137). When performing a meta-analysis on the biologic or pathophysiologic effects induced by TNF and nucleus pulposus, one may find that there is almost a perfect match. For instance, TNF is known to induce axonal and myelin injury similar to that observed after nucleus pulposus application (138–144), intravascular coagulation (145–147), and increased vascular permeability (147). Tumor necrosis factor is also known to be neurotoxic (141,143,148,149) and to induce painful behavioral changes (138,150) as well as ectopic nerve activity when applied locally (139,151). Interestingly, TNF is sequestered in a membrane-bound form and is activated after shedding by certain enzymes. Matrix metalloproteinases (MMP) are particularly important in this regard. MMP-9 and MMP-2 are up-regulated immediately after a

nerve injury (152). Matrix metalloproteinases process the inactive, membrane-bound form of TNF and its receptors to the biologically active form. MMP-9 and TNF receptors are also retrogradely transported from the site of nerve injury to the corresponding dorsal root ganglion and spinal cord (153), where they may have a direct role in gene regulation. This may relate to the observation that cell membranes of disc cells are sufficient to mediate nucleus pulposus-induced effects (119).

Tumor necrosis factor was found in disc cells; when TNF was inhibited with a nonspecific cytokine inhibitor, the nucleus pulposus-induced reduction in nerve conduction velocity following experimental application of nucleus pulposus in a pig model was completely blocked (125). When using more specific TNF inhibitors, such as a monoclonal antibody to TNF (infliximab) and a soluble TNF-receptor (etanercept), the inhibition was equally effective (154). Application of selected cytokines in the pig model showed that TNF reduced the nerve conduction velocity per se (155). IL-1B and interferon- $\gamma$  only induced a slight reduction of nerve conduction velocity.

Application of certain cytokines to intraspinal nerves may also increase the somatosensory neural response (156). Discharges from wide dynamic range neurons following stimulation of a receptor field of a dorsal root ganglion exposed to nucleus pulposus increased significantly following application (157). This may be related to the sensitization of the sensory system caused by proinflammatory cytokines and the production of low-grade spontaneous electrophysiologic activity in nociceptors by TNF (151), which by itself is an important factor that contributes to sensitization. The administration of an antibody specific for TNF efficiently inhibited this effect. An *in vivo* study assessing changes in spontaneous behavior clearly showed that changes induced by the combined action of mechanical deformation and disc incision was markedly inhibited by intraperitoneal injection of a monoclonal antibody specific for TNF (59). It seems that TNF is an important mediator both for the observed effects on nerve function and pain induced by local application of nucleus pulposus. Additional support for this hypothesis comes from previous work which showed that blockade of TNF up-regulation in macrophages by thalidomide (137) and down-regulation of TNF by IL-10 administration (158) reduced the magnitude and duration of hyperalgesia following nerve injury. Because cytokine interactions are complex, other cytokines, such as IL-1B and IL-6, may be involved as well (155,156,159,160). However, because these cytokines are induced by TNF, their exact role has not been completely evaluated.

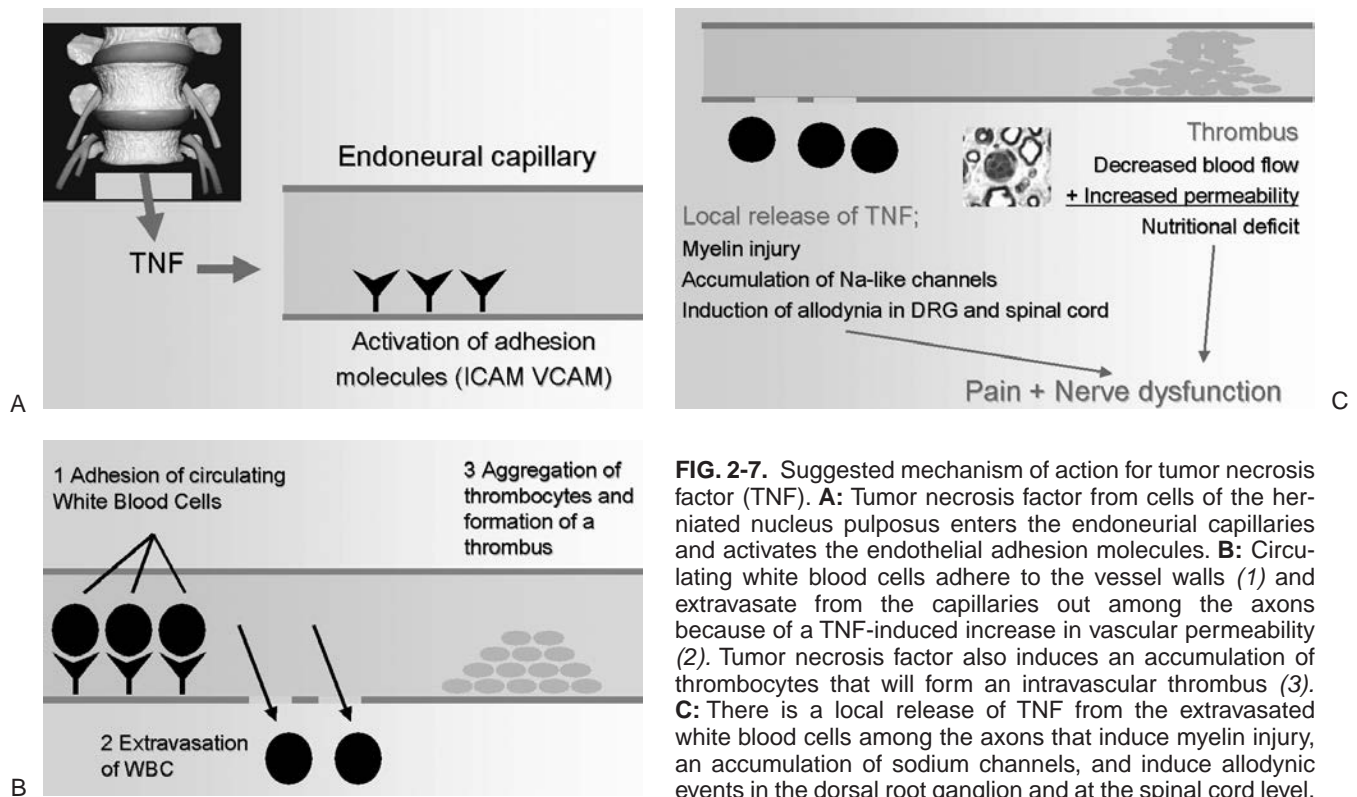

### **Suggested Mechanism of Action of Tumor Necrosis Factor**

It is known that even relatively large substances that are placed in the epidural space are found in the intra-

neural capillaries of the nerve root and dorsal ganglion (103). Therefore one may assume that TNF may reach the intraneural capillaries following release from disc cells in the herniated nucleus pulposus. Tumor necrosis factor induces an activation of endothelial adhesion molecules (e.g., ICAM and VCAM), thereby adhering circulating immune cells to the vessel walls (Fig. 2-7) (129,161,162). Because of the TNF-induced increased vascular permeability, these cells migrate into the endoneurial space where the axons are located (163–165). The cells then release their content of TNF and other cytokines, which may induce an accumulation of ion channels locally in the axonal membranes (166–168). The channels may allow for an increased passage of sodium and potassium, which may result in spontaneous discharges and discharges of ectopic impulses following mechanical stimulation. Tumor necrosis factor by itself can cause spontaneous electrical activity in A-delta and C-nociceptors (151). Such discharges, regardless of whether they come from a pain fiber or a nerve fiber transmitting other sensory information, are interpreted as pain by the brain (169–172). Such a mechanism may relate to the sensitization of the nerve roots seen in the mentioned experimental and clinical studies and may relate to motion-evoked sciatic pain, such as the straight-leg raising test.

Studies have also indicated that local application of nucleus pulposus may disintegrate the myelin sheath (71, 73). This is a known effect of TNF (138,163,173–175). In particular, this injury seems to affect the Schmidt-Lanterman incisures, which are responsible for the ion exchange between the axon and surrounding tissues (176–179). This could also contribute to the formation of ectopic impulses and the sensitization to mechanical stimuli.

Recent work regarding molecular events in the pathophysiology of neuropathic pain has suggested a potential role of TNF for inducing allodynia (139,180–185). Tumor necrosis factor may mediate the formation of allodynic states in both the dorsal root ganglion and spinal cord level because of its local up-regulation, which occurs via a positive feedback loop caused by TNF itself. Interestingly, this cycle seems to be broken by a direct effect of TNF on the up-regulation of anti-inflammatory cytokines such as IL-10, which eventually leads to a reduction of TNF and the physiologic balance of proinflammatory and anti-inflammatory cytokines. Such regulation seems to be induced both by mechanical injury to peripheral parts of the axons and also as a direct effect of TNF exposure, and thereby further enhances the impression that TNF may be an important mediator of neuropathic pain. Tumor necrosis factor is a potent activator of cells, and because it is

**FIG. 2-7.** Suggested mechanism of action for tumor necrosis factor (TNF). **A:** Tumor necrosis factor from cells of the herniated nucleus pulposus enters the endoneurial capillaries and activates the endothelial adhesion molecules. **B:** Circulating white blood cells adhere to the vessel walls (1) and extravasate from the capillaries out among the axons because of a TNF-induced increase in vascular permeability (2). Tumor necrosis factor also induces an accumulation of thrombocytes that will form an intravascular thrombus (3). **C:** There is a local release of TNF from the extravasated white blood cells among the axons that induce myelin injury, an accumulation of sodium channels, and induce allodynic events in the dorsal root ganglion and at the spinal cord level. The thrombus, together with the edema, induces a nutritional deficit in the nerve root because of increased permeability. Both the local effects of TNF and the nutritional deficit may induce pain and nerve dysfunction.

retrogradely transported from the site of nerve injury to the DRG and spinal cord, it may be this proinflammatory stimulus that activates central glia and neurons (153).

Apart from directly affecting the endoneurially located axons, TNF may also indirectly interfere with the axons by compromising the nutritional transport. It is known that TNF may induce intravascular coagulation, similar to nucleus pulposus, following local application (73,145, 154,186,187). This reduces the local blood flow in the intraneural capillaries (75). A nutritional reduction induces ischemia in the nerve root, which may induce neuroischemic pain.

There is evidence that TNF may be an important mediator of nerve dysfunction and pain. The unfortunate circumstance that TNF is produced and released from cells in the nucleus pulposus, when displaced from its natural environment in the center of the intervertebral disc out into the spinal canal in close contact to the nervous structures, may be one key event for the onset of nerve dysfunction and sciatic pain.

### **CYTOKINE INHIBITORS IN CLINICAL STUDIES FOR THE TREATMENT OF SCIATICA**

Based on the recent experimental findings that TNF may both mimic nucleus pulposus-induced nerve dysfunction and pain, pilot clinical trials regarding the possible use of TNF inhibition for the treatment of sciatica have been initiated. Karppinen et al. administered a monoclonal antibody specific for TNF (infliximab, Remicade) to 10 volunteers waiting for surgery for radiologically verified disc herniations with severe sciatica (188). In this open-label study, infliximab reduced pain assessed by the Visual Analogue Scale (VAS) by 50% 1 hour after infusion. After 2 weeks, 60% of the patients were pain free. Three months after the single infusion, 90% were pain free. No adverse drug reactions were seen and no patients required surgery.

Genevay et al. administered a TNF inhibitor in the form of a soluble TNF-receptor (etanercept, Enbrel [Immunex Corporation, Thousand Oaks, CA]) by three subcutaneous injections to 10 patients with severe sciatica (189). Ten days after commencing the treatment, the patients had a 70% reduction of VASL (leg pain assessed by VAS). At 6 weeks the reduction was 83%. The results were statistically significantly better than for seven patients treated with three intravenous injections of methylprednisolone.

Taken together, these preliminary, open-label observations strongly indicate a potential clinical effect of TNF inhibition for the treatment of sciatica. It may be surprising that TNF inhibition seems to be so much superior to anti-inflammatory treatment by NSAID or methylprednisolone or even morphine. One may conclude that it is more efficient to act at the responsible mediators directly than aiming at general anti-inflammatory effects. This

clinical comparison strongly supports the TNF hypothesis of neuropathic pain (67,125,154). Sciatica has a neuropathic pain component; nonspecific anti-inflammatory medication and morphine are less efficient in such conditions. Nevertheless, it must be remembered that clinical studies so far have only been open label and the role of TNF inhibition must be evaluated in randomized, prospective studies before any conclusions regarding its efficacy for the treatment of sciatica may be drawn (190).

### **SILENT DISC HERNIATIONS AND LOW BACK PAIN**

The relationship between the herniated disc and sciatica may seem well established. However, circumstances imply that we are still unaware of some mechanisms. For instance, why do approximately one third of all persons who have never suffered from sciatica have disc herniations that may be visualized by radiology? If the presence of a disc hernia is a prerequisite for sciatica, why do not all patients displaying disc herniations have sciatica? Sciatica is a special form of pain, which (unlike low back pain) is sharp, distinct, and usually located to the distribution area of one spinal nerve root segment. It is most likely a form of neuropathic pain (i.e., pain resulting from direct pathology of the involved nerve), and it is likely that sciatica may occur because of irritation or injury of the nerve root in the spinal canal adjacent to a herniated disc. As described, recent research has demonstrated that the pathology leading to nerve root pain (i.e., sciatica) is based on the combined action of a sensitization of the nerve by proinflammatory cytokines derived from the intervertebral disc cells and simultaneous mechanical deformation of the nerve root (58,60,191). Thus, from an experimental standpoint it seems necessary that there is both a sensitization and mechanical deformation in order to produce pain, and that disc leakage or mechanical deformation per se do not produce pain, at least not at detectable levels.

It can be demonstrated that acute injection (experimental herniation) of nucleus pulposus material into the spinal canal does not result in nerve root compression. Instead, the gel-like nucleus pulposus spreads among the intraspinal nervous structures, almost reaching the adjacent disc levels (Fig. 2-8). This is most likely what happens when there is an acute herniation when the semiliquid nucleus pulposus leaks through a rupture of the annulus fibrosus (Fig. 2-9A,B). Later, the herniated nucleus pulposus is partly resorbed and a healing process around the site of rupture at the surface of the disc is initiated. This may result from a reactive process induced by the cytokine activity of the disc, which significantly activates fibroblastic processes. The result, based on the degree of resorption and scar formation, is a slight rounded scar over the rupture site of the disc (Fig. 2-9C). This scar is probably what is referred to as a herniated

**FIG. 2-8.** Epidural injection of nucleus pulposus in the pig lumbar spine studied by radiology. Nucleus pulposus was obtained from another pig. **A:** The abdomen was incised and a needle connected to a syringe with nucleus pulposus mixed with Mixobar and Urografin was introduced into the disc from the abdominal side. The tip of the needle was placed in the epidural canal, just penetrating the dorsolateral annulus fibrosus. **B:** The nucleus pulposus in an amount approximately corresponding to one intervertebral disc was gently injected into the spinal canal, resembling an acute herniation (*black*). The injected material spread in the spinal canal, almost reaching both adjacent disc levels. **C:** In the antero-posterior view it was seen that the injected material was mainly located on the side of the injection. An asterisk indicates the injection site. **D:** Thirty minutes after the injection, the lumbar segment was removed and the specimen was radiographed in the axial direction. It was seen that the injected material (1) after injection from the dorsolateral aspect of the disc (2) was located in the epidural space, outside the thecal sac (3). The thecal sac was displaced slightly to the contralateral side to the injection (**left**). The nerve root adjacent to the injection site (4) did not seem to be compressed. Instead, it was covered by the injected material on the dorsal side.

disc in the clinical setting. Because of the absence of a mechanical factor, the patient has not experienced any neuropathic pain (i.e. sciatica) during this process and the disc hernia is called a “silent disc herniation” when encountered by radiology. However, because local application of nucleus pulposus is known to induce reduced nerve function in experimental models, one may assume that the patient may suffer from various degrees of reduced sensibility and motor function during the leakage of nucleus pulposus material, maybe at a subclinical level. Likewise, if there is already mechanical compres-

sion of the nerve root (e.g., by lateral canal stenosis or an osteophyte), the sensitization of the nerve root induced by cytokines from the leaking disc may induce sciatic pain. However, no disc herniation is seen by radiology or at surgery in this case. Repeated episodes of leakage may result in a larger scar at the disc surface and there may be a build-up of a scar. At some point the scar will be large enough to interact with the nerve root mechanically. A new leakage of disc material at this point therefore may induce both a sensitization of the nerve root and mechanical deformation by the disc herniation scar, and there

**FIG. 2-9.** Formation of a disc herniation. **A:** The nerve root (1) and the central thecal sac with nerve roots and at some levels the spinal cord (2) are located just dorsal to the intervertebral disc with its connective tissue ring annulus fibrosus (3) and its semiliquid center nucleus pulposus (4). **B:** If the annulus fibrosus ruptures there may be a leakage or herniation of nucleus pulposus, as indicated by the black arrow out onto the surface of the disc and into the spinal canal (5). The surface of the disc is innervated by local sensory nerve endings (6) and the nucleus pulposus may irritate and stimulate these nerve endings. Because this leakage is not combined with any compression of the nerve root, there will not be any sciatic pain. **C:** The disc herniation heals and becomes organized, and a dense scar will form (7). This dense herniation scar may compress the nerve root (1) mechanically but because the biologic activity of the herniated intervertebral disc is now reduced, there is no radicular pain. This is what is called a “silent disc herniation” when accidentally found at radiologic examination. **D:** At later herniations the newly herniated nucleus pulposus material (8) will reach the nerve root. In this case, the combined action of the nucleus pulposus and the previous scar tissue (7) induce nerve root pain (i.e., sciatica).

may be neuropathic or sciatic pain in that specific nerve root (Fig. 2-9D). Radiology at this time reveals the scar from the previous leakage and, rightfully, is regarded as the cause of the present problems, although not in the sense previously assumed.

One also may consider if the so-called silent disc is silent. As discussed, patients may have discrete reduction in sensory and motor function in the early phases of a new disc leakage. However, we also know that there are sensory nerve endings at the surface of the intervertebral disc (192–195). Because many of the substances produced and released from the disc cells may be neurotoxic and neuroirritative, they may stimulate the local nerves at the disc surface. Cavanaugh et al. showed that silent receptors at the disc surface are triggered by a proinflammatory substance such as carrageenan (196). Disc-derived proinflammatory cytokines may have a similar action. Although pain from sensitization of a nerve root with locally derived ectopic nerve impulses from the axons induces a sharp neuropathic pain in the corresponding dermatome of that specific nerve root, the pain derived from local stimulation of nerve endings has a different localization and different characteristics. Kuslich et al. showed that local stimulation of the posterior surface of the disc in conscious volunteers results in a dull pain in the lumbar area, and suggests that the poste-

rior disc surface is the site of low back pain (88). Taken together, irritation of local nerve endings by disc-derived substances might induce spontaneous discharges that induce low back pain in relation to a herniation of disc material into the spinal canal. We speculate that each time there is a leakage of disc material there is an episode of low back pain. In relation to the previous discussion about repeated episodes of disc leakage leading to a disc herniation scar that eventually will mechanically affect the adjacent nerve root, one may assume that there will be repeated episodes of back pain as well. Repeated episodes of low back pain are common in patients with sciatica, and low back pain is in fact the strongest predictor of sciatica (197). This clinical observation thus may closely relate to this speculative scenario. It is also common that sciatica is preceded by several days of low back pain, which based on the previous discussion may be explained as direct stimulation of nerve endings of the disc surface before the sensitization of the nerve root and the subsequent neuropathic pain develops. Silent disc herniations (i.e., leakage of nucleus pulposus without sciatica) may thus be silent with respect to sciatica, but may be a not previously recognized mechanism for low back pain.

## CONCLUSIONS

The pathophysiology of sciatica is a complex event with numerous substances and mechanisms acting at various levels. Recently, these mechanisms have attracted attention also by basic scientists, and thus a number of studies looking into neuroimmune events have provided important insights to the pathophysiologic mechanisms that account for the human problem. It seems clear that the intervertebral disc per se has certain biologic effects that contribute directly to these pathophysiologic processes. Epidural application of nucleus pulposus induces both structural and functional changes, which relate closely to the nerve dysfunction seen in radiculopathies such as sciatica. Nucleus pulposus also seems to sensitize the nerve roots to produce pain when exposed to mechanical deformation, whereas nucleus pulposus application or mechanical deformation alone does not seem to induce significant pain. These experimental observations correlate with the clinical impression that preoperative touching of nerve roots that have been exposed to disc herniation under local anesthesia reproduces the sciatic pain, and that surgical removal of the mechanical compression of the nerve root often relieves the symptoms. It thus seems that substances from the nucleus pulposus, in combination with mechanical deformation, initiate the pathophysiologic events leading to pain and nerve dysfunction. The substance of importance in this regard clearly seems to be TNF. The activation and up-regulation of this ubiquitous proinflammatory cytokine produces acute pain and the neuropathologic changes associated with chronic pain states. Tumor necrosis factor stimulates fibroblast scar formation in a

vicious cycle whereby the local presence of TNF stimulates other cells to up-regulate this cytokine. Thus, initiation of this cycle by the leakage of TNF from herniated nucleus pulposus produces a cascade of tissue injury, scar formation, and local pain. Superposition of mechanical injury to the nerve root in this environment exacerbates the neural immune insult, causing macrophage mediated wallerian degeneration with significant increases in TNF concentrations. We suggest that these combined events explain the problem of sciatica. Interestingly, there is also ongoing research indicating an immune reactivity in some patients after disc herniation, which might be involved in the later pathophysiologic phase, thus contributing to chronicity of the symptoms. The recent success of human trials with anti-TNF agents strongly supports this interpretation of the neural immune studies summarized in this chapter. Although the pathophysiology of sciatica is far more complex than one might first suspect, we are certain that future research will reveal both substances and mechanisms of importance to the induction of symptoms in sciatica, and we hope that such research may provide a basis for improved diagnosis and treatment of this common disorder.

## CHAPTER 3

# Biomechanical Considerations of Disc Degeneration

Allison M. Kaigle Holm and Sten H. Holm

---

Mobility and stability of the spine are governed by a complex neuromusculoskeletal system. Panjabi (1) eloquently described the spinal stabilizing system as three subsystems (Fig. 3-1): *passive* (disc, ligament, bone, and passive muscle), *active* (tendons and active muscle), and *neural* (the nervous system and neural components within the passive and active structures). The biomechanical characteristics of the lumbar spine are dependent upon the integrity of all three subsystems. Under normal conditions, the musculoskeletal structures interact in a highly coordinated and optimized fashion via neural networks, to produce the desired movements and achieve the requirements for stability. However, injury or degenerative processes disrupt the intricate balance, and cause a transfer in unfavorable loads onto other spinal structures. This often leads to pain or dysfunction. With regard to the intervertebral disc, degenerative processes are believed to alter the disc's mechanical properties as well as the surrounding structures. This underlying belief has fueled an extensive amount of research aimed at elucidating the biomechanical consequences of disc degeneration.

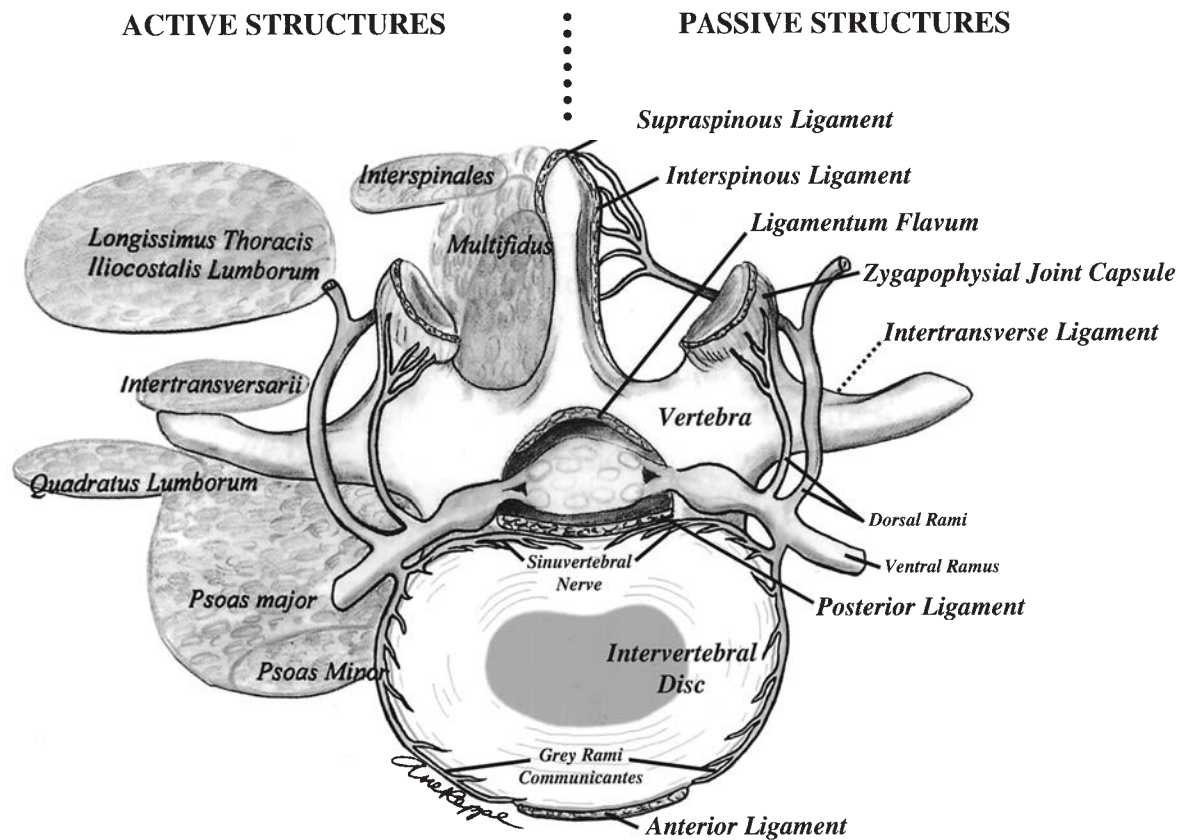

### STRUCTURE AND FUNCTION

It is important to have some basic knowledge of the individual structures of the lumbar spine, as well as their functions and interactive processes, in order to understand how disturbances to a single structure can adversely affect secondary structures, and ultimately the spinal system as a whole. Many examples of this can be found in the literature. Disc degeneration transmits unfavorable stresses onto other spinal structures, particularly the facet joints. A radiographic study by Butler et al. (2) found that disc degeneration caused secondary osteoarthritic changes in the facet joints, most likely due to a shift in the mechanical loading. Using a sheep model, facet joint arthrosis has been shown

to occur in response to experimentally induced disc degeneration (3). Substantial bone remodeling in vertebrae adjacent to intervertebral discs that sustained lesions of the annulus has also been observed (4). Changes in muscle fiber type of the multifidus and erector spinae muscles (5–7), and structural changes in the connective tissue of the multifidus (8) have been reported clinically in patients with lumbar disc herniation.

The intervertebral disc is a deformable connective structure, with a very low capacity for remodeling and repair due to its avascularity in the mature state. This makes it particularly vulnerable to fatigue failure. A turgid central nucleus pulposus exists in the healthy state; it is designed to sustain and transmit pressure while surrounded by an annulus fibrosus, a highly organized arrangement of collagen fiber layers that can resist movements in all directions due to the fibers' alternating oblique orientation. Due to the arrangement of the annulus fibers and regardless of the type of loading, the disc annulus, partly or in whole, is subjected to tensile stresses. The three major constituents of the intervertebral disc are water, collagen, and proteoglycans. Their proportions vary radially within the disc, as well as with aging and degeneration (9,10). The outer annulus has the highest collagen content and the lowest water and proteoglycan contents, whereas the nucleus has high water and proteoglycan contents and low collagen content (11). The biomechanical properties of the intervertebral disc depend largely on the tissue's hydration. The collagen fibrils provide the tensile strength of the intervertebral disc. The turgid action of the water-binding proteoglycans surrounded by the collagenous framework provides the load-bearing capacity (12). The principal functions of the intervertebral disc are to allow joint mobility and transfer axial loads between the vertebrae. Together with the vertebrae, the disc resists approximately 80% of the compressive force acting on the spine in the upright standing

**FIG. 3-1.** Schematic of the bilateral active and passive structural arrangement and sensory innervation on the L3-L4 level.

posture (13). The intervertebral disc allows rotations (flexion-extension, lateral bending, and axial) between the vertebrae, as well as translational movements caused by compressive or shear forces.

A cartilaginous end plate, which joins the vertebral body and intervertebral disc, provides a nutritional pathway to the avascular intervertebral disc. The end plates deflect when sufficient axial loads are transferred between the intervertebral disc and vertebral body. Disruption in the nutritional pathways through the end plate is believed to be a key mechanism for disc degeneration (14).

The zygapophysial joints, or commonly called facet joints, are synovial joints formed between the superior and inferior articular processes of adjacent vertebrae. These cartilage-covered articulating processes or facets, along with the fibrous capsule that encloses the joint, provide a locking mechanism that can resist shear translation and axial rotation between the vertebrae. Bony impact, as well as tension of the joint capsule, play major roles in providing passive stability during bending of the lumbar spine. According to Adams and Hutton (15), the facet joints normally bear approximately 20% of the spinal compressive force, but if there is a loss in disc height due to degenerative changes, load bearing can be as high as 70%. In a lumbar motion segment, the intervertebral disc provides approximately 40% to 50% torque strength, while the

remaining strength is attributed to the posterior elements and the interspinous ligaments (16).

The ligaments of the lumbar spine provide passive tensile resistance to external loads. The amount of stability provided by a particular ligament depends not only on its strength, but also on its architectural arrangement and the loading circumstances. Ligaments are most effective in resisting loads along the same direction of their fibers. With disc degeneration, narrowing of the disc space can reduce the ligamentous tension, and thus decrease its effectiveness in providing passive translatory or rotatory stability.

Devoid of the muscles, the osseoligamentous spine is inherently unstable at low loads (approximately 90 N) (1,17). Therefore, the neuromuscular system must fulfill the supplementary and adaptive role of maintaining postural stability *in vivo*. Disturbances in the precise motor control strategies, particularly those of repetitive nature, may have detrimental effects on the lumbar spinal structures (e.g., cause pain or dysfunction). The lumbar spine is directly influenced by a number of bilateral muscles, both intersegmental and polysegmental, acting in a well-coordinated manner in order to balance the actions of gravity or execute controlled movements, as well as provide passive elastic tension. The muscles not only produce movements, but also generate compressive and shear forces that contribute to the high internal forces to which the lumbar spine

is subjected. The complex recruitment patterns of the lumbar musculature are not well established. However, biomechanical and neurophysiologic evidence suggests that the deep intrinsic muscles are recruited to control motions at the intervertebral level, whereas the long multisegmental muscles may be involved in a more “global” control of the overall spinal orientation (18–20).

The innervation patterns of the active and passive structures of the lumbar spine have, for the most part, been determined. The load-sensitive nerve endings, or mechanoreceptors, found in muscle (muscle spindles) and tendon (Golgi tendon organs), provide proprioceptive information regarding tension levels, essential for controlling muscle tone. Although the presence of nerve endings in the passive structures has been well documented (21–28), their role has not been clearly established. Regarding the articular structures, the outer annulus of the intervertebral disc and the capsules of the facet joints contain both free nerve endings and mechanoreceptors. These structures act as proprioceptive transducers for monitoring the position and movements of the motion segment. The neurologic feedback from these passive structures provides sensory information needed to regulate muscle tension, and hence the mobility and stability of the lumbar spine. In addition to a regulatory function, the presence of a nerve supply in the articular structures makes these structures potential sources of pain (22).

### **BIOCHEMICAL AND STRUCTURAL CHANGES ASSOCIATED WITH DISC DEGENERATION**

Disc degeneration is the deterioration and remodeling of the physical and chemical properties of the tissue—whole or in part—with retrogressive pathologic changes in the cells or macromolecules (14). The changes observed in degenerated discs are similar to those found in normal aging (29,30), but they are more pronounced with disc degeneration, may occur earlier in life and with more severe changes, and are often associated with clinical symptoms (31).

The principal biochemical sign of disc degeneration and aging is the loss in proteoglycans and hence loss of water, particularly in the nucleus (11,30,32,33). Cells in the nucleus change their shape and begin to synthesize collagen types not found in normal intervertebral discs (34). Structurally, the nucleus pulposus becomes progressively more fibrous and opaque, with increased pigmentation (34–37). The demarcation between the annulus-nucleus boundary becomes less distinct and delamination of the mid-to-outer annulus occurs, particularly in the anterior annulus (38,39) (Fig. 3-2). Delamination is believed to be a precursor stage for the development of concentric tears in the annulus fibrosus (40). Abnormalities can be found in the ultrastructural features of the collagen fibrils of the annulus fibrosus (e.g., widened fibrils or irregular fibril cross-sectional diameters) (41). Radial fissures and cracks

in the annulus fibrosus can form cavities within the disc (42). There can be inward buckling of the inner annulus as well as increased radial bulging of the annulus (43,44). Radiographically identifiable pathology associated with disc degeneration includes disc space narrowing, osteophyte formation around the margins of the vertebral bodies, and sclerosis of the vertebral end plates (45,46).

For describing the degree of degeneration according to morphologically observed changes, Nachemson (47) created an integer grading scale ranging from 0 (no macroscopic signs of degeneration) to 4 (severely degenerated). This grading scheme or versions similar to it are commonly referred to when classifying the degeneration status of specimens used in biomechanical studies. Kirkaldy-Willis (48) described the process of degeneration as having three sequential phases: (a) an early phase of dysfunction, where the motion segment does not function normally but the pathologic changes are minimal (grade 1); (b) instability, an intermediate phase where there is increased joint laxity which may be exemplified as abnormal segmental motion (grade 2); and (c) the restabilization phase characterized by fibrosis in the posterior joints and osteophyte formations, which lead to decreased segmental motion (grades 3 and 4).

### **MECHANICAL FACTORS AS POSSIBLE PATHOMECHANISMS OF DISC DEGENERATION**

There are several theories about the possible pathomechanisms of disc degeneration. Mechanical, chemical, age-related, autoimmune, hereditary, and genetic factors have all been implicated (49). Considerable attention has focused on trying to understand the etiologic role mechanical loading plays in disc degeneration. This partially stems from the fact that back pain is the leading cause of disability among the working population (50). There is an underlying belief that pathology leading to back symptoms can result from mechanical factors that damage spinal structures (51–53). Farfan et al. (16), for example, postulated that intervertebral disc degeneration results from imposed torsional strains that cause impairment in the function of the facet joints. Although there is no clear dose-response relation between occupational loading exposure and degenerative findings, physical workload has been found to predict spinal injury in truck drivers (54). Suspected occupational risk factors for back pain include the following physical demands: heavy physical loading; materials handling including lifting, bending, twisting, pulling or pushing; prolonged static postures; and whole body vibration (52,55–57). However, there are discrepancies in the literature regarding which physical factors are associated with an increased prevalence of low back pain. Marras et al. (58) assessed the contribution of dynamic trunk motions to the risk for low

**FIG. 3-2.** Comparative photographs of cross-sectional and sagittal views of a degenerated disc (**A, B**) and the adjacent disc (**C, D**) from an experimental model (end-plate injury) of disc degeneration, showing gross morphologic changes in both the annulus and nucleus structures. (From Kawchuk GN, Kaigle AM, Holm SH, et al. The diagnostic performance of vertebral displacement measurements derived from ultrasonic indentation in an *in vivo* model of degenerative disc disease. *Spine* 2001;26:1348–1355, with permission.)

back disorders during occupational lifting in industry. An increase in the magnitude of the following workplace factors significantly increased the risk for low back disorders: lifting frequently, load movement, trunk lateral velocity, trunk twisting velocity, and trunk sagittal angle.

There is evidence to suggest that occupational exposures have an effect on disc degeneration, specifically with regard to lumbar disc degeneration; however, the contribution of such risk factors appears to be modest, particularly when compared to familial influences (52). A critical review of the literature was recently made by Hansson and Westermalm (59) to assess whether or not existing scientific evidence substantiates relationships between low back problems and the following different physical work exposures: patient handling and care, lifting of patients, materials handling, heavy physical work, heavy lifting, bent or twisted work positions, standing or walking, prolonged sitting, and exposure to whole body vibration. The review revealed that

there is strong evidence of an association between an increased occurrence of low back problems and frequent heavy lifting (greater than 15 kg) and twisted or bent working positions, whereas frequent lifting of less than 10 kg shows a strong negative association. Moderate evidence supports an association between whole body vibration and an increased occurrence of low back problems. Limited evidence yields an association between patient handling and care, patient lifting, and heavy physical work and an increased occurrence of low back problems. There is currently insufficient evidence for an association between low back pain and standing, walking, or prolonged sitting.

Loading effects on the lumbar spine during physically demanding tasks are not only dependent on the load magnitude, but also the loading rate and history (60,61). This is partly because the intervertebral disc and ligaments are viscoelastic structures. The viscoelastic behavior has been well documented for the intervertebral disc, both normal

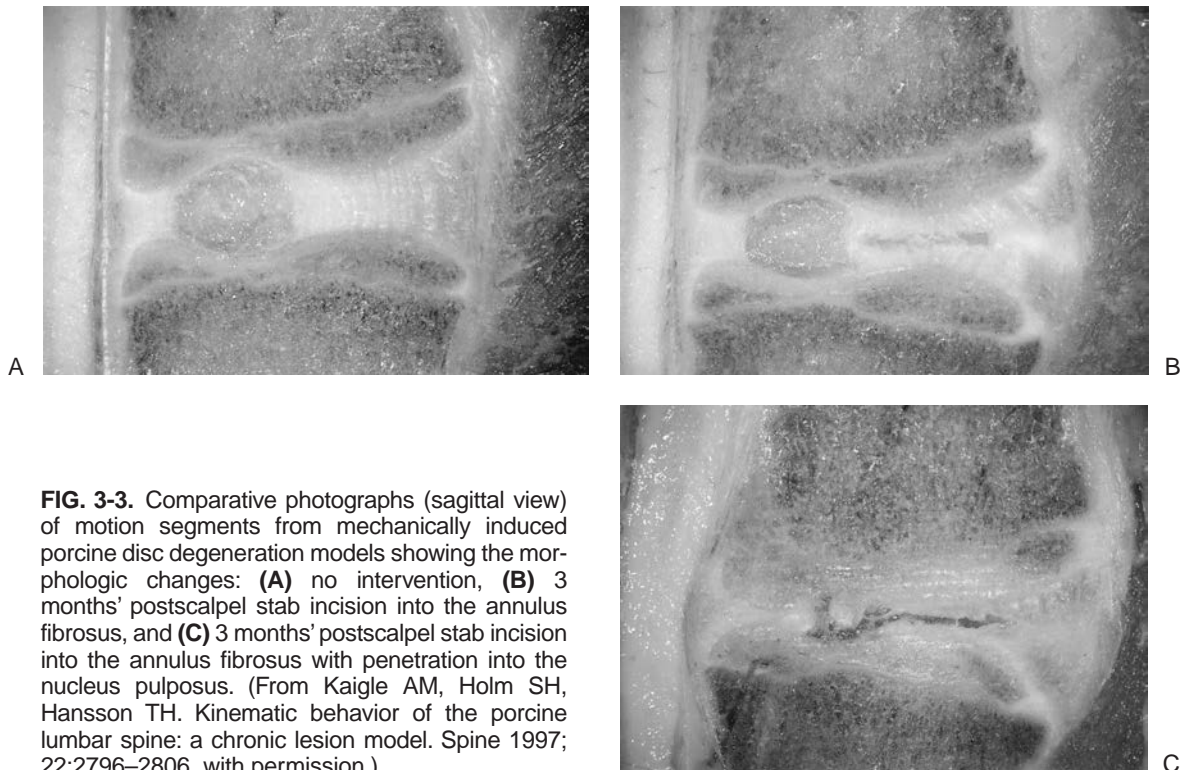

and degenerated (62–70). The outflow of tissue fluid and the stretching of the collagen fibers of the annulus fibrosus under loading cause approximately a 20% reduction in the height and volume of the disc (71). Intradiscal pressure has also been shown to decrease with creep loading (72). Such reductions make the tissue more elastic (73), less resistant to bending (60) and shear loading (74), and causes greater axial loading on the facet joints (75). When loading is removed, the disc imbibes fluid and recovers from the deformation, although complete recovery requires a considerable amount of time. With repetitive physical tasks, even at relatively low physiologic loads, the spinal structures may suffer from fatigue. Mechanical fatiguing can make the disc, as well as other viscoelastic spinal structures (e.g., ligaments, tendons, and fascia) more vulnerable to microdamage. Considering the very low repair capacity of the mature intervertebral disc, accumulative structural damage is believed to be an underlying cause of disc degeneration and low back pain (76).

Trying to establish cause and effect in disc degeneration is extremely difficult. In a degenerated disc, structural disruption is accompanied by cell-mediated changes in composition. It is not clear as to whether progressive biochemical changes in the disc alter its structural integrity, or whether mechanical disturbances precipitate biochemical changes in disc cell metabolism (77). Adams and Dolan (76) described how structural failure may cause biologic degeneration of tissues by a number of mechanisms: by altering the mechanical environment of the cells, by inter-

fering with metabolite transport to and from the cells, or by breaking down barriers and allowing an inflammatory or even autoimmune reaction to occur. Biochemical observations by Pearce et al. (78) support the hypothesis that low proteoglycan concentrations in all the discs of a spine precede degeneration.

### EXPERIMENTAL MODELS OF DISC DEGENERATION

In order to perform controlled investigations of the etiology and progression of disc degeneration, animal models are often used. Experimental models have the advantage of allowing standardized evaluations of biomechanical, histochemical, and morphologic phenomena of the degenerative process, directly from initiation of the process. There are several different ways in which experimental disc degeneration can be induced *in vivo*, either chemically or mechanically. Injection of a matrix-degrading enzyme (e.g., chymopapain), into the disc can produce degenerative changes (79). A number of investigators have mechanically produced degeneration *in vivo* in rat and mice tail discs chronically loaded with an external compression device (80–82). Disc degeneration as a result of torsional injuries has been demonstrated *in vivo* in rabbit models (83,84). A scalpel stab incision into the annulus fibrosus, with or without penetration into the nucleus pulposus (Fig. 3-3), is a technique that has frequently been used to mechanically induce disc degenera-

**FIG. 3-3.** Comparative photographs (sagittal view) of motion segments from mechanically induced porcine disc degeneration models showing the morphologic changes: (A) no intervention, (B) 3 months' postscalpel stab incision into the annulus fibrosus, and (C) 3 months' postscalpel stab incision into the annulus fibrosus with penetration into the nucleus pulposus. (From Kaigle AM, Holm SH, Hansson TH. Kinematic behavior of the porcine lumbar spine: a chronic lesion model. *Spine* 1997; 22:2796–2806, with permission.)

tion (85–94). In rabbit, sheep and pig, this model has been shown to cause progressive degeneration which biochemically and structurally resembles that in human disc degeneration. A new injury model, involving penetration of the end plate via the vertebral body, has been shown to produce symmetrically widespread degenerative changes in the disc that resemble human disc degeneration (i.e., declines in concentrations of water, cells, and proteoglycans as well as intradiscal pressure) (38). This is a model in which the severity of the degenerative changes can vary according to the penetration diameter or depth (38,95). Loss in hydrostatic pressure in the nucleus and disruption of nutritional pathways through the end plate are believed to be two key mechanisms behind this model of disc degeneration. Deficient metabolite transport has been linked with degenerative changes (96). This model mimics human degeneration caused by end-plate fractures or nucleus herniation through the end plate.

### BIOMECHANICAL CONSEQUENCES OF DISC DEGENERATION

In everyday life, the structures of the lumbar spine are continuously subjected to pure as well as combined physiologic loads (e.g., compressive, tensile, shear, torsional, and combinations thereof). Disc degeneration affects both the geometry and material properties of the motion segment. While geometric changes can be expected to decrease flexibility, changes in material properties may cause the opposite response. The extent to which each of these factors affects the spinal behavior is also dependent on the direction of loading. For these reasons, along with the fact that the intervertebral disc is an anisotropic structure, it is necessary to perform biomechanical testing which includes both simple and complex loading modes.

For several decades, numerous studies have been performed in order to assess how the biomechanical properties of the lumbar spine are affected by intervertebral disc degeneration. Accurate knowledge of the intervertebral disc's biomechanical properties in healthy, injured, or diseased states is essential for performing valid mathematical analyses of the intervertebral disc, for refining injury (failure) criteria, and for developing artificial disc replacements, as a few examples. Studies have used various methodologies in order to quantify the physical properties—elastic and viscoelastic—as well as the kinematic behavior. Since the degenerative status can be determined, the majority of studies of intervertebral disc degeneration are conducted using cadaveric material (isolated discs, motion segments, or whole lumbar spines) or *in vivo* animal models. Methodologies for performing such analyses have primarily employed servohydraulic-type material testing devices or used similar techniques that can measure the load-displacement behavior.

### Elastic Behavior

With regard to biomechanical testing, axial compression has been a popular test mode for studying the intervertebral disc, perhaps due to physiologic as well as practical considerations; namely that the disc is a major compression-carrying structure in the spine (97) and that compression testing is a relatively straightforward experimental test mode that can provide considerable information about the disc's physical properties. Early biomechanical studies from the 1950s by Brown et al. (98) and Hirsch et al. (99–101) described the nonlinear mechanical characteristics of *in vitro* lumbar motion segments under axial compression, as well as other test conditions. Studies such as these were motivated by the fact that disc degeneration was viewed as a possible pathologic anatomical explanation for low back pain, and although no pain mechanisms were identifiable at the time, the importance of mechanical factors was strongly recognized. Hirsch and Nachemson (101) demonstrated differences in the mechanical behavior between cadaveric motion segments with normal and degenerated discs, noting that for the same applied axial load, degenerated discs deformed more easily than healthy discs, particularly at higher loads. Nachemson et al. (102) reported differences in stiffness between less degenerated discs [grades 0 to 2 on a total 5-point scale of 0 (normal) to 4] and grossly degenerated discs (grades 3 and 4) that were dependent on the loading configuration. In axial compression, less degenerated discs were stiffer than grossly degenerated discs. However, in flexion and extension modes, more degenerated discs were found to be less flexible, while in lateral bending and torsion, there were no significant differences. Fibrosis in the posterior joints of the grossly degenerated discs may explain the observed increase in stiffness in the flexion and extension loading modes observed in the degenerated discs. Keller et al. (68) also reported a decrease in axial compressive stiffness with increasing grades of degeneration [1 to 3 on a total 4-point scale of 1 (normal) to 4]. In a recent *in vitro* study, Brown et al. (103) examined lumbar motion segment stiffness under flexion-traction loading. A nonlinear trend, which coincided with the degenerative process described by Kirkaldy-Willis (48), dysfunction-instability-restabilization, was observed between motion segment stiffness and degeneration grade; reduced stiffness was found in discs with early stages of degeneration whereas discs with more severe degenerative changes showed a tendency toward increased stiffness.

### Viscoelastic Behavior

Using static and dynamic axial compression test modes, it has been shown that degeneration alters the viscoelastic (time-dependent) behavior of the intervertebral disc. Virgin (70) was the first to demonstrate that the hys-

teresis behavior was greater in discs that showed actual signs of degeneration than in middle-aged or older discs that did not show any degenerative signs. This means that, in the degenerate state, there is greater energy loss during loading-unloading cycles, which can be of considerable importance with regard to repetitive axial vibration. Koeller et al. (69) studied the effects of age and degeneration on the creep response of the intervertebral disc under dynamic axial compression. From the middle of the third to the beginning of the sixth decade, only slight alterations in the biomechanical properties were found, whereas later in life, where there was a greater occurrence of disc degeneration, increased creep was observed in the lumbar spine. Kazarian (65) performed static axial compression tests on older cadaveric lumbar motion segments with various degrees of degeneration. The creep behavior was found to correlate with the degree of degeneration; the degenerate discs exhibited greater initial deformation and approached equilibrium at a more rapid rate compared with the nondegenerate discs. Similar behavior has been confirmed by Keller et al. (68).

### Internal Disc Mechanics

With the intervertebral disc being an inhomogeneous structure, there are regional material property differences, particularly in the annulus fibrosus, which reflect the variations in structural and biochemical composition. Such regional properties will affect the manner in which the intervertebral disc responds to loading and must be taken into consideration when performing analytical representations. Brown et al. (98) were perhaps the first group to map the regional tensile strengths of the intervertebral disc. Rectangular vertebra-disc-vertebra sections from different locations of the disc were axially stretched to failure. In this normal material, the strongest areas were found to be in the anterior and posterior portions of the disc, while the central portion was the weakest.

More recent studies of the radial and circumferential variations in the tensile properties of nondegenerate lumbar disc specimens have reported that, when loaded along the plane of the lamella, the anterior annulus is stiffer and stronger than the posterolateral regions, and the outer annulus is stiffer and stronger than the inner regions (10,104). Ebara et al. (104) speculated as to how load distribution would benefit from a lower tensile modulus in the inner annulus fibrosus. They stated that the lower values for the tensile modulus and the larger values for strain suggest that the inner annulus fibrosus is likely to be more deformable, and thus be more successful at distributing applied loads in a uniform manner across the inner annulus fibrosus, as compared to the more restrictive outer annulus. Therefore, the more deformable inner annulus fibrosus may provide for significant energy dissipation within the tissue. Acaroglu et al. (105), using

multiple-layer annulus specimens, evaluated the effects of aging and degeneration on the regional tensile properties when loaded along the plane of the lamellae. Degeneration was found to be accompanied by significant decreases in the failure properties (i.e., failure stress and strain energy density), indicating that degenerated annulus fibrosus will fail at lower stresses and require less energy to fail. Also, a significant decrease in the Poisson ratio, which is a ratio of the transverse and axial strains in the tissue, was found. This indicates structural changes in the annulus lamellae, which will affect the internal stresses in the disc and thus the overall manner in which the disc bears loads. Fujita et al. (106) studied *in vitro* the radial tensile properties of normal and degenerated lumbar annulus fibrosus, when loading perpendicular to the plane of the lamellae. The radial tensile behavior of the annulus was highly nonlinear and showed region-dependent behavior that was likely due to radial variations in interlaminar weaving. Compared to specimens from both the inner and outer annulus of normal discs, specimens from the middle layers were stiffer and failed at smaller strain magnitudes with radial tensile loading. Differences due to degeneration were noted; moderately degenerated discs showed a 30% decrease in yield and ultimate stress compared with normal discs.

Umehara et al. (107) studied variations in the disc's axial compressive properties as a function of location in the disc and degeneration. Using an indentation technique on whole disc specimens, the axial compressive elastic modulus was assessed in lumbar discs with various degrees of degeneration. In normal discs, the elastic moduli were lowest in the nucleus as well as the lateral portions of the annulus, whereas the values were significantly greater in the posterior and anterior annulus, being greatest in the anterior portion. This normal distribution pattern, which correlated with the distributions of tensile strengths reported in earlier studies, was affected by disc degeneration. In normal discs, the distribution was symmetrical about the midsagittal plane, whereas the more severely degenerated discs showed asymmetrical and irregular profiles and higher nucleus moduli. In the slightly degenerated discs, the lowest values of the elastic moduli were found in the posterolateral portions of the disc, which is also the region where disc disruption is clinically found to occur most frequently (108). Farfan et al. (16) found that the location of maximum stress under torsional loading was at the posterolateral angles of the intervertebral disc, again coinciding with the common site of clinical disc protrusion.

Annular lesions of the radial, circumferential, or rim-lesion type compromise the disc's internal mechanical integrity. Such lesions appear to evolve independent of age or each other (40), and may be the result of fatigue failure or part of a degeneration process. A study has examined how the type and severity of such lesions in lumbar intervertebral discs alter the biomechanical prop-

erties (109). Flexion-extension stiffness increased with greater tear severity, which was believed to be partly due to the accompanied loss in disc height. Increasing severity of circumferential tears and rim lesions correlated with decreasing joint axial torsional stiffness. With a circumferential tear, interlamellar bonding is absent in a portion of the annulus; thus the disc's ability to transfer shear forces induced by torsional loading is reduced. It has been suggested that interlaminar separation and matrix failure between the lamellae might be a more clinically relevant injury mechanism than tensile failure of the collagen fibers within a lamella (106). It is believed that with loss of cohesion between the annulus lamellae, other structures of the motion segment, particularly the facet joints, have to provide a greater portion of torsional resistance, and that this could play a major role in early degenerative changes (16). With a rim lesion, there is a defect in the annulus attachment close to the bone of the vertebral rim, which compromises the transferring of torsional loads across the motion segment. Thompson et al. (109) reported that radial tears showed little or no effect on the axial torsional stiffness. Schmidt et al. (110) compared the stiffness (flexion-extension, axial rotation, lateral bending) in cadaveric motion segments with and without high intensity zones (i.e., radial tears, in the annulus fibrosus viewed on magnetic resonance images). In this study, the presence of a radial tear was associated with a significant reduction in stiffness in the motion segment in axial rotation.

A direct means for measuring loading on the spine is with intradiscal pressure measurement techniques. In a healthy disc, the pressurized gelatinous nucleus pulposus acts as a hydraulic cushion that generates tensile stresses in the annulus, permitting applied loads and pressures to be evenly distributed over multiple spinal segments. The lamellae of the annulus fibrosus are believed to primarily bulge radially outward due to the hydrostatic pressure in the nucleus. However, with aging and degenerative processes, the reduction in water content and increased fibrosis in the nucleus result in reduced hydrostatic behavior, and there are structural disruptions in the annulus lamellae and end-plate regions. In degenerated discs, there have been reported observations of inward bulging of the inner lamellae (43,44,77), and that such bulging is associated with pressure loss in the nucleus (81). Under loading, such changes alter the internal disc mechanics, producing high stress concentrations that may cause pain or even further disc disruption. Since the nucleus of a severely degenerated disc does not always exhibit hydrostatic behavior, discometric studies of such material must be interpreted with caution.

In a number of pioneering *in vivo* human studies, Nachemson et al. (111–116) measured intradiscal pressure in lumbar intervertebral discs during various activities. From these and the later studies by Andersson et al. (117,118) and Schultz et al. (119), intradiscal pres-

sure measurements, electromyographic data, and biomechanical modeling have altogether provided vital information that has been used to establish workplace recommendations as well as clinical treatment strategies for disc diseases. Recent *in vivo* investigation (120,121) using modern pressure transducer technology has substantiated the findings of the intradiscal pressure studies from the 1960s and 1970s. In a healthy male volunteer, Wilke et al. (121) measured the intradiscal pressure in the L4-L5 disc and found good correlation with Nachemson's data, with two exceptions. First, intradiscal pressure was found to be lower in relaxed sitting than in relaxed standing, and second, the pressures while lying supine and lying on the side were essentially the same, whereas Nachemson found a threefold pressure increase in side lying. However, in a larger group of subjects (8 healthy volunteers and 28 patients with low back pain), Sato et al. (120) measured L4-L5 intradiscal pressures during various postures that corroborated the earlier findings of Nachemson et al.

Several investigators have examined how the internal disc mechanics are altered by disc degeneration. In moderately degenerated human discs, the intradiscal pressure has been shown to be approximately 30% less than in nondegenerate discs (111,114). Using an *in vivo* porcine model, Ekström et al. (122,123) and Holm et al. (38) measured the intradiscal pressure in normal lumbar discs and discs with experimentally induced degeneration, as well as the disc adjacent to the degenerated level. The intradiscal pressure in the disc adjacent to the degenerated level, which did not show morphologic signs of degeneration, was found to be slightly higher than in normal discs. This increase can be expected due to the redistribution in mobility demands and alignment of the segments adjacent to those with increased stiffness (i.e., degenerated or fused) (124). Intradiscal pressure has been shown to be highly dependent on the angle of the motion segment (120). Similar to the *in vivo* human studies discussed previously, the intradiscal pressure in the degenerated disc was significantly lower (more than 50%) compared to the pressures in the adjacent and normal discs. Sato et al. (120) reported a progressive decline in intradiscal pressure with increasing disc degeneration grade. Using stress profilometry, age-related degenerative changes in cadaveric lumbar motion segments have been shown to reduce the sagittal diameter of the central hydrostatic region (nucleus and inner annulus) of the disc by approximately 50% and the pressure by 30%, and increase the width of the "functional" annulus by 80% (125) (Fig. 3-4). Structural disruptions, such as radial fissures or fractures in the end plate, increase the space available to nucleus material, thus reducing the central intradiscal pressure (77). Stress profilometry has shown that compressive stresses are transferred from the nucleus to the annulus, particularly the posterior region where increases in peak

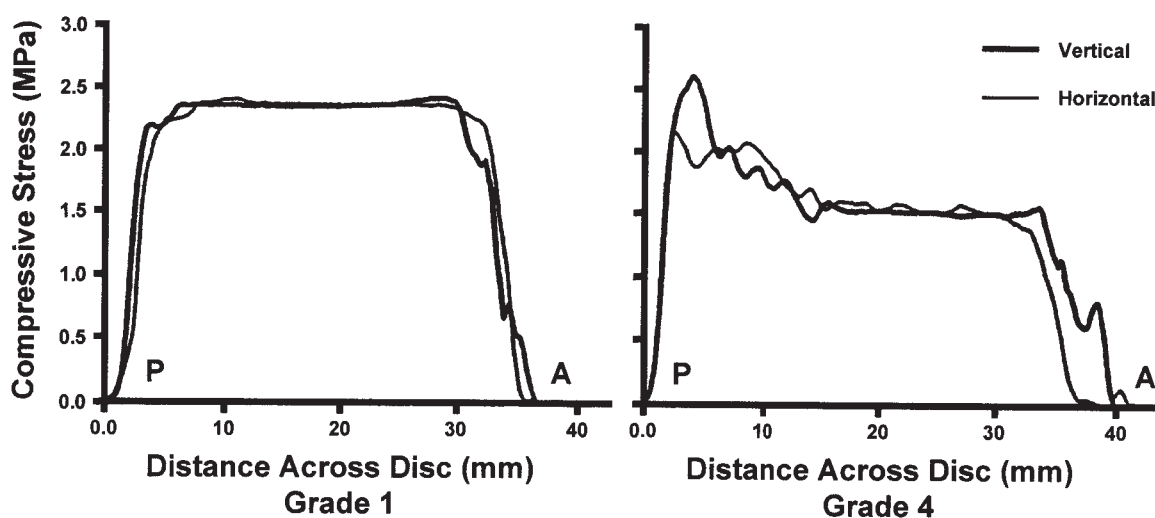

stresses by 160% have been reported (125). Similar effects in the stress redistribution (i.e., reduced nucleus pressure and increased peak compressive stresses in the posterior annulus) have been observed with sustained (creep) loading (72).

### Spinal Kinematics

Several biomechanical investigations, both *in vitro* and *in vivo*, have looked at the effects of disc degeneration on spinal kinematics. Mimura et al. (126) performed a comprehensive investigation into the relationship between multidirectional flexibility of whole cadaveric lumbar spines and disc degeneration. Flexion-extension, lateral bending, and axial rotation pure movements were applied and the motion parameters used to describe the nonlinear spinal behavior were neutral zone, range of motion, and neutral zone ratio. The neutral zone is an absolute measure of the joint laxity around the neutral position, where little resistance is offered by the passive spinal column (127). In an *in vitro* study, the neutral zone has been shown to increase with disc degeneration, particularly in axial rotation and anteroposterior shear motions, and is considered to be a more sensitive parameter than range of motion in relating to disc degeneration (128). The neutral zone ratio, a quotient of the neutral zone and the range of motion, increases in value with greater joint laxity. In the presence of increasing disc degeneration, Mimura et al. (126) reported an increase in intervertebral joint laxity around the neutral position, believed to be due to lax collagenous tissues, as demonstrated by an increase in the neutral zone ratio for all three types of loading

modes. With regard to range of motion, a significant decrease in lateral bending was found, perhaps resulting from facet hypertrophy. Tendencies toward decreased flexion-extension and increased axial rotation ranges of motion were observed. In a clinical study, a reduction in disc height was found to be significantly associated with reduced flexion-extension range of motion (129). The finding of an increase in axial rotation with higher degrees of disc degeneration has been corroborated in other studies (128,130–132), presumably due to fissure formations in the annulus fibrosus and a reduction in disc height. While segmental motion has been shown to increase with increasing severity of degeneration, a decrease has been found at the highest grade of degeneration (126,131). This is in accordance with the final phase of degeneration, as reported by Kirkaldy-Willis (48), where there is a restabilization due to osteoarthrotic changes.

Using an *in vivo* porcine model, Kaigle et al. (133) studied dynamically the alterations in segmental kinematics during flexion-extension as a result of acute interventions to the passive stabilizing components of the lumbar spine and to the musculature. Acute injury to the intervertebral disc resulted in greater axial joint laxity during flexion-extension maneuvers, while acute injury to the facet joints caused greater segmental sagittal plane rotation. A facetectomy resulted in considerable destabilization of the motion segment, particularly in the neutral region, where erratic behavior was exhibited during flexion-extension. Although increasing the flexion-extension range of motion, activation of the lumbar paraspinal muscles was shown to have a stabilizing effect on the segmental patterns of motion in the

**FIG. 3-4.** Stress profiles (posterior-anterior). **Left:** Grade 1 disc, female, 27 years old, L1-L2. **Right:** Grade 4 disc, female, 82 years old, L4-L5. (Redrawn from Adams MA, McNally DS, Dolan P. Stress distributions inside intervertebral discs. The effects of age and degeneration. *J Bone Joint Surg Br* 1996;78:965–972, with permission.)

acutely injured porcine motion segment by reducing the abrupt kinematic behavior in the neutral region. Similar findings were reported in an *in vitro* study by Panjabi et al. (134), where it was demonstrated that the application of simulated intersegmental muscle forces maintained or decreased intervertebral motions (i.e., maintained or decreased neutral zone) for intact and injured motion segments, except the range of motion in flexion which increased with muscle force. In a chronic lesion model, however, the musculature was overall less efficient at providing stability when the intervertebral disc or facet joints were degenerated (87). This may have been due to altered mechanisms in the neuromuscular feedback system in the degenerated motion segments and consequently, the lumbar spine as a whole.

In the clinical situation, there are some important aspects to consider regarding increased joint laxity. Daily activities involve movements across the neutral position (e.g., right-to-left lateral bending, forward flexion to extension, etc.). This transition requires well-coordinated activation/deactivation of various different muscles. With increased joint laxity, there may be insufficient tension in the spinal ligaments and annulus fibers, both of which are known to contain nerve endings that allow them to act as proprioceptive transducers. Lack of sufficient tension may delay or even prevent the detection and delivery of sensory information needed to regulate muscle tension. Stability becomes compromised when the recruitment of the appropriate sequence of muscles needed to overcome the loading demands is too slow, too late, or insufficient.

In a clinical study, *in vivo* segmental motion, overall trunk bending, and myoelectric activity of the lumbar erector spinae muscles were continuously measured during flexion-extension maneuvers in patients with suspected degenerative instability and in healthy volunteers (135). Segmental motion as well as trunk mobility was significantly less in the patients during flexion-extension. Reduced range of motion on functional radiographs has previously been found in patients with low back pain and degenerative changes in the lumbar spine (136–138). The patterns of motion in flexion were also significantly different from the controls. Using videofluoroscopy, Okawa et al. (139) found that, compared to a control group, patients with lumbar degenerative spondylolisthesis showed disordered patterns of motion in forward flexion and a tendency toward smaller ranges of motion, however, the degree of disc degeneration alone did not correlate with the disordered motion patterns. In contrast, in patients with degenerative disorders in the lumbar spine, it has been reported that anterior translatory instability as measured on flexion-extension radiographs is positively associated with disc degeneration and facet joint osteoarthritis, while other forms of sagittal plane instability (rotatory, posterior) have shown no association (140).

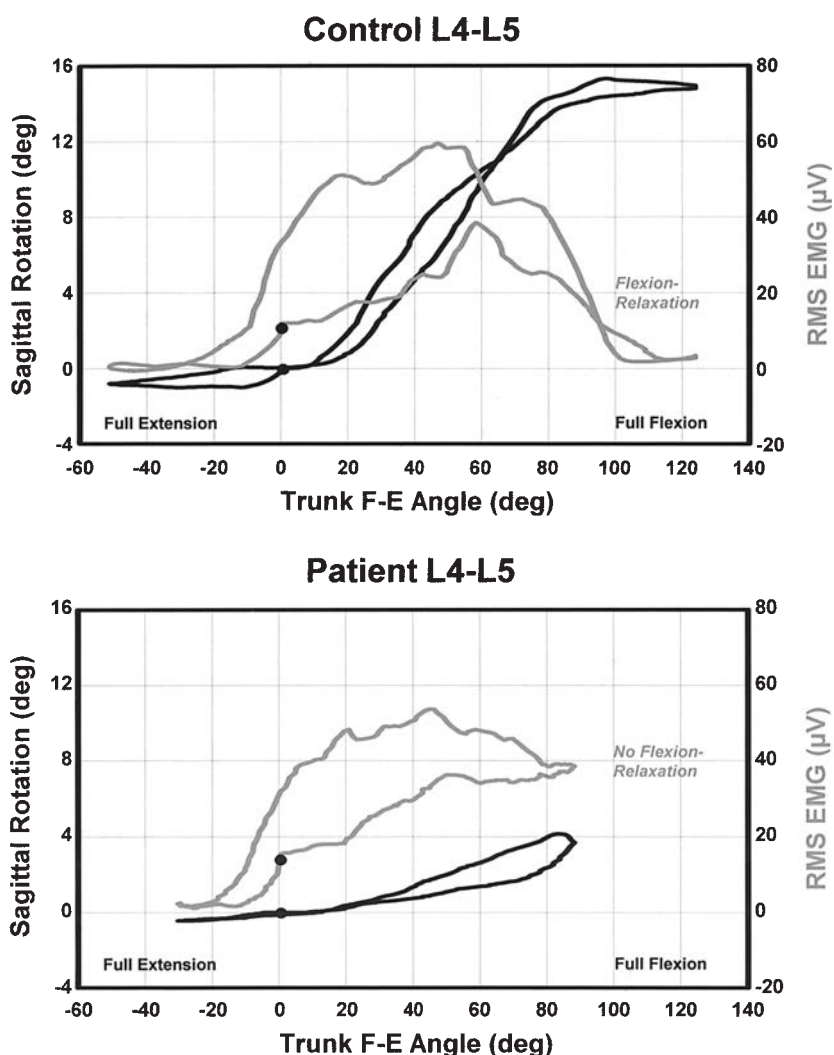

In a clinical study, McGregor et al. (141) were unable to find a relationship between degenerative disc disease as seen on plain lateral radiographs and the overall lumbar range of motion. Altogether, the findings suggest that degenerative changes in the lumbar spine and the accompanying aberrant kinematic behavior are associated with alterations in the neuromuscular system. Analyzing the muscular behavior during flexion-extension, Kaigle et al. (135) found that flexion relaxation (i.e., decreased myoelectric activity with extreme trunk flexion) was demonstrated in healthy volunteers but not in the group of chronic low back pain patients with suspected degenerative instability (Fig. 3-5). The restricted segmental mobility found in these patients was believed to be due to the persistent activation of the musculature. It is conceivable that the activated muscles behaved more as stabilizers rather than mobilizers, compensating for the laxity in the diseased motion segment. Such activation would also allow loads to be transferred via the muscles instead of the diseased passive structures, perhaps as a means for avoiding pain. Pain is one factor that has been shown to inhibit flexion relaxation (142,143). Ahern et al. (144) showed that pain behavior, particularly guarded movement, was significantly related to flexion relaxation. Wolf et al. (145) suggested that chronic low back pain patients develop postural abnormalities, such as guarded movement and splinting, in order to compensate for actual or anticipated pain, and that over time, these postural adjustments could alter the normal neuromuscular function.

## CONCLUDING REMARKS

The behavior of the lumbar spine is dependent upon the characteristics of its passive, active, and neural subsystems, any of which can become injured or diseased, and all of which undergo the aging process. The neuromuscular system controls the movements and stability in the lumbar spine and can compensate, to a certain degree, for loss in function of one or more of the structures. As conceptually described by Panjabi (1), dysfunction in any of the subsystems may lead to one or more of the following responses in the other subsystems: (a) an immediate, compensatory response, which would result in normal function; (b) a long-term adaptation response, which would result in normal function but with an altered spinal stabilizing system; and (c) an injury which would lead to overall system dysfunction, producing, for example, low back pain.

Numerous investigations have demonstrated that disc degeneration alters the biomechanical behavior of the lumbar spine in a number of ways. However, discrepancies in the literature exist regarding the exact manner in which a disc's biomechanical properties are affected by degeneration. Although grouping of *in vitro* disc specimens according to degeneration grade facilitates compar-

**FIG. 3-5.** Segmental kinematic (sagittal rotation) and myoelectric [right-side erector spinae surface Root Mean Square electromyography (RMS EMG)] experimental data as a function of the overall trunk flexion-extension angle during a flexion-extension cycle from the L4-L5 motion segment of a control subject (**top**) and a patient with degenerative instability (**bottom**). Note the absence of flexion-relaxation in patient myoelectric data.

isons, averaging results in groups of motion segments with diverse degenerative changes may obscure the effects of degeneration on the biomechanical response. This may be a factor contributing to the disparities reported in the literature. Additionally, it has also been pointed out by Vernon-Roberts et al. (40) that to properly classify disc disease, it is essential to examine disc slices at multiple levels within a disc since abnormalities are three-dimensionally complex. However, very few studies have reported employing such procedures. It should also be noted that the majority of *in vitro* studies have been performed on lumbar motion segments obtained from cadaveric specimens beyond the sixth decade in age, suggesting that the degenerative changes were age-related. Although biochemical and biomechanical changes due to normal aging are similar to those found in degeneration,

it would be more appropriate to perform biomechanical studies on degenerate discs from specimens in the middle decades of life, which is the time in life where there is a maximal incidence of disc-related back problems (146).

Since disc degeneration is a process, the biomechanical properties will undergo changes throughout this process. An observed increase in flexion-extension stiffness, for example, during one stage of the degenerative process may not necessarily be present at a later point in time. Even at a similar point in time, while changes in the material properties may increase the flexibility of the motion segment, geometric changes may produce an opposite affect, thus producing no net effect on the overall behavior. Clinically, patients suspected of having degenerative segmental instability display vertebral misalignment on functional radiographs, accompanied by

morphologic changes in the intervertebral disc, vertebrae, and possibly facet joints. However, clinical studies as a whole have been unable to demonstrate segmental hypermobility (i.e., greater range of motion), which correlates with the pathologic signs and symptoms. On the contrary, the majority of studies have found hypomobility in the suspected 'unstable' motion segment. This raises an important issue regarding the ability of the neuromuscular feedback system to compensate for joint laxity or abnormal movements in a lumbar motion segment. To better understand the mechanisms by which the passive, active, and neural structures interact, refer to Chapter 11.

In summary, the overall findings reported in the literature indicate that with disc degeneration, the biochemical and structural changes compromise the disc's structural integrity, regionally and subsequently as a whole. The effects of disc degeneration on the motion segment stiffness are a function of the loading mode. When loaded in axial compression or torsion, degenerated discs display a reduction in stiffness, whereas in flexion-extension and lateral bending, a stiffening effect has generally been found. Disc degeneration alters the normal stress distribution patterns. The failure properties of the annulus lamellae are reduced along with the intradiscal pressure in the nucleus. This produces high stress concentrations in the posterior annulus, the region where disc disruption is clinically found to occur most frequently. Such alterations in the internal disc mechanics may cause pain or precipitate further disc disruption. Degenerative changes in the lumbar spine cause aberrant kinematic behavior, particularly around the neutral position. Although increased intervertebral laxity around the neutral position has been associated with disc degeneration, the majority of *in vivo* studies have found reduced ranges of motion. Persistent muscle activation is believed to be a mechanism by which the neuromuscular system provides stabilization in order to guard diseased passive structures from abnormal motion, which may cause pain or further tissue damage.

## CHAPTER 4

# Morphologic Changes of End Plates in Degenerative Disc Disease

Robert J. Moore

---

The vertebral bodies of the axial skeleton are separated by intervertebral discs, which are highly specialized structures that enable a range of physiologic and mechanical functions associated with motion. The discs have three main structural components—a central nucleus pulposus surrounded by the annulus fibrosus and the end plates, which are located at the cranial and caudal interfaces with the vertebrae. While the structure and function of the annulus and nucleus are well characterized, much less is known about the end plates. Perhaps this is because their constitution has not yet been consistently defined, or because structural changes to the end plates are more subtle than changes to other disc components, and therefore easily overlooked.

In some early anatomical studies the end plates were described as the transitional zone between the vertebral body and the adjacent disc because they possessed both an osseous and a hyaline cartilage component (1,2). Other authors, however, proposed a more limited situation, and described the end plates as the thin layer of hyaline cartilage interposed between the vertebral body and the disc (3,4). For whatever reason, this latter concept has survived and they are now more commonly known as the “cartilage end plates” or simply the “end plates.”

Volumes of literature have been devoted to the normal development of the end plates that are recognizable from an early embryologic stage and retain their cartilaginous nature during normal maturation while the adjacent vertebrae undergo ossification (5). The cartilaginous component of the mature end plate is essentially an aqueous gel containing large proteoglycan molecules within a dense mesh of collagen fibrils that are aligned along the longitudinal axis (horizontally in the human). Although it has been suggested that there is no direct physical connection between the end plates and the underlying bone (6), their juxtaposition almost certainly contributes to the strong bond that is essential for the normal function of the end

plate (7). When the epiphyses fuse in the young adult spine, only the outer rim of the end plates is ossified, leaving a broad central cartilaginous plate. The lamellae of the outer annulus attach directly to the adjacent bone, while the fibers of the inner annulus connect the end plates directly with the disc.

The end plates are thin, particularly in the center of the disc, measuring no more than 1 mm at maturity (8), but there can be considerable variation from one side to the other (9). In the lower lumbar spine the end plates are roughly cardioid to elliptical in shape (10). While this fact in itself may seem to have little relevance, shape is the only one of several parameters investigated by computed tomography-myelography that is claimed to be significantly related to the development of disc herniation (11). The most abundant cell type in the end plate is the chondrocyte, distributed more uniformly than the clearly defined layers of cells within articular cartilage. Otherwise the end plate bears a close similarity to the articular cartilage of synovial joints.

The biochemical characteristics of the end plates, from normality through the spectrum of degenerative conditions, are well documented (12,13). The two most abundant families of molecules in the disc are the collagens and the proteoglycans that are found in varying proportions in the annulus, the nucleus, and the end plates. Of the several species of collagen, type X is probably the most important in the end plates because it is a marker of hypertrophic chondrocytes and is thought to be involved in cartilage calcification (14). It has been detected mainly in the central region (15).

Proteoglycan molecules are essential for the maintenance of the water content and overall integrity of the nucleus (16). It is known that altered tissue levels of proteoglycans can adversely influence disc function (17). The proteoglycans of the end plate have not been studied extensively, but suffice to say loss of proteoglycans from

the end plate is implicated in loss of proteoglycans from the nucleus (18). It follows that disc degeneration invariably is preceded by widespread degradation of disc proteoglycans (19). It has long been suspected that alterations to the biochemical composition of the end plate, particularly during the growth phase, may be involved in the development of scoliosis (20–22).

Heterozygous inactivation of the Col2a1 gene allele in 1-month old mice has been shown to lead to lower glycosaminoglycan concentration in the end plates and thicker and more irregular end plates that become calcified prematurely (23).

The developing discs receive essential nourishment from two sources. From the embryonic stage, a network of blood vessels penetrates the annulus no deeper than about one-third of its total thickness (24). Most of these vessels do not persist beyond maturity and by adulthood they can be seen in only the outer two or three lamellae. Blood vessels also penetrate the end plates from the vertebral body margins (5) and arise from ramifications of a large primary nutrient artery on the dorsal surface of each vertebral body. With maturation however, these small vessels also disappear, leaving only a limited blood supply in the form of capillary buds that perforate the osseous component of the end plate (25). It is curious that mammalian discs have evolved in this way, since the central nucleus pulposus in the adult human can be up to 20 mm from the nearest blood vessels and is therefore totally reliant on diffusion of solutes across the end plates and the annulus for nutrition. No other tissue in the body is so distanced from a blood supply, and presumably therefore so susceptible to deterioration.

Extensive *in vitro* study of the transport of solutes, disc nutrition, and metabolism using small dye molecules has shown that the lateral end plate at the vertebral rim is relatively impermeable compared with the central portion, and even the entire annulus fibrosus (26). The contribution of the periannular blood supply was well accepted, but the permeability of the capillary network immediately beneath the end plate attracted new attention. Quantitative analysis of human autopsy specimens that had been injected with dye solution subsequently confirmed that there were significantly more marrow contacts along the central end plate adjacent to the nucleus than there were in the lateral margins (27,28).

While determining the significance of these vessels to disc nutrition and cell metabolism, diffusion was shown to be the principal mechanism for transporting small dissolved solutes into the disc (29). Further, the size and ionic charge of the molecules were also shown to govern the rate and extent of diffusion (29,30). As the high proteoglycan content in the nucleus confers a net negative charge to the normal disc, small, uncharged molecules such as glucose and oxygen and positively charged ions such as sodium and calcium diffuse into the disc with relative ease. Conversely, it is much more difficult for neg-

atively charged molecules such as sulfate and chloride ions to enter the nucleus. Macromolecules such as immunoglobulins and enzymes are totally excluded.

The relative contribution and importance of the end plate and annular routes to disc nutrition were established independently using biochemical (31), histologic (25), and radiologic (32) methods. Each of these studies confirmed the importance of the central end plate in the metabolic processes of the disc.

Soon after maturity the cartilage of the end plate undergoes extensive mineralization and eventually this tissue is resorbed and replaced by true bone (33,34). It is likely that this remodeling, as well as the calcification of vascular channels in the end plate region both contribute substantially to a reduction in the normal exchange of nutrients across the end plate with increasing age (35).

Since the end plate is capable of remodeling after maturity it seems reasonable to expect the obliteration and loss of vascular channels could also be reversed. This does appear to be possible, and in fact has been demonstrated in an experimental ovine model of annular lesions (36). In the context of that study it was presumed that neovascularization was a basic survival mechanism for discs undergoing severe pathologic deterioration, although it was in vain, since they continued to degenerate. Although not specifically tested in that study it is likely that such new blood vessels are formed by activation of normally latent enzymes of the matrix metalloproteinase (MMP) family, which are regulated by tissue inhibitors (37–41). Increased levels of several MMP species have been detected in surgical and postmortem samples of human discs (40,42), and although the end plate itself was not analyzed in these studies, it is reasonable to assume that they would be no different.

As well as providing an axis for the diffusion of nutrients to the avascular disc, the end plates also are important for the mechanical function of the spine. In the course of normal physical activity, mechanical loading (especially axial compression) can alter the shape of the disc to the extent that the end plates and the subchondral trabecular bone become deformed (43). This deformation is reversible in young healthy end plates that are subjected to even moderate loading, but when the forces are higher and applied repeatedly, the end plates sustain irreversible damage. There is evidence that the integrity of the end plate and subchondral bone, rather than the degree of disc degeneration, influence how much damage occurs during axial compression (44). It was also noted that the radiographic appearance of the end plates in this study was similar to those of osteoporotic patients, in whom the end plates become more concave with age and progressive vertebral osteopenia (45,46).

Morphologic changes to the end plates occur with advancing age but also may be seen in association with pathology in either the nucleus or the annulus. Either way, the changes are essentially microscopic and become evi-

dent macroscopically only in the advanced stages of disease (47).

In the earliest changes after maturity fissures and clefts appear along the length of the end plate in the horizontal plane. Occasionally there is evidence of chondrocyte death. The cartilage may be invaded by microscopic blood vessels and there also may be ossification extending from the adjacent bony end plate. With time the cartilage becomes depleted progressively and undergoes further ossification. The nucleus fills the small voids created as more blood vessels perforate the end plate, but these defects do not breach the bony end plate.

The most dramatic changes occur after the fifth decade. It is not unusual to observe nuclear material protruding into the adjacent vertebral marrow with foci of bony sclerosis resulting from active remodeling at these sites. Often there is total loss of the cartilage end plate. In an experimental murine spondylosis model disc degeneration, including loss of the end plate, was accompanied by increased apoptosis in end plate chondrocytes relative to naturally aged mice, suggesting that programmed cell death plays a role in age-related changes of the disc (48).

Of all the structural elements that constitute the disc, the end plate appears to be most susceptible to mechanical failure. Theoretical modeling using finite element analysis has shown that mechanical failure always begins with separation of the end plate from the subchondral bone (49), in complete agreement with the microscopic observations of Vernon-Roberts (47). Autopsy studies also confirm that portions of the end plate become separated from the vertebral body and are herniated from the disc along with attached annular fibers (50,51). A significant weak point of the motion segment appears to be near the epiphyseal ring, where the annulus fibers insert directly into the vertebral bone. Not only is it a common site for fracture causing back pain and radiculopathy in adolescents and young adults (52) but it has been shown to be particularly susceptible to failure during experimental mechanical compression tests in the adolescent pig (53). This is a different injury pattern to that seen in adults, where the end plate and adjacent trabecular bone are affected (54,55).

Schmorl nodes are relatively common features of the end plate that have been characterized in considerable detail. These vertical protrusions of nucleus pulposus into either (and occasionally both) of the adjacent vertebrae were first described by Luschka in the late 19th century and subsequently named by Schmorl (2). They are found in more than 70% of autopsy spines with equal frequency above and below the age of 50 years, suggesting that they appear relatively early in life (56). Schmorl observed that they were twice as common in men up to the age of 59 years and attributed this to lifestyle factors, in particular a greater risk of occupational trauma. After the age of 60 years, however, they are twice as common in women, presumably at a stage when the disc is more liable to rupture

due to changes associated with advanced age, including vertebral osteopenia. In any case there is clear evidence that discs with Schmorl nodes are more degenerate than other discs at an early age (57).

Schmorl nodes are encountered less frequently on clinical radiographs than by autopsy examination (2,58). In general this is because they are small, but in other instances they can be so immature to have not yet caused any significant structural changes. Ultimately there is loss of disc height from nuclear prolapse or subsequent formation of a cartilaginous cap and eventually new bone around the prolapsed tissue.

Despite being relatively common, it is still not known how Schmorl nodes are formed. It seems obvious that nuclear protrusion can only occur through openings in the end plate, but under normal circumstances these defects do not exist. Schmorl himself suggested that these lesions could result from weaknesses in the end plate due to foci of degenerate cartilage (2). In the absence of significant destruction, such as direct trauma or neoplasm, it is assumed that scar tissue in the end plates is a legacy of the closure and repair of the nutrient vessels in the developing years (59), and this leaves congenitally weak spots through which protrusion is possible (60). The latter study also demonstrated a significantly higher proportion of marrow contacts in the end plates of specimens with Schmorl nodes, and suggested that these lesions could contribute to further pathology such as Scheuermann disease in which they feature prominently.

With the development of implantable devices aimed at augmenting spinal fusion, the end plate assumes a critical role. It was previously thought that mechanical stability, and therefore a good clinical outcome following interbody fusion, could be achieved only if the end plates were preserved, whether bone was used alone or in conjunction with these devices (61). The design of implants therefore appears to be critical for successful fusion. It is claimed, for instance, that threaded cages compromise end-plate integrity, but while nonthreaded cages address this problem, their design generally does not conform to the normal profile of the end plate, providing limited opportunity for bony incorporation (62). The inherent strength of titanium cages offers greater resistance to axial loading, which can be achieved by preservation of the end plates in thoracolumbar column reconstruction (63). More recent work in cadavers however, suggests that an implant with only peripheral support provides the same axial strength as an implant with full support, and that there is no mechanical advantage gained by maintaining a solid implant face (64). In fact, it has been claimed that removal of the central end plate actually promotes graft incorporation without affecting mechanical strength. In another study that has implications for interbody cage design, both the sacral and inferior end plates were shown to be stronger than the superior lumbar end plates, while the central region of both the lumbar and sacral end plates was also identified as being a

structurally weak point (65). The importance of preserving the end plate to prevent graft subsidence was further emphasized in a report of compression testing conducted on cervical spine segments (66). As we move from “classical” fusion methods to the realm of spinal arthroplasty, where the aim is to maintain or even restore function as well as relieve pain, it is clear that these considerations will have major implications for the design of implantable devices in spinal surgery (67).

## CHAPTER 5

# Clinical Spinal Instability Resulting from Injury and Degeneration

Manohar M. Panjabi, Vijay K. Goel, Allison M. Kaigle Holm, Malcolm H. Pope

---

The origin of most cases of low back pain is unknown (1). Clinical spinal instability is considered as one of the most common causes (2). It is hypothesized that mechanical derangement by degeneration, injury, or muscle dysfunction produces spinal instability that results in pain or dysfunction. It is assumed that an underlying intervertebral motion abnormality exists, which is magnitude and direction dependent (3).

Although the phrase spinal instability is commonly used in a clinical setting, there is no single accepted definition (4). Thirty spine surgeons were asked to define clinical instability and its symptoms and signs, and 30 different answers were received! Clinical instability has two parts: mechanical derangement and clinical consequences. It has been concisely put in a definition with which many clinicians agree. It is the loss of the ability of the spine to maintain its physiologic patterns of displacement that cause no incapacitating pain or neurologic dysfunction (3).

Spinal stability is provided by three interrelated systems: the spinal column (passive system); spinal muscles (active system); and control system, which coordinates the muscles in response to the stability needs of the spine (Fig. 5-1). Instability results when single or multiple components of the systems fail or malfunction (5). This conceptual framework is useful in understanding the roles of various spinal system components in providing spinal stability.

Clinical spinal instability may be described by its causes, methods for its diagnosis, and treatments. Past research concerned with these aspects of spinal instability is described. At present, the causes are thought to be injury, degeneration, and muscle dysfunction or insufficiency, or a combination of all three. Diagnostic methods generally include flexion-extension roentgenograms, but other techniques such as magnetic resonance imaging (MRI) are now available. Treatment methods include

exercises and surgery. Also presented are future directions for research.

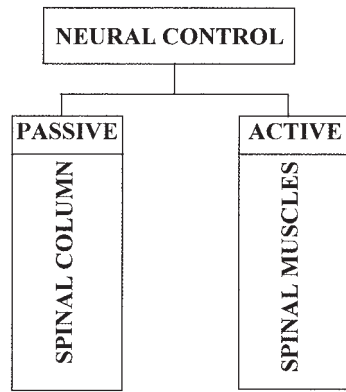

### CAUSES OF SPINAL INSTABILITY

The degenerative process of the functional spinal unit (FSU) is usually described by dysfunction, instability, and restabilization (6). (The FSU is the smallest unit of the spine, consisting of two adjacent vertebrae and the connecting ligaments, disc, and facet capsules.) The unstable phase is characterized by reduction in disc height, laxity of the ligaments and facet capsules, and degeneration of the facet joint, which result in abnormal spinal movement. A positive relationship with low back pain was found if the disc height decreased by 40% (7). Osteophytes have been proposed as indicators of instability (8). A traction spur is said to result from increased tensile stresses at the annulus, whereas the claw spur results from compressive loads.

### Injury

Microtrauma occurring for long periods may lead to accelerated degeneration and spinal instability (9). This can include occupational exposures (e.g., whole-body vibrations) (10). A major overload may fracture facets and end plates, produce annular tears of the disc, or rupture ligaments, which also may lead to spinal instability. Surgical procedures (e.g., total facetectomies) may cause instability as well.

What roles do the ligaments, facets, and disc components play in providing stability? The contribution of the facet joints in the lumbar spine was experimentally determined to be 50% in resisting torsional loads (9). The other 50% is provided by the intervertebral disc. Using pure moments and measuring three-dimensional 6 degrees-of-freedom intervertebral motions, the effects of

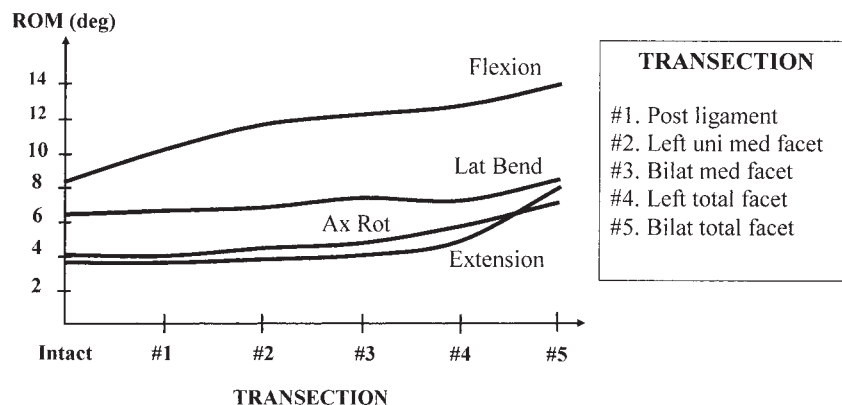

**FIG. 5-1.** The spinal stabilizing system. A conceptual framework in which the passive spinal column, active spinal muscles, and neuromuscular control subsystems together provide the spinal stability. (From Panjabi M. The stabilizing system of the spine. Part I. Function, dysfunction, adaptation, and enhancement. *J Spinal Disord* 1992;5(4):383–389.)

posterior ligamentous injury and partial and total facetectomies were recorded (11). With physiologic loads of 8 nm, the average ranges of motion (and neutral zones) for the intact lumbar spine were found to be as follows: flexion, 8.2 (0.93) degrees; extension, 4 (0.93) degrees; lateral bending, 6.2 (0.97) degrees; and axial rotation, 3.5 (1.1) degrees (Fig. 5-2). (The concept of neutral zone is indicated in Figure 5-5.) Cutting of the supraspinous and interspinous ligaments produced a 2-degree increase in flexion, but no change in other motions. Unilateral facetectomies produced increases of 4.2 degrees in flexion and 1.8 degrees in rotation, but no marked changes in other motions. Bilateral total facetectomy, compared with the case with the spine intact, produced increases of 63% in flexion, 78% in extension, 15% in lateral bend-

ing, and 126% in axial rotation. Thus, the facets play a significant mechanical role, especially in rotatory stability. The conclusion was made that the partial facetectomy of one or both facets at a single level does not cause spinal instability, whereas the loss of a complete facet joint on one or both sides makes the spine acutely unstable. These *in vitro* experimental results should be carefully interpreted for clinical use because they do not include the muscles and effects of healing. To understand the role played by all spinal column components in providing stability, fresh cadaveric functional spinal units were studied in response to either flexion or extension loads, while the various spinal components were transected from either a posterior-to-anterior direction or vice versa (12). Vertebral movements in response to transection of the components were monitored in the sagittal plane. This study formed the basis of the guidelines for determining thresholds of clinical instability in the lumbar (1).

Does an injury to the disc repair itself? The disc does not have the healing potential of most other structures in the body because it lacks a blood supply (13). Repair, however, involves a process of vascular ingrowth. The concept of a mechanical self-sealing phenomenon that would seal off the defect was advocated (14) but was later shown to be a fallacy, especially for multidirectional instabilities (15,16).

The process of repair and restabilization after injury, if it occurs, cannot be studied by *in vitro* biomechanical studies. Neither can the clinical studies provide useful information concerning the natural time course of an injury, because all significant injuries in humans are usually surgically or otherwise stabilized. Thus, there is limited information regarding the natural history of most spinal injuries. In a set of *in vivo* experiments using two

**FIG. 5-2.** Average multidirectional intervertebral ranges of motion of fresh cadaveric lumbar spine specimens as functions of injury. The motions were: flexion, extension, lateral bending, and axial rotation. The injuries sequential were: posterior ligaments (supraspinous and interspinous), left unilateral medial facetectomy, bilateral medial facetectomy, left total facetectomy, and bilateral total facetectomy. (From Abumi K, Panjabi MM, Kramer KM, et al. Biomechanical evaluation of lumbar spinal stability after graded facetectomies. *Spine* 1990;15:1142–1147.)

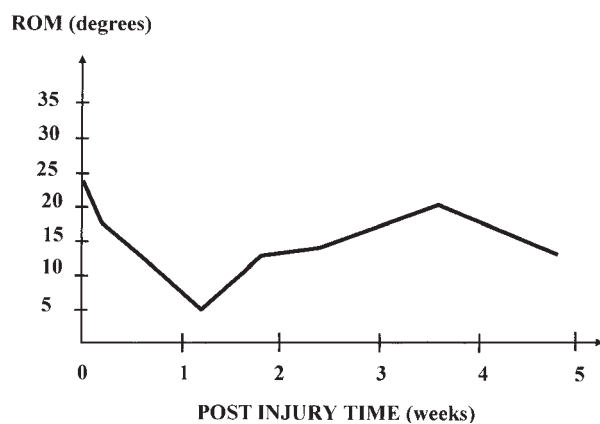

different animals, three graded spinal injuries (interspinous and supraspinous ligament transections, laminectomy, and facetectomy) at the C4-5 level were studied by functional flexion-extension stereoradiographs for up to 24 weeks (17,18). In these *in vivo* animal experiments, contrary to expectations, the spine at the injury site became more stable (even compared with the intact spine) as measured by standardized functional X-ray studies during the healing period (Fig. 5-3). Although the facetectomy resulted in the largest increase in motion acutely, it also produced the largest decrease in motion *in vivo*. At 6 weeks after the injury, the range of motion (ROM) decreased from 23 degrees preoperatively to 5 degrees postoperatively. These findings are supported by studies using a canine (19) and a porcine model (20). In the later study, explanation was provided for the decreased motion. At 3 months post facetectomy, we found hypertrophy of the facet joints, which limited the range of motion.

### Degeneration

For an in-depth description of degeneration, please see Chapter 3.

The spine degenerates with age; this is a normal process that results in altered mechanical characteristics. It also may lead to low back problems. Kirkaldy-Willis (6) provided a classification of degeneration of the spine based on three stages.

**Stage 1. Dysfunction.** This includes low back pain with nonspecific syndrome. The facet capsule may be lax and disc degeneration is of grade 1 to 2 on a scale of 1 to 4.

**FIG. 5-3.** Average intervertebral range of motion at the injury site as a function of healing time. The injury was bilateral facetectomy at C4-5 in a canine model. The injury was unprotected during the entire healing phase, and the motion measurements were made using functional flexion-extension stereoradiographs. (From Panjabi M, Pelker K, Crisco J, et al. Biomechanics of healing of posterior cervical spinal injuries in canine model. Spine 1988;13:803-807.)

**Stage 2. Instability.** This is marked by increased facet joint laxity and moderate disc degeneration (grades 2 to 3). Clinical syndrome can be identified, and the instability can be measured by functional X-ray studies.

**Stage 3. Restabilization.** This is characterized by fibrosis in posterior joints and osteophytic formations leading to decreased overall motion. Disc generation has reached the final stage (grades 3 to 4).

A recent study has confirmed the biomechanical aspects of the preceding hypothesis using an intraoperative instrumented lamina spreader (21). It consisted of an electric motor, which spread the adjacent laminae, and the strain gauges attached to the spreader legs, which measured the force applied. Based on a study of nearly 300 patients and 650 FSUs intraoperatively, we conclude the following. The average stiffness reaches its peak of 120 N/mm at about 25 years of age, decreases thereafter to less than 20 N/mm at about 55 years, and then increases once more to about 80 N/mm above the age of 60 (Fig. 5-4). The stiffness seems to have an inverse relationship to the disc degeneration and range of motion.

The degeneration effect on the mechanical properties of the spine is specific and direction dependent. Several parameters may be obtained from load-displacement curves of a lumbar spine specimen to quantify the mechanical properties. These are: the neutral zone (NZ), representing "looseness" of the specimen; the elastic zone (EZ), which may equate with elastic deformation; and the range of motion (Fig. 5-5). Another parameter is the neutral zone ratio (NZR), equal to NZ divided by ROM. In a study using fresh cadaveric lumbosacral spine specimens, intervertebral flexion-extension, lateral bending, and axial rotation were measured and plotted against disc degeneration grade (22). In flexion-extension, there was some tendency for ROM to decrease and NZ to increase. The lateral bending showed significant decrease in ROM and significant increase in NZR. In axial rotation there were significant changes in ROM, which decreased, and in NZ and NZR, both of which increased.

The preceding knowledge has been obtained mostly from *in vitro* experiments. The general degeneration of the spine, seen on X-ray films as decreased disc height, deformed end plates, and osteophyte formation, has not been found to be a reliable predictor of subsequent low back pain. On the other hand, evidence suggests that increased disc degeneration carries a significantly higher risk of low back problems (23). During discography, 23% of patients with nondegenerated discs reported pain, and 77% felt either pressure only or no pain at all. On the other hand, among patients with a severely degenerated annulus, 90% reported pain during discography, whereas only 10% felt no pain or simply some pressure. Thus, a significant relationship seems to exist between disc degeneration and low back pain, even though it may not

**FIG. 5-4.** Functional spinal unit (FSU) stiffness distribution with age. (From Brown MD, Holmes DC, Heiner AD, et al. Intraoperative measurement of lumbar spine motion segment stiffness. *Spine* 2002;27(9):954–958.)

be a one-to-one correspondence. This and similar *in vivo* studies provide a link to the *in vitro* biomechanical studies, by which the mechanical characteristics of the spine and the clinical symptoms of low back pain may be related.

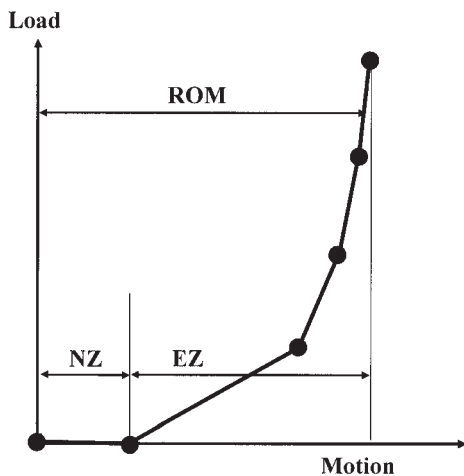

**Role of Spinal Muscles**

The understanding of the primary role of musculature in providing spinal stability and the extent to which the

musculature contributes to pain production, modulation, and prevention is not well understood. Muscle dysfunction may result from muscle weakness, in the form of decreased strength or endurance, and possibly from a disturbance in the neuromuscular control system, in the form of altered recruitment patterns. Muscle spasm and pain may be indicators of muscular overload owing to the reduced efficiency in weakened passive structures of the spinal system. As described, muscles form an important subsystem of the overall spinal stabilizing system.

A lumbo-sacral (L1-sacrum) spinal column that is devoid of musculature is a mechanically unstable structure, with a load-carrying capacity of less than 90 N (or 20 pounds) (24). However, with properly coordinated muscle action, the spine can sustain large loads, which is exemplified by the action of weight lifters. In the past, the complexity of the muscular anatomy and physiology hindered the development of biomechanical models for studying the stabilizing role of muscle, as well as various passive components of the spine (e.g., ligaments, discs, vertebrae, and facet joints). Detailed morphologic and biomechanical analyses of the lumbar musculature are now available (25–27). The spinal muscles may be conceptualized as local (intersegmental) and global (multi-segmental), which helps us to understand their functions of stabilizing the spine and producing motion (28,29). Advanced mathematical models are helping us to better understand the instability (30).

A modeling study based on radiographs from normal subjects was performed to determine the effects of flexion on the forces exerted by the lumbar muscles (27). The

**FIG. 5-5.** Load-displacement curve of a spine specimen. The measurements for neutral zone (NZ), elastic zone (EZ), and range of motion (ROM) are obtained from the curve.

act of flexing caused substantial elongation of many muscle fascicles, which consequently reduced the maximum active tension they could exert. Consequently, it was found that the compressive forces and moments exerted by the back muscles in full flexion are not significantly different from those in the upright posture. However, major changes in shear forces were found, particularly at L5-S1, where there was a reversal from a net anterior to a net posterior force. These shear forces must be considered when prescribing therapeutic exercise, particularly in patients with translatory instability in the lower lumbar and lumbosacral region.

Using an anatomically detailed biomechanical model, the role of the lumbar erector spinae musculature in offsetting the anterior shear forces on L4-5 (58 to 324 N) and upper body mass during different dynamic lifts (squat and stoop) were studied (31,32). They found that, during the squat lift, the maximum peak forces supported by the facet joints and possibly the disc remained relatively constant at approximately 200 N, regardless of the load mass. When comparing the two different lifting styles, the stoop lift, which produced a more flexed lumbar spine than did the squat lift, and had greater contributions from the passive lumbar structures (e.g., ligamentous strain), although the peak moments provided by these tissues were less than 60 nm.

The effects of simulated intersegmental muscle forces on spinal instability in an *in vitro* experiment have been investigated (33). In flexion loading, range of motion increased and neutral zone decreased with the application of muscle forces, whereas both variables decreased in extension loading. Similar observations have been made in an *in vivo* investigation using a porcine model to study alterations in segmental kinematics as a result of injury to the passive stabilizing components and stimulation of the lumbar musculature (34). When compared with the unstimulated situation, stimulation of the paraspinal muscles produced significantly greater range of motion in sagittal rotation and shear translation in the L3-4 motion segment after injuries to the disc or facet joints. Although it increased the range of motion, the increased muscular activity also stabilized the injured motion segment. This stabilization was indicated by a reduction in the abrupt changes in the pattern of motion for sagittal rotation during the transitional phase between dynamic flexion and extension (neutral region).

Electromyographic signals of the paraspinal and abdominal muscles have been studied both in normal subjects and in patients with low back pain. Some studies have shown that the electromyographic patterns displayed some abnormalities in patients with low back pain compared with the normal group (35–37). Also, the flexion-relaxation phenomenon of the erector spinae muscle group is absent in some patients with acute low back pain but returns after the pain has gone. The flexion-relaxation phenomenon is the myoelectric silence at approximately

two thirds of maximum flexion angle, at which the load moment is carried by the soft tissues (e.g., ligaments, fascia, and passive elongated muscle) (38,39). It is now believed that intra-abdominal pressure stabilizes the spine (40).

However, studies show diverging results as to whether increased intra-abdominal pressure loads or unloads the spine (30,41,42). The muscles not only apply loads and provide stability, but also help control the posture and movement (5). In a study of low back patients and healthy controls, patients demonstrated poorer balance control while sitting on an unstable hemisphere and had longer reaction times to sudden horizontal loadings (43).

## DIAGNOSTIC METHODS

### Roentgenographic Motion Studies

Besides the grades of disc degeneration, which are related to a greater risk of low back pain, other motion and posture measures can be obtained from radiographs or computed tomography or MRI images. Functional radiographs (e.g., a pair of radiographs taken, generally, at the extremes of a motion in a certain plane) form the basis of most clinical studies of motion. Knutsson (44) was probably the first to indicate a relationship between excessive anteroposterior translation seen on flexion-extension radiographs and low back problems. In another study, patients with low back pain were examined in lateral bending, and centers of rotation were calculated for various positions of the lumbar spine. An increased area occupied by the locus of the centers of rotation at a particular level was found to be directly related to the pain at that level (45). In another study, motions were measured from lateral radiographs taken in three specified postures (46). Normal patients were found to be different from the patients with spondylosis in translation and rotation and in coupling between these motions.

The spinal movements of patients with low back pain who are suspected of having instability may not always be greater in magnitude. It is known clinically, quantified using stereoradiographic analysis, that patients with low back pain have restricted flexion-extension intervertebral motion. The total flexion (L1-S1) of about 50 degrees in normal individuals decreases to less than 20 degrees in patients with low back pain and nerve root tension signs (47). Associated with the restricted flexion-extension spinal motion are increased coupled motions (i.e., lateral bends and axial rotations). The coupled motion is defined as the associated motion produced during the main motion (e.g., lateral bending or axial rotation produced during flexion). Theoretically, there are up to five coupled motions for every main motion. Both observations may be explained by the fact that spinal instability resulted in activation of the muscular system. Increased muscle forces restricted the overall motion of the spine

and at the same time, owing to muscle imbalance, resulted in asymmetric spinal movements (e.g., out-of-sagittal plane coupled motion during flexion-extension). Functional flexion-extension X-ray studies were performed passively on a patient population that was subdivided into different groups having similar pathologic conditions (48). When compared with a normal population, all patients exhibited less motion, except for high-performance athletes who showed more motion compared to the controls. Therefore, it was concluded that a kinematic analysis of the lumbar spine using passive flexion-extension was not a clinically useful method.

Inferior-superior loading using functional X-ray examinations also has been investigated as a measure of spinal instability (49,50). The motion was measured at two extremes of motion obtained by (a) spinal traction (suspending the individual from his or her hands); and (2) compression (using a weighted backpack during standing). Anteroposterior translation measurements were taken from lateral X-ray films of patients who had spondylolisthetic or retrospondylolisthetic displacement. In accordance with the severity of symptoms, the patients were divided into the following groups: (a) asymptomatic patients; (b) those with moderate symptoms and (c) patients with severe symptoms. The degree of primary anterior slip was almost equal in the three groups, but the translator movement differed significantly among them, as follows: 0.7, 5.2, and 7.5 mm, respectively.

Stereoradiographic techniques have been used to analyze three degrees-of-freedom sagittal plane motion (sagittal rotation, antero-posterior translation, and inferior-superior translation) in patients with low back pain and suspected segmental spinal instability (51). The average angular ROM in patients at the unaffected level (9.67 degrees) was not different from that at the affected level (8.45 degrees). The same was true for antero-posterior shear translation values, which were 1.54 and 0.92 mm, respectively. However, the ratio (i.e., coupled shear translation divided by the flexion angle) was significantly different (+0.18 versus -0.13 mm/degree) at the unaffected and affected levels, respectively. The retrodisplacement (anterior-to-posterior translation during flexion from extended position) was associated with the restricted motion, especially for sagittal plane rotations of less than 5 degrees, but was not correlated with the specific clinically unstable levels.

In a recent study, three-dimensional coupled motions were measured in low back pain patients (52). The patients were asked to move in three planes (sagittal, transverse, and frontal) while the intervertebral motions of pedicle screws inserted into the vertebrae above and below the suspected painful level were measured. During flexion-extension, there were small out of plane rotations. During axial rotation there was considerable variability in the coupled motions. The same was true for the lateral bending. The authors concluded that in contrast to well-

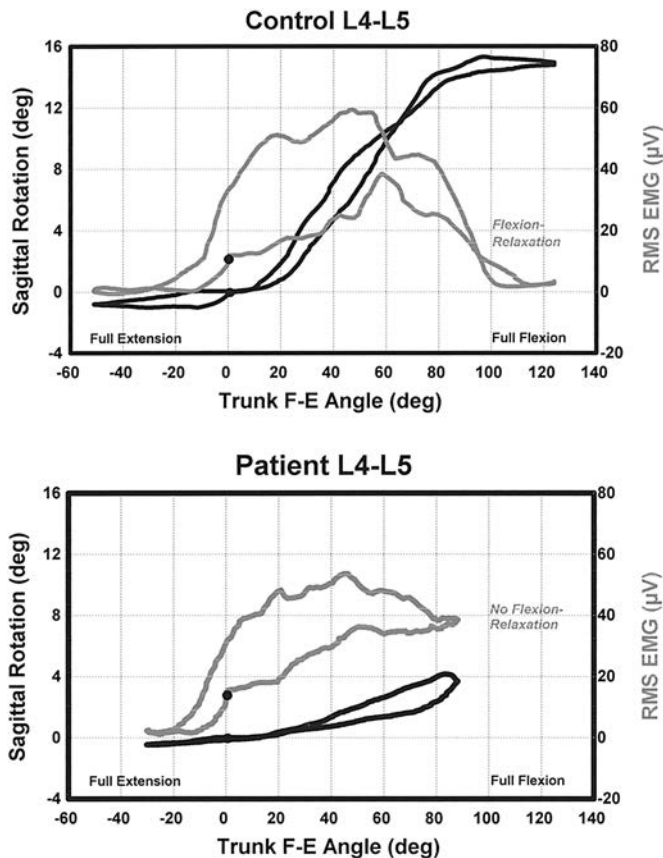

defined *in vivo* and *in vitro* coupling patterns observed in the controls, the low back pain patients showed significantly greater variability. The inherent coupling pattern of the osseoligamentous spine was modified by the altered muscle pattern or pain.

### Other Measures of Instability

Measurement of ROM, especially flexion-extension, is easy *in vivo*. For this reason, the ROM has been used often as an indicator of instability (4). Unfortunately, the ROM is not related to clinical instability, as exemplified by a young gymnast who may have extensive ROM but no clinical symptoms of instability (3). Further, the measurement of the ROM is affected by voluntary effort that the subject applies at the time of examination and motion limitation because of pain. Thus, investigating other measures of motion as possible indicators of instability has merit.

One such variable is the neutral zone, which represents looseness of the spinal column around the neutral position. Support for the coupled motions concept is provided by an *in vivo* study, which documented the presence of these motions in patients with suspected clinical instability (47). The neutral zone has been studied only *in vitro*. The increase in the neutral zone was found to be associated with disc degeneration and its decrease was related to simulated muscle force application (22,33). No direct clinical evidence is yet available. Because both measures are generally smaller in magnitude compared with the ROM, new and more accurate diagnostic methods are needed. In a recent study using ultrasound Doppler effect, the neutral zones of the sacroiliac joint have been measured in subjects without pain (53). Future studies with low back pain patients using this technique will be interesting to see if the neutral zone concept is clinically useful.

Using an intervertebral motion device for continuously measuring sagittal plane motion in the human lumbar spine, the intervertebral motion, along with the overall trunk angle, was measured dynamically during standing flexion-extension, both in normal subjects in patients suspected of having clinical instability in a lumbar motion segment (39). There exists a characteristic pattern of motion during flexion-extension for normal lumbar motion segments and patients (Fig. 5-6). The main findings were the following. Motion was significantly less, by at least 50%, in patients compared to the controls. A 78% reduction in muscle activity at full flexion (flexion relaxation) occurred in controls, whereas only a 13% reduction was found in patients. These observations were explained by hypothesizing that the neuromuscular control system provides active stabilization needed to protect the injured or diseased passive structures from movements that may cause pain, similar to the stabilization concepts proposed by Panjabi (5).

**FIG. 5-6.** Segmental kinematics (sagittal rotation) and myoelectric experimental data during a flexion-extension (F-E) cycle from the L4-5 motion segment plotted as a function of trunk F-E angle for a control and a patient. (Neutral standing position = trunk F-E angle = 0 degrees. Root mean square of the right-side erector spinae myoelectric activity (RMS EMG).) (From Kaigle AM, Wessberg P, Hansson T. Muscular and kinematic behavior of the lumbar spine during flexion-extension. *J Spinal Disord* 1998;11(2):163–174.)

## TREATMENTS

Spinal instability is treated clinically by diverse conservative methods, some of which seem to be paradoxical. Both the flexion exercises, which strengthen abdominal muscles, and the extension exercises, which strengthen back muscles, have been effective (54). To increase spinal stability co-contraction of both the front and back muscles is needed (55). This may be the explanation for the effectiveness of both the flexion and extension exercises. Rotational exercises have been found to be effective in patients who did not respond to other treatments (56). In addition to strengthening the spinal muscles, improving muscle coordination is important in enhancing spinal stability (5). Muscle stabilization has been advocated and shown to be effective in treating back pain patients (57). Various fusion techniques are reported to have clinical success (3).

## FUTURE RESEARCH

Several aspects of spinal instability need to be investigated from the biomechanical viewpoint. A short list is provided.

1. By means of *in vitro* simulations (using human cadaveric material), *in vivo* animal models, and mathematical models, investigate the role of intersegmental (deep) as well as multisegmental (superficial) muscles in providing spinal stability.
2. Develop techniques that measure the dynamic intervertebral motion continuously.
3. Using *in vivo* animal models, study the role of healing and adaptation after injury in altering the spinal stability.
4. Develop new and more accurate diagnostic methods for determining abnormalities of coupled motion, neutral zones, and other motion variables, which may help to provide more sensitive and specific measurements of spinal instability than are presently available.
5. Conduct clinical studies (prospective, double blind, and controlled) that correlate carefully obtained measures of instability of intervertebral motions (representing spinal column) and muscle function (representing neuromuscular control) with the clinical symptoms. These studies may help to bridge the gap between instability indicators and clinical symptoms.

## CHAPTER 6

# Spinal Instrumentation

Vijay K. Goel, Manohar M. Panjabi, Huroshi Kuroki, Setti S. Rengachary, D. McGowan, and N. Ebraheim

---

In recent years, surgeons have well-accepted surgical stabilization and fusion of the spine using instrumentation. Accordingly, the number of available devices for use by a surgeon has increased (1–4). The types and complexity of procedures (e.g., posterior, anterior, interbody) (3) have produced novel design challenges, requiring sophisticated testing protocols (3). In addition, most contemporary implant issues of stabilization and fusion of the spine are mostly mechanical in nature (4). [Biologic factors related to the adaptive nature of living tissue further complicate mechanical characterization (3,5,6).] Accordingly, researchers have designed various methods of testing to assess the mechanical nature of the spine and implants, both as separate and united entities. These evaluation regimens have produced valuable information and have led to the design and development of state-of-the-art systems. The most efficient way to describe the biomechanical issues relating to stabilization and fusion in the thoracolumbar region is to group the literature that concerns the major testing modalities. Results of specific studies are presented to show the type of information provided by the various testing methods.

### CLINICAL SCOPE AND OBJECTIVE OF SPINAL FUSION

Low back pain is responsible for approximately 14% of visits to physicians that do not involve preexisting conditions (2). Others have estimated 70% of the population in the United States has experienced back pain in their lives, leading to surgical intervention of the lumbar spine in 4% of the population (2). Surgical treatments most often promote fusion of the painful segments, with an estimated 25% of the 280,000 operations involving the lumbar spine (4,7).

The objective of spinal fusion is to eliminate pain and allow the patient to resume normal activities. Elimination of relative motion between the affected joints often

reduces this type of segmental pain. Spinal fusion is also performed to prevent or correct deformity (3) and stabilize the spine after trauma. Pathologic degeneration of the bony elements, intervertebral disc, and soft tissues are also indicators for fusion (3). Although intervertebral disc conditions seem to account for a significant proportion of the lesions leading to fusion, other indications include segmental instability, both degenerative and iatrogenic, and failed previous surgery. Although the aforementioned indications are commonly cited in the literature as grossly appropriate, there is considerable debate as to the degree of the lesion that indicates fusion (8).

Properly applied, spinal instrumentation maintains alignment and shares spinal loads until a solid, consolidated fusion is achieved. As instrumentation procedures have become increasingly popular, the number of available fixation systems has grown. With few exceptions, these hardware systems are used in combination with bone grafting procedures, and may be augmented by external bracing systems.

### BIOMECHANICAL EVALUATION OF INSTRUMENTATION PERFORMANCE

Spinal implants typically follow loosely standardized testing sequelae during the design and development stage and in preparation for clinical use. The design and development phase goal, from a biomechanical standpoint, seeks to characterize and define the geometric considerations and load-bearing environment to which the implant will be subjected. Various testing modalities exist that elucidate which components may need to be redesigned. Not including the testing protocols for individual components of a device, plastic vertebrae (corpectomy) models are one of the first-stage tests that involve placing the assembled device on plastic vertebral components in an attempt to pinpoint which component of the

assembled device may be the weakest mechanical link in the worst case scenario, vertebrectomy. The *in vivo* effectiveness of the device may be limited by its attachment to the vertebrae (fixation). Thus, testing of the implant-bone interface is critical in determining the fixation of the device to biologic tissue. Construct testing on cadaveric specimens provides information about the effectiveness of the device in reducing intervertebral motion across the affected and adjacent segments during quasi-physiologic loading. Animal studies provide insight with respect to the long-term biologic effects of implantation. Analytic modeling, such as the finite element method, is an extremely valuable tool for determining how implants and osseous loading patterns change with varying parameters of the device design. This type of modeling may also provide information about temporal changes in the bone quality due to the changing loading patterns as bone adapts to the implant (e.g., stress shielding-induced bone remodeling). After a certain level of confidence in the implant's safety and effectiveness is established through all or some of the aforementioned tests, controlled clinical trials allow for the determination of an implant's suitability for widespread clinical use. The following sections discuss each of these testing modalities, with specific examples used to illustrate the type of information that different tests can provide.

## Implant-Bone Interface

### *Device-Vertebra Interface*

Depending upon the spinal instrumentation, the device-vertebra interface may deal with laminae, pedicles, the vertebral body itself, or the end plates.

### *Interlaminar Hooks*

Interlaminar hooks are used as a means for fixing the device to the spine. Hook dislodgment, slippage, and incorrect placement have led to loss of fixation, however, resulting in nonfusion and pseudoarthrosis. Purcell et al. (9) investigated construct stiffness as a function of hook placement with respect to affected level in a thoracolumbar cadaver model. They created posterior ligamentous defects through sectioning and imposed bony fracture at T-12 and L-1 by flexion testing to failure. The unstable spines were instrumented with Harrington distraction instrumentation and interlaminar hooks placed initially on T-11 and L-2. The hooks were relocated to various levels about the affected area and the construct retested. The failure moment was found to be a function of the hook placement. The authors recommended hook placements three levels above and two levels below the affected area. This placement reduced vertebral tilting (analogous to intervertebral motion) across the stabilized area, where fusion is to be promoted.

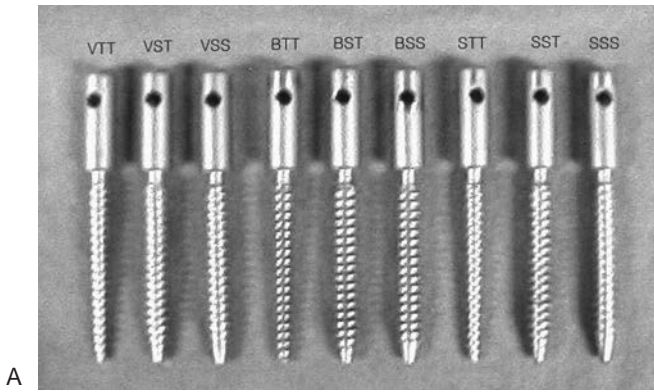

### *Transpedicular Screws*

Proper application of screw-based anterior or posterior spinal devices requires an understanding of screw biomechanics, including screw characteristics and insertion techniques, as well as an understanding of bone quality, pedicle and vertebral body morphometries, and salvage options (10–12). This is best illustrated by the fact that the pedicle, rather than the vertebral body, contributes approximately 80% of the stiffness and about 60% of the pullout strength across the screw-bone interface (10).

Carlson et al. (13) evaluated the effects of screw orientation, instrumentation, and bone mineral density (BMD) on screw translation, rotation at maximal load, and compliance of the screw-bone interface in human cadaveric bones. An inferiorly directed load was applied to each screw, inserted either anteromedially or anterolaterally, until failure of the fixation was perceived. Anteromedial screw placement with fully constrained loading linkages provided the stiffest fixation at low loads and sustained the highest maximal load. Larger rotation of the screws, an indication of screw-out failure, was found with the semi-constrained screws at maximal load. BMD directly correlated with maximal load, indicating that bone quality is a major predictor of bone-screw interfacial strength. Peiffer et al. and Ryken et al. also found a significant correlation between BMD and torque ( $p < .0001$ ,  $r < 0.42$ ), BMD and pullout force ( $p < .0001$ ,  $r < 0.54$ ), and torque and pullout force (14–16).

Since the specimens used for pullout strength studies primarily come from older adult subjects, Choi et al. used foams of varying densities to study the effect of BMD on the pullout strength of several screws (17). Pedicle screws (6.0 mm × 40 mm, 2 mm pitch, titanium alloy) of several geometric variations were used for the study. They included the buttress (B), square (S), and V-shape (V) screw tooth profiles. For each type of tooth profile, its core shape (i.e., minor diameter) also varied, either straight (i.e., cylindrical, core diameter < 4.0 mm) or tapered (i.e., conical, core diameter < 4.0 mm/2.0 mm). In addition, for the cylindrical screws the major diameter was kept straight or tapered. The conical screws had their major diameters tapered only. Therefore, screws with a total of nine different geometries were prepared and tested (Fig. 6-1A). Nomenclature used for identifying each screw type followed this sequence: tooth profile, the shape of the major diameter, and core type. For example, BST represents the screw with the buttress tooth profile and straight major diameter on a tapered core. The screws were implanted in the rigid polyurethane foams (77 cm × 127 cm × 77 cm) (Sawbones, Pacific Research Laboratory, Vashon Island, WA) of three different grades (grades 10, 12, and 15). These grades “simulated” the variations in BMD (10 lbf/ft<sup>3</sup>, 12 lbf/ft<sup>3</sup>, and 15 lbf/ft<sup>3</sup>, respectively) of the cancellous bone of a vertebra. Screws were implanted according to the American Society for Testing and Materials (ASTM: F1839-97) protocol. The

**FIG. 6-1. A:** Different types of screws used in the foam model to determine the pullout strengths of various designs. The nomenclature used is as follows: thread shape—square (S), buttress (B), V-shape (V); screw diameters—straight major diameter on straight core (SS), straight major diameter on tapered core (ST), tapered major diameter on tapered core (TT). **B:** Regression analysis. The maximum and minimum values from pullout test for each foam grade were used regardless of tooth or core profiles. (From Choi W, Lee S, Woo KJ, et al. Assessment of pullout strengths of various pedicle screw designs in relation to the changes in the bone mineral density. Paper presented at: 48th Annual Meeting of the Orthopedic Research Society; February 10–13, 2002; Dallas, TX.)

screws were pulled out at a loading rate of 5 mm per minute (ASTM: F1691-98) using MTS858 Bionix Machine (MTS Corp., Eden Prairie, MN). A one-way analysis of variance (ANOVA) test was done for the statistical analysis with SPSS 7.0 (SPSS, Inc., Chicago, IL). Comparison of the

pullout strength between the screw types was assessed with the Tukey test and Scheffe test. *P* values less than 0.05 were regarded as statistically significant.

The maximum pullout strengths for various screw designs are shown in Table 6-1. The highest purchasing

**TABLE 6-1.** Axial strength (N) data for different types of screws pulled out in foam of different densities

Foam grade	Body profile	Tooth profile (mean ±SD)		
		Square	Buttress	V-shape
10	SS	591 ± 22	497 ± 80	615 ± 36
	ST	622 ± 43	598 ± 25	634 ± 19
	TT	525 ± 36	547 ± 30	568 ± 74
12	SS	864 ± 50	769 ± 56	987 ± 55
	ST	956 ± 30	825 ± 108	1,005 ± 92
	TT	811 ± 41	808 ± 25	944 ± 32
15	SS	1,397 ± 93	1,303 ± 126	1,516 ± 78
	ST	1,582 ± 82	1,438 ± 36	1,569 ± 79
	TT	1,197 ± 43	1,352 ± 88	1,396 ± 68

SD, standard deviation; SS, straight major diameter on straight core; ST, straight major diameter on tapered core; TT, tapered major diameter on tapered core.

Source: Choi W, Lee S, Woo KJ, et al. Assessment of pullout strengths of various pedicle screw designs in relation to the changes in the bone mineral density. Paper presented at: 48th Annual Meeting of the Orthopedic Research Society; February 10–13, 2002; Dallas, Texas.

power in any screw design was observed in foams with the highest density (grade 15). Exponential increase in pullout strength was seen when the foam density increased from grade 10 through 15 (Fig. 6-1B). The VST screws exhibited the highest strength while the BSS the lowest with grades 10 and 12. The SST type screws were strongest against pullout with grade 15 foam while the STT the weakest. Statistical analysis showed that regardless of the foam grades or tooth profiles, the conical screws with straight major diameter (i.e., ST types) were stronger than the other two designs (i.e., SS or TT,  $p < .05$ ). Within the ST types, the buttress (B) tooth screws showed the lowest pullout strength among the three tooth profiles ( $p < .05$ ), while there was no statistical difference between the square and V-shape tooth with grades 12 and 15. However, with grade 10 foam, no significant difference was observed statistically among the three. In a case for the SS type screws, the buttress (B) tooth was the weakest regardless of the foam grades. Between the square and V-shape tooth screws, no difference was found. As for the TT types, V-shape screws had higher pullout strength than the square with grades 12 and 15. No statistical differences were found between the V-shape and the buttress (B) screws with grades 12 and 15, nor were any found among the three tooth types with grade 10.

The use of foam for pullout tests afforded a control on the variability in the quality of bone that is prevalent in other studies. Thus, the foam allowed for characterization of the effects of screw variables on the pullout strength. Overall, results demonstrate that the conical screws are consistently more effective against the pullout than the cylindrical designs. This is especially evident when the major diameter of the screw is kept straight. In this case, the contact area between the screw thread and surrounding foam is large. Although no consistent statistical superiority was found with the tooth profiles, results did suggest that the V-shape tooth screws ranked highest in many statistical comparisons and the buttress types showed comparatively lower pullout strength than the other types. This finding may be somewhat different from the literature. This can be due to the absence of the cortical purchase in foam model used in this study. On the other hand, the square tooth screws fared well in terms of pullout strength when the major diameter was kept straight but did not do so when tapered. Results also suggest that as the density of the host site is decreased no clear choice of tooth profile could be found.

Likewise, McKinley et al. developed a synthetic model to study the role of variations in pedicle morphology on the loads in pedicle screws (18). Synthetic vertebral analogs were fabricated, varying in pedicle height, length, or width independently. Pedicle screws internally instrumented with strain gauges were used as load transducers to determine screw-bending moments within the pedicle and body of the analog. Analogs were loaded in compression to simulate loading of an unstable burst fracture.

Screw bending moments within the pedicle increased incrementally with increasing pedicle length, rising 30% as length increased from 8 mm to 12 mm. Screw moment increased 20% when pedicle height dropped below 15 mm, consistent with a threshold effect. Changes in pedicle width did not affect screw loads within the pedicle. Thus, *in situ* pedicle screw loads increased significantly as pedicle length increased and as pedicle height decreased.

Lim et al. investigated the relationship between the BMD of the vertebral body and the number of loading cycles to induce loosening of an anterior vertebral screw (19). (Screw loosening was defined as 1 mm displacement of the screw relative to bone.) There was a positive correlation between the number of loading cycles to induce screw loosening and BMD ( $r < 0.8$ ,  $p < .01$ ). The average number of loading cycles to induce screw loosening was significantly less for specimens with BMD less than 0.45 g/cm<sup>2</sup> compared to those with BMD greater than or equal to 0.45g/cm<sup>2</sup>. These findings suggest that BMD may be a good predictor of anterior vertebral screw loosening as well, just like the pedicle screws.

These findings of increase in pullout strength, number of cycles to failure, and tightening torque with BMD, however, are not fully corroborated with the corresponding *in vivo* work. For example, moments and forces during pedicle screw insertion were measured *in vivo* and *in vitro* and correlated to BMD, pedicle size, and other screw parameters (material, diameter) (20). The mean *in vivo* insertion torque (1.29 Nm) was significantly greater than the *in vitro* value (0.67 Nm). The linear correlation between insertion torque and BMD was significant for the *in vitro* data but not for the *in vivo* data. No correlation was observed between insertion torque and pedicle diameter. However, another investigation that clinically evaluated 52 patients who underwent pedicle screw fixation augmenting posterior lumbar interbody fusion (PLIF) supports the *in vitro* findings. BMD was measured using dual energy X-ray absorptiometry (DEXA) and radiographs were assessed for detecting loosening and at the pedicle screw bone interface. BMD was found to have a close relationship with the stability of pedicle screw *in vivo*, and BMD values below  $0.674 \pm 0.104$  g/cm<sup>2</sup> suggested a potential increased risk of "nonunion". Similar studies pertaining to screw vertebral body interface for the anterior instrumentation have yet to be undertaken.

The current literature is based on studies of cylindrical pedicle screw designs. Conical screws have been introduced that may provide better "fit and fill" of the dorsal pedicle as well as improved resistance to screw bending failure. However, there is concern about loss of fixation if conical screws must be backed out after insertion (21). Abshire et al. evaluated these issues by pulling out cylindrical and conical screws inserted in pedicles of porcine vertebrae (21). Pullout results were comparable to data

from healthy human vertebrae. Conical screws provided a 17% increase in the pullout strength compared with cylindrical screws of the same size and thread design. The results also suggest that appropriately designed conical screws can be backed out 180° and 360° for intraoperative adjustments without loss of pullout strength, stiffness, and so forth. These findings are in agreement with the foam specimen work described earlier by Choi et al. (17).

Most recently, due to the experience gained with the use of pedicle screw-based fixation systems for the lumbar region, surgeons have extended the indications for such devices to the thoracic region. However, most of the basic science work and consequently our understanding of the biomechanics of thoracic pedicle screws is extrapolated from the work of various researchers on the lumbar spine. The specifics of how thoracic pedicle screw biomechanics may differ and hence any differences in use or application have not been elucidated (10).

### Cages

Total disc removal alone or in combination with other surgical procedures invariably leads to a loss of disc height and an unstable segment. Both allograft and autologous bone grafts have been used as interbody spacers. Associated with the harvest and use of autogenous bone grafts are several complications: pain, dislodgment of the anterior bone graft, loss of alignment, and so forth. Recently, the use of inserts, fabricated from synthetic materials (metal or bone-biologic), has gained popularity. These may be implanted through an anterior or posterior approach. Interbody devices promote fusion by imparting immediate postoperative stability, by load bearing, while allowing long-term fusion incorporation of the bone chips packed inside and around the cage (22). Anterior procedures used to implant cages often involve extensive removal of the anterior portion of the annulus fibrosis and anterior longitudinal ligament. The strength of the construct relies in part on the tension capacity of the remaining annulus (22,23). The posterior interbody fusion procedures involve removal of various posterior elements. Iatrogenic or acquired (spondylytic) posterior column instability frequently necessitates the application of posterior fusion hardware. Combined fusions of the lower lumbar spine (posterior arthrodesis with anterior or posterior interbody fusion) usually involve partial or complete facetectomy and removal of the pars interarticularis with the required partial or complete discectomy. These constructs require a significant amount of load bearing by the graft (or cage) construct and posterior hardware to resist external forces (22,23).

The cages of varying sizes, shapes, and materials have been made available to surgeons. Thus, like the screw-bone interface, one needs to understand the biomechanics of cage-end-plate interaction. The interface mechanics are affected by several factors: size, shape, and material

of the cage; end-plate properties such as BMD and preparation (contact area with cage and removal of the central bony region), and the approach used to place the cage. Both axial compressive strength and pullout resistance functions are important parameters to study (24).

### *Axial Compression Force*

In axial compression, higher failure loads were observed with greater bone densities (25). Steffen et al. undertook a human cadaveric study with the objectives to assess the axial compressive strength of an implant with peripheral end-plate contact as opposed to full surface contact, and to assess whether removal of the central bony end plate affects the axial compressive strength (25). Neither end-plate contact region nor its preparation technique affected yield strength or ultimate compressive strength. Age, bone mineral content, and the normalized end-plate coverage were strong predictors of yield strength ( $p < .0001$ ;  $r^2 < 0.459$ ) and ultimate compressive strength ( $p < .0001$ ;  $r^2 < 0.510$ ). An implant with only peripheral support resting on the apophyseal ring offers axial mechanical strength similar to that of an implant with full support. Neither supplementary struts nor a solid implant face has any additional mechanical advantage, but reduces graft-host contact area. Removal of the central bony end plate is recommended because it does not affect the compressive strength and promotes graft incorporation.

Tsantrizos et al. compared compressive strength of PLIF implants using a new cortical bone spacer machined from allograft to that of titanium-threaded and non-threaded PLIF cages [Ray Threaded Fusion Cage (TFC), Contact Fusion Cage, and PLIF Allograft Spacer] (26). The Contact Fusion Cage and PLIF Allograft Spacer constructs had a higher ultimate compressive strength than the Ray TFC. The PLIF Allograft Spacer is biomechanically equivalent to titanium cages but is devoid of the deficiencies associated with other cage technologies.

There are drawbacks to using threaded cylindrical cages (e.g., limited area for bone ingrowth and metal precluding radiographic visualization of bone healing). To somewhat offset these drawbacks, several modifications have been proposed, including changes in shape and material (27–29). For example, the central core of the barbell-shaped cage can be wrapped with collagen sheets infiltrated with bone morphogenetic protein. The biomechanical properties of an anterior lumbar interbody reconstruction using 18 mm diameter threaded cylindrical cages, or barbell cages (18 mm diameter and 6 mm wide at both cylindrical ends, with a round 4 mm diameter bar joining the two ends) were compared. Following the axial compression tests to failure, the specimens with cage *in situ* were then radiographed and bisected through the disc, and the subsidence (or penetration) of the cage(s) into the cancellous bone of the vertebral bodies

was measured. There was no difference in terms of stiffness between the motion segments with the threaded cylindrical cage(s) inserted and those with the barbell cage(s) inserted ( $p > .15$ ). The average values of subsidence were 0.96 mm for the threaded cylindrical cage group and 0.80 mm for the barbell cage group (difference not significant:  $p < .38$ ). The femoral ring allograft (FRA) and PLIF spacers have been developed as biological cages that permit restoration of the anterior column with a machined allograft bone (27). Test results demonstrate that the FRA and PLIF spacers have a compressive strength over 25,000 N. According to Bianchi, the average load-bearing capacity of allograft spacers ranged from 10,308 N to 31,015 N (30). Strength dropped by less than 2% per decade of age of the donors and did not depend on the sex of the donor. Thus, the load-carrying capacity of the allografts exceeded the applied compressive loads of the spine. These precision cortical grafts withstand much higher loads when compared to conventional allografts that are composed mostly of cancellous bone.

#### *Pullout Strength*

Dietl et al. pulled out cylindrical threaded cages (Ray TFC, Raymedica Inc, Bloomington, MN), bullet-shaped cages, and newly designed rectangular titanium cages with an end-plate anchorage device used as posterior interbody implants (31). The Stryker cages required a median pullout force of 130 N (minimum, 100 N; maximum, 220 N), as compared with the higher pullout force of the Marquardt cages (median, 605 N; minimum, 450 N; maximum, 680 N), and the Ray cages (median, 945 N; minimum, 125 N; maximum, 2230 N). Differences in pullout resistance were noted depending on the cage design. A cage design with threads or a hook device provided superior stability, as compared with ridges. The pyramid-shaped teeth on the surfaces and the geometry of the implant increased the resistance to expulsion at clinically relevant loads (1053 N and 1236 N, respectively) (31).

#### **Construct Testing**

Spinal instrumentation needs to be applied to a spine specimen to evaluate its effectiveness. As a highly simplified model, two plastic vertebrae serve as the spine model. Loads are applied to the plastic vertebrae and their motions are measured. This provides some idea of the rigidity of the instrumentation. However, a better picture can be obtained by attaching the device to the cadaveric spine specimen and by evaluating the assembly. One may choose a free level above and below the instru-

mented segment to choose the length of the specimen, as the specimen is anatomically identical to the *in vivo* situation, more clinically relevant results concerning the device performance are obtained.

#### *Plastic Vertebra (Corpectomy) Models*

Clinical reviews of failure modes of the devices indicate that most designs satisfactorily operate in the immediate postoperative period. Over time, however, these designs can fail because of the repeated loading environment to which they are subjected. Thus, fatigue testing of newer designs has become an extremely important indicator of long-term implant survivorship. Although cadaveric studies have proved extremely valuable in the evaluation of screw and hook fixation designs, the rapid deterioration of cadaveric material precludes this testing method for long-term fatigue evaluation in which testing may continue over periods of weeks. Protocols have been developed wherein the vertebrae are represented by plastic components, usually medical-grade ultra-high-molecular-weight polyethylene (UHMWPE) (32). A plastic vertebra protocol was developed by Goel et al. (33) for the evaluation of the Kaneda device (first-generation design [DePuy Spine, Inc., Raynham, MA]). The test design (Fig. 6-2) resulted in axial loading, producing a flexion-bending moment secondary to the offset of the hardware

**FIG. 6-2.** Fixture used to determine the static and cyclic bending failure loads of a posterior device.

from the loading axis. Quasi-static bending loads to failure showed that the paraspinal rods permanently deformed at an axial load of  $806.3 \pm 6.0$  N. This loading produced an associated bending moment on the paraspinal rods of  $28.8 \pm 0.2$  Nm. Fatigue testing showed that the endurance limit of the construct was 380.0 N with a bending moment of 13.6 Nm. The preceding protocol was modified to accommodate evaluation of semi-rigid or flexible devices using a plastic vertebra approach (34). Because appreciable compression-bending support is not afforded by the flexible devices, the testing protocol was changed to include a steel fulcrum that bridged the UHMWPE block gap.

Cunningham et al. undertook testing of 12 anterior thoracolumbar instrumentation systems in static and fatigue modes using a plastic vertebra model (32). The static destructive and fatigue tests up to 2 million cycles at three-load levels were conducted, followed by the failure mode analysis. Twelve anterior instrumentation systems, consisting of five plate and seven rod systems were compared in stiffness, bending strength, and cycles to failure. Static and fatigue test parameters both demonstrated highly significant differences between devices. The stiffness ranged from 280.5 kN/m in the Synthes plate (Synthes, Paoli, PA) to 67.9 kN/m in the Z-plate (Sofamor-Danek, Memphis, TN). The Synthes plate and Kaneda SR (new design) titanium (AcroMed, Cleveland, OH) formed the highest subset in bending strength of 1516.1 N and 1209.9 N, respectively, whereas the Z-plate showed the lowest value of 407.3 N. There were no substantial differences between plate and rod devices. In fatigue, only three systems: the Synthes plate, the Kaneda SR titanium, and the Olerud plate (Nord Opedic AB, Sweden) withstood 2 million cycles at 600 N. The failure mode analysis demonstrated plate or bolt fractures in plate systems and rod fractures in rod systems.

Clearly, studies such as these involving missing vertebra (corpectomy) artificial models reveal the weakest components or linkages of a given system. Results must be viewed with caution since they do not shed light on the biomechanical performance of the device. Furthermore, we do not know the optimum strength of a fixation system. These protocols do not provide any information about the effects device implantation may have on individual spinal components found *in vivo*. For these data, osteoligamentous cadaveric models need to be incorporated in the testing sequelae and such studies are more clinically relevant

### ***Osteoligamentous Cadaver Models***

For applications, such as fusion and stabilization, initial reductions in intervertebral motion are the primary determinants of instrumentation success, although the optimal values for such reductions are not known and

probably not needed to determine relative effectiveness. Thus, describing changes in motion of the injured and stabilized segments in response to physiologic loads is the goal of most cadaveric studies. Many times, these data are compared with the intact specimen, and the results are reported as the instrumentation's contribution to providing stability (35). To standardize, the flexibility testing protocol has been suggested (36). Here a load is applied and resulting motions are measured. Three loads, flexion/extension, lateral bending, and axial torsion, are applied one at a time. It is suggested that the loads be pure moments so that the entire length of the specimen is subjected to the same moment. This method standardizes the testing protocol and helps identify weakness in the construct (36). Additionally, most of these studies involve quasi-static loading; however, short-term fatigue characteristics have also been investigated. Both posterior and anterior instrumentation employed for the promotion of fusion have been evaluated using cadaveric specimens. Examples of both these types of devices, which are discussed within the context of this testing modality, follow.

The stability analysis of devices with varying stiffness is best exemplified in a study by Gwon et al. (37) who evaluated the stability characteristics of three different transpedicular screw devices: spinal rod-transpedicular screw system (RTS), the Steffee System (Variable Screw Plate System [VSP], DePuy Spine, Inc., Raynham, MA), and Crock device (CRK). All devices provided statistically significant ( $p < .01$ ) motion reductions across the affected level (L4-L5). The differences among the three devices in reducing motion L4-L5, however, were not significant. Also, the changes in motion patterns of segments adjacent to the stabilized level compared with the intact case were not statistically significant. These findings have been confirmed by Rohlmann et al. who used a finite element model to address several implant-related issues, including this one (38).

In an *in vitro* study, Weinhoff et al. (39) measured intradiscal pressure in lumbosacral cadaver specimens subjected to constant displacement before and after applying bilateral pedicle screw instrumentation across L4-S1. They noted that intradiscal pressure increased in the disc above the instrumented levels. Also, the adjacent level effect was confounded in two-level instrumentation compared with single-level instrumentation. Opposite results, however, are presented by several others (37,40). These authors tested intact and stabilized spines under constant loads. Results based on *in vitro* studies must be interpreted with caution, being dependent on the testing mode chosen (displacement or load control) for experiments. In the displacement control-type studies, in which applied displacement is kept constant during testing of intact and stabilized specimens, higher displacements and related parameters (e.g., intradiscal pressure) at the adjacent segments are reported. This is not true for the results

based on the load control-type studies, in which the applied loads are kept constant.

Lim et al. assessed the biomechanical advantages of diagonal transfixation compared to horizontal transfixation (41). Diagonal cross-members yielded more rigid fixation in flexion and extension but less in lateral bending and axial rotational modes, as compared to horizontal cross-members. Furthermore, greater stresses in the pedicle screws were predicted for the system having diagonal cross-members. The use of diagonal configuration of the transverse members in the posterior fixation systems did not offer any specific advantages, quite contrary to the common belief.

Using an experimental approach in which pressure sensors were inserted into the disc space and strain gauges were mounted on the spinal rods, Cripton et al. determined the load sharing among the spinal components in response to external loads (42). A large majority of the applied moments were found to be supported by an equal and opposite force pair between the intervertebral disc and fixator rods in flexion, extension, and an equal and opposite force pair between the left and right fixator rods in lateral bending. Torsional moments were shared approximately equally between the posterior elements; intervertebral disc, an equal and opposite shear force pair in the transverse plane between the right and left fixators and internal fixator moments. The authors concluded that when posterior instrumentation devices are used to stabilize severe anterior column injuries, the implants may be at risk of fracture secondary to reversed bending moments.

Biomechanical cadaveric studies of anterior fusion-promoting and stabilizing devices have become increasingly more common in the literature, due to this procedure's rising popularity. For example, *in vitro* testing was performed using the T9-L3 segments of human cadaver spines (43). An L-1 corpectomy was performed, and stabilization was achieved using one of three anterior devices: the anterior thoracolumbar locking plate, (ATLP [Synthes, Paoli, PA]) in nine spines, the smooth rod Kaneda, (SRK [DePuy Spine, Inc. Raynham, MA]) in ten, and the Z-plate in ten. Specimens were load tested. Testing was performed in the intact state, in spines stabilized with one of the three aforementioned devices after the devices had been fatigued to 5,000 cycles at  $\pm 3$  Nm, and after bilateral facetectomy. There were no differences between the SRK-instrumented and Z-plate-instrumented spines in any state. In extension testing, the mean angular rotation ( $\pm$  standard deviation) of spines instrumented with the SRK ( $4.7^\circ \pm 3.2^\circ$ ) and Z-plate devices ( $3.3^\circ \pm 2.3^\circ$ ) was more rigid than that observed in the ATLP-stabilized spines ( $9^\circ \pm 4.8^\circ$ ). In flexion testing after induction of fatigue, however, only the SRK ( $4.2^\circ \pm 3.2^\circ$ ) was stiffer than the ATLP ( $8.9^\circ \pm 4.9^\circ$ ). Also, in extension postfatigue, only the SRK ( $2.4^\circ \pm 3.4^\circ$ ) provided more rigid fixation than the ATLP ( $6.4^\circ \pm 2.9^\circ$ ). All

three devices were equally unstable after bilateral facetectomy. The SRK and Z-plate anterior thoracolumbar implants were both more rigid than the ATLP, and of the former two, the SRK was stiffer. The results suggest that in cases in which profile and ease of application are not of paramount importance, the SRK has an advantage over the other two tested implants in achieving rigid fixation immediately postoperatively. Lee et al. also reached similar conclusions (44).

The biomechanical properties of several different spinal instrumentations have been studied in various spinal injury models. Only a few studies, however, investigate the stabilization methods in spinal tumor vertebral body replacement surgery (45). Thus, the biomechanical characteristics of short-segment anterior, posterior, and combined instrumentations in lumbar spine tumor vertebral body replacement surgery were investigated in a cadaver model. The L2 vertebral body was resected and replaced by a carbon-fiber cage. Different fixation methods were applied across the L1 and L3 vertebrae. One anterior, two posterior, and two combined instrumentations were tested. The anterior instrumentation, after vertebral body replacement, showed greater motion than the intact spine, especially in axial torsion (range of motion,  $10.3^\circ$  vs.  $5.5^\circ$ ; neutral zone,  $2.9^\circ$  vs.  $0.7^\circ$ ;  $p < .05$ ). Posterior instrumentation provided greater rigidity than the anterior instrumentation, especially in flexion-extension (range of motion,  $2.1^\circ$  vs.  $12.6^\circ$ ; neutral zone,  $0.6^\circ$  vs.  $6.1^\circ$ ;  $p < .05$ ). The combined instrumentation provided superior rigidity in all directions compared with all other instrumentations. Posterior and combined instrumentations provided greater rigidity than anterior instrumentation. Anterior instrumentation should not be used alone in vertebral body replacement.

Lim et al. undertook a study to test the biomechanical efficacy of using polymethylmethacrylate (PMMA) block, tricortical iliac crest bone graft, one large Harms cage, and two small Harms cages as spacers in a corpectomy model (46). The Harms cage, especially one large cage, improved the axial rotational stability significantly in both anterior and posterior fixation groups as compared with the iliac bone or polymethylmethacrylate. No significant difference in the stabilizing role was found among different grafting devices in lateral bending, flexion, and extension. These results suggest that a more rigid spinal construct can be obtained by using a metal cage with improved friction at the cage-bone interface.

Oda et al. nondestructively compared three types of anterior thoracolumbar multisegmental fixation to investigate the effects of rod diameter and rod number on construct stiffness and rod-screw strain (47). Three types of anterior fixation were then performed at L1-L4: (a) 4.75 mm diameter single-rod system, (b) 4.75 mm dual-rod system, and (c) 6.35 mm single-rod system. A carbon fiber cage was used for restoring intervertebral disc space. Single screws at each vertebra were used for sin-

gle-rod fixation and two screws were used for dual-rod fixation. The 6.35 mm single-rod fixation significantly improved construct stiffness compared with the 4.75 mm single rod fixation only under torsion ( $p < .05$ ). The 4.75 mm dual-rod construct resulted in significantly higher stiffness than did both single-rod fixations ( $p < .05$ ), except under compression. For single-rod fixation, increased rod diameter neither markedly improved construct stiffness nor affected rod-screw strain, indicating the limitations of a single-rod system. In thoracolumbar anterior multisegmental instrumentation, the dual-rod fixation provided higher construct stiffness and less rod-screw strain compared with single-rod fixation.

### Cage-Related Studies

Restoring stability to the anterior column is essential for achieving normal spinal biomechanics. A variety of mechanical spacers have been developed and advocated for both anterior and posterior approaches. These devices have been used to enhance the fusion process and reduce the complications associated with the traditional autografts. Due to widespread use of the cages as interbody spacers, we have decided to devote this entire section to dealing with construct evaluation using cages. These studies range from evaluations of cages as stand-alone devices to use of anterior or posterior instrumentation for additional stabilization. The orientation of the cage within the disc space can also be varied. Finally, radiodense cage materials impede radiographic assessment of the fusion, and may cause stress shielding of the graft. The following studies describe the biomechanics of the cage-based constructs from these perspectives.

### Cage-Along Studies

The changes in stiffness and disc height of porcine functional spinal units (FSUs) by installation of a threaded interbody cage and those by gradual resection of the annulus fibrosus were quantified (48). Flexion, extension, bending, and torsion testing of the FSUs were performed in four sequential stages:

- Stage I, intact FSU
- Stage II, the FSUs were fitted with a threaded fusion cage
- Stage III, the FSUs were fitted with a threaded fusion cage with the anterior one-third of the annulus fibrosus excised, including excision of the anterior longitudinal ligament
- Stage IV, in addition to stage III, the bilateral annulus fibrosus was excised.

Segmental stiffness in each loading in the four stages and a change of disc height induced by the instrumentation were measured. After instrumentation, stiffness in all loading modes ( $p < .005$ ) and disc height ( $p < .002$ )

increased significantly. The stiffness of FSUs fixed by the cage decreased with gradual excision of the annulus fibrosus in flexion, extension, and bending. These results suggest that distraction of the annulus fibrosus and posterior ligamentous structures by installation of the cage increases the soft-tissue tension, resulting in compression to the cage and a stiffer motion segment. This study explains the basic mechanism through which the cages may provide the stability in various loading modes.

Three PLIF implant constructs (Ray TFC, Contact Fusion Cage, and PLIF Allograft Spacer) were tested for stability in a cadaver model (26). Changes in the neutral zone, and range of motion were analyzed. None of the stand-alone implant constructs reduced the neutral zone. The constructs decreased the range of motion in flexion and lateral bending. The data did not suggest any implant construct to behave superiorly. Specifically, the PLIF Allograft Spacer is biomechanically equivalent to titanium cages and is devoid of the deficiencies associated with metal cages. Therefore, the PLIF Allograft Spacer is a valid alternative to conventional cages. Lund et al. has confirmed these results in a similar study (23).

Murukami et al., in an *in vitro* model, compared the stability of a posterior interbody reconstruction using two standard threaded cages (18 mm diameter), a single mega-cage (24 mm diameter), or a reconstruction using dual-nested cages (22 mm diameter) (29). After testing, each specimen was bisected through the disc and the surface area of the reamed (exposed) vascular bed was calculated. The dual-nested cages produced the stiffest reconstruction. However, there was no significant difference between the standard and nested cages, and compared with the mega-cage, the only difference was in flexion. The surface area of cancellous bone exposed by reaming for each of the three reconstructions showed the greatest value with the dual-nested cages. These findings, together with the improved safety afforded by the nested or mega-cage, suggest that they are appropriate alternatives to the standard dual-threaded cage reconstruction.

Nibu et al. (40) investigated the stability afforded by the BAK interbody fusion device (Spine Tech, Minneapolis, MN) in four human cadaveric specimens (L5-S1) with implants placed from the anterior approach. The BAK device increased the stiffness of the spinal unit for all motions except extension ( $p < .05$ ) (Table 6-2). Finite element model analyses of the spinal segment with and without the cage have also revealed similar results (49,50) (Fig. 6-3).

The lateral orientation of the cage placement within the disc has been increasingly used for fusion, but a direct biomechanical comparison between cages implanted either anteriorly or transversely in human cadaveric spines has not been performed (51). Fourteen spines were randomized into the anterior group (anterior discectomy and dual anterior cage—TFC placement) and the lateral group (lateral discectomy and single transverse cage

**TABLE 6-2.** Average stiffness (Nm/deg) calculated from the flexibility data between zero and 10 Nm load

Stiffness (N/degree)	Intact	Flexion	Increase (%)
Flexion	1.15	2.12	84.3
Extension	1.25	1.09	-12.8
Axial rotation	8.30	13.90	67.5
Lateral bending	1.90	5.54	191.6

placement) for load-displacement evaluations. Segmental ranges of motion were similar between spines undergoing either anterior or lateral cage implantation. Combined with a decreased risk of adjacent structure injury through

a lateral approach, these data support a lateral approach for lumbar interbody fusion.

When used alone to restore stability, the orientation of the cage (oblique vs. posterior) affected the outcome (52). In flexion, both the OBAK (oblique placement of one cage) and CBAK (conventional posterior placement of two cages) orientations provided significant stability. In lateral bending, CBAK orientation was found to be better than OBAK. In axial mode, CBAK orientation was significantly effective in both directions while OBAK was effective only in right axial rotation. Owing to the differences in the surgical approach and the amount of dissection, the stability for the cages when used alone as a function of cage orientation was different.

The metallic cages being very stiff may lead to stress-shielded environments within the devices with potential adverse effect on growth of the cancellous bone within the

**FIG. 6-3.** **A:** The finite element model of a ligamentous motion segment was used to predict load-displacement behavior of the segment following cage placement. *Alc*, anterior longitudinal ligament completely removed/cut; *Alp*, partially cut; *Ali*, intact. **B:** Percentage change in density of the bone surrounding the BAK cage. Adaptive internal bone remodeling of the vertebral body following an anterior interbody fusion: a computer simulation. Paper presented at the 24th Meeting of the International Society for the Study of the Lumbar Spine; June 3-6, 1997; Singapore.)

cage itself (53). Using a calf spine model, a study was designed to compare the construct stiffness afforded by 11 differently designed anterior lumbar interbody fusion devices: four different threaded fusion cages (BAK device, BAK Proximity, Center Pulse, Minneapolis, MN; Ray TFC; and Danek TIBFD, Sofamor-Danek, Memphis, TN), five different nonthreaded fusion devices (oval and circular Harms cages, Brantigan PLIF and ALIF cages, and InFix device); two different types of allograft (femoral ring and bone dowel), and to quantify their stress-shielding effects by measuring pressure within the devices. Before testing, a silicon elastomer was injected into the cages and intra-cage pressures were measured using pressure needle transducers. No statistical differences were observed in construct stiffness among the threaded cages and nonthreaded devices in most of the testing modalities. Threaded fusion cages demonstrated significantly lower intra-cage pressures compared with nonthreaded cages and structural allografts. Compared with nonthreaded cages and structural allografts, threaded fusion cages afforded equivalent reconstruction stiffness but provided a more stress-shielded environment within the devices. (This stress shielding effect may further increase in the presence of supplementary fixation devices.)

It is known that micromotion at the cage–end-plate interface can influence bone growth into its pores. Loading conditions, mechanical properties of the materials, friction coefficients at the interfaces, and geometry of spinal segments would affect relative micromotion and spinal stability. In particular, relative micromotion is related closely to friction at bone-implant interfaces after arthroplasty. A high rate of pseudarthrosis and a high overall rate of implant migration requiring surgical revision have been reported following PLIF using BAK threaded cages. A high rate of both pseudarthrosis and implant migration may be due to poor fixation of the implant, in addition to stress-shielding phenomena previously described. Thus, Kim developed an experimentally validated finite element model of an intact FSU and the FSU implanted with two threaded cages to analyze the motion of threaded cages in PLIF (54). The model responses were analyzed, without preload, under forces of axial compression (600 N), torsion (25 Nm), and shearing force (250 N). Motion of the implants was not seen in compression. In torsion, a rolling motion was noted, with a range of motion of 10.6° around the central axis of the implant when left/right torsion (25 Nm) was applied. The way the implants move within the segment may be due to their special shape: the thread of the implants cannot prevent the BAK cages rolling within the disc space. However, it must be noted that the author considered the torsional load value to high; such values may not be clinically relevant. Using a finite element approach, Kim also studied the effects of mechanical parameters at bone-implant interfaces of the lumbar spine segments on micromotion (54). Relative micromotion (slip distance

on the contact surfaces), posterior axial displacement, and stress were predicted as a function of coefficient of friction, loading conditions, and age-related material-geometric properties of the spinal segments. Relative micromotion (slip distance) at the interfaces was obvious at their edges under axial compression. The slip occurred primarily at the anterior edges under torsion with preload, whereas it occurred primarily at the edges of the left cage under lateral bending with preload. Relative micromotion at the interfaces increased significantly as the apparent density of cancellous bone or the friction coefficient of the interfaces decreased. A significant increase in slip distance at the anterior annulus occurred with an addition of torsion to the compressive preload. Relative micromotion was sensitive to the friction coefficient of the interfaces, the bone density, and the loading conditions. A reduction in age-related bone density was less likely to allow bone growth into surface pores of the cage. It was likely that the larger the disc area the more stable the interbody fusion of the spinal segments. However, the amount of micromotion may change in the presence of posterior fixation technique, an issue that was not reported by the author.

Almost every biomechanical study has shown that interbody cages alone, irrespective of their shapes, sizes, surface type, material, and approach used for implantation, do not stabilize the spine in all of the modes. It is suspected that this may be caused by the destruction of the appropriate spinal elements like the anterior longitudinal ligament and anterior annulus fibrosus or facets. Thus, use of additional instrumentation to augment cages seems to have become a standard procedure.

The three-dimensional flexibility in six human lumbar functional spinal units was measured after the anterior or anterolateral insertion of an interbody cage with transfacet screws (55). The implant used was a central, porous, contoured implant with end-plate fit. The translaminar screw fixation masked the differences in stability due to cage orientation and construct became stable in all directions.

Wang et al. used a multisegmental cadaveric spine model to quantify the load-displacement behavior of intact spine specimens, injured and stabilized using BAK cages as lumbar interbody fusion devices with posterior instrumentation across two levels (L4-S1) (52). The obliquely inserted BAK cage has the advantages of reducing exposure and precise implantation. The biomechanical efficacy of this procedure is sparse, especially in comparison to the PLIF with posterior instrumentation. With the supplementary posterior fixation, the differences in stability due to the orientations were not noticeable at all, both before and after cyclic tests; underscoring the importance of using instrumentation when cages are used as PLIFs. However, the oblique insertion may be more favorable since it requires less exposure, enables precise implantation, and is less expensive.

Tsantrizos et al. undertook a human cadaveric study to compare the initial segmental stability of a PLIF construct tested with supplemental pedicle screw fixation (26). Three PLIF implant constructs (Ray TFC, Contact Fusion Cage, and PLIF Allograft Spacer) were tested nondestructively in axial rotation, flexion-extension, and lateral bending. Supplemental pedicle screw fixation decreased the neutral zone in flexion-extension and lateral bending. It significantly decreased the range of motion in all loading directions with no differences between implant constructs. The biomechanical data did not suggest any implant construct to behave superiorly with supplemental posterior fixation.

Lund et al. examined the effects of cross-bracing the posterior instrumentation in stabilizing the intervertebral disc implanted with one of the three cage designs from the posterior side (23). As compared to stabilization with posterior instrumentation, the addition of cross-bracing had a stabilizing effect in axial rotation.

### *Cyclic Loading*

The function of interbody fusion cages is to stabilize the spinal segment primarily by distracting it as well as allowing bone ingrowth and fusion (22). An important condition for efficient formation of bone tissue is achieving adequate spinal stability. However, the initial stability may be reduced due to repeated movements of the spine during activities of daily living. Before and directly after implantation of a Zientek, Stryker, or Ray PLIF cage, 24 lumbar spine segments were evaluated for stability analyses (22). The specimens were then loaded cyclically for 40,000 cycles at 5 Hz with an axial compression load ranging from 200 N to 1,000 N. The specimens were tested again in the spine tester. Generally, a decrease in motion in all loading modes was noted after insertion of the Zientek and Ray cages and an increase after implantation of a Stryker cage. In all three groups, greater stability was demonstrated in lateral bending and flexion then in extension and axial rotation. Reduced stability during cyclic loading was observed in all three groups; however, loss of stability was most pronounced in the Ray cage group. The authors thought that this may be due to the damage of the cage—bone interface during cyclic loading which was not the case for the other two since they have flat brick-type interfaces.

### **Animal Models**

An approximation of the *in vivo* performance of spinal implants in humans can be attained by evaluation in animal models (56,57). Specifically, animal models provide a dynamic biologic and mechanical environment in which the implant can be evaluated. Temporal changes in both the host biologic tissue and instrumentation can be assessed with selective incremental sacrificing of the ani-

mals. Common limitations of animal studies include the method of loading (quadruped vs. biped) and the size adjustment of devices needed so that proper fit is achieved in the animals.

Animal studies have revealed the fixation benefits of grouting materials in the preparation of the screw hole. Spivak et al. (58) undertook an investigation in which 16 dogs were subjected to bilateral drilling and placement of transpedicle screws from L1 to L6 and sacral alar screws. The lumbar screw population included both standard and plasma-sprayed hydroxyapatite (HA)-coated screws, both with and without HA grout added to over-drilled screw holes before screw insertion. The major findings showed that the HA grouting of the screw hole bed before insertion significantly increased fixation (pullout) of the screws. Scanning electron microscopy analysis revealed that HA plasma spraying had deleterious effects on the screw geometry, dulling the self-tapping portion of the screw and reducing available space for bony ingrowth.

An animal model of anterior and posterior column instability was developed by McAfee et al. (59) to allow *in vivo* observation of bone remodeling and arthrodesis after spinal instrumentation. An initial anterior and posterior destabilizing lesion was created at the L5-6 vertebral levels in 63 adult beagle dogs. Observations 6 months after surgery revealed a significantly improved probability of achieving a spinal fusion if spinal instrumentation had been used. Nondestructive mechanical testing after removal of all metal instrumentation in torsion, axial compression, and flexion revealed that the fusions performed in conjunction with spinal instrumentation were more rigid. Quantitative histomorphometry showed that the volumetric density of bone was significantly lower (i.e., device-related osteoporosis occurred) for fused versus unfused spines. In addition, a linear correlation occurred between decreasing volumetric density of bone and increasing rigidity of the spinal implant; device-related osteoporosis occurred secondary to Harrington, Cotrel-Dubouset, and Steffee pedicular instrumentation. These studies have several limitations, in addition to the ones already stated. In their model, the spinal implant spanned two vertebral bodies completely separated from each other, with the exceptions being the spinal cord and some perispinous ligaments. In patients, a degenerated disc or interbody bone graft (or a similar device) is always present between the two vertebral bodies. Thus, the implant was subjected to 100% load in McAfee's models as opposed to the load-sharing role the device plays in patients. The clinical follow-up studies also do not lend support to the animal model-based findings. Thus, the stress-induced changes in the bone quality found in the animal models are not likely to correlate well with the actual changes in the spinal segment of a patient. In fact, it is suggested that the degeneration in a patient may be determined more by individual characteristics than by the fusion itself (60).

In long bone fractures, internal fixation improves the union rate but does not accelerate the healing process. Spinal instrumentation also improves the fusion rate in spinal arthrodesis. However, it remains unclear whether the use of spinal instrumentation expedites the healing process of spinal fusion (61). Accordingly, an *in vivo* sheep model was used to investigate the effect of spinal instrumentation on the healing process of posterolateral spinal fusion (61). Sixteen sheep underwent posterolateral spinal arthrodeses at L2-L3 and L4-L5 using equal amounts of autologous bone. One of those segments was selected randomly for further augmentation with transpedicular screw fixation (Texas Scottish Rite Hospital spinal system; Sofamor Danek, Memphis, TN). The animals were euthanized at 8 weeks or 16 weeks after surgery. Fusion status was evaluated through biomechanical testing, manual palpation, plain radiography, computed tomography, and histology. Instrumented fusion segments demonstrated significantly higher stiffness than noninstrumented fusions at 8 weeks after surgery. Radiographic assessment and manual palpation showed that the use of spinal instrumentation improved the fusion rate at 8 weeks (47% vs. 38% in radiographs, 86% vs. 57% in manual palpation). Histologically, the instrumented fusions consisted of more woven bone than the noninstrumented fusions at 8 weeks after surgery. The 16-week-old fusion mass was diagnosed biomechanically, radiographically, and histologically as solid, regardless of pedicle screw augmentation. The results demonstrated that spinal instrumentation created a stable mechanical environment that enhanced the early bone healing of spinal fusion.

Strain-gauge instrumented interbody implants were placed into the L4-5 disc space of a motion segment in two baboons (62) to directly measure *in vivo* loads in the lumbar spine by telemetry transmitter. Radiographs were taken monthly to assess fusion. During extreme activity, highest measurable strain values were indicative of loads in excess of 2.8 times body weight. Measuring load on an intradiscal implant over the course of healing provides key information about the mechanics of this process and may assist with the implant design. More recently, Kanayama et al. (61) performed a study in 24 skeletally mature sheep in which they sought to characterize load sharing between the instrumentation and the fusion mass through the osseous union process. The authors destabilized the posterior elements (via bilateral facetectomy, excision of the spinous processes, and excision of the supraspinous and interspinous ligaments) between L3-4 and L5-6. The segments were stabilized with the Texas Scottish Rite Hospital instrumentation, which uses transpedicular screws and short segment rods. Bone graft from the spinous processes and iliac crest was applied to one of the stabilized levels, with the other stabilized level used as the control. Animals were euthanized at 0 (control data), 4, 8, 12, and 16 weeks; their spines were

removed and kept frozen until mechanical testing. The spine was divided into the two-instrumented functional spinal units, L3-4 and L5-6, and each was tested separately. Strain on the hardware was measured using uniaxial strain gauges and loads applied in axial compression (500 N), flexion-extension ( $\pm 6$  Nm), and lateral bending ( $\pm 6$  Nm). After the instrumented spines were tested, the device was removed and the fusion mass mechanically evaluated in the same manner. The data indicated that the posterolateral fusion masses were significantly stiffer ( $p < .01$ ) beginning at 8 weeks compared with the 0-week controls. Also the fusion masses had higher stiffness beginning at 12 weeks ( $p < .05$ ), compared with the instrumented controls. Strain recordings on the spinal rods indicated that deformation with the fusion mass during lateral bending, and axial compression was significantly decreased ( $p < .05$ ) at 8 weeks. Flexion and extension strain recordings showed that this parameter became statistically significant at 16 weeks compared with 8 weeks. This study conclusively showed that the instrumentation became unloaded as the fusion mass developed. [However, as shown in the next section, the *in vivo* clinical investigation of Rohlmann et al. contradicts these findings and thus suggest that additional studies in this area are needed (38,63–66).] Histologic and radiographic evaluations did not indicate complete maturation of the fusion mass even though the mechanical data showed that the bony union had achieved sufficient biomechanical integrity. Studies such as these provide biomechanists and clinicians with observations about how bone adapts to the disrupted *in vivo* loading environment with the implantation of the device to the destabilized area, thus providing a window to clinical performance.

## IN VIVO CLINICAL STUDIES

Loads in posterior implants were measured in 10 patients using telemeterized internal spinal fixation devices (63–66). The telemeterized internal spinal fixator allowed the measurement of three force components and three moments acting in the fixator. Implant loads were determined in up to 20 measuring sessions for different activities, including walking, standing, sitting, lying in the supine position, and lifting an extended leg while in the supine position. Implant loads often increased shortly after anterior interbody fusion was performed. Several patients retained the same high level even after fusion had taken place. This explains the reason why screw breakage sometimes occurs more than half a year after implantation. The time of fusion could not be pinpointed from the loading curves. The results showed that fixators may be highly loaded even after fusion has occurred. A flexion bending moment acted on the implant even when the body was in a relaxed lying position. This meant that shortly after the anterior procedure, the shape of the spine was not neutral and unloaded, but slightly deformed,

which loaded the fixators. Pedicle screw breakage more than half a year after insertion does not prove that anterior interbody fusion had not occurred. In another study the same authors used the telemeterized internal spinal fixation devices to study the influence of muscle forces on the implant loads in three patients before and after anterior interbody fusion. Contracting abdominal or back muscles in a lying position was found to significantly increase implant loads. Hanging by the hands from wall bars as well as balancing with the hands on parallel bars reduced the implant loads compared with standing; however, hanging by the feet with the head upside down did not reduce implant loads, compared with lying in a supine position. When lying on an operating table with only the foot end lowered so that the hips were bent, the patient had different load measurements in the conscious and anesthetized state before anterior interbody fusion. The anesthetized patient evidenced predominately extension moments in both fixators, whereas flexion moments were observed in the right fixator of the conscious patient. After anterior interbody fusion had occurred, the differences in implant loads resulting from anesthesia were small. The muscles greatly influence implant loads. They prevent an axial tensile load on the spine when part of the body weight is pulling (e.g., when the patient is hanging by his or her hands or feet). The implant loads may be strongly altered when the patient is under anesthesia.

Fusion is currently determined using radiographic techniques. Discrepancies exist between radiographic evidence and more direct measurements of fusion such as operative exploration and biomechanical or histologic measurements (67). To facilitate the return of patients to full unrestricted activity, it would be useful to develop a technique for accurate *in vivo* determination of fusion. The technique developed by Rohlmann et al., as described earlier, is not only impractical for use in a larger patient population but also cannot provide an indication of the time when the fusion has taken place in a patient. Szivek et al. undertook a study to identify strain-gauge placement sites by testing cadaver spines *in vitro*, and to evaluate an implantable gauge bonding technique and subminiature radio transmitter for accurate strain monitoring *in vivo* (67). Three cadaver spines were tested during anteroposterior bending and torsional loading in the control, instrumented, and instrumented plus polymethylmethacrylate states. The spines were instrumented with an ISOLA (AcroMed Corporation, Cleveland, OH) construct, and a simulated fusion was achieved through the application of PMMA. Strain gauges were attached in uniaxial, biaxial, and rosette configurations. The principal strains were calculated. Calcium phosphate (CaP) ceramic-coated gauges were implanted in patients and recovered after up to 15 months *in vivo*. A radio transmitter was developed and tested for use in patients. The largest and most consistent strain changes after simulated fusion were recorded during torsional loading on the laminae of a vertebra directly underneath a hook. CaP ceramic-

coated strain gauges showed excellent bone bonding to the lamina when fusion occurred. Radiotelemetry accurately tracked strain magnitudes and strain rates expected in patients. The consistency obtained in torsional loading indicated that this type of loading will provide the most useful data from patients *in vivo*.

### Finite Element Models

Investigations *in vitro* and animal studies *in vivo* contain numerous limitations, including that these are both time-consuming and monetarily expensive. The most important limitations of *in vitro* studies are that muscle contributions to loading are not usually incorporated and the highly variable quality of the cadaver specimens. As stated earlier, *in vivo* animal studies usually involve quadruped animals, and the implant sizes usually need to be scaled according to the animal size. In an attempt to complement those previously discussed protocols, several finite element (FE) models of the ligamentous spine have been developed.

Goel et al. (68) generated osteoligamentous FE models of intact lumbar one segment (L3-L4) and two segments (L3-L5). Using the L3-L4 model, they simulated fusion with numerous techniques in an attempt to describe the magnitude and position of internal stresses in both the biologic tissue (bone and ligament) and applied hardware. Specifically, the authors modeled bilateral fusion using unilateral and bilateral plating. Bilateral plating models showed that cancellous bone stresses were significantly reduced with the instrumentation simulated in the immediate postoperative period. Completely consolidated fusion mass load transmission led to unloading of the cancellous bone region, even after simulated removal of the device. Thus, this model predicted that removal of the device would not alleviate stress shielding-induced osteopenia of the bone and that this phenomenon may truly be a complication of the fusion itself. As would be expected, unilateral plating models revealed higher trabecular bone stresses than were seen in the bilateral plating cases. The degree of stability afforded to the affected segment, however, was less. Thus, a system that allows the bone to bear more load as fusion proceeds may be warranted. Several solutions have been proposed to address this question.

For example, a fixation system was developed that incorporated polymer washers in the load train (Steffee variable screw placement, VSP). The system afforded immediate postoperative stability and reduced stiffness with time as the washers undergo stress relaxation (a viscoelastic effect) (69). FE modeling of this system immediately after implantation showed that internal bony stresses were increased by about 20% over the same system without the polymeric material. In addition, mechanical property manipulation of the washers simulating their *in vivo* stress relaxation revealed these stresses were

continuously increasing, promoting the likelihood that decreased resorption would occur. The other solution is the use of dynamized fixation devices, which will be discussed later in this chapter.

The ability of a hinged pedicle screw-rod fixation (dynamized) device to transmit more loads across the stabilized segment compared with its rigid equivalent system was predicted using the FE models (70). In general, the hinged screw device allowed for slightly larger axial displacements of L3, while it maintained flexion rotational stability similar to the rigid screw device (Table 6-3). Slightly larger axial displacements may be sufficient enough to increase the load through the graft since the stiffness of the disc was increased by replacing it (shown as the “nucleus” in the tables) with a cancellous, cortical, or titanium interbody device to simulate the fusion mass in the model (Table 6-4).

The work of Goel et al. described above neglects the effect of muscle forces on the construct mechanics. Rohlmann et al. developed a set of FE models of the lumbar segment to address such issues (66). The diameters of the longitudinal rod of the fixator were also varied to be 3, 5, 7, and 10 mm in the model, and the forces of the trunk muscles were simulated. The diameter of the longitudinal rod strongly affected the fixator loads but hardly influenced the stresses in the vertebral end plates. The stresses in the bridged discs were strongly reduced. However, the internal fixator had only a minor influence on the stresses in the annulus fibrosus and the pressure in the nucleus pulposus of the adjacent discs. These results support the cadaver-based motion data of Gwon et al. described in an earlier section (37).

FE modeling coupled with adaptive bone remodeling algorithms has been used to investigate temporal changes associated with interbody fusion devices. Grosland et al. (50) have predicted the change in bone density distribution after implantation of the BAK device (Fig. 6-3). The major findings include hypertrophy of bone directly in the load train (directly overlying and underlying the implant) and lateral atrophy secondary to the relatively high stiffness of the implant. The model also predicted that bone grows into and around the larger holes in the implant, resulting in sound fixation of the device. Further insight into the biomechanics of the cages using the FE models was provided in an earlier section of this chapter.

**TABLE 6-3.** Axial displacement and angular rotation of L3 with respect to L4 for the 800 N axial compression

Graft	Axial displacement (mm)		Rotation (degrees)	
	Rigid	Hinged	Rigid	Hinged
Cancellous	-0.258	-0.274	0.407	0.335
Cortical	-0.134	-0.137	0.177	0.127
Titanium	-0.132	-0.135	0.174	0.126

**TABLE 6-4.** Loads transferred through the “nucleus” and the device for the 800 N axial compression

Graft	Rigid		Hinged	
	“Nucleus”	Device	“Nucleus”	Device
Cancellous	712.4	87.6	767.9	32.1
Cortical	741.2	58.8	773.5	26.5
Titanium	742.5	57.5	774.3	25.7

Obviously the value of FE modeling is that mapping of the osseous, ligamentous, and instrumentation stresses and strains can be obtained in a relatively inexpensive and time-efficient manner. Predictions of temporal changes of bone in response to the implantation of a device have yielded important data. Also, design perturbations can be quickly assessed as to their relative advantages (and disadvantages).

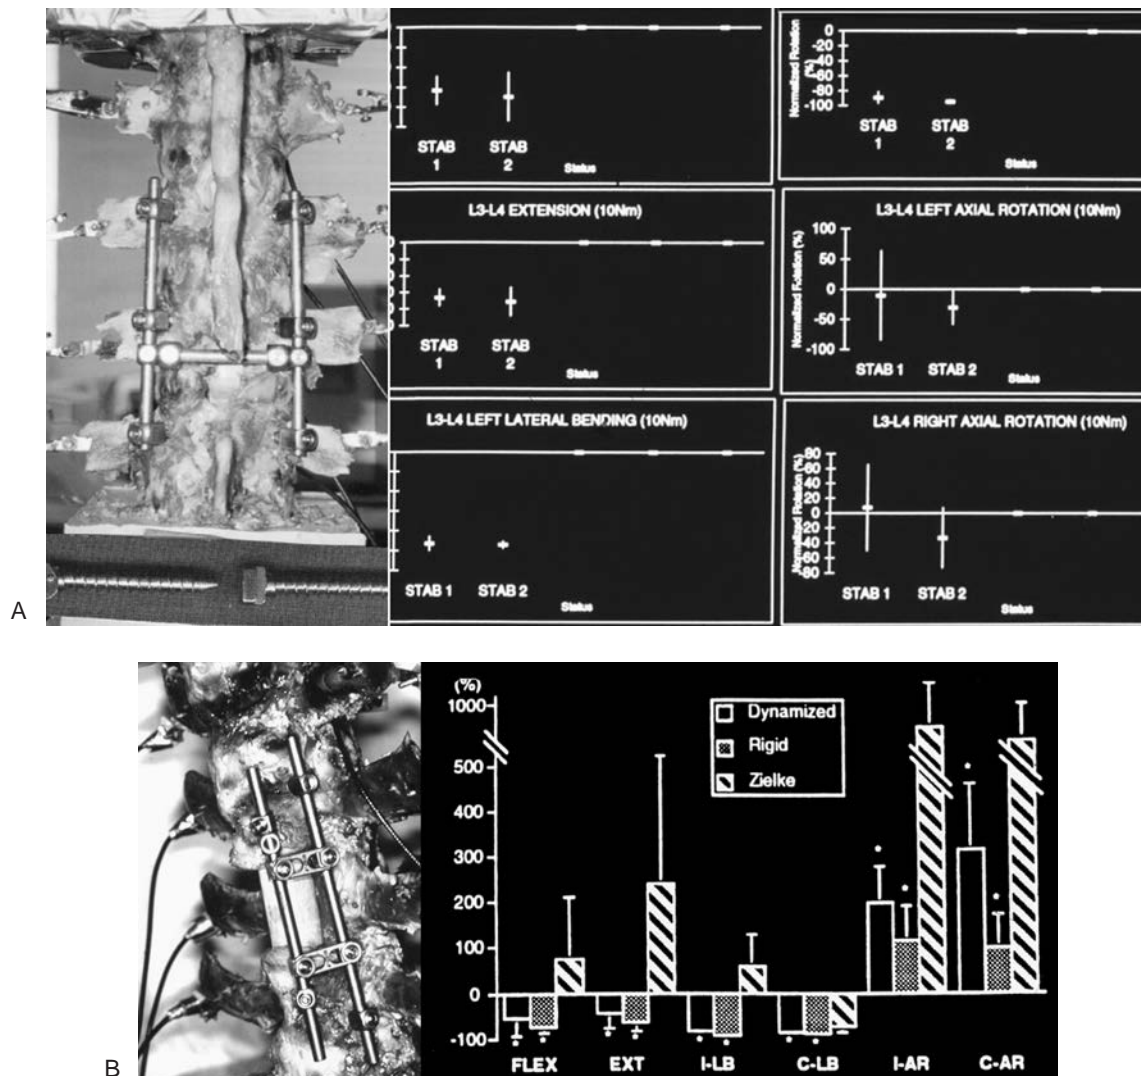

### MORE RECENT FUSION INITIATIVES

The preceding review clearly shows that a large number of fusion enhancement instrumentation is available to surgeons. However, none of the instrumentation is totally satisfactory in its performance and there is room to improve the rate of fusion success, if fusion is the goal. Naturally, alternative fusion approaches (mechanical, biological) are currently being pursued.

The rigidity of a spinal fixation device and its ability to share load with the fusion mass is considered essential for the fusion to occur. If the load transferred through the fusion mass, however, is increased without sacrificing the rigidity of the construct, a more favorable environment for fusion may be created. To achieve this objective, posterior as well as anterior “dynamized” systems have been designed (70–72). One such posterior system consists of rods and pedicle screws and has a hinged connection between the screw head and shaft compared with the rigid screws (73,74) (Fig. 6-4A). Another example of the dynamized antero-lateral compression device (ALC [DePuy Spine, Inc., Raynham, MA]) is shown in Figure 6-4B. Load-displacement tests were performed to assess the efficacy of these devices in stabilizing a severely destabilized spinal segment. The hinged and rigid posterior systems provided significant stability across the L2-L4 segment in flexion, extension, and lateral bending as compared with the intact case ( $p < 0.05$ ). The stabilities imparted by the hinged-type and its alternative rigid devices were of similar magnitudes (Fig. 6-4A) (71). The ALC dynamized and rigid anterior systems also provided significant stability across the L3-L5 segment in flexion, extension, and lateral bending ( $p < .05$ ). The stability imparted by the Dynamized ALC and its alternate rigid system did not differ significantly (Fig. 6-4B) (72).

Anterior bone graft in combination with posterior instrumentation has been shown to provide superior sup-

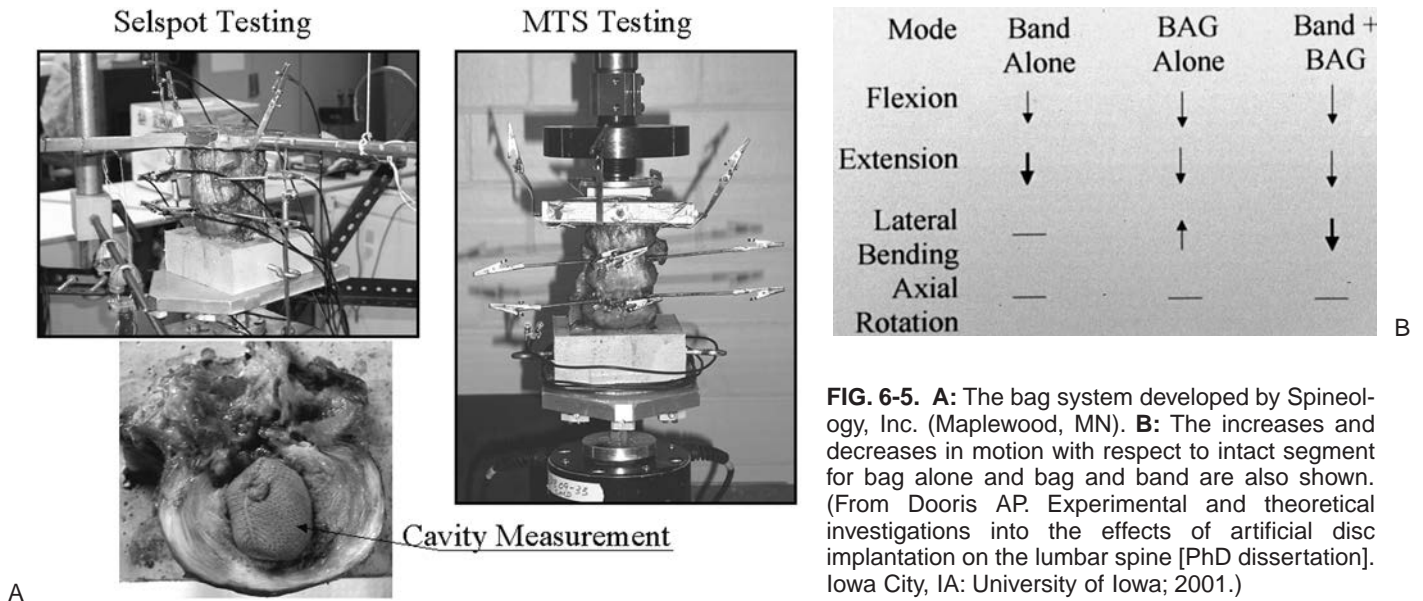

**FIG. 6-4.** The two different types of dynamized systems used in a cadaver model to assess their stability characteristics. The data were compared with the corresponding "rigid" systems. **A:** Posterior system. **B:** Anterior system. (From Scifert J, Sairyo K, Goel VK, et al. Stability analysis of an enhanced load sharing posterior fixation device and its equivalent conventional device in a calf spine model. *Spine* 1999;24:2206–2213 and Hitchon PW, Goel VK, Rogge T, et al. Biomechanical studies of a dynamized anterior thoracolumbar implant. *Spine* 2000;25(3):306–309.)

port because the graft is in line with axial loads and posterior elements are left intact. However, employing posterior instrumentation with anterior grafting requires execution of two surgical procedures. Furthermore, use of a posterior approach to place an interbody graft requires considerable compromise of the posterior elements, although it reduces the surgery time. It would be advantageous to minimize surgical labor and structural damage caused by graft insertion into the disc space through a posterior approach. This issue has been addressed by preparing an interbody bone graft using morselized bone (73,74). This device consists of a gauze bag of Dacron inserted into the disc space, filled with morselized bone,

and tied shut (Fig. 6-5). Testing *in vitro* measured the rotations of each vertebral level of mechanically loaded cadaver lumbar spines, both in intact and several experimental conditions. With the tension band alone, motion was restored to the intact case, except in extension where it was reduced (Fig. 6-5). With the graft implant, motion was restored to intact in all of the loading modes, except in flexion where it was reduced. With the tension band and graft, motion was again restored to intact except in flexion and extension where it was reduced. The *in vitro* results suggest that a tension band increases stability in extension, while the bag device alone seems to provide increased stability in flexion. The implanted bag filled

**FIG. 6-5. A:** The bag system developed by Spineology, Inc. (Maplewood, MN). **B:** The increases and decreases in motion with respect to intact segment for bag alone and bag and band are also shown. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

with morselized bone in combination with a posterior tension band, restores intact stiffness. Postcyclic results in axial compression suggest that the morselized bone in the bone-only specimens either consolidates or extrudes from the cavity despite confinement. Motion restoration or reduction as tested here is relevant both to graft incorporation and segment biomechanics. The posterior interbody grafting method using morselized bone is amenable to orthoscopy. It produces an interbody graft without an anterior surgical approach. In addition, this technique greatly reduces surgical exposure with minimal blood loss and no facet compromise. This technique would be a viable alternative to current 360° techniques pending animal tests and clinical trials.

Bone grafting is used to augment bone healing and provide stability after spinal surgery. Autologous bone graft is limited in quantity and unfortunately associated with increased surgical time and donor-site morbidity. Recent research has provided insight into methods that may modulate the bone healing process at the cellular level in addition to reversing the effects of symptomatic disc degeneration which is a potentially disabling condition, managed frequently with various fusion procedures. Alternatives to autologous bone graft include allograft bone, demineralized bone matrix, recombinant growth factors, and synthetic implants. Each of these alternatives could possibly be combined with autologous bone marrow or various growth factors. Although none of the presently available substitutes provides all three of the fundamental properties of autograft bone (osteogenicity, osteoconductivity, and osteoinductivity), there are a number of situations in which they have proven clinically useful. A literature review indicates that alternatives to autogenous bone grafting find their greatest appeal when autograft bone is limited in supply or when acceptable

rates of fusion may be achieved with these substitutes (75). For example, bone morphogenetic proteins have been shown to induce bone formation and repair (75).

Relatively little research has been undertaken to investigate the efficacy of osteoconductive protein 1 (OP-1) in the aforementioned stated role (75,76). Grauer et al. performed single-level intertransverse process lumbar fusions at L5-L6 in 31 New Zealand White rabbits (76). These were divided into three study groups: autograft, carrier alone, and carrier with OP-1. The animals were euthanized 5 weeks after surgery. Five (63%) of the eight in the autograft group had fusion detected by manual palpation, none (0%) of the eight in the carrier-alone group had fusion, and all eight (100%) in the OP-1 group had fusion. Biomechanical testing results correlated well with those of manual palpation. Histologically, autograft specimens were predominantly fibrocartilage, OP-1 specimens were predominantly maturing bone, and carrier-alone specimens did not show significant bone formation. OP-1 was found to reliably induce solid intertransverse process fusion in a rabbit model at 5 weeks.

Smoking interferes with the success of posterolateral lumbar fusion and a group of authors from the aforementioned investigation extended their study to review the effect of using OP-1 to enhance the fusion process in patients who smoke (77). OP-1 was able to overcome the inhibitory effects of nicotine in a rabbit posterolateral spine fusion model, and to induce bony fusion reliably at 5 weeks.

Magin et al. undertook a study to determine whether the use of recombinant human (rh) OP-1 or HA would improve on the intercorporeal fusion achieved by interbody autologous bone grafting in a sheep model (78). Vertebral fusion quality was examined by plain radiograph at 4-week intervals, by scintigraphy at 3 and 6

months, and by computed tomography scan, magnetic resonance imaging, biomechanical testing, and histologic evaluation. All examination methods demonstrated superior fusion after administration of rhOP-1, with radiologic fusion apparent at 4 months. Autologous bone grafts eventually produced bony healing in most cases, albeit of a lower quality than with rhOP-1. HA use led only to the formation of a tight pseudoarthrosis. The results indicated that rhOP-1 use was an appropriate method for improving interbody fusion in the sheep spine. In addition to offering the potential for improved bone healing, rhOP-1 use may permit less invasive surgery such as transpedicular fusion and the use of cages. In another similar study, Sandhu et al. investigated the efficacy of recombinant human bone morphogenetic protein 2 (rhBMP-2)-collagen composite in comparison with autograft to enhance spinal interbody fusion. Comparisons were drawn from temporal radiographic and end-point biomechanical and histologic data (79). Twelve sheep underwent single-level anterior lumbar interbody fusion performed with a cylindrical fenestrated titanium interbody fusion device (INTER FIX, Medtronic Sofamor Danek, Inc., Memphis, TN). The device was filled either with rhBMP-2-collagen ( $n < 6$ ) or autogenous iliac crest bone graft ( $n < 6$ ). Radiographs revealed a bony bridge anterior to the cage in five of six rhBMP-2-treated animals, whereas it was present only in one of five in the autogenous bone graft group. Segments treated with rhBMP-2 were 20% stiffer in flexion than autograft-treated segments at 6 months. All six in the rhBMP-2 group and two of six in the autograft group showed complete fusion. There was a significantly higher rate of bony continuity observed at the fenestrations of the rhBMP-2 group. Three times more cage fenestrations in the rhBMP-2 group demonstrated "all-bone" when compared with the autograft group ( $p < .001$ ). Further, the scar tissue in and around the autograft-treated cages was 16-fold more ( $p < .01$ ) than that seen for rhBMP-2-treated cages. The study demonstrated that rhBMP-2 can lead to earlier radiologic fusion and a more consistent increased stiffness of the segments when compared with autograft in sheep anterior lumbar interbody fusion. Furthermore, a three times higher histologic fusion rate was attainable with significantly reduced fibrous tissue around the implant when rhBMP-2 is used.

## NONFUSION TREATMENT ALTERNATIVES

Various methods have been employed in the characterization of device effectiveness for which spinal fusion is indicated. Because of the nonphysiologic nature of fusing the spinal segments that are supposed to provide motion/flexibility, adjacent-level degeneration, and other complications associated with the fusion process, alternatives to fusion have been proposed.

## Nucleus Replacements

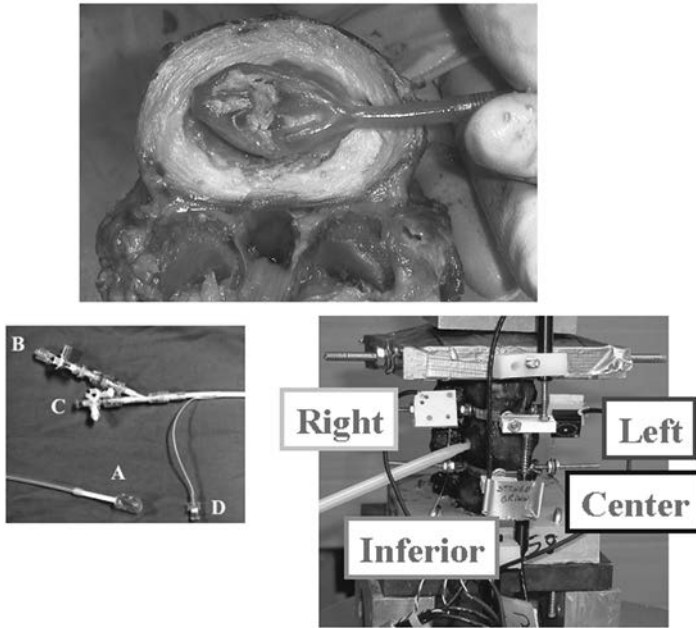

### *Ray Nucleus*

In 1988 Ray presented a prosthetic nuclear replacement consisting of flexible woven filaments (Dacron) surrounding an internal semipermeable polyethylene membranous sac filled with hyaluronic acid and a thixotropic agent (i.e., a hydrogel) (73,80). As a nucleus replacement, the implant can be inserted similar to a thoracolumbar interbody fusion device, either posteriorly or transversely. Two are inserted per disc level in a partly collapsed and dehydrated state, but would swell due to the strongly hygroscopic properties of the hyaluronic acid constituent. The designer expects the implant to swell enough to distract the segment while retain enough flexibility to allow a normal range of motion. An option is to include therapeutic agents in the gel that would be released by water flow in and out of the prosthesis according to external pressures.

Recent reports on biomechanical tests of the device show that it can produce some degree of stabilization and distraction (73,80). Loads of 7.5 Nm and 200 N axial were applied to six L4-L5 specimens. Nucleotomized spines increased rotations by 12% to 18% depending on load orientation, but implanted spines (implant placed transversely) showed a change of -12% to +2% from the intact with substantial reductions in neutral zone. Up to 2 mm of disc height was recovered by insertion. The implant, however, was implanted and tested in its nonhydrated form. The biomechanics of the hydrated prosthesis may vary considerably from its desiccated form.

### *In situ Curable Prosthetic Intervertebral Nucleus Device*

The prosthetic intervertebral nucleus (PIN) device (Disc Dynamics, Inc., Minnetonka, MN) consists of a compliant balloon connected to a catheter (Fig. 6-6) (73,74). This is inserted and liquid polymer injected into the balloon under controlled pressure inflating the balloon, filling the cavity, and distracting the intervertebral disc. Within 5 minutes the polymer is cured. Five fresh-frozen osteoligamentous three-segment human lumbar spines, screened for abnormal radiograph and low bone density, were used for the biomechanical study. The spines were tested under four conditions: intact, denucleated, implanted, and fatigued. Fatiguing was produced by cyclic loading from 250 to 750 N at 2 Hz for at least 100,000 cycles. Nucleotomy was performed through a 5.5 mm trephine hole in the right middle lateral side of the annulus. The device was placed in the nuclear cavity as described earlier. Following biomechanical tests, these specimens were radiographed and dissected to determine any structural damage inflicted during testing. Middle segment rotations generally increased with discectomy

**FIG. 6-6.** *In situ* curable prosthetic intervertebral nucleus (PIN) device being developed by Disc Dynamics, Inc., Minnetonka, MN. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

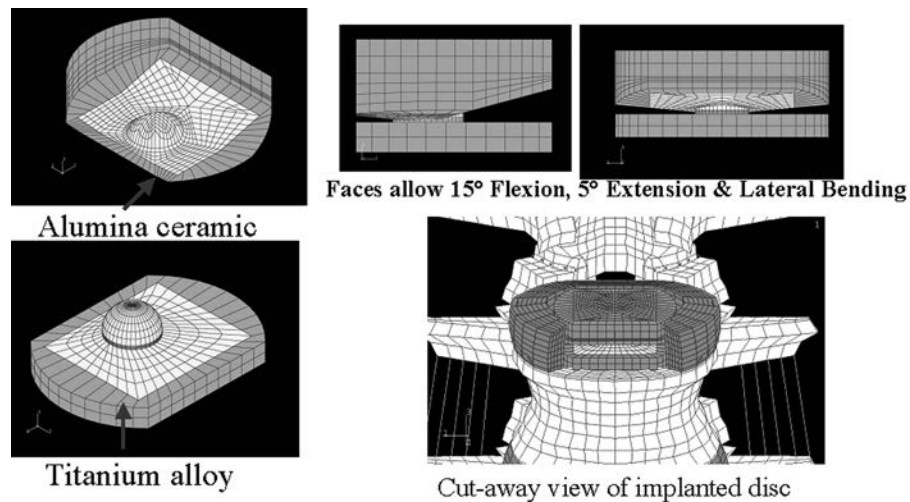

but were restored to the normal intact range with implantation. After fatiguing, rotations across the implanted segment increased. However, these were not more than, and often less than the intact adjacent segments. During polymer injection under compressive load, the segment distracted as much as +1.8 mm (average) at the disc center as determined by the surrounding gauges. Over 1.6 mm was maintained during polymer cure with compression. The immediate goals of a disc replacement system are to restore disc height and provide segment mobility without causing instability. This study showed that the PIN device could reverse the destabilizing effects of a nucleotomy and restore normal segment stiffness. Significant increases in disc height can also be achieved. Implanting the majority of disc replacement systems requires significant annulus removal. This device requires minimal surgical compromise and has the potential to be performed arthroscopically.

### Artificial Disc

One of the most recent developments for nonfusion treatment alternatives is replacement of the intervertebral disc. The goal of this treatment alternative is to restore the original mechanical function of the resected disc (81). One of the stipulations of artificial disc replacement is that the remaining osseous spinal and paraspinal soft tissue components are not compromised by pathologic changes. Bao et al. (82) have classified the designs of total disc replacements into four categories: (a) low-friction sliding surface; (b) spring and hinge systems; (c) contained fluid-filled chambers; and (d) discs of rubber and other elastomers. The former two designs seek to take advantage of the inherently high fatigue characteristics

that all-metal designs afford. The latter two designs attempt to incorporate some of the viscoelastic and compliant properties that are exhibited by the normal, healthy intervertebral disc. The disc must be able to maintain its mechanical integrity to approximately 85 million cycles; consist of biocompatible materials; exist entirely within the normal disc space and maintain physiologic disc height; restore normal kinematic motion wherein the axes of each motion, especially sagittal plane motion, are correctly replicated; duplicate the intact disc stiffness in all three planes of rotation and compression; provide immediate and long-term fixation to bone; and, finally, provide *fail-safe* mechanisms so that if an individual component of the design fails, catastrophic failure is not immediately imminent and does not lead to peri-implant soft tissue damage. This is certainly one of the greatest design challenges that bioengineers have encountered to date. In the following paragraphs, some of the methods are discussed that are being employed in an attempt to meet this rigorous challenge.

One of the available studies reviews iterative design of the artificial disc replacement based on measured biomechanical properties. Lee et al. (83,84) looked at incorporating three different polymers into their prosthetic intervertebral disc design and tried to represent the separate components (annulus fibrosis and nucleus) of the normal disc in varying proportion. They loaded their designs under 800 N axial compression and in compression-torsion out to 5°. The results indicated that discs fabricated from homogeneous materials exhibited isotropy that could not replicate the anisotropic behavior of the normal human disc. Thus, 12 layers of fiber reinforcement were incorporated in an attempt to mimic the actual annulus fibrosis. This method did result in more closely approxi-

**FIG. 6-7.** The intact finite element model of a ligamentous segment was modified to simulate the ball-and-socket type artificial disc implant. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

imating the mechanical properties of the normal disc. Through this method of redesign and testing, the authors claim that eventually “a disc prosthesis that has mechanical properties comparable to the natural disc could be manufactured” (83, 84).

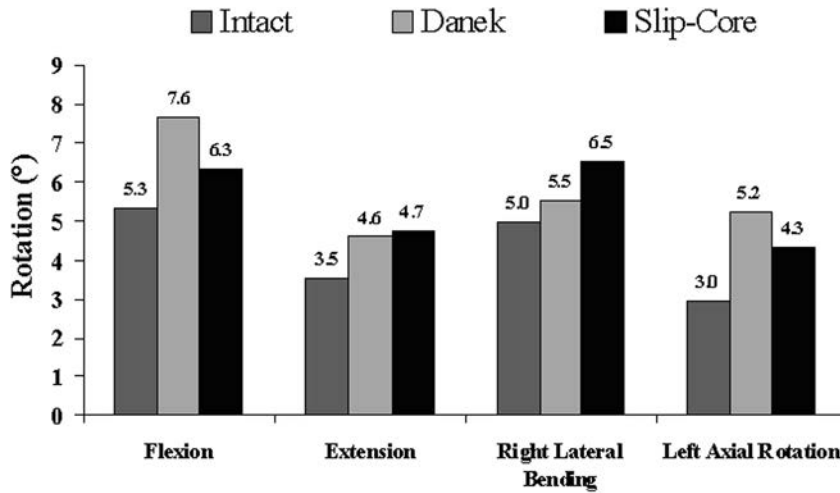

Another artificial intervertebral disc has been developed, and its intrinsic biomechanical properties, bioactivity, and effectiveness as a total disc replacement were evaluated *in vitro* and *in vivo* (85). The artificial intervertebral disc consists of a triaxial three-dimensional fabric (3-DF) woven with a UHMWPE fiber, and spray-coated with bioactive ceramics on the disc surface. The arrangement of weave properties was designed to produce mechanical behavior nearly equivalent to the natural intervertebral disc. Total intervertebral disc replacement at L2-L3 and L4-L5 was performed using a 3-DF disc with or without internal fixation in a sheep lumbar spine model. The segmental biomechanics and interface histology were evaluated after surgery at 4 and 6 months. The tensile-compressive and torsional properties of prototype

3-DF were nearly equivalent to those of human lumbar disc. The lumbar segments replaced with the 3-DF disc alone showed a significant decrease of flexion-extension range of motion to 28% of control values as well as partial bony fusion at 6 months. However, the use of temporary fixation provided a nearly physiologic mobility of the spinal segment after implant removal as well as excellent bone-disc fusion at 6 months. An artificial intervertebral disc using 3D-F demonstrated excellent *in vitro* and *in vivo* performance in both biomechanics and interface histology. There is a potential for future clinical application.

FE analyses have also been recruited in an effort to perturb design with an eye toward optimizing the mechanical behavior of artificial discs. Langrana et al. (83) generated an FE model that examined the effect of orientation of the synthetic disc fiber layers, number of fiber layers, and the order of the reinforcing layers. Dooris et al. modified a previously validated intact FE model to create models implanted with a ball-and-socket

**FIG. 6-8.** The intact finite element model of a ligamentous segment was modified to simulate the slip-core-type artificial disc implant. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

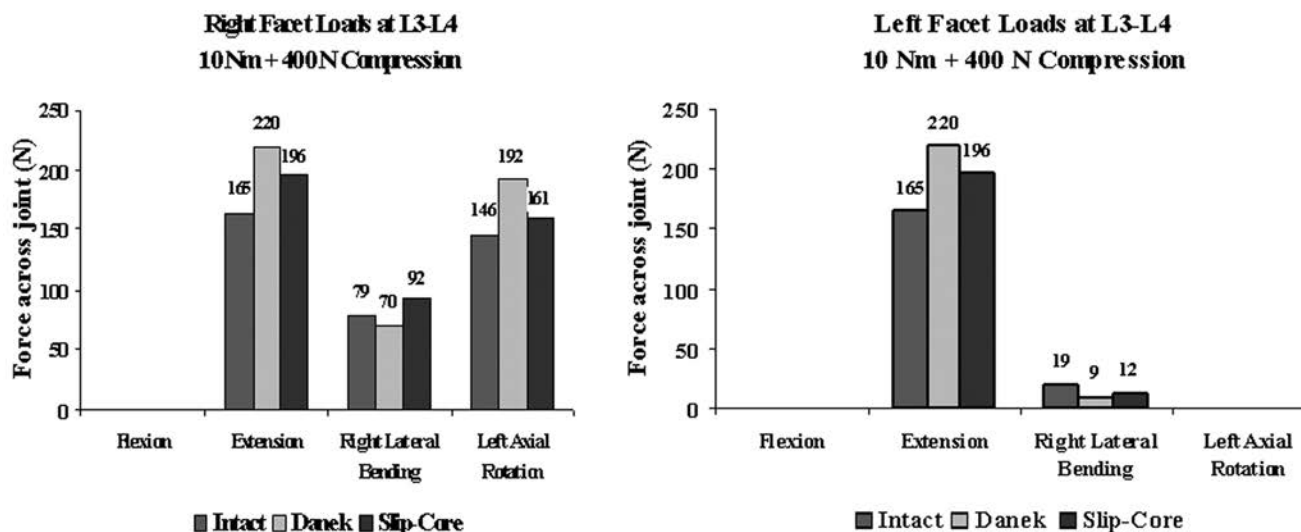

**FIG. 6-9.** Predicted rotations for the ball-and-socket and slip-core disc designs as compared to the intact case. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

and slip-core-type artificial disc models through an anterior approach (73,86) (Figs. 6-7, 6-8). To study surgical variables, small and large windows were cut into the annulus, and the implants were placed anteriorly and posteriorly within the disc space. The anterior longitudinal ligament was also restored. Models were subjected to either 800 N axial compression force alone or to a combination of 10 Nm flexion-extension moments and 400 N axial preload. Implanted model predictions were compared with those of the intact model. The predicted rotations for the two-disc implanted models were in agreement with the experimental data (73).

For the ball-and-socket design facet loads were more sensitive to the anteroposterior location of the artificial disc than to the amount of annulus removed. Under 800 N axial compression, implanted models with an anteriorly placed artificial disc exhibited facet loads 2.5 times

greater than loads observed with the intact model, whereas posteriorly implanted models predicted no facet loads in compression. Implanted models with a posteriorly placed disc exhibited greater flexibility than the intact and implanted models with anteriorly placed discs. Restoration of the anterior longitudinal ligament reduced pedicle stresses, facet loads, and extension rotation to nearly intact levels. The models suggest that, by altering placement of the artificial disc in the anteroposterior direction, a surgeon can modulate motion-segment flexural stiffness and posterior load sharing, even though the specific disc replacement design has no inherent rotational stiffness. The motion data, as expected, differed between the two disc designs (ball and socket, and slip core) and as compared to the intact disc as well (Fig. 6-9). Similar changes were observed for the loads on the facets (Fig. 6-10).

**FIG. 6-10.** Predicted facet loads for ball-and socket and slip-core disc designs as compared to the intact case. (From Dooris AP. Experimental and theoretical investigations into the effects of artificial disc implantation on the lumbar spine [PhD dissertation]. Iowa City, IA: University of Iowa; 2001.)

The experimentally validated FE models of the intact and disc-implanted L3-L5 segments revealed that both of these devices do not restore motion as well as loads across facets back to the intact case. (These designs restore the intact biomechanics in a limited sense.) These differences are not only due to the size of the implants but the inherent design differences. Ball-and-socket design has a more “fixed” center of rotation as compared to the slip-core design in which the center of rotation (COR) undergoes a wider variation. A further complicating factor is the location of the disc within the annular space itself, a parameter under the control of the surgeon. Thus, it will be difficult to restore biomechanics of the segment back to normal using such designs. Only clinical follow-up studies will provide the effects of such variations on the changes in spinal structures as a function of time (8).

### MORE RECENT AND FUTURE INITIATIVES

Although many of the well-accepted investigation techniques and devices have been discussed herein, other techniques for the stabilization/fusion of the spine and nonfusion approaches are currently being investigated. These concepts are likely to play a significant role in the future and are discussed in the following sections.

#### Vertebroplasty

A citation of the review article by Garfin et al. is the most appropriate way to introduce this topic for further discussion. Painful vertebral osteoporotic compression fractures lead to significant morbidity and mortality (87). This relates to pulmonary dysfunction, eating disorders (nutritional deficits), pain, loss of independence, and mental status change (related to pain and medications). Medications to treat osteoporosis (primarily antiresorptive) do not effectively treat the pain or the fracture, and require over 1 year to reduce the degree of osteoporosis. Kyphoplasty and vertebroplasty are new techniques that help decrease the pain and improve function in fractured vertebrae.

Vertebroplasty is the percutaneous injection of PMMA cement into the vertebral body. While PMMA has high mechanical strength, it heals fast and thus requires only a short handling time. Other potential problems of using PMMA injection may include damage to surrounding tissues by a high polymerization temperature or by the non-reacted toxic monomer, and the lack of long-term biocompatibility. Bone mineral cements, such as calcium carbonate and CaP cements, have longer working time and low thermal effect. They are also biodegradable while having a good mechanical strength. However, the viscosity of injectable mineral cements is high, and the infiltration of these cements into vertebral body has been questioned. Recently, the infiltration properties of a CaP cement have been significantly improved, which is ideal

for the transpedicular injection to the vertebral bodies for vertebroplasty or augmentation of osteoporotic vertebral body strength. Little is known, however, about the biomechanics of this treatment. Various authors have evaluated the biomechanical efficacy of this procedure by comparing it with respect to the intact, the axial strength of the vertebral body following fracture and injection of the cement, and the corresponding load-displacement behavior of the constructs.

Lim et al. evaluated the compression strength of human vertebral bodies injected with new CaP cement with improved infiltration properties before compression fracture and also for vertebroplasty in comparison with PMMA injection (88). The bone mineral densities of 30 vertebral bodies (T2-L1) were measured using DEXA. Ten control specimens were compressed at a loading rate of 15 mm per minute to 50% of their original height. The other specimens had 6 mL of PMMA ( $n < 10$ ) or the new CaP ( $n < 10$ ) cement injected through the bilateral pedicle approach before being loaded in compression. Additionally, after the control specimens had been compressed, they were injected with either CaP ( $n < 5$ ) or PMMA ( $n < 5$ ) cement using the same technique, to simulate vertebroplasty. Loading experiments were repeated with the displacement control of 50% vertebral height. Load to failure was compared among groups and analyzed using analysis of variance. Mean bone mineral densities of all five groups were similar and ranged from 0.56 to 0.89 g/cm<sup>2</sup>. The size of the vertebral body and the amount of cement injected were similar in all groups. Load to failure values for PMMA, the new CaP, and vertebroplasty PMMA were significantly greater than that of controls. Load to failure of the vertebroplasty CaP group was higher than the control group but not statistically significant. The mean stiffness of the vertebroplasty CaP group was significantly smaller than control, PMMA, and the new CaP groups. The mean height gains after injection of the new CaP and PMMA cements for vertebroplasty were minimal (3.56% and 2.01%, respectively). Results of this study demonstrated that the new CaP cement can be injected and infiltrates easily into the vertebral body. It was also found that injection of the new CaP cement can improve the strength of a fractured vertebral body to at least the level of its intact strength. Thus, the new CaP cement may be a good alternative to PMMA cement for vertebroplasty, although further *in vitro*, *in vivo* animal, and clinical studies should be done. Furthermore, the new CaP may be more effective in augmenting the strength of osteoporotic vertebral bodies, and for preventing compression fractures considering our biomechanical testing data and the known potential for biodegradability of the new CaP cement. Belkof et al. found that the injection of either Orthocomp (Orthovita, Malvern, PA) or Simplex P (Howmedica, Inc., Allendale, NJ) resulted in vertebral body strengths that were significantly greater than initial strength values (89). Vertebral

bodies augmented with Orthocomp recovered their initial stiffness; and, vertebral bodies augmented with Simplex P were significantly less stiff than they were in their initial condition. However, these biomechanical results have yet to be substantiated in clinical studies.

Previous biomechanical studies have shown that injections of 8 to 10 mL of cement during vertebroplasty restore or increase vertebral body strength and stiffness; however, the dose-response association between cement volume and restoration of strength and stiffness is unknown. Belkof et al. (89) investigated the association between the volume of cement injected during percutaneous vertebroplasty and the restoration of strength and stiffness in osteoporotic vertebral bodies. Two investigational cements were studied: Orthocomp and Simplex 20 (Simplex P with 20% by weight barium sulfate). Compression fractures were experimentally created in 144 vertebral bodies (T6-L5) obtained from 12 osteoporotic spines harvested from female cadavers. After initial strength and stiffness were determined, the vertebral bodies were stabilized using bipedicular injections of cement totaling 2, 4, 6, or 8 mL and recompressed, from which posttreatment strength and stiffness were measured. Strength and stiffness were considered restored when posttreatment values were not significantly different from initial values. Strength was restored for all regions when 2 mL of either cement was injected. To restore stiffness with Orthocomp, the thoracic and thoracolumbar regions required 4 mL, but the lumbar region required 6 mL. To restore stiffness with Simplex 20, the thoracic and lumbar regions required 4 mL, but the thoracolumbar region required 8 mL. These data provide guidance on the cement volumes needed to restore biomechanical integrity to compressed osteoporotic vertebral bodies.

Liebschner et al. undertook an FE-based biomechanical study to provide a theoretical framework for understanding and optimizing the biomechanics of vertebroplasty, especially the effects of volume and distribution of bone cement on stiffness recovery of the vertebral body, just like the preceding experimental study (90). An experimentally calibrated, anatomically accurate FE model of an older adult L1 vertebral body was developed. Damage was simulated in each element based on empirical measurements in response to a uniform compressive load. After virtual vertebroplasty (bone cement filling range of 1 to 7 cm<sup>3</sup>) on the damaged model, the resulting compressive stiffness of the vertebral body was computed for various spatial distributions of the filling material and different loading conditions. Vertebral stiffness recovery after vertebroplasty was strongly influenced by the volume fraction of the implanted cement. Only a small amount of bone cement (14% fill or 3.5 cm<sup>3</sup>) was necessary to restore stiffness of the damaged vertebral body to the pre-damaged value. Use of a 30% fill increased stiffness by more than 50% compared with the pre-damaged value. Whereas the unipedicular distributions exhibited a comparative stiffness to the

bipedicular or posterolateral cases, it showed a medial-lateral bending motion (“toggle”) toward the untreated side when a uniform compressive pressure load was applied. Only a small amount of bone cement (15% volume fraction) is needed to restore stiffness to pre-damage levels, and greater filling can result in substantial increase in stiffness well beyond the intact level. Such overfilling also renders the system more sensitive to the placement of the cement because asymmetric distributions with large fills can promote single-sided load transfer and thus toggle. These results suggest that large fill volumes may not be the most biomechanically optimal configuration, and an improvement might be achieved by use of lower cement volume with symmetric placement. These theoretical findings support the experimental observations described in the preceding paragraph, except these authors did not analyze the relationship between cement type and volume needed to restore strength.

Hitchon et al. compared the stabilizing effects of the HA product with PMMA in an experimental compression fracture of L-1 (91). No significant difference between the HA- and PMMA-cemented-fixated spines was demonstrated in flexion, extension, left lateral bending, or right and left axial rotation. The only difference between the two cements was encountered before and after fatiguing in right lateral bending ( $p < .05$ ). The results of this study suggest that the same angular rigidity can be achieved by using either HA or PMMA. This is of particular interest because HA is osteoconductive, undergoes remodeling, and is not exothermic.

According to Garfin et al. both vertebroplasty and kyphoplasty have had a very high acceptance and use rate (87,92). There is 95% improvement in pain and significant improvement in function following treatment by either of these percutaneous techniques. Kyphoplasty improves height of the fractured vertebra, and improves kyphosis by over 50%, if performed within 3 months from the onset of the fracture (onset of pain). There is some height improvement, though not as marked, along with 95% clinical improvement, if the procedure is performed after 3 months. Complications occur with both and relate to cement leakage in both, and cement emboli with vertebroplasty. Kyphoplasty and vertebroplasty are safe and effective, and have a useful role in the treatment of painful osteoporotic vertebral compression fractures that do not respond to conventional treatments. Kyphoplasty offers the additional advantage of realigning the spinal column and regaining height of the fractured vertebra, which may help decrease the pulmonary, gastrointestinal, and early morbidity consequences related to these fractures. Both procedures are technically demanding.

### Bioartificial Disc

The rapidly advancing field of tissue engineering opens new possibilities to solving spine problems. By

seeding and growing intervertebral disc cells, it could be possible to grow a new bioartificial disc to be implanted into the spine. Studies are in progress at a number of centers, including our own (93).

The FE model studies can be used to simulate even the smallest of systems. For example, Baer et al. have developed an FE model to study the cell micromechanical environment in the intervertebral disc (94). Hopefully, this approach can be used to investigate the effects of various spinal instrumentations at the cellular level.

## CONCLUSION

The prevalence of spinal fusion and stabilization procedures is continuously increasing. This chapter has presented many of the contemporary biomechanical issues germane to stabilization and fusion of the spine. Because of the wide variety of devices available, various testing protocols have been developed in an attempt to describe the mechanical aspects of these devices. Many *in vitro* studies are performed during the earlier stages of implant development to characterize and optimize the mechanical behavior of the device. In addition, the investigations reveal comparative advantages (and disadvantages) of the newer designs to existing hardware. Subsequent *in vivo* testing, specifically animal models, provides data on the performance of the device in a dynamic physiologic environment. All of the testing, *in vitro* and *in vivo*, helps to build confidence that the instrumentation is safe for clinical trial. The biomechanical testing and evaluation of spinal fusion and stability has produced an extensive knowledge base that has allowed for the design, development, and implementation of various devices. Future biomechanical work is required to produce newer devices and optimize existing ones, with an eye toward reducing the rates of nonfusion and pseudarthrosis. In addition, novel devices and treatments that seek to restore normal spinal function and loading patterns without fusion continue to necessitate advances in biomechanical methods. These are the primary challenges that need to be incorporated in future biomechanical investigations. Finally, one has to gain understanding of the effects of devices at the cellular level and one must undertake outcome assessment studies to see if the use of instrumentation is warranted for the enhancement of the fusion process.

## ACKNOWLEDGMENTS

This chapter is based on the work sponsored by various funding agencies over the last 20 years. Part of the literature review and writing of the actual manuscript was done while the senior author (Goel) was a Visiting Professor at the Department of Electronic and Computer Engineering, Tokyo Denki University, Ishizaka, Hatoyama-machi, Hiki-Gun, Saitama 350-0394, Japan.

## CHAPTER 7

# Fracture and Repair of Lumbar Vertebrae

Tony S. Keller, Victor Kosmopoulos, and Thomas Steffen

---

The lumbar spine, located between the sacrum and thoracic regions of the vertebral column (the lower back), typically consists of five vertebrae. These five vertebrae generally increase in size from the superior to the inferior lumbar spine and are larger than both the cervical and thoracic vertebrae. Similar to size, the weight-bearing ability of lumbar vertebrae is often greater, resulting in a higher incidence of pain following injury. From a mechanical point of view, the weight-bearing or structural capacity (force at failure) of the vertebrae depends on both material properties (bone mineral content, trabecular bone tissue density, and apparent density) and geometric properties (size, orientation, and connectivity of bone elements). A close association between bone mineral loss due to osteoporosis and the risk of fracture has been clearly established. Skeletal structures such as the vertebral bodies, which are comprised primarily of trabecular bone, are particularly at risk. The purpose of this chapter is to discuss the mechanics of vertebral compression fractures and trabecular bone damage. An understanding of microdamage and microfracture of vertebrae is used to facilitate discussions of cement repair strategies.

### STRUCTURAL AND MECHANICAL BEHAVIOR OF LUMBAR VERTEBRAE

Mechanical properties not only vary from vertebra to vertebra or level to level, but also can vary dramatically within a given vertebral body. Trabeculae tend to be denser, rodlike structures in the inferior and superior sections in contrast to the less dense, platelike trabeculae that are associated with the central region of the lumbar vertebral centrum (1). Studies that have examined the physical and mechanical properties of lumbar vertebral trabecular bone have also shown that trabecular bone underlying the normal intervertebral disc nucleus is significantly stronger, stiffer, and denser in comparison to trabecular bone underlying the disc annu-

lus (2–4). Such intravertebral variations in trabecular bone properties have been attributed, in part, to adaptation to the heterogeneous pressure distribution within the normal intervertebral disc (4). Namely, the pressurized disc nucleus exerts higher stresses on the underlying end plate and trabecular bone compared to pressure transmitted by the disc annulus. Keller et al. (2,4) also noted that disc degeneration reduces intravertebral variations in trabecular bone-apparent stiffness, strength, and density in regions adjacent to the end plate, which presumably reflects a more uniform or homogeneous distribution of pressure and stress within the degenerated disc.

The architectural design or structure of bone in human vertebrae and elsewhere in the body is very complex ranging from a very porous solid (trabecular bone) to a very dense solid (compact bone). The anterior column, or centrum, of human vertebrae is comprised of only a very thin cortical shell (less than 2 mm), which is virtually indistinguishable from the trabeculae that comprise the bulk of the vertebral centrum (Fig. 7-1). Silva et al. (5) performed a finite element analysis of an idealized lumbar vertebrae, and reported that the cortical shell's contribution was only 10% of the total vertebral strength, thus making the trabecular centrum the main load-bearing structure. Using anatomically accurate microstructural finite element simulations, the authors estimate that removal of the trabecular centrum, leaving only the vertebral shell, results in over an eightfold decrease in apparent stiffness compared to the intact vertebrae (having both the vertebral shell and centrum) (Fig. 7-2). Finite element analysis of vertebral mechanics is covered in more detail in later sections of this chapter.

Given the porous nature of bone, the relative amount of bone tissue is described histologically using apparent density ( $\rho_a$ ). Apparent density is defined as the mass of bone tissue present within a given volume. Clinically, estimates of bone mass are most commonly obtained using dual energy X-ray absorptiometry (DEXA). This

**FIG. 7-1.** Volume rendering of microcomputed tomography scan image of T10 osteopenic vertebral body (1.8-mm thick section). (From Keller TS, Kosmopoulos V, Liebschner MAK. Modeling of bone loss and fracture in osteoporosis. In: Gunzburg R, Szpalski M, eds. Vertebral osteoporotic compression fractures. Philadelphia: Lippincott Williams & Wilkins, 2002: 35–50.)

low-radiation method provides measures of the bone mineral content (BMC, g/cm) and bone mineral density (BMD, g/cm<sup>2</sup>) distributions within the body (6).

Although BMC and BMD are not true volumetric measures of tissue mass or apparent density, both have been shown to be useful predictors of bone fragility (2,7–9). Hansson (8) performed *in vitro* mechanical compression tests on 109 intact L1-L4 vertebral centrum specimens from subjects spanning five decades in age (31 to 79 years). In this test series, the BMC ranged from 1.44 g/cm to 6.39 g/cm (mean 3.33 g/cm), and the compressive force at failure  $F_{ult}$  ranged from 1,520 Newtons (N) to 10,987 N (mean 3,850 N). From this data the following linear correlations are obtained (10):

$$F_{ult} = 1,535 \text{ BMC} - 1,258 \quad (R^2 = 0.74)$$

$$F_{ult} = -75 \text{ AGE} + 8,199 \quad (R^2 = 0.30)$$

Examination of these relationships indicates that the compressive strength of the lumbar vertebral centrum is strongly and positively correlated to BMC, but is weakly and negatively correlated to subject age. After age 30, lumbar vertebral compressive strength is predicted to decrease 750 N per decade, declining to 1,500 N at 89 years of age. When the lumbar vertebral strength decreases to 1,500 N or lower, failure of the vertebral structures can occur under postural loads imposed by the weight of the body above the vertebrae (10,11).

From a mechanical point of view, ultimate force is a structural property that is dependent upon both the size

**FIG. 7-2.** Finite element microstructural models used to simulate experimental compression of (A) just the cortical shell (without the trabecular centrum) and (B) of the complete vertebral body (cortical shell and trabecular centrum).

(geometry) and composition (material) of the tissue. Thus, one cannot directly compare the ultimate force of vertebrae from different regions in the spine because the size of the cervical, thoracic, and lumbar vertebrae varies appreciably from each other and from one level to the next. For this reason, material property measurements, such as stress or force/area are often preferred, since they account for geometry variations of different size structures. An estimate of the apparent stress at failure ( $\sigma_{ult}$ , MPa or  $10^6$  N/m<sup>2</sup>) can be obtained for Hansson's data by dividing the ultimate force ( $F_{ult}$ , N) by the cross-sectional area (mm<sup>2</sup>) reported for the vertebral end plate. The apparent stress at failure of the lumbar vertebrae is found to range from 0.95 to 4.95 MPa (mean 2.29 MPa). Here apparent stress refers to the fact that we still have not accounted for the porosity of the vertebral centrum. Namely, two similar size vertebrae can have very different structural properties if their porosity or apparent density differs appreciably.

Keller (12) published empirical relationships from *in vitro* mechanical tests that can be used to calculate the compressive apparent strength ( $\rho_a$ , MPa) of vertebral bone:

$$\sigma_a = 97.8 \rho_a^{2.30}$$

where  $\rho_a$  is the apparent density ( $0.05 < \rho_a < 0.30$  g/cm<sup>3</sup>). Note that the approximately square exponent means that a relative reduction in apparent density of one half will produce a corresponding relative reduction in compressive apparent strength of one fourth. In older adults (more than 70 years), the apparent density of human vertebral trabecular bone can be as low as 0.05 g/cm<sup>3</sup>, which corresponds to an ultimate compressive strength of only 0.05 MPa. Stresses much greater than 0.05 MPa are produced in vertebrae when subjected to compressive forces associated with weight bearing in upright postures (10).

## OSTEOPOROSIS

Osteoporosis is a skeletal disorder distinguished by weakened skeletal architecture caused by suboptimal bone development or a reduction in bone mass. It is a disease that weakens the structural properties of bone in both men and women, and results in fracture when loads applied to bone exceed the bone's ability to support those loads. Thus, osteoporosis is a significant risk factor for fracture and its incidence increases with age. In the United States, 10 million individuals have been diagnosed with osteoporosis and another 18 million have low bone mass, which places them at increased risk for osteoporosis and fracture. Treatment of osteoporotic fracture is estimated to be as high as \$15 billion annually (13).

Osteoporosis is accompanied by reduced bone strength, and has been clinically characterized using non-invasive radiographic measures such as BMD, BMC, and apparent density ( $\rho_a$ ). The standard diagnosis for osteoporosis is 2.5 standard deviations or more below the mean BMD (or BMC) for an average 30-year-old adult of the same sex. Osteoporosis affects bone quality, which refers to bone architecture, rate of adaptation/remodeling, level of mineralization, and damage accumulation (13).

In osteoporosis perforations exist within the structure causing increased fragility (Fig. 7-3). One reason for this fragility increase is due to the replacement of the plate-like closed cell trabecular structures by open cell rodlike structures, resulting in an increasingly porous appearance. Mechanically, trabecular-buckling strength is dependent on the diameter, length, distance between cross-links, and the material properties of individual trabeculae. In osteoporosis the vertebral trabeculae become thinner and cross-linking continuity with horizontal trabeculae is reduced without compensation by the vertebral shell. Throughout the progression of this disease, deterioration of the trabecular structure induces the

**FIG. 7-3.** Volumetric rendering of a 2.56 mm  $\times$  2.56 mm  $\times$  2.56 mm region of trabecular bone from the human lumbar vertebral centrum. The panels (from left to right) illustrate progressive and uniform bone loss resulting in a decrease of the bone volume fraction from 15.3% to 11.1% to 7.66%. Note that there is significant loss of trabecular connectivity following the simulated bone loss. The 20  $\mu$ m voxel (volume pixel) images were reconstructed from a histologic specimen using a quantitative serial imaging and marching cubes algorithm. (From Saxena R, Keller TS. Computer modeling for evaluating trabecular bone mechanics. In: An YH, Draughn RA, eds. Mechanical testing of bone and the bone-implant interface. Boca Raton, FL: CRC Press, 1999:407–436.)

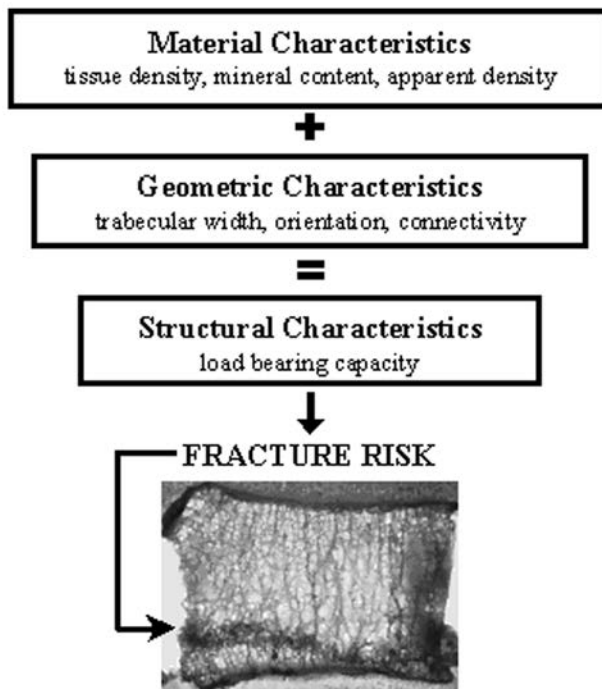

reduction in bone mass (and thus density) ensuring an increased rate of fracture.

### VERTEBRAL FRACTURE

Approximately 700,000 osteoporotic vertebral fractures occur per year in the United States with 230,000 resulting in chronic disabling pain (13,14). Vertebral fractures alter force transmission to the vertebral body segments, lead to vertebral body collapse, increase fracture risk (fivefold) to neighboring vertebrae (15), and result in progressive spinal deformity (e.g., kyphosis) (16).

Vertebral fracture may occur as a result of a traumatic force exceeding the load-bearing capacity of the vertebral body, or by the accumulation of trabecular tissue-level damage (microdamage) from repeated (fatigue), uniform and nonuniform, everyday subfailure-type postural loading (no trauma) (10,11,17). A traumatic force can result from high-impact falls to normal lifting and bending (13).

Apparent density and its clinical counterpart BMD provide good estimates of bone mechanical properties but are not definitive in predicting vertebral strength (12). The load-bearing capacity of the lumbar vertebrae (structural characteristics) coupled with the applied loads (magnitude, duration, rate) determine fracture risk (Fig. 7-4). Vertebral

**FIG. 7-4.** Vertebral material, geometry, and structure are biomechanical determinants of fracture risk. Loading characteristics (magnitude, profile, duration, and rate) also influence fracture risk.

fracture is about four times more common in women than in men, and the risk for a vertebral fracture has been found to increase almost exponentially with age. The frequency of osteoporotic vertebral fracture also increases during menopause in women and continues to steadily increase in frequency throughout the remainder of life. Furthermore, depending on the age groups studied (40 years to more than 80 years), the prevalence of osteoporotic vertebral fractures varies from around 5% to somewhat over 50% (18–21).

### Compression Fracture Classification

Vertebral compression fractures are primarily caused by excessive axial loads that may result in vertebral body height reductions, and in the more extreme cases, deformities. The axial failure loads for lumbar vertebrae have been estimated and classified by age. In general, a force of approximately 4,200 N produces fracture in individuals over the age of 60, whereas under the age of 40, an increased load of approximately 7,600 N causes fracture (22,23). As we noted earlier, however, the compressive strength of lumbar vertebrae is closely dependent on the size and quality of the segment, and, in the case of osteoporosis, can be substantially lower than 4,200 N.

Different postural loading conditions (e.g., uniform and nonuniform) endured by the vertebral body result in different vertebral fracture geometries at failure. In the most general case, postural loads are greatest on the anterior aspect of the vertebral body resulting in what is known as anterior wedge-type compression fractures. Anterior compression fractures have been classified into four subtypes (22): (a) both end plates are damaged; (b) only the superior end plate is damaged (most common); (c) only the inferior end plate is damaged; and (d) both end plates are intact but anterior cortical shell is damaged.

In the least severe case, hairline fractures to the cortical shell or the vertebral end plate may occur. These types of hairline fractures are difficult to diagnose and may plague the patient with pain. End-plate damage can occur in the central regions, periphery regions, or as transverse cracks across the end plate (22). End-plate damage has been proposed to be the initial stage of more severe vertebral compression fractures (1,24,25). Burst fractures are the most severe and can range from an end-plate fracture resulting in disc intrusion into the vertebral body (22) to complete shattering of the vertebral body. Burst fractures occur at axial loads ranging from 6,000 to 10,000 N (26).

### Clinical Definition of Vertebral Fracture

Radiographic detection of vertebral compression fractures is often the confirmation of the presence of osteoporosis or bone fragility. Without any known pathomorphologic aberrations distinguishing osteoporotic

bone from nonosteoporotic bone tissue, the fracture itself defines pathology. Since the occurrence of a fracture is not only the result of the mechanical properties of the bone, but is also a function of the fracturing trauma, both factors must be considered when defining osteoporosis. In the presence of a patient with a recent fracture, knowing nothing or very little about the patient's bone quality or the forces involved in the trauma, the most practical way for clarifying whether a fracture is osteoporotic or not is Harold Frost's criterion of the "everyday trauma." Frost stated that a fracture occurring because of an everyday trauma indicates that the patient has osteoporosis or bone fragility. Even if current technology allows us to determine, for example, the amount of bone mineral in different parts of the human skeleton, we still lack practical techniques for measuring the fracture-generating forces. Therefore the "everyday trauma" definition is still a practical measure for estimating bone fragility (27). Hence, development of models that can simulate both the loading and structural (trabecular) damage behavior of vertebral bodies are important for understanding clinical pathologies (e.g., osteoporosis) and for predicting bone fragility and its risk for fracture.

### TRABECULAR BONE DAMAGE

Trabecular bone is a porous structure (Figs. 7-1 to 7-4), which behaves similarly to typical engineering materials (and cortical bone) in compression until the ultimate stress is reached. The mechanical behavior in trabecular bone shows a relatively linear or elastic response for deformations less than 1% (Fig. 7-5). The point at which the mechanical behavior becomes nonlinear (strain increasing at a greater rate than the stress) is defined as the yield strain and permanent or inelastic deformation and damage occurs beyond yield. The yield point of ver-

tebral trabecular bone is similar for both compression and tension: 0.84% and 0.78% indicate compressive and tensile yield strain, respectively, for vertebral trabecular bone specimens (28). However, beyond yield the compressive load capacity of trabecular bone does not go to zero as would be expected. Instead the load is maintained or may even show a slight increase compared to the previously recorded ultimate load (Fig. 7-5B.).

Physically this behavior can be explained by understanding the compressive mechanics of porous structures. As the pore spaces begin to collapse, the trabeculae collide and compress into each other increasing the trabecular bone-volume fraction (bone volume/combined bone and pore space volume) of the specimen. This reduction in pore space and consequent increase in volume fraction results in a temporary load tolerance by the trabecular structure. Thus, the load-carrying capacity of trabecular bone is still quite substantial following compression fracture, and results in a large post-yield stress-strain response (28). This behavior is similar to elastoplastic materials having large post-yield regions and therefore can be modeled as such. In contrast, during tensile loading the load-carrying capacity of trabecular bone is minimal resulting in a smaller post-yield region and abrupt failure. Note that in studying the mechanics of porous structures it is often useful to clarify between whole specimen properties (e.g., vertebral body) by referring to them as "apparent" and site-specific properties of the individual constituents (e.g., trabeculae) by referring to them as "tissue."

### Stress-Strain Behavior

The inelastic stress-strain behavior of bone is mainly a result of cracks, plasticity, and viscous creep. Cracks degrade stiffness, strength, and other material properties

FIG. 7-5. Experimental stress-strain curve displaying the load-unload-reload mechanical behavior (A) and post-yield mechanical behavior (B) of an osteoporotic vertebral body.

because of the imposed material discontinuities. The complex strain behavior of vertebral trabecular bone and other porous materials is a result of the cumulative effects of the elastic strain, inelastic strain due to damage accumulation, plastic strain, and anelastic (viscous) strain (29). Such strain behavior can be differentiated using a load-unload-reload protocol. After unloading from a damaging event, the stress-strain behavior of bone (trabecular and compact) is similar to that of composites (30). Namely, bone recovers approximately three-fourths of the total inelastic strains (29). Damaged bone shows relatively small changes in its elastic modulus or stiffness during the initial onset (at low strain levels) of a reload. As loads are increased (relatively high strain levels) however, cracks propagate, and residual stresses are relieved resulting in a curvilinear stress-strain behavior (Fig. 7-5) (31). This cyclic load-unload-reload behavior in time produces bone fatigue, which in turn reduces bone strength and stiffness (32–36). Bone damage resulting from fatigue or creep can occur under elastic conditions (pre-yield loading) and has been accepted as a normal physiologic process (37–39).

### Damage Mechanics

A microstructural reduction in tissue mechanical properties (e.g., strength, stiffness) is often referred to as microdamage. The accumulation of microdamage, microfracture, leads to local tissue discontinuities within a single trabecula and a decrease in apparent vertebral bone strength. Both microdamage and microfracture are load-dependent, although bone microdamage occurs at a higher incidence than microfracture (40). Microdamage or microfracture may act as a precursor for bone remodeling (41–44). The resorption phase of bone remodeling can in turn induce further microdamage (45,46) by increasing pore size. This increase in pore size (decrease in apparent density and volume fraction) consequentially reduces the apparent modulus, increases the tissue strain, and results in a temporary increase in bone fragility and osteoporotic fracture risk (39,47–50). Gross vertebral fracture can be a result of extensive microdamage or microfracture accumulation to the trabecular structure (47,51,52).

Continuum damage mechanics (CDM) is a rapidly developing area in the study of bone fracture. For a simple isotropic or axisymmetric material, the presence of cracks or damage ( $D$ ) can be expressed as a simple scalar representing the loss of load-carrying area (Fig. 7-6) (53). An effective modulus ( $E_{EFF}$ ) can then be determined by scaling the elastic modulus ( $E$ ) by the damage parameter ( $D$ ):

$$E_{EFF} = (E)(D)$$

where  $D$  is continuous between zero (fractured material) and 1 (undamaged material).

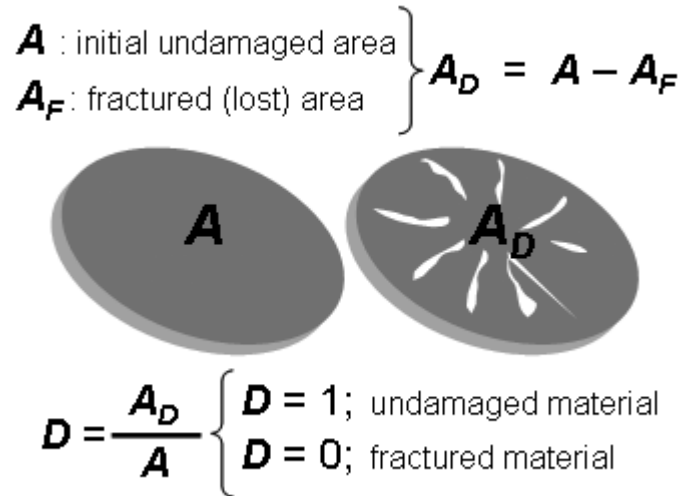

FIG. 7-6. Schematic illustration of the isotropic damage concept defined by continuum damage mechanics.

To study vertebral trabecular bone damage a quasi-continuum CDM approach has been developed based on an empirical nonlinear stress-strain relationship (generalized tangent hyperbolic law) (54,55) and an elastoplastic modulus reduction (EPMR) scheme (56,57). The latter assumes that the evolution of trabecular bone microdamage ( $D$ ) can be modeled as a change in bone elastic modulus or stiffness, wherein the elastic modulus of bone is assumed to be proportional to the apparent density cubed (discussed earlier) (12,58). The EPMR scheme is easily implemented using the finite element method and can therefore be used to model the damage evolution behavior of complex material geometries. The following sections illustrate the use of CDM and the finite element method to study vertebral damage and cement repair.

### Finite Element Damage Simulations

The finite element method is a numerical technique that provides approximations to theory. Finite element analysis is an efficient method used to solve differential equations over complex domains or structures. The structure is discretized and represented by finite elements formed by nodes. Finite element modeling is especially attractive in the analysis of heterogeneous and anisotropic structures, such as trabecular bone, for which a closed form solution using analytic methods will be impossible. In recent years, anatomically accurate models of trabecular bone can and have been investigated (59–61). These microstructural finite element models are usually constructed from micro-computed tomography raster arrays at spatial resolutions of 150  $\mu\text{m}$  or less for large volumes and 50  $\mu\text{m}$  or less for small volumes of bone (less than 50  $\text{mm}^3$ ). Microstructural

finite element models enable calculation and visualization of internal tissue stresses and strains.

Damage simulations of complex structures, such as that of trabecular bone in the vertebral body, can be studied using microstructural finite element models. Continuum damage and EPMR approaches have been integrated within the finite element numerical framework and used as a research tool to investigate existing or potential bone damage (56,57,62–65). Furthermore, finite element bone damage models can be used to study the mechanics of surgical repair. To date however, only a few studies have used finite element damage models to study the failure mechanisms (56,57,64–67) and surgical repair (vertebroplasty) efficacy (56,64,67) of the vertebral body. Simulation of vertebral body damage using the finite element approach is presented in the following section, and repair simulations will be discussed later in this chapter.

Kosmopoulos and Keller (64) coupled the EPMR damage approach with an anatomically accurate two-dimensional (2D) microstructural finite element model of a midsagittal vertebral body section. Two vertebral loading postures were simulated by using a uniform loading profile and a nonuniform (ramped) loading profile. Compressive loads were applied incrementally over a stress range of 0 to 3 MPa. The experimentally validated (65) EPMR scheme and iterative finite element analysis resulted in a nonlinear stress-strain response (Fig. 7-5A) and a decrease in the apparent modulus of the vertebral body. At the highest stress the uniformly loaded model resulted in a total vertebral body apparent modulus reduction of 32%, while the ramp-loaded model resulted in a 95% apparent modulus reduction, compared to the initial undamaged vertebral body apparent modulus ( $E_0 = 444$  MPa). Microdamage initiation (modulus reduction of 5%) was first apparent at an applied stress level of 1.5 MPa for both the uniform-loaded and ramped-loaded cases. At the maximum applied stress there was a trabecular bone modulus reduction of 40% or more in 10.4% and 15.9% of the total bone elements for the uniform-loaded and ramped-loaded microdamage models, respectively (Fig. 7-7). For the uniform-loaded vertebral body the distribution of highly stressed elements followed a column-wise (superior-inferior) pattern within the cortical shell and more centrally located trabeculae, in contrast to the ramped-loaded case where the highly stressed elements were located on the posterior vertebral shell. The ramp-loaded model resulted in a substantially greater number of highly stressed bone elements (20.9% of bone elements with stress concentrations greater than 3) compared to the uniform-loaded model (4.2% of bone elements with stress concentrations greater than 3).

## VERTEBRAL REPAIR

Most compressive fractures do not affect the spinal cord, are relatively stable, and are therefore asymptomatic

in nature. These types of fractures rarely require surgical intervention (68,69) and are treated using conservative nonsurgical approaches. These treatments often involve a short period of postural reduction (bed rest) directly after incidence, followed by external immobilization, and finally by gradual ambulation (16,70). Bed rest is usually recommended for the first 4 to 6 weeks followed by 6 to 12 weeks of bracing using a rigid orthosis. In severe cases of burst fractures, tissue fragments may enter the spinal canal and cause myelopathy (71). Fractures may lead to progressive deformity and instability, spinal stenosis, neurologic deficit, and pain requiring surgical intervention. The probability of fracture healing without surgery decreases as the severity or amount of tissue involved in the fracture increases (72).

## Bone Cement Augmentation

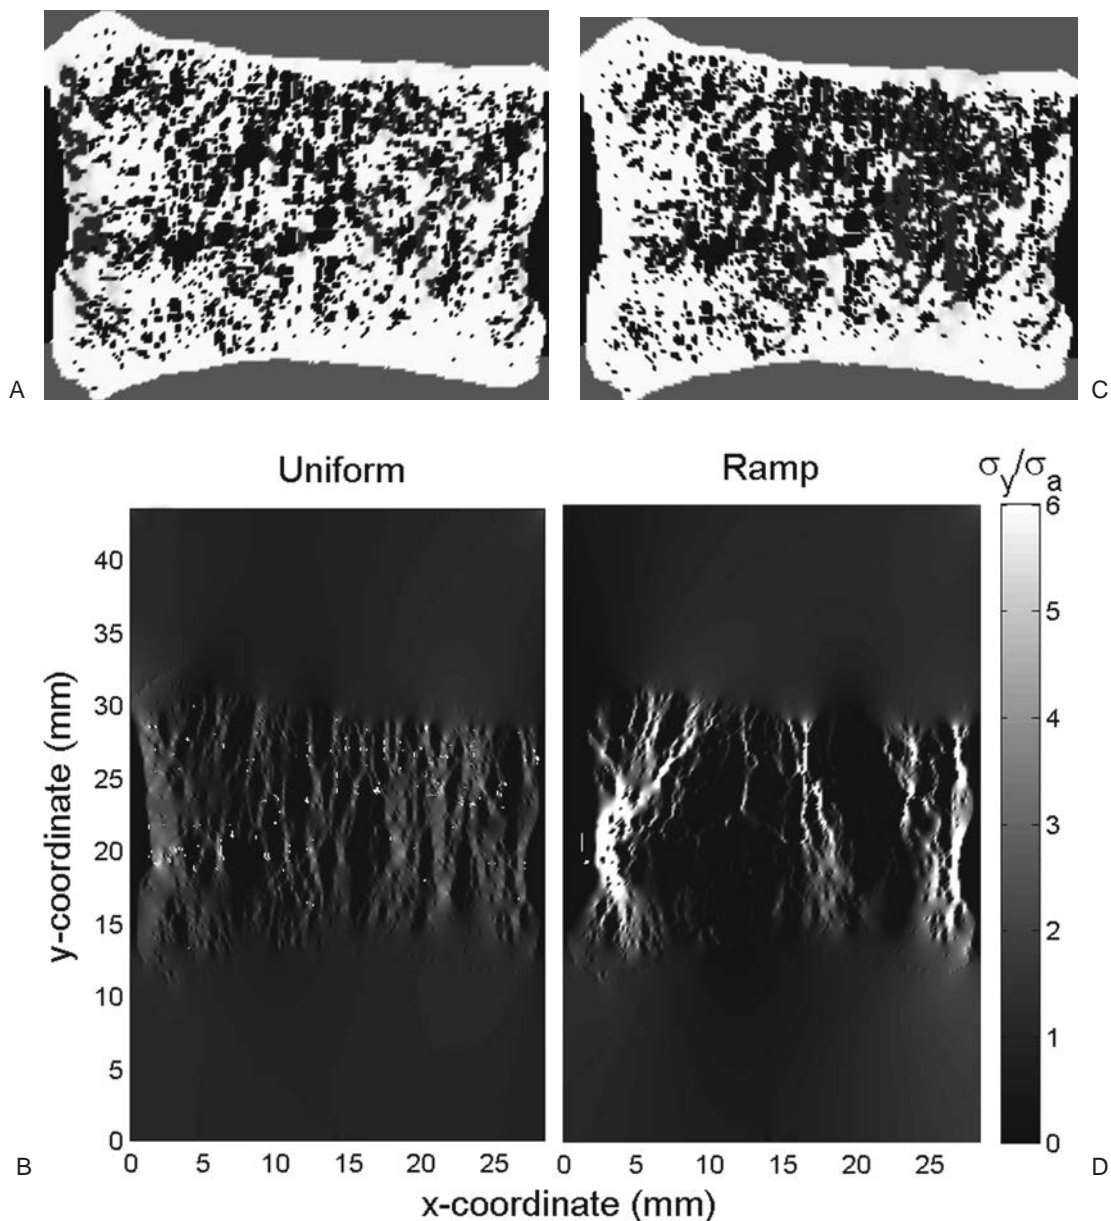

Vertebroplasty and kyphoplasty are two recently developed minimally invasive repair techniques for the treatment of vertebral compressive fractures. Unlike traditional treatments, these bone cement augmentation repair procedures help to restore spinal alignment and decrease chronic pain (73).

Vertebroplasty involves the forced injection, usually using either a parapedicular or transpedicular approach, of bone cement, usually polymethylmethacrylate (PMMA), through one (unipedicular) or two bone (bipedicular) biopsy needles into the closed space of a collapsed vertebral body (16,73). The injections are performed under continuous fluoroscopic guidance, and for high-risk cases, computed tomography is also used (74,75). This technique provides pain relief and stabilization, but typically does not restore the height of the collapsed vertebral body.

Kyphoplasty involves the insertion of a bone balloon into the vertebral body using biplanar fluoroscopic image guidance. The balloon is inflated causing the trabecular bone to compact, resulting in a suitable cavity to re-expand the vertebral body. In kyphoplasty, bone cement is injected with more control and with less pressure than during vertebroplasty. Another advantage of kyphoplasty is the restoration of vertebral body height and reduction of spinal deformity (16,73).

The main complication with each of these cement repair techniques is associated with the use of PMMA. In vertebroplasty cement, extravasation may occur since the PMMA is injected at much higher pressures. The rates of this occurrence have been reported to be as high as 40% when PMMA cement is used in the treatment of osteoporotic compression fractures (15), and is greater when using higher injection volumes or less viscous cement (76). Another concern with PMMA is its high polymerization temperature. Polymerization has been reported to produce average peak cement core temperatures of 87°C and 108°C for small (approximately 14.9 cm<sup>3</sup>) and larger (approximately 27.6 cm<sup>3</sup>) cement volume fills (77).

**FIG. 7-7.** Numerical simulation of vertebral trabecular bone microdamage using the elastoplastic modulus reduction finite element scheme. Four-node isoparametric elements were used to represent the vertebral body structure, which was assumed to have isotropic material properties. The applied compressive stress (3 MPa) corresponds to upright posture loads acting on the lumbar spine (10). Two vertebral loading postures were simulated by using a uniform (**A**, **B**) and a nonuniform or ramped (**C**, **D**) loading profile. In (**A**) and (**C**) the bone and marrow tissues are depicted as white and black elements, respectively, whereas bone tissue damage (modulus reduction of 40% or greater) is depicted by the dark gray elements. In (**B**) and (**D**), the gray scale intensity plots show the resulting stress concentrations (element axial stress/apparent stress,  $\sigma_y/\sigma_a$ ) following the uniform and ramp loading profiles, respectively. Highly stressed elements are depicted as lighter gray (max  $\sigma_y/\sigma_a < 6$ ) and less severely stressed elements as darker gray to black (min  $\sigma_y/\sigma_a > 0$ ).

Bone-forming cells (osteoblasts) have been shown to undergo thermal necrosis when exposed to relatively lower temperatures than cement polymerization (as low as 50°C for more than 1 minute) (78,79). Clinically the complication rate (between 1% to 3%) associated with PMMA-induced temperature elevation and PMMA extravasation is insignificant for treatment of vertebral fracture (74), but long-term effects are still being investigated. Another noteworthy complication from the resulting increased strength and stiffness of cement-augmented vertebrae is the modified load transfer to adjacent vertebral bodies. Recent findings suggest that the cement augmentation results in higher stresses and strains to adjacent vertebrae, thus facilitating their future collapse (80).

### Biomechanical Studies of Cement Augmentation

Biomechanical studies of cement augmentation have demonstrated that vertebroplasty treatment of experimentally created compression fractures is an effective means to restore the strength, and to a lesser extent, the stiffness of the damaged vertebrae (81). These authors noted that 2 mL of PMMA cement restored the strength of thoracolumbar and lumbar vertebrae, but 8 mL and 4 mL of cement were necessary to restore the stiffness of the thoracolumbar and lumbar vertebrae, respectively, to predamage levels using a bipedicular approach. Furthermore, it has been shown that lumbar vertebral strength can be significantly restored using either a unipedicular (6 mL injection through one pedicle) or bipedicular (5 mL injections through each pedicle) approach (70).

The biomechanical aspects of kyphoplasty are less well understood. Reductions in risk of cement extravasation and vertebral height restoration have been suggested as the main advantages of kyphoplasty compared to vertebroplasty (16). Researchers have reported a 47% restoration in vertebral height in 70% of the collapsed vertebral bodies following kyphoplasty (16). Furthermore their findings support that lower pressure, higher viscosity cement injections reduced the rate of cement extravasation as compared to published findings for vertebroplasty.

Computer models and numerical tools to simulate and guide surgical repair are becoming more routine, and are rapidly advancing treatment of musculoskeletal disorders (82). One of the main advantages of computer models is that they can be used as their own repeated measure. Different cement repair strategies can be studied using a single bone specimen and can be evaluated in an unlimited manner using different loading modes and boundary conditions. The ability of microstructural finite element models to represent complex structures lends this technique to the study of trabecular bone microdamage and repair. Numerical examples of cement augmentation repair are discussed and presented in the following sections.

### Numerical Simulations of Cement Augmentation

Validated finite element models can act as replacements to experimental testing (44). Liebschner et al. (67) used an experimentally validated apparent lumbar vertebral damage model to investigate vertebroplasty cement repair. In their study, cement repair was modeled by the introduction of PMMA cement elements within the vertebral centrum. Four PMMA cement bolus volumes (1.0, 3.5, 5.0, and 7.0 cm<sup>3</sup>) were investigated with an assumed cylindrical cement shape. Using this repair modeling approach, the authors reported that only small amounts of PMMA (approximately 14% fill or 3.5 cm<sup>3</sup>) were required to restore apparent stiffness to intact levels, and that symmetric PMMA placement was preferential compared to asymmetric distributions.

The EPMR damage simulation scheme and finite element method was recently used to investigate damage-repair of human vertebrae (64). Microstructurally damaged finite element models were repaired using four different PMMA cement repair strategies:

- replacement of marrow elements by PMMA cement elements at each of the four interior corners of the mid-sagittal model (referred to as model A)
- central placement of cement consistent with a parapedicular surgical approach (model B)
- strategic placement of equivalent cement quantities at five damage initiation sites (model C), and
- complete vertebral cement fill (replacement of all marrow elements) (model D) (Table 7-1).

The first three repair strategies used equivalent amounts of cement elements (25% of the marrow elements were replaced by PMMA bone cement). For the third strategy, the five trabecular microdamage initiation sites were used as the central locus for repair (each

**TABLE 7-1.** Summary of finite element simulations of several PMMA cement repair strategies<sup>a</sup>

Loading regimen	Vertebroplasty repair regimen	Normalized apparent modulus ( $E_R/E_0$ )	Bone element stress concentrations (% >3)
Uniform	Undamaged	1.0	4.5
	Damaged	0.68	5.5
	Repair A	1.67	3.5
	Repair B	1.60	3.3
	Repair C	2.10	3.4
Ramped	Repair D	4.06	0.0
	Undamaged	1.0	4.6
	Damaged	0.05	20.1

	Repair D	3.53	0.4

PMMA, polymethylmethacrylate.

<sup>a</sup>See text for definitions of repair regimens.

site with PMMA comprising 5% of the marrow elements). The motivation for studying partial cement fill was the notion that reductions of cement volume during vertebroplasty may reduce the likelihood of cement leakage. Plane stress, static finite element analyses were performed on each of the damage-repair models (eight in total). Loading profiles used for the repair models were identical to the EP MR damage simulation (uniform and nonuniform). Stress-strain results (apparent modulus) were normalized to undamaged vertebral body results.

Examination of the eight-vertebroplasty repair models revealed that only the ramp-loaded central placement cement regimen (model B) did not restore the microstructurally damaged vertebral body apparent modulus to the initial undamaged apparent modulus ( $E_0 = 444$  MPa). The repair strategy using a central placement, cement regimen (model B), was the least effective of all the partial fill repair strategies for both loading conditions in increasing vertebral body structural stiffness (Table 7-1). In the case of the uniform-loaded microdamage regimen, model B resulted in a repair modulus/initial modulus ratio  $E_R/E_0 = 1.60$ , which is still significantly (135%) above the damaged apparent modulus ( $E_D = 302$  MPa). Of the strategic partial cement fill regimens, model C was most effective in increasing the apparent modulus above the initial undamaged apparent modulus for both the uniform ( $E_R/E_0 = 2.10$ ) and ramped ( $E_R/E_0 = 1.52$ ) microdamage models. Each of the partial cement repair strategies (models A through C) resulted in complete recovery of the apparent modulus above the undamaged levels except model B for the severely damaged ramp-loaded case.

In the case of the complete fill repair regimen (model D), the number of highly stressed elements (trabecular bone stress concentrations greater than 3) decreased to less than 0.4% (98% reduction) of the total bone elements for the ramp-loaded model and were completely removed (100% reduction) for the uniform-loaded microdamage model. The least effective cement repair strategy for reducing the number of highly stressed bone elements was model A for the uniform-load microdamage model (36% reduction with respect to the untreated damage model), and model B for the ramp-load microdamage model regimen (14% reduction with respect to the untreated damage model) (Table 7-1). Strategic placement of cement at damage initiation sites, model C, resulted in a 38% and 43% reduction in the number of highly stressed elements for the uniform-loaded and ramp-loaded microdamage models, respectively, compared to the untreated damaged model.

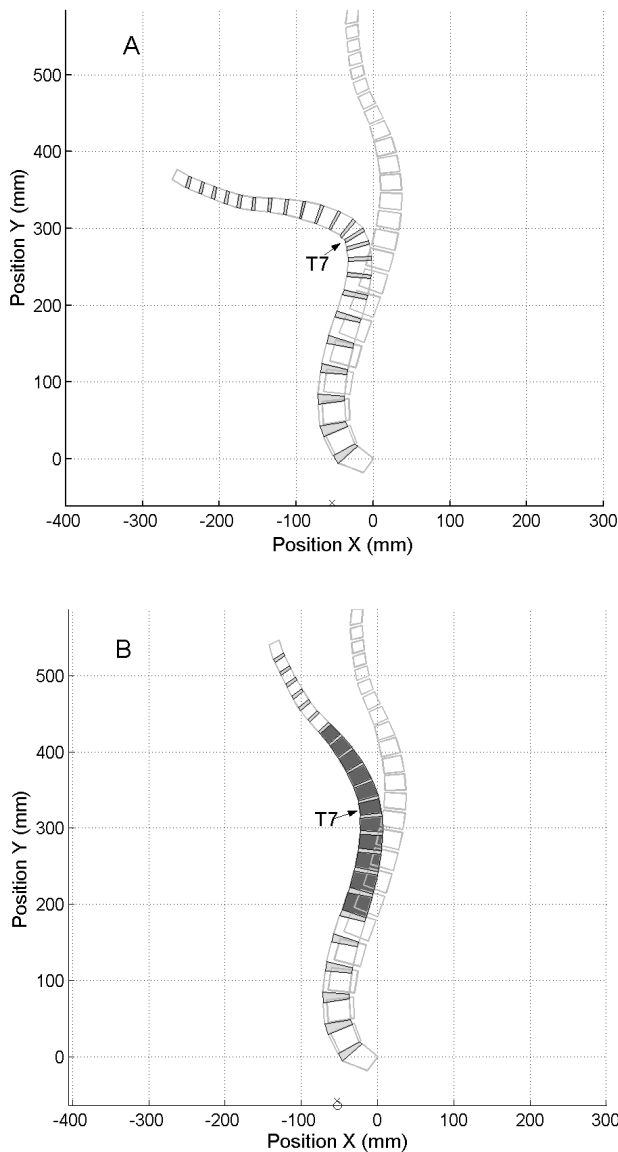

The previous analysis was limited to a single vertebral body. Keller et al. (10) studied the effects of spinal deformity and vertebral height loss associated with osteoporosis using an anatomically accurate sagittal plane postural loading model of the anterior spinal col-

umn (C2-S1) in conjunction with the EP MR scheme. This analytic model was found to reproduce the salient features of thoracic spinal deformities caused by osteoporotic wedge fractures (Fig. 7-8A). This model was used to simulate the effects of vertebral cement augmentation (vertebroplasty) on spinal deformity. Spine stiffness was parametrically varied over the range of  $1\times$  to  $2\times$  that of a normal healthy spine. An increase of  $2\times$  in vertebral body stiffness corresponds to complete cement fill of the normal vertebral body (64). Increases in thoracic kyphosis and decreases in vertebral body height resulted in a 34.9% overall decrease in spinal height (C2-S1), 12.0% decrease in body height, and a 22.8 cm anterior translation of C2. The resulting thoracic kyphotic deformity ( $86.4^\circ$  T2-T10) qualitatively resembled deformities observed in elderly individuals with osteoporotic compression fractures.

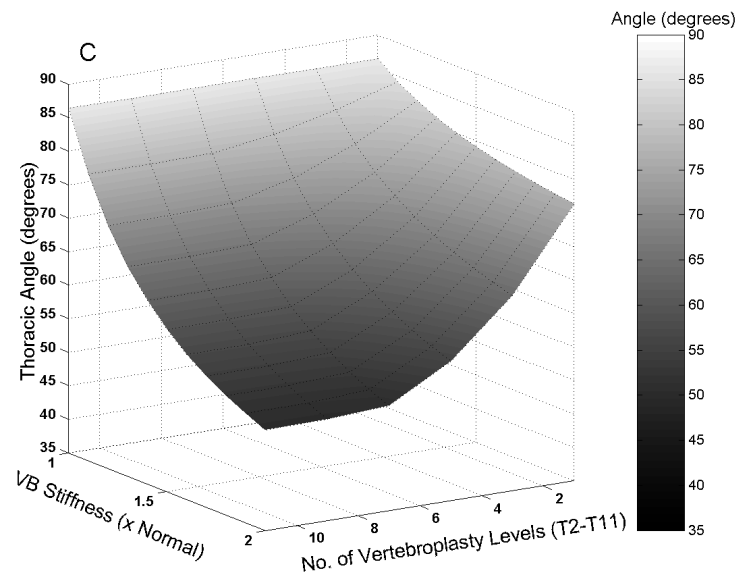

To prevent severe thoracic deformity (greater than  $70^\circ$ ) cement augmentation of three or more thoracic segments and a 60% increase in vertebral body stiffness was required. Doubling the vertebral body stiffness of one segment resulted in only a  $10^\circ$  reduction in thoracic kyphosis deformity, whereas stiffness doubling combined with augmentation of 11 segments (T2-T12) reduced the kyphotic deformity to  $50^\circ$  (height change = 2.4%, C2 translation = 10.9 cm) (Fig. 7-8B). The effects of cement augmentation on postural load-induced osteopenic thoracic kyphosis are summarized in Figure 7-8C. These analytic results suggest that cement augmentation of vertebrae can reduce the severity of osteoporotic spine deformities. Model data provide insight for surgical procedures (optimal cement material and volume, number of treatment levels) designed to prevent or treat vertebral fractures and deformity of the thoracolumbar skeleton. Ultimately, identification of subjects who are at risk for vertebral microdamage and fracture may facilitate early prophylactic treatments using cement augmentation. Clinical repair of fractures using small cement quantities at locations where damage is greatest or where damage initiates may become comparable to current cement-filling regimens used during vertebroplasty.

## CONCLUSION

Lumbar vertebral compression fractures are primarily caused by overloading, but even postural loads may result in vertebral body height reduction, deformity, myelopathy, and pain. Restoration of vertebral geometry and mechanical properties to undamaged levels using cement repair strategies is dependent on a number of factors including bone density, damage, cement quantity, quality (modulus) and placement (within a single and at multiple vertebral segments), and surgical approaches and techniques. These factors, together with the complexity of vertebral bone geometry and material properties, suggest

**FIG. 7-8.** Graphic depiction showing the resulting spinal deformity and anterior wedge-type fractures of the T7 and T8 vertebral bodies following osteoporosis simulations (A) and multisegment vertebroplasty repair (B). The three-dimensional surface plot depicts thoracic angle changes (vertical axis) with respect to cement augmentation (represented by changes in segment stiffness from 1× to 2× normal) and the number of augmented segments (thoracic levels, T1-T12) (C).

that computational tools and algorithms using anatomically precise two-dimensional and three-dimensional vertebral geometry derived from radiographic images may prove to be valuable for clinical management of vertebral osteoporotic compression fractures and tumors. In this regard, simple analytic models and more complex microstructural finite element models provide a framework for understanding microdamage and fracture of vertebrae, and investigating surgical treatment, including design and development of tissue-engineered fracture repair materials. Additional work is needed to identify the effects of cement augmentation on the load transfer and stress distributions of adjacent vertebrae. Whether or not altered load transfer is sufficient to facilitate collapse of adjacent (untreated) vertebral bodies, as has been recently suggested (80), remains to be determined.

## CHAPTER 8

# Genetic Transmission of Common Spinal Disorders

Michele C. Battié and Tapio Videman

---

Spinal disorders such as disc degeneration and herniation, sciatica, and back pain have commonly been attributed to the accumulation of environmental effects, primarily mechanical insults and injuries, imposed on normal aging changes. Accordingly, environmental factors received much attention as possible risk factors during the prior half-century, and only recently have studies on hereditary aspects of disc degeneration, disc failure, and back symptoms begun to accumulate (1).

A decade ago, in reviewing the epidemiology of degenerative disc disease, Frymoyer wrote: “Among the factors associated with its occurrence are age, gender, occupation, cigarette smoking, and exposure to vehicular vibration. The contribution of other factors such as height, weight, and genetics is less certain” (2). Research since that time has dramatically changed views of genetic and environmental determinants of many common spinal disorders. When reviewing the same topic of “disc disease” in 2002, Ala-Kokko came to the following conclusion: “Even though several environmental and constitutional risk factors have been implicated in this disease, their effects are relatively minor, and recent family and twin studies have suggested that sciatica, disc herniation and disc degeneration may be explained to a large degree by genetic factors” (3). We concur and will discuss the basis for this tentative conclusion in this chapter.

The role of genetics in common musculoskeletal disorders has been studied more in primary osteoarthritis than in spinal disorders. In a recent review article, Loughlin concluded that primary osteoarthritis has a major genetic component, but that osteoarthritis “is rarely transmitted as a Mendelian trait and that environmental factors play a significant role in disease expression.” He also classified osteoarthritis as a common, oligogenic, multifactorial genetic disease (4). These views are concordant with those on common spinal disorders,

which would be logical because joints and intervertebral discs are to a major part composed of the same proteins. To date more than a dozen gene loci associated with osteoarthritis have been identified, and a half dozen associated with disc degeneration, mainly from chromosomes 2, 4, 6, 7, 11, 16, and X. Only a few loci have been associated with both joint and spine degeneration. However, it is likely that the genes representing the most significant genetic susceptibility to these common conditions have yet to be identified. (4).

We will briefly review the evidence suggesting genetic transmission, from case reports and more formal studies of familial aggregation to classic twin studies attempting to separate genetic and shared environmental influences, to the identification of gene forms. The primary focus of this chapter is on genetic influences on common spinal disorders, including disc degeneration and herniation, sciatica, and back pain.

### IDENTIFYING AND CONFIRMING GENETIC INFLUENCES

Studies of the genetic epidemiology of common spinal disorders begin with determining whether familial aggregation of the disease or disorder is present. This is done by examining the frequency of disease in relatives of those affected as compared to the frequency of disease in the general population. If relatives are at increased risk, the pattern of familial aggregation can be further defined through various types of family studies (5). Most of the studies on common spinal disorders fall into this category. Once evidence for familial aggregation has been obtained, there is a need to distinguish between biologic (genetic) and social (cultural inheritance) sources of familial similarity (6). One method of accomplishing this is through classic twin studies of monozygotic and dizygotic twin pairs.

The genetic architecture of a trait includes information on how many gene loci are involved and which of the loci are polymorphic, with at least two common forms of the genes or alleles. The number of alleles and their frequencies are then determined for each gene locus. Allele frequencies and average effects associated with the alleles determine the contribution of allelic variation to the overall genetic variation. These can be further partitioned into additive genetic variance, due to gene “dosage,” and variance due to dominance (7).

A growing number of monogenic diseases have been successfully analyzed down to the molecular level and have shown how a biochemical defect evolves from a single mutation, which parts of a gene are indispensable for normal function, and how phenotypes develop from different mutations. Based on these insights, molecular genetics can yield information on normal traits and common diseases. Normal traits and common diseases generally have a genetic contribution from more than one gene locus.

Genes suspected of involvement in the etiology of disease are called candidate genes. Candidate genes may be used as targets, with potential genetic variation leading to differences in the proteins encoded by the genes. These proteins are part of the physiologic system that, when disturbed, gives rise to the disease being studied. Also, for specific genes and some environmental factors, gene-gene interactions and gene-environment interactions may exist. For example, Solovieva et al. presented evidence suggesting that the effect of weight on lumbar disc degeneration is modified by COL9A3 gene polymorphisms in Finnish men (8). Simple linear models may, therefore, fail to grasp the complexity of the real world, and unraveling the contribution of genes and environment in diseases of multifactorial etiology is a challenging proposition (9).

## DISC HERNIATION AND SCIATICA

The clearest association between back-related symptoms and the disc is for severe sciatica, often leading to surgery to remove an offending herniated disc. This condition also has been the focus of several investigations into genetic influences on common spinal disorders. As is typically the case, observations of familial aggregation lead to hypotheses of genetic susceptibility for sciatica and disc herniation.

It should be noted, however, that in juveniles and adults, persons identified as having disc herniations are those who access and receive spine surgery for pain with the diagnosis of disc herniation. Although discectomy may appear to be a clear indicator of the presence of a symptomatic disc herniation, the significant regional variations in rates of spine surgery demonstrate that this outcome is likely to be significantly influenced by other factors as well (10). Thus, some degree of classification error is involved when studying the occurrence of severe

symptomatic disc herniation using the surrogate of discectomy.

### Familial Aggregation of Juvenile Lumbar Disc Herniation

Two reports in 1990 documented cases of identical twins with similar histories of radicular symptoms and lumbar disc herniation. Matsui et al. documented a case of a 16-year-old girl who was admitted to a hospital for low back and left leg pain (11). Myelography and subsequent laminotomy revealed a protruded mass at the L4-5 level with left L5 root compression. Two years later, the patient's identical twin was admitted complaining of back pain of 2 years' duration and right leg symptoms of approximately 8 months. Results from myelography and discography prompted the surgeon to perform laminotomy and discectomy at the L4-5 and L5-S1 levels. The observation that herniated lumbar discs in young patients are relatively rare and the absence of a history of trauma, suggested that the similarity of the local disc pathology in the twins was not a chance occurrence. Matsui et al. thus concluded that their findings suggest that genetic factors are involved in the development of juvenile herniated nucleus pulposus (11).

Gunzburg et al. documented a similar case of identical twin girls who experienced radicular pain within 1 year of one another when they were approximately 13 years of age (12). Computed tomography scans revealed posterior bulging at the L4-5 level and herniation at the L5-S1 level in both. As in the case presented by Matsui et al., the onset of symptoms was similar and neither twin cited an injury or trauma (11). The twins experienced progressive symptoms that led to surgery in one case and chemonucleolysis in the other, with subsequent pain relief and return to normal activities.

These case reports demonstrate that familial aggregation occurs, but clarifying whether or not it occurs more often than would be expected through random occurrence requires comparison to controls or a reference group. The generally low incidence of juvenile disc herniation would suggest that such aggregation as seen in the cases just described would be extremely unlikely chance events. A rare population-based study of the incidence of surgeries for juvenile disc herniation was conducted among more than 75,000 Japanese elementary, junior high, and high school students. It revealed incidence rates of 1.69 per 100,000 person-years for 10- to 12-year-olds, 3.2 for 13- to 15-year-olds, and 9.4 for 16- to 18-year-olds. The mean incidence rate for all the schoolchildren was 5.4 per 100,000 person-years (13).

Two subsequent papers reported on the degree of familial aggregation in cases versus control groups. Vartolotta et al. investigated the incidence of severe low back pain, sciatica, and surgically treated herniated discs among the parents of 63 patients under 21 years of age

who had herniated lumbar discs and the parents of a control group of nonback patients (14). They also tried to eliminate reporting bias by family members by requiring confirmation from medical records. The estimated risk of developing a herniated disc before the age of 21 was four to five times greater for patients who had a positive family history, as compared to those who did not.

A year later Matsui et al. reported on the occurrence of lumbar disc herniation in the siblings and parents of 40 patients under 18 years of age who had undergone surgery for lumbar disc herniation and a referent group composed of the families of 120 controls (patients treated in the same department who had “normal spines”) (13). The odds ratio of a patient with juvenile disc herniation to have a family history of disc surgery was 5.61 times that of a patient without disc herniation. The authors concluded that their results “strongly suggest that lumbar disc herniation in patients aged 18 years or younger shows familial predisposition and clustering.”

Because family members can become affected even though the disease is not familiarly transmitted, the risk in family members ideally should be compared with the population risk. The finding by Matsui et al. of a higher incidence of a positive family history in juveniles with disc herniation, yielding an odds ratio of 5.61, is directly useful clinical information when combined with the incidence of 5.4 per 100,000 children and adolescents (13). Varlotta et al. used matched patient-control pairs in their series of 63 disc herniations in patients under 21 years of age (14). The age-adjusted relative risk of herniation in family members of patients compared to family members of controls was 4.5, which was quite similar to that found by Matsui et al. despite differences in methods and sample populations (13).

Younger patients who had undergone discectomy also were found to be significantly more likely to have a family history of back disorders by Nelson et al. in a study comparing three age groups, those 9 through 15, 16 through 19, and 20 through 25 years of age (15). Such a finding would be consistent with genetic epidemiologic literature, indicating that stronger genetic effects are associated with earlier onset.

### **Familial Aggregation of Lumbar Disc Herniation in Adults**

There also have been over a half-dozen reported observations of familial aggregation of lumbar disc herniation in adults, raising interest in the possibility of genetic susceptibility (16–19). Scapinelli described a striking family history of a 44-year-old patient who had undergone surgery for lumbosacral disc herniation (17). Six of the patient’s 14 siblings (five brothers and one sister) also had undergone surgery for lumbar disc herniation, with unusually large volumes of herniated disc material noted. In addition, two other siblings, one brother and one sister,

had been diagnosed as having lumbar disc herniation and were treated conservatively. The author noted an early onset of symptoms, usually in the third decade, which was not precipitated by trauma. He concluded that the high proportion of members of this generation affected could be due to transmission by both branches of the family of a genetic predisposition to premature degeneration or soft tissue weakness. He also hypothesized that a defective autosomal-dominant major gene with low penetrance may be responsible for increasing risk among some persons.

Similarly, Varughese and Quartey reported on the case histories of four brothers who had spinal surgery between 27 and 39 years of age for severe leg pain associated with disc herniation and concomitant spinal stenosis (18). Both parents reported similar histories of symptoms and spine surgery. The authors concluded that the familial aggregation, along with the relatively young ages of the brothers at the time of their acute radicular symptoms, suggest that developmental or hereditary factors may have been responsible for the pathogenesis of spinal problems in this family.

These observations were followed by several case-control studies of familial aggregation of disc herniation or “discogenic” low back pain. For example, Postacchini et al. studied the occurrence of “discogenic” low back pain in the relatives of patients attending a low back pain clinic for persistent and recurrent symptoms, patients who had undergone discectomy for lumbar disc herniation, and individuals with no history of low back pain (20). They identified familial aggregation in families of discogenic low back pain and surgery for herniated discs. Of the patients with discogenic low back pain and discectomy, 35% and 37%, respectively, had first-degree relatives with a history of discogenic low back pain. Five percent of patients with discogenic pain and 10% of those with discectomy had first-degree relatives who had undergone disc surgery. In comparison, only 12% of subjects without a history of back pain problems had relatives with discogenic low back pain and 1% had relatives with discectomy (20).

In one other case-control study, Simmons et al. investigated the family histories of back problems in first- and second-degree relatives of 65 patients who underwent surgery for “degenerative disc disease,” as compared to 67 controls who had undergone orthopedic surgery for nonspine-related problems (21). Patients who had undergone spine surgery were 2.4 times more likely to have a positive family history of recurrent, incapacitating low back pain as those in the control group. In the spine surgery group, 18.5% of the relatives had a history of having spinal surgery, as compared with only 4.5% of the control group, yielding an odds ratio of 4.8 (21).

Richardson et al. noted methodologic limitations in earlier investigations of familial aggregation of disc-related low back problems, including unknown reliability

of questionnaires to identify “discogenic” low back pain, overly exclusive control group criteria, and failure to control for potentially confounding extrinsic factors (22). They attempted to address these methodologic issues in a study of symptoms of lumbar disc herniation in the immediate relatives of 38 patients with disc herniation confirmed at surgery and 50 control subjects with upper extremity disorders. Although the numbers of subjects were relatively small and response rates limited, subjects with disc herniation confirmed at surgery were 16.5 times more likely to have a family history of symptoms of disc herniation as compared to the control subjects.

Matsui et al. assessed disc degeneration and herniation in 24 subjects with a history of disabling low back pain or unilateral leg pain who sought medical care and who also had immediate relatives who had undergone surgery for disc herniation (23). The frequency and extent of degenerative changes were then compared to those of 72 age- and sex-matched controls with a similar symptom history, but without a family history of disc surgery. The grade of disc degeneration according to magnetic resonance imaging (MRI) signal intensity was significantly more severe, and the incidence of lower lumbar herniation/bulging was higher in cases with a family history of disc surgery compared to controls. These findings led the authors to speculate that a familial predisposition for disc herniation may be an expression of disc degeneration (23).

Collectively, the observations and studies of familial aggregation make a convincing case that intervertebral disc herniations for which care is sought in juveniles and adults are indeed influenced by familial factors. The studies do not, however, provide data on the relative contributions of genetic and shared environmental factors and their complex interactions.

### **Classic Twin Studies of Disc Herniation and Sciatica**

Classic twin studies comparing concordance of findings within monozygotic and dizygotic twin pairs provide a methodologic strategy for disentangling genetic and shared environmental influences. Heikkilä et al. conducted such a study of sciatica and hospitalization for disc herniation by comparing pair-wise concordance of monozygotic and dizygotic twins (24). The data from this Finnish study are valuable in that both self-report and hospital data are available, covering mild cases, which are less reliably reported, and generally more severe cases, which are more reliably categorized but more selected. In addition, the series was large (more than 9,000 same-sex twin pairs) and representative. Heritability estimates were 21% for sciatica and 11% for associated hospitalizations. The difference in the observed versus expected incidence of sciatica between monozygotic and dizygotic pairs decreased with increasing age. Thus, genetic influences were more significant in persons under 40 years of age. This finding is consistent with the literature, which indi-

cates that stronger genetic effects are associated with an earlier onset of disease (5). The apparently greater genetic influence in younger subjects may be due, in part, however, to a higher rate of misclassification caused by forgetfulness that occurs with advancing age.

### **Direct Genetic Evidence for Disc Herniation and Sciatica**

Two collagen IX alleles have been recently identified to be associated with sciatica and lumbar disc herniation, confirming the role of genetics in spinal disorders. A study from 1999 reported that a tryptophan allele (Trp2) in the human COL9A2 gene was associated with sciatica, although it was present only in about 4% of the patients (25). There was also a trend for increased prevalence of radial tears in nonherniated discs among the Trp2 allele-positive subjects (3 of 6 patients with sciatica and 3 of 11 family members) (26). More recently it was discovered that 12.2% of patients with sciatica had a Trp3 allele in the COL9A3 compared with 4.7% among controls (27). Ala-Kokko has concluded from these findings that disc disease is not one entity, but instead is likely to consist of several related phenotypes (3).

### **LUMBAR DISC DEGENERATION**

It is of little surprise that the size and shape of spinal structures in family members are more similar than in unrelated individuals. The reports of twin pairs that demonstrate similarities in spinal and other skeletal morphology simply provide confirmatory evidence (11, 28–31). Such similarities have been amply demonstrated for other anthropometrics, such as height and dental structure (16,32). Of greater interest is the possibility that degenerative changes commonly attributed primarily to environmental factors may be, in part, a function of genetic predisposition, and that this influence may be substantial. Disc degeneration is of interest because it is believed to be a factor in the pathogenesis of disc herniation and may play a contributory role in back symptoms.

### **Familial Aggregation of Disc Degeneration**

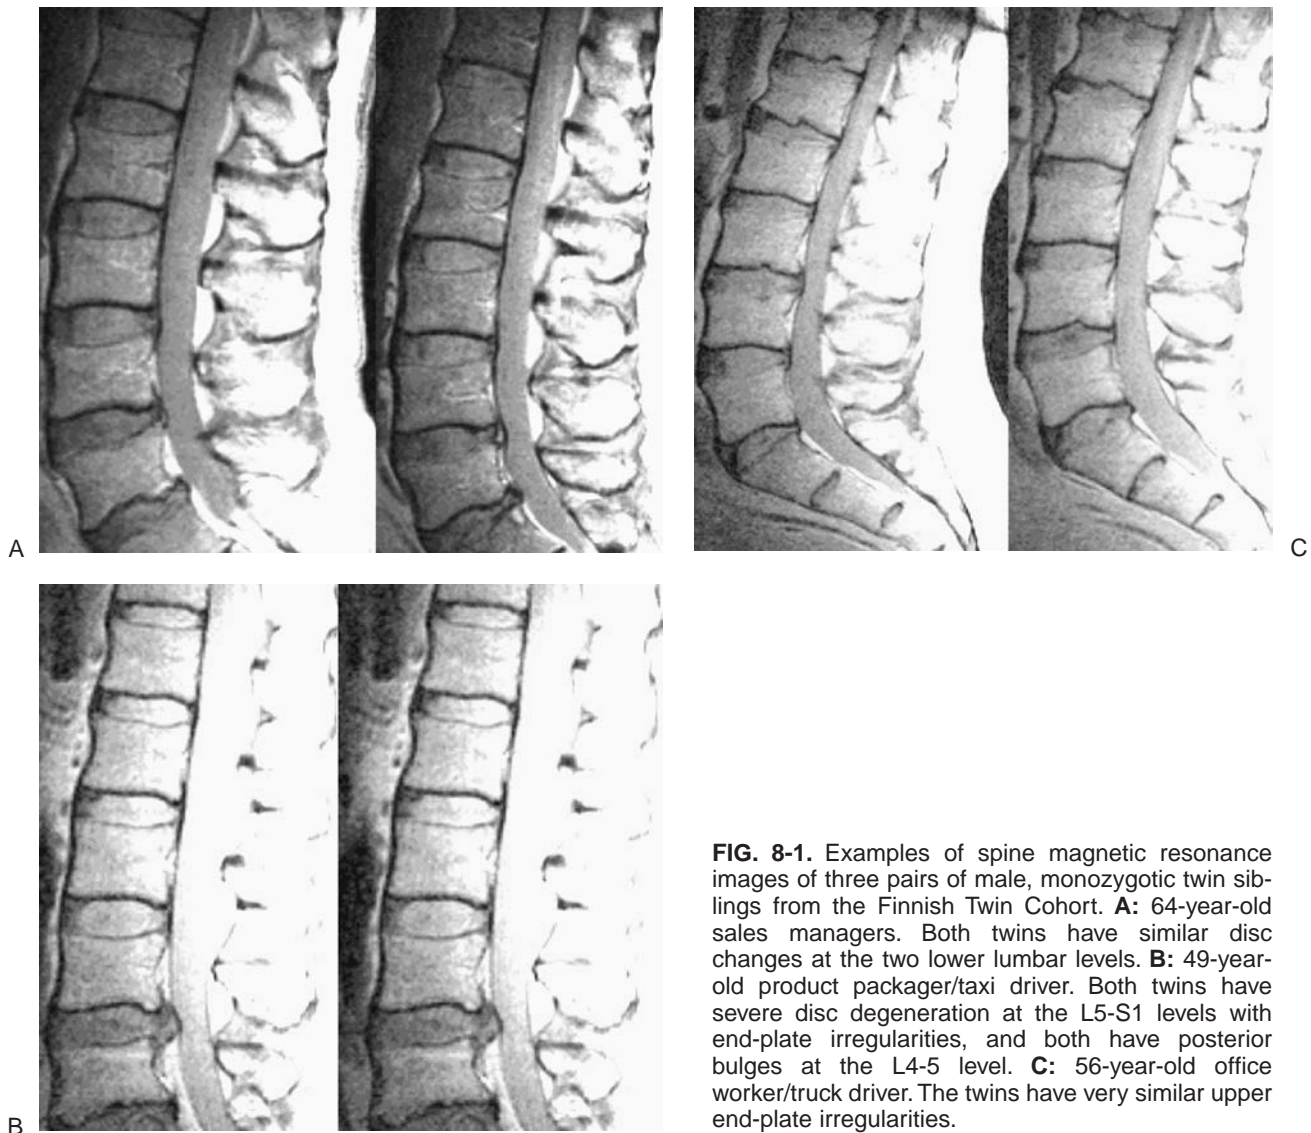

We presented evidence of substantial familial aggregation of disc degeneration in terms of extent and location of changes in two earlier studies of monozygotic twins published in 1995 (33,34). The first study assessed the degree of similarities in degenerative findings by spinal level in the lumbar discs of 20 pairs of monozygotic twins from 36 to 60 years of age, relative to what would be expected by chance based on the prevalence of the findings by level among all 40 subjects (33). The MRI assessments were conducted blinded to twinship and revealed a higher degree of twin similarities than would be expected by chance. Only 15% of the variance in disc bulging/her-

niation was explained by age and smoking, but the variance explained rose to 54% with the addition of a variable representing familial aggregation in the L1-L4 discs. Approximately 26% of the variance was explained by familial aggregation in the L4-5 and L5-S1 levels. These results suggested a substantial familial influence on lumbar disc degeneration and warranted further investigation.

In a later study spine MR images of 115 pairs of male identical twins were assessed blinded to twinship and exposure history to estimate the effects of commonly suspected risk factors on disc degeneration, as determined from signal intensity, bulging, and height narrowing, relative to the effects of age and familial aggregation (34). In the multivariable analysis of the T12-L4 region, occupational physical loading conditions explained 7% of the variance in disc degeneration scores among the 230 subjects; this rose to 16% with the addition of age and to 77% with the addition of a variable representing familial

aggregation. In the L4-5 and L5-S1 region, leisure-time physical loading was the only behavioral or environmental factor investigated that entered the multivariate model and it explained only 2% of the variance in disc degeneration summary scores. The portion of the variance in lower lumbar disc degeneration scores explained rose to 9% with the addition of age and to 43% with the addition of familial aggregation. Examples of spine MR images from three pairs of twin siblings from this study cohort are provided in Figure 8-1.

Significantly more of the variance in degeneration remained unexplained in the lower lumbar region, as compared to the upper lumbar region. This discrepancy could be due to environmental conditions, which are likely mechanical in nature, and interact with spinal anthropometrics in such a way as to have a disproportional effect on the lower lumbar levels. However, the factors involved are not simply a function of the magnitude

**FIG. 8-1.** Examples of spine magnetic resonance images of three pairs of male, monozygotic twin siblings from the Finnish Twin Cohort. **A:** 64-year-old sales managers. Both twins have similar disc changes at the two lower lumbar levels. **B:** 49-year-old product packager/taxi driver. Both twins have severe disc degeneration at the L5-S1 levels with end-plate irregularities, and both have posterior bulges at the L4-5 level. **C:** 56-year-old office worker/truck driver. The twins have very similar upper end-plate irregularities.

of occupational physical loading from materials handling and work postures. The study findings indicated that disc degeneration may be explained primarily by familial influences, which are most likely genetic, and as yet unidentified factors, which may include complex interactions. This study provides a first estimate of the relative importance of specific environmental agents and overall familial influences, including genetic factors (34). The remaining variance that is unaccounted for by the specific environmental and familial sources of variation is due to measurement error and yet unknown environmental effects.

### Classic Twin Studies of Disc Degeneration

Following the earlier studies suggesting the possibility of a substantial genetic influence, Sambrook et al. conducted a classic twin study to examine the hypothesis that disc degeneration has a major genetic component (35). Spine MR images were obtained for 86 pairs of monozygotic twins and 154 dizygotic twins, 80% of who were female, from Australian and British twin registries. A substantial genetic influence on disc degeneration was found. For an overall score of disc degeneration, comprised of disc height, signal intensity, bulging, and anterior osteophyte formation, heritability estimates were 74% [95% confidence interval (CI), 64% to 81%] for the lumbar spine and 73% (95% CI, 64% to 80%) for the cervical spine. Heritability estimates were adjusted for age, weight, smoking, occupation, and physical activity. An analysis of individual MRI findings suggested that disc bulging and height were the primary contributors to the genetic determination of the disc degeneration summary score. Interestingly, a genetic influence was not apparent for signal intensity (35).

The findings of Sambrook et al. indicate a substantial genetic influence. What is not known is whether specific gene effects of relatively large magnitude exist or if the genetic contribution is due to small effects of many genes (35).

### Direct Evidence of a Genetic Influence on Disc Degeneration

Genetic influences on intervertebral disc degeneration in humans were confirmed in 1998. In a study, using spine MRI it was shown that low-signal intensity of thoracic and lumbar discs was associated with TaqI tt-genotypes of the vitamin D receptor gene. A similar pattern was found between the summary scores of signal intensity, bulging, and disc height for both TaqI and FokI genotypes (36). TaqI and FokI each accounted for a substantial portion (6% to 7%), of the inter-individual variance in disc degeneration as measured through signal intensity. Another study using spine X-ray found an association between Taq polymorphisms and the severity of

osteophytosis and presence of disc narrowing, and more weakly, with the presence of osteophytosis (37).

A later investigation of the associations of vitamin D receptor TaqI polymorphisms and spine degeneration demonstrated that those with the tt genotype also had more anular tears but less bulges and osteophytes than those with the TT genotype (38). These findings emphasized the need for caution in combining specific suspected degenerative phenomena into summary scores. Also, the finding of the association between anular tears and genetics could be of importance because anular tears may be related to the pathophysiology of back pain. In another study, multilevel and severe lumbar disc degeneration was observed among 64 women with shorter variable numbers of tandem repeat length of the aggregate gene (39). In addition, the 5A5A and 5A6A genotypes of metalloproteinase-3 gene were associated with more degenerative findings in elderly individuals than those with the 6A6A genotype (40).

In animal studies, accelerated joint and intervertebral disc degeneration were observed in transgenic mice (COL9A1) based on X-rays and histologic methods. The spinal changes included shrinkage of the nucleus pulposus, anular fissures and herniations, and slight osteophyte formation (41). However, none of the known mutations in COL9A1 have been associated with disc degeneration in humans.

Although several gene forms associated with various aspects of disc degeneration have already been identified, it is likely that new gene forms associated with lumbar degeneration, pathology, and symptoms will be found over the coming years with the rapid growth in genetic research.

Several mechanisms have been suggested through which hereditary factors could influence disc degeneration and herniation. Genetic effects on the size and shape of spinal structures could affect the spine's mechanical properties, and thus its vulnerability to external forces (42). Biologic processes associated with the synthesis and breakdown of the disc's structural and biochemical constituents could be genetically predetermined, in part, leading to accelerated degenerative changes in some persons relative to others. The latter hypothesis has received some support from the recent findings of Annunen et al. and Paasilta et al. who found mutations in two collagen IX genes, COL9A2 and COL9A3, to be associated with disc pathology and symptoms (25,27).

### BACK PAIN

Much more than just structural variations need to be considered in genetic and other determinants of back pain. For example, genetic influences could affect pain through a variety of mechanisms dealing with structural, neurologic, inflammatory, other physiologic and behavioral characteristics.

The relative importance of genes versus experience in human pain perception remains unclear; in animal studies there are significant individual differences in both nociceptive and analgesic sensitivity. Yet such differences are not necessarily attributable to genetics. Most often the familial aggregation of pain has been attributed to shared environmental influences and familial modeling (43–46). MacGregor et al., in a classic twin study of sensitivity to forehead pressure pain threshold, found heritability estimates of only 10%, indicating that shared family environmental factors may be significant in pain thresholds (47).

### Classic Twin Studies Suggesting Genetic Susceptibility

Little is known about the role of genes in common low back pain problems or the pathways or mechanisms through which they may influence these problems. There have, however, been a couple classic twin studies suggesting a genetic component. Bengtsson and Thorson investigated possible genetic influences on back pain in a cohort of 5,029 monozygotic and 7,876 dizygotic Swedish twin pairs (48). Back pain was defined as an affirmative answer to the question, “Have you had so much back pain during the last few years that you found it difficult to work?” Such pain was reported by about 15% of this cohort of twins ranging from 15 to 47 years of age. Pain concordance among twins with similar physical work environments was higher among monozygotic (25%) than dizygotic (15%) twin pairs (except in men performing light work), leading the authors to conclude that there is a relationship between genetic factors and back pain (48). The Swedish data are reported by gender, workload, and zygosity, but not by age, which is unfortunate given the findings of Heikkilä et al. of a differential effect of heredity by age on sciatica and associated hospitalizations (24).

Another classic twin study using over 700 twin pairs was presented by MacGregor et al. at an American College of Rheumatology meeting in 1999 (49). They found a substantial genetic contribution to the occurrence of severe back pain, with genetic factors accounting for 73% of the variance in population liability. They also reported on a subset of 97 monozygotic and 234 dizygotic pairs that had MR images available for analyses and found that more than 50% of the total genetic variance in back pain remained unexplained by genes involved in MRI changes. This suggests that there are other mechanisms through which genes may influence back pain than simply through structural changes in the disc. Mogil has noted that pain is considered both a sensation and an emotion, with considerable complexity and subjectivity. Yet, pain is also being studied at the level of the gene (50). The aforementioned studies should motivate more studies of the roles and relative

contributions of cultural and genetic inheritance of back pain.

### OTHER SPINAL DISORDERS WITH GENETIC CONTRIBUTIONS

Genetic contributions have been suggested or identified for a number of other spinal disorders, such as scoliosis, Scheuermann disease, spondylolysis, spina bifida, and spinal stenosis. Several family studies indicate that heredity has a role in scoliosis. Nearly identical “mirror images” of congenital lumbar scoliosis for a brother and sister, and two sets of identical twins with concordant scoliotic curves have been reported (51). In one family study from 1975, scoliosis appeared in 15 members of a family in 3 generations (52).

Segregation analysis was applied to 101 pedigrees from Russia with idiopathic scoliosis (more than 10°) and to 90 pedigrees with Scheuermann disease. Using transmission probability models, a significant contribution of one major causal gene was established and inheritance could be described according to a dominant major gene diallele model for both diseases. The authors concluded that only the carriers of the mutant allele develop pronounced forms of the disease. For scoliosis, only 30% of males and 50% of females with the mutant gene should manifest the disease (53). All male carriers of the mutant allele develop Scheuermann disease, while only half of female carriers manifest the disease. The frequency of scoliosis in the families with Scheuermann disease was 8%. The authors concluded that the “familial aggregation of these two spinal pathologies in the present sample may indicate a genetic unity of Scheuermann disease and idiopathic scoliosis” (53,54).

Scoliosis can also be a consequence of other severe diseases such as Marfan syndrome, familial dysautonomia, spondylocostal dysostosis, congenital lordoscoliosis due to lumbar segmentation defects and incomplete formation of lumbar vertebrae, diastrophic dwarfism, and familial Rett syndrome (55–57). The occurrence of scoliosis in the presence of other hereditary connective tissue syndromes raises the possibility that idiopathic scoliosis and congenital scoliosis are in fact a heterogeneous group of disorders with varied pathogenetic mechanisms (58).

From a systematic review using different genome databases, there were three candidate loci for human scoliosis (58). Genome-wide linkage surveys in large multiplex families indicate concordantly a limited number of genetic loci predisposing to idiopathic scoliosis: three loci on chromosomes 6p, distal 10q, and 18q in one family and distal chromosome 10q on another (59). The role of genetic factors in the development of scoliosis has been well documented; however, reports of the specific mode of genetic inheritance are inconclusive. These facts, combined with the phenotypic variability of this disorder, suggest that the genetic expression of idiopathic scoliosis

may be dependent upon multiple factors and genetic interactions (60).

Spondylolysis also is suspected of having a genetic component. Spondylolysis was found in 13% of young Eskimos and in 74% of older Eskimos, a rate that is higher in the older age group than in other ethnic groups, leading Simper et al. to suspect a genetic influence (61). Several family studies support that there is an inheritance component in spondylolysis: 21% of descendants of a male ancestor with spondylolysis also had the condition, 4% had also spina bifida occulta. This pedigree was consistent with autosomal-dominant inheritance and incomplete (about 75%) penetrance for spondylolysis (56). One other survey identified 19% of relatives with spondylolysis (57). In addition, the reported cases of multiple lumbar spondylolysis could indicate the hereditary component (62–64). Spondylolysis can also be part of other syndromes, such as osteopetrosis, where other findings usually are clinically more important (65).

There are several reports about small case series indicating familial aggregation of spinal stenosis, commonly associated with a narrow cervical canal and disc herniations and sometimes with other congenital anomalies (66–69). Familial spinal canal stenosis has also been associated with autosomal-dominant osteosclerosis, and acrodysostosis (70). In addition, there are also case reports about hypophosphatemic vitamin D-resistant rickets as a cause of spinal canal stenosis (71).

## SUMMARY

The study of genetic influences on common spinal disorders is rapidly progressing. Studies of familial aggregation were an initial step along this line of inquiry. Familial aggregation, well beyond what would be expected by chance occurrence, has been found for outcomes such as hospitalizations for disc herniation in juveniles and adults, sciatica, back pain, and disc degeneration. Familial aggregation also has been found to be greater in younger than older subjects in the case of hospitalizations for disc herniation, which would be congruent with a genetic component to this condition. The classic twin studies reported to date also suggest a genetic component to common spinal disorders and in some cases, such as for disc degeneration, a substantial one that overshadows the role of suspected environmental risk factors. Specific gene forms associated with these conditions also have been identified, which may eventually provide key insights into the mechanisms underlying back disorders. Although the complex contributions and interactions of genetic and environmental factors are currently unknown, these are fertile areas for future research.

## CHAPTER 9

# Genetic Applications to Lumbar Disc Disease

Christian Lattermann, Lars G. Gilbertson, and James D. Kang

---

The etiology and pathophysiology of degenerative disc disease (DDD) are still unknown. However, it is believed, that it is the result of a complex interaction between biologic and mechanical factors.

New biologic techniques may allow for addressing intervertebral disc degeneration on a molecular level. Recent advancements in recombinant DNA technology have led to the decoding of many human genes that appear to be attractive for the scientific and clinical use in musculoskeletal disorders (1,2). Growth factors and embryogenic differentiation factors have been isolated and studied for many musculoskeletal conditions. Bone morphogenetic proteins (BMPs), for example, are successfully being used to enhance bone healing and fusion in humans (3). Other growth factors such as transforming growth factor  $\beta$  (TGF- $\beta$ ), or insulin-derived growth factor 1 (IGF-1) have been shown to be able to influence the proliferation and extracellular matrix production of various different musculoskeletal tissues (4–6).

After this brief overview we will introduce several novel approaches involving molecular genetic techniques and how their use can be advantageous for the treatment of DDD in the lumbar spine.

### **IDENTIFICATION OF GENES FOR TARGETED GENE MANIPULATION**

Intervertebral disc disease occurs because of a complex interaction of cells, cell products, inflammatory cytokines, and degradative processes occurring in the intervertebral disc. All of these to-date identified mechanisms are naturally occurring processes that are designed to maintain the intervertebral disc homeostasis. One or multiple unknown triggers mark the beginning of disc degeneration by causing a shift of the anabolic/catabolic equilibrium. The goal of any biologic therapy for DDD therefore must be to reinstate the equilibrium or slow down the shift of the anabolic/catabolic equilibrium.

In order to be able to identify the different pathways in which a gene therapy protocol would be able to intervene toward a slowing of the degenerative process one has to understand the process of disc degeneration. While there are still many secrets to be solved in the complex process of disc degeneration it seems that there is a fundamental concept of homeostasis that is gradually disrupted during the degeneration of the intervertebral disc. To facilitate the understanding of the complex process of intervertebral disc degeneration and the possible ways of therapeutic intervention one can group the different mechanisms responsible for maintenance of disc homeostasis into two major categories: nutritional and catabolic.

### **Nutritional**

One of the first steps in disc degeneration may be the increase in fibrochondrocytes along the annulus fibrosus. This increased fibrosis has been observed parallel to a decrease in diffusion of substances throughout the intervertebral disc. This in turn may be responsible for the declining oxygen tension within the intervertebral disc. A decrease in oxygen tension most likely will result in impairment of cellular function within the nucleus and thus may lead to a decrease in matrix synthesis. Decreased matrix synthesis will lead to a favored production of the smaller, less complex keratan sulfate shifting the equilibrium toward a higher concentration of nonaggregated proteoglycans that bind fewer water molecules (7–9). As a result, the overall capacity of the nucleus pulposus to imbibe water decreases. In addition there seems to be an abundance of smaller proteoglycan fragments that appear in early disc degeneration secondary to the collapse of adequate matrix proteoglycan production. These smaller, nonaggregate proteoglycans and breakdown products decrease the fluid flow throughout the disc and thus, even further inhibit the diffusion capacity of nutrients throughout the disc. This again lim-

its the oxygen tension and nutrient supply to and from the intervertebral disc cells.

A further cascade involved in disruption of normal disc homeostasis is the constant maintenance of different collagen types within the intervertebral discs. The intervertebral disc is predominantly composed of type I and II collagen. The annulus is predominantly composed of type I collagen fibers. Type II collagen is mainly found in the nucleus pulposus. The distribution shows a small gradient toward the periphery, with the concentration of collagen type II decreasing and type I collagen fibers increasing toward the annulus. Despite the fact that this collagen scaffold does not seem to change significantly during the aging process, DDD shows significant alteration of the collagen composition early on. In early degeneration more type I and II collagen is expressed, however, in tandem with an increase in minor collagen types (III, V, VI). During the course of further degeneration collagen type II will disappear in the nucleus and be replaced by collagen type I. The minor collagen types of fibrosis (III, IV, and X) become more abundant within the nucleus pulposus and gradually lead to a loss of elasticity.

### Catabolic

An inflammatory component has been discussed as a major entity in degeneration of the intervertebral disc. Nitric oxide (NO), interleukin-1 (IL-1) and 6 (IL-6), and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) are powerful inflammatory mediators which have been shown to be elevated in degenerated human intervertebral discs. Although the mechanisms are not fully understood to date NO, IL-6, and PGE<sub>2</sub> appear to be up-regulated in response to the main inflammatory cytokine IL-1. It is likely that these inflammatory mediators have multiple functions but one of their functions is to support the breakdown of proteoglycans mediated by degradative enzymes called matrix metalloproteinases (MMPs). These MMPs are a family of enzymes responsible for the breakdown of collagens and extracellular matrix. The MMPs include well-known enzymes such as, collagenase 1-3, gelatinases, stromelysin, or aggrecanase. These powerful catabolic enzymes are able to breakdown different sizes of matrix proteoglycans and collagens and show a significantly higher activity in degenerated intervertebral disc cells than in normal discs. It is surprising, however, that the actual amount of MMPs is not increased in the degenerated intervertebral disc. In fact, the increase in proteoglycan breakdown may be more likely a result of the lack of inhibition of the MMPs.

In a normal intervertebral disc MMPs are inhibited by molecules called tissue inhibitors of metalloproteinases (TIMPs). The concentration of these TIMPs is greatly decreased in degenerated intervertebral discs. This mechanism, therefore, suggests a breakdown of the anti-catabolic system within the intervertebral disc during degeneration.

Strategies that result in a net increase in proteoglycans may have therapeutic potential in altering the natural history of disc degeneration. These strategies could involve increasing the production of proteoglycans, blocking their catabolic degradation, or a combination of both.

### Possible Targets for Gene or Protein Transfer

One common way to increase the productivity of cells in the presence of impaired function uses small proteins called *growth factors*. These growth factors have the ability to override and steer cellular protein synthesis in less than optimal surroundings. Naturally occurring, these growth factors offer a way in which intervertebral disc cells can be influenced and guided to produce extracellular matrix and collagen when disc degeneration occurs and thus counteract the degradation of the intervertebral disc.

Several promising growth factors have been isolated which have the ability to increase extracellular matrix production and collagen production in intervertebral disc cells. Transforming growth factor- $\beta$  (TGF- $\beta$ 1) and bone morphogenetic proteins (BMPs) are two examples of growth factors (out of many) with strong potential for altering intervertebral disc (IVD) biology. Thompson et al. studied the *in vitro* response of canine IVD tissue to the following growth factors: human recombinant IGF-1, epidermal growth factor (EGF), fibroblast growth factor (FGF), and TGF- $\beta$ 1. Incorporation rates by the tissue regions of up to five times the control rate were reported, with the nucleus and transition zone responding more than the annulus. TGF- $\beta$ 1 and EGF elicited greater response than FGF, while IGF-1 produced only a marginally significant response in the nucleus and no response in the annulus and transition zone (10). Our group showed that the use of TGF- $\beta$ 1 and BMP-2 lead to higher levels of proteoglycan production in degenerative human and rabbit nucleus pulposus cells (6). Takegami et al. studied the effect of human recombinant osteogenic protein (hrOP-1) on cell proliferation as well as on proteoglycan production and collagen synthesis. They showed that there is a dose-dependent increase in proliferation rate as well as collagen and proteoglycan production of rabbit intervertebral disc cells treated with hrOP-1. They were also able to show the restoration of proteoglycan in previously proteoglycan-depleted cultures of intervertebral disc cells if they were treated with hrOP-1 (11). Our laboratory has just recently shown that the treatment of degenerative intervertebral disc cells with TIMP-1 will increase proteoglycan production and the rate of proteoglycan synthesis by a factor of 5.

However, the critically important issue for the delivery of growth factors is the length of therapeutic effect of these exogenous growth factors to targeted cells in the IVD. The normal half-life for most of these growth factors *in vivo* is approximately 20 minutes. Therefore, the therapeutic effect of injecting growth factors directly into the IVD may be too transient to have a major long-lasting

effect on a chronic disorder such as DDD, and repeated injections may not be practical or well tolerated by patients.

### THE CONCEPT OF GENE TRANSFER

A sophisticated way to deliver sustained levels of growth factors to musculoskeletal tissues has been shown to be gene transfer technology. Particularly, the use of viral vectors appears to be highly efficient in the delivery of the desired transgene to most mesenchymal tissues.

Gene transfer is a novel technique in which genes of interest are inserted into target cells, causing them to synthesize the protein encoded by the inserted gene. This technique can be used as an approach for treating genetic diseases by compensating for mutant genes or as a means of delivering a therapeutic substance to the area of interest.

Protein synthesis within a mammalian cell involves several steps. At first a gene, consisting of specific DNA sequence is transcribed into a complementary chain heterogeneous to nuclear RNA. This is then processed into messenger RNA (mRNA) by a series of modifications that include capping, splicing, and the addition of a polyadenosine tail. The mature mRNA leaves the nucleus of the cell and is translated by ribosomes into a sequence of amino acids that form the protein. When an exogenous gene is introduced into the nucleus of a cell, it is also transcribed into mRNA and thus produces the protein encoded by the gene. The cell may normally not make this protein of interest, or it may be made in insufficient amounts. There are different techniques available that aid the insertion of a foreign gene into the genome of a mammalian cell. Gene transfer to cells normally requires the assistance of a vehicle or vector, which may be viral or nonviral in nature. The nonviral techniques typically use small particles like liposomes or spheroblasts carrying the gene of interest. These particles have the ability to fuse with the target cell or to enter the cell by endocytosis. Other techniques like elec-

troportation and microparticle bombardment use physical strain or electric shock in order to break small temporary defects into the cell wall without severely damaging the cell, allowing the DNA strand to travel into the cell. Another approach uses a direct microinjection of the gene into the cell. These methods tend to be inefficient (5).

Viral-based vectors generally use the inherent capacity of a virus to attach to the surface of a cell, through specific receptors, and insert its genome into the cell (Fig. 9-1). For safety reasons the viral vector must be altered to render the virus incapable of replicating. Hence viral vectors are engineered such that endogenous gene sequences required for replication and pathology are removed. The ideal viral vector therefore carries the genes of interest into cells with high efficiency, but does not replicate or cause pathology.

By far the most commonly used vectors are retroviral and most are based upon the Molony murine leukemia virus. Retroviral vectors specifically infect dividing cells with a very high efficiency. They insert their genes into the chromosomes of the target cell. This leads to reproduction of the inserted gene each time the infected cell divides. Clinical trials have already been successfully initiated using retroviral vectors. Although retroviral vectors are the most commonly used vectors in human clinical trials at present, there are certain disadvantages in their use. For example, retroviruses do not infect nondividing cells. Furthermore, there is a theoretical risk of mutagenesis due to the random integration of the viral DNA into the chromosome of the target cell. If chromosomal integration occurs near a site of an oncogene, activation may occur causing the cell to transform. Because of this potential risk, most investigators have used the retroviral vectors in an *ex vivo* approach (discussed later in the chapter). Presently, however, there are no reports of malignancy caused by gene therapy using retroviral vectors.

The second most commonly used viral vector is derived from the adenovirus. This is a DNA virus that is highly infectious to a number of different cell types. The

**FIG. 9-1.** The DNA coding for a growth factor is engineered into a vector (i.e., adenoviral vector capsid). The vector is applied to the tissue or cell culture and attaches to the cell membrane. The DNA is inserted into the cell and travels to the nucleus where it integrates episomally or integrates into the chromosome. The inserted DNA then uses the regular transcription and translation process of the host cell and is translated into the protein of interest. The treated cell now begins to produce the protein of interest in high amounts.

adenoviral vector infects dividing as well as nondividing cells and can be prepared in high titers. In contrast to the retroviral vectors, the genome of the adenoviral vector is not integrated into the chromosome of the target cell. The adenoviral vector inserts its genome as an episome within the nucleus of the target cell. Thus, the inserted genes will not be automatically passed on during cell division. As a result the percentage of infected daughter cells will rapidly decrease as a result of dilution with every cell generation. However, adenoviral vectors are highly antigenic and initiate strong immune responses. Likewise, herpes viral vectors, which have the capability of including multiple transgenes, are also antigenic and often cytotoxic to the host cell or tissues. Currently, new generations of viral-based vectors are under development. These will increase the efficiency of transduction of both dividing and nondividing cells. The most promising of these are based upon adeno-associated virus (AAV), the herpes simplex virus (HSV), and the lenti-retrovirus. These vectors show a high infectivity and may provide a long-term expression. The goal is to generate new viral vectors which can escape the surveillance of the host immune system and which can express the desired gene product in a tissue-specific manner.

Gene transfer can be accomplished by two main approaches, *ex vivo* or *in vivo*, in order to transduce target cells.

The *ex vivo* approach transduces target cells after harvest and culture *in vitro* under sterile conditions. The cells are transduced and selected in culture and then prepared for injection into the recipient tissue. Because no viral particles enter the human body, *ex vivo* gene therapy provides a measure of safety that is not found with *in vivo* gene delivery.

*In vivo* transduction is a more straightforward procedure. The vector is directly applied into the tissue of interest by catheter or needle injection. This approach however, does not allow control over the rate of target cell transduction. Due to the direct introduction of viral particles into the body, safety concerns are higher. The choice of the approach to achieve target cell transduction is dependent upon the desired longevity of gene expression, the viral vector chosen, the anatomy and physiology of the target organ, safety considerations, and the underlying cause of the disease to be treated. Generally, the *ex vivo* approach is usually employed when using retroviral vectors because of the necessity for high rates of cell division and safety concerns surrounding the injection of retrovirus into the body. Due to their high infectivity and ability to infect nondividing cells, adenoviral vectors are often used experimentally in the *in vivo* approach (5).

### Gene Transfer to the Intervertebral Disc

Several authors have previously shown successful transfer of exogenous genes to musculoskeletal tissues. In

our laboratory we have pioneered the viral gene transfer to the intervertebral disc using adenoviral and retroviral gene transfer protocols.

Wehling et al. reported the successful gene transfer of the LacZ marker gene as well as the interleukin receptor antagonist gene (IRAP) to bovine intervertebral disc cells (12). Subsequently, Nishida et al. performed a study which showed that the adenoviral transfer of the LacZ marker gene to the rabbit intervertebral disc is feasible and will lead to long-term expression of the marker gene (13). This has since been proved to be the case with different viral vectors including AAV (Figs. 9-2 and 9-3A,B). Surprisingly the intervertebral disc allowed for long-term gene expression after use of an adenoviral vector, suggesting that the intervertebral disc may be an immune-privileged site within the human body. This observation has since been underlined by Park et al. He found an unusually high expression of FAS ligand, a suppressor of cellular immunity, within the intervertebral disc (14). In a follow-up study Nishida et al. transferred the gene for TGF- $\beta$  to rabbit intervertebral discs *in vivo* and could show that the overall proteoglycan production of the intervertebral disc cells increased (15). Moon et al.

**FIG. 9-2.** *In vitro* transduction of human intervertebral disc cells with two different viral vectors. The adeno-associated virus vector (AAV) and the adenoviral vector (*ad*) both transfer the LacZ marker gene to human intervertebral disc cells. Both viruses show a clearly dose-dependent transduction efficacy. The adenoviral vector is overall more efficient. Adenoviral vectors have the advantage of efficient transduction of nondividing cells. The AAV shares this advantage but in addition is much less immunogenic and is not associated with any known disease in humans. Thus, the AAV vectors may be potentially safer than adenoviral or retroviral vectors.

**FIG. 9-3.** *In vivo* transduction of intervertebral disc cells in rabbits can be achieved using a simple injection technique. Adenoviral gene transfer of the LacZ marker gene (**A**) at 6 weeks can be traced as long as 1 year post-injection. The *in vivo* delivery of the LacZ marker gene using the novel AAV vector (**B**) can be detected for at least 6 weeks post-injection.

investigated the effect of different growth factors transferred to human intervertebral disc cells using an adenoviral vector. He showed synergism between the expression of TGF- $\beta$ , BMP-2, and IGF-1 with respect to the overall proteoglycan production in culture (6). In a recently published study Yung et al. applied a pellet culture technique in order to grow intervertebral disc cells in a three-dimensional matrix. Transduction of these pellet cultures with an adenoviral vector coding for the BMP-2 gene led to an increase in proteoglycan synthesis and total proteoglycan content (16).

### FUTURE PERSPECTIVES

Clearly there are still many obstacles to overcome before a viral or nonviral gene transfer protocol can be used as a viable treatment option in DDD. Molecular biologists and surgeons, however, are feverishly working to develop safer methods of gene transfer in order to be able to influence the biologic environment within soft tissues such as the intervertebral disc. We know from animal experimental data that the approach is feasible *in vivo*. Safety studies are currently underway to determine if these technologies may be applicable to humans.

In addition to the development of novel and safe vectors researchers are developing new models to mimic intervertebral discs *in vitro* and *in vivo*.

Finally, it is important to understand the goal of any therapeutic approach to disc degeneration. The major issue to overcome at this time is still the early detection of disc degeneration. Questions that need to be answered, address the time course of degeneration. When is a disc too degenerated for therapy? How much regeneration potential does a degenerated disc have? How well does the magnetic resonance image signal change correlate with the biologic activity of the intervertebral disc? All these questions will have to be addressed before a broad-

based attempt to treat this disease using gene therapy can be made. As of now, we still do not know the exact cause of disc degeneration. It is certainly not feasible to prophylactically treat all degenerated discs at all levels with a gene therapy approach. It is therefore important to focus treatment using this new technology to very limited and clearly defined problems. One of these problems, for example, is disc degeneration occurring above and below fusions in the lumbar or cervical spine. At the time of fusion an injection into the adjacent discs could be performed without any problems.

In conclusion, gene transfer technology offers a sophisticated way to influence the biochemical environment inside the degenerated intervertebral disc and may be a useful tool to treat this highly prevalent disease in the future. The transfer of growth factors to the intervertebral disc may be able to limit disc degeneration or it may be able to prevent disc degeneration if the gene transfer is done prophylactically at a junctional level at the time of posterior spinal fusion. Viral or nonviral gene transfer is an emerging technology that will be able to offer exciting new perspectives in research and treatment of intervertebral disc disease.

## CHAPTER 10

# Clinical Neurophysiologic and Electrodiagnostic Testing in Disorders of the Lumbar Spine

Jiri Dvorak and Scott Haldeman

---

Patients with symptoms related to the lumbar spine can be differentiated into two groups: those with neurologic deficits and those with more benign pathology causing pain. This differentiation carries significant clinical importance when considering prognosis as well as the necessity for nonsurgical or surgical intervention. The patient presenting with neurologic findings suggestive of a spinal cord or cauda equina lesion may represent a medical or surgical emergency. Patients with acute or progressive radiculopathy may respond to nonsurgical care but require more intense investigation than the patient without radiculopathy and may benefit from surgical decompression.

Patients with chronic neurologic lesions carry a poorer prognosis than appropriately treated patients with acute neurologic deficits. For this reason the documentation of neurologic deficits is one of the primary goals of the diagnostic process when evaluating patients with disorders of the lumbar spine.

When neurologic deficits are noted on examination of patients with lumbar radicular pain syndromes due to disc herniation or stenosis there may be a discrepancy between clinical and neuroradiologic imaging (magnetic resonance imaging, computed tomography, myelogram) findings. Furthermore, virtually all forms of nondestructive pathology noted on an imaging test can exist in the absence of symptoms. This can make it difficult to identify the particular nerve root or spinal cord level responsible for the patient's complaints. In other patients the clinical examination may be equivocal and there may be considerable doubt regarding the presence of neurologic deficits when patients present with vague nonspecific sensory or motor symptoms in the lower extremities.

Neurologic deficits in the lower extremities, even in patients with low back pain, may represent disorders that

are not related to the lumbar spine. There are a number of compression lesions such as peroneal neuropathy and tarsal tunnel syndrome that can mimic radicular clinical pictures, especially if the symptoms are diffuse or the clinical examination is superficial. Surgery to the lumbar spine in these patients is unlikely to be of any benefit in reducing such deficits.

A surgeon contemplating surgery often has to answer two questions. The first is the determination of the presence and degree of neurologic loss. The second is the level of a spinal cord lesion or the nerve root that may respond to decompressive surgery. If there is close concordance between clinical and imaging findings there is no need to consider further testing. However, in cases where imaging and clinical findings are not in complete agreement, the surgeon may require additional testing in order to make the correct decision on whether to operate and at what level surgery should be contemplated. It is in these cases, where there is doubt as to the presence of neurologic deficits or the level of such deficits, that neurophysiologic and electrophysiologic tests can become important in the diagnostic process.

There still remain some questions related to the sensitivity, specificity, and positive predictive value of certain electrophysiologic tests that often raise unreasonable expectations for these tests. There has also been a trend toward the indiscriminate ordering of batteries of tests in patients with sciatica. This has often led to confusing results that may not be of much help to the treating physician. Despite these shortcomings, the use of electrodiagnostic testing has become routine in most clinical settings that treat patients with disorders of the lumbar spine. This chapter will attempt to outline the most common electrophysiologic tests and to describe how they can be of the

most value to both surgical and nonsurgical treating physicians.

### ELECTRODIAGNOSTIC TESTING

Electrodiagnostic testing can be divided into three distinct areas of interest.

1. *The investigation of a suspected radiculopathy.* This is often the primary goal of electrodiagnostic testing. In this setting the testing is used to document the presence of and the level of a radiculopathy as well as to give some indication of the chronicity of the neurologic loss. The mainstay of this testing is electromyography (EMG). Electromyography, however, can be supplemented by the use of H-reflexes and possibly F-responses in order to make the testing more meaningful.

2. *The investigation of myelopathy.* The presence of symptoms suggestive of a myelopathy may represent a medical emergency and may have to be confirmed in a confusing clinical setting. Somatosensory evoked potentials (SEPs) and motor evoked potentials (MEPs) are most commonly used to investigate conduction within the spinal cord. SEP-techniques can be used to evaluate the sensory pathways within the spinal cord whereas MEPs allow for assessment of lesions that affect motor neuron pathways. Both SEPs and MEPs, however, are impacted by lesions that affect nerve roots as well as the lumbosacral plexus and depend on the integrity of peripheral nerves for accurate recording. This can make it difficult to interpret these tests if more than one lesion is present in a patient.

3. *The differentiation of proximal nerve root lesions from other peripheral or entrapment neuropathies.* The primary tool for this process is peripheral motor and sensory nerve conduction studies or conventional neurography (electronystagmogram, or ENG). It is often necessary to supplement these studies or at least correlate findings from ENG studies with F-wave, H-reflex, and EMG findings. Electromyography of limb and paraspinal muscles, for example, may allow a distinction to be made between lesions affecting motor roots and more peripheral nerve elements. Electroneurography, F-wave, and H-reflex studies may be the only manner to distinguish between proximal root and peripheral nerve disease with a high degree of confidence.

### SEPS

SEPs can be recorded over the scalp adjacent to the sensory cortex on electric stimulation of the large mixed motor-sensory nerves, small sensory peripheral nerves, or the skin over specific dermatomes. Responses can also be recorded on magnetic stimulation of paraspinal and peripheral muscles. The recording of these potentials, due to their small amplitude in comparison with the background electrical noise, requires the computer averaging of multiple responses. Most laboratories will

record simultaneously the sensory action potential within the peripheral nerve and, where possible, a response over the lower lumbar spine. The latter, however can be difficult in older patients and especially in overweight patients.

The nerves most commonly used for the diagnosis of spinal cord lesions are the large mixed sensory-motor posterior tibial and common peroneal nerves of the lower limbs usually at the level of the ankle. The absolute latency of scalp response and the difference in latency of the responses from the two legs can be used as an indication of reduced conduction within the spinal cord. By recording the peripheral sensory nerve conduction and measuring the height of the patient, it is possible to calculate the expected normal latency. If a spinal response is obtained, a central conduction time can be calculated by subtracting the latency of the spinal response from the latency of the cortical response.

Attempts to diagnose radiculopathy by stimulating dermatomes and small sensory nerves have led to disappointing results and suggest that the sensitivity, specificity, and reliability of SEPs in radiculopathy is not sufficient for general use. These tests are also very time-consuming and technically challenging as the responses have much smaller amplitude than those obtained from larger nerves. The use of mixed nerve responses is very insensitive in the diagnosis of radiculopathy because both the posterior tibial and peroneal nerves contain fibers from multiple nerve roots. However, in patients with multilevel radiculopathy or plexopathy marked abnormalities can be seen on stimulation of these large nerves.

SEPs have, however, been shown to be of value in documenting cauda equina and spinal cord lesions that affect bowel, bladder, and sexual function. In these patients cortical evoked potentials and bulbocavernosus reflex responses on stimulation of the pudendal nerve may give some indication whether the bowel, bladder, or sexual dysfunction is due to a lesion within the spinal cord or more peripherally within the nerve root and pudendal nerve.

### MEPS

Barker et al. first introduced the method of painless magnetoelectric transcranial stimulation of the cerebral cortex in 1985 (1,2). They applied short magnetic pulses to the scalp produced by a device designed to stimulate peripheral nerves, and recorded muscle action potentials from upper and lower limb muscles. The magnetic field produced by this instrument passes through scalp and skull to stimulate the cerebral cortex. Magnetoelectric stimulation can also be used to stimulate deep-lying proximal segments of peripheral nerves and nerve roots (3), thus allowing for evaluation of central and proximal peripheral pathways. This equipment has also been used to stimulate paraspinal muscles and record cortical evoked potentials that can be influenced by muscle spasm.

The muscles most commonly used for recording cortically evoked MEPs in the lower extremities are the quadriceps, tibialis anterior, gastrocnemius, extensor hallucis, and abductor hallucis muscles (4). Surface recording electrodes are placed over the motor end plate. The segmental innervation of these muscles is used to determine the level of the lesion.

When recording MEPs on stimulation of motor roots at the lumbar spine, the intensity of the stimulator must be adjusted so that a potential with a steep negative rise can be recorded. In this situation the onset latency is not critically dependent on the positioning of the coil or the stimulation strength (3). The site of excitation of the nerve root is most probably the nerve root as it exits from the intervertebral foramen (3).

In order to interpret the MEP waveform it is necessary to obtain an M-wave recording by means of conventional neurography. The M-wave is the electric potential recorded from the muscle in response to a supramaximal stimulus of the peripheral nerve. This provides a measure of muscle electric response "size" (5) and is used as a reference signal with which transcranial stimulation MEP amplitude and duration are compared (i.e., MEP amplitude and duration are expressed as ratios of M-wave amplitude and duration).

### F-WAVES

F-waves are long latency responses recorded over distal muscles on stimulation of motor nerves innervating the muscle. This is achieved through the stimulation of a Renshaw cell in the anterior horn of the spinal cord through antidromic stimulation of the motor nerve. Distinct left-right latency differences that exceed normal values or a reduced number of F-waves after a given number of supramaximal peripheral stimuli in the presence of normal distal motor conduction can be a sign of a proximal neuronal lesion in the sciatic plexus or nerve root. F-waves, however, must be interpreted with caution. The F-wave is often normal in mild cases of radiculopathy, especially if only one nerve root is involved.

In conjunction with MEPs, however, F-wave recordings may give information about conduction times in motor fibers within the proximal segments of spinal nerves that may be compressed by a disc herniation. F-wave recordings allow for the determination of peripheral nerve conduction time or peripheral latency (PL), the time it takes for impulses to travel from the anterior horn cell to the muscle. This latency includes conduction over the motor root from the spinal cord through its exit from the intervertebral foramen to the muscle where it is recorded. Calculation of PL is especially important in lumbar spine disorders where motor roots measure 10 to 20 cm (6) and contribute considerably to peripheral latency. F-wave recordings can therefore help localize the site of a lesion (7).

### H-REFLEX

The H-reflex was first described by Hoffmann in 1918 (8). It is a reflex motor response within a muscle elicited on electric stimulation of large, low-threshold sensory nerve fibers within the nerve from that muscle. The response on stimulation of this nerve results in excitation of the motor neuron pool that innervates the muscle (from which the H-wave is recorded) through the same nerve. It is a monosynaptic reflex response that has a strong correlation with the tendon jerk but bypasses the muscle spindles.

In adults the H-reflex is recordable in a limited group of extensor muscles, especially the soleus/gastrocnemius muscles in the calf innervated by the S1 nerve root. Low-amplitude voluntary muscle contraction may facilitate the H-response (9). Stimulation of the tibial nerve at the knee with slowly increasing intensity from subthreshold to submaximal levels allows for recording of H-responses with increasing amplitude from the soleus muscle. Further increase in stimulus intensity elicits M-waves of increasing size, while the H-reflex diminishes progressively and is eventually replaced by the F-wave on supramaximal stimulus intensity. H-reflexes and F-waves have similar latencies when stimulus and recording sites are at the same location. S1 sensory or motor root deficits reduce H-responses and increase their latency. Right/left latency differences can be a sensitive indicator of unilateral S1-radiculopathy. Braddom et al. and Aiello et al. noted a 90% to 100% true-positive rate and 0% true-negative rate in S1 radiculopathies using the H-reflex from the soleus/gastrocnemius muscles (10,11).

### EMG

EMG performed with concentric or monopolar needle electrodes is the oldest and the most widely used neurophysiologic test for the diagnosis of nerve root compression syndromes (12). It is often used as an extension of the physical and neurologic examination and the muscles selected for testing are usually selected based on the clinical findings (Fig. 10-1).

Needle EMG requires the physician to study the muscle under different conditions of muscle contraction. Four specific forms of electric muscle activity are recorded and noted for each muscle tested:

1. *Insertional activity* is evaluated at the time of insertion of the needle into the bulk of the muscle and at each repositioning of the needle electrode within the muscle. It is common practice to sample muscle electric activity at 10 to 20 locations within the muscle.

2. *Spontaneous activity* is studied with the muscle at rest. At each location within the muscle, the needle electrode is maintained in a stationary and stable positioning and muscle electric activity is recorded with the muscle at rest. This allows for the detection of abnormal electric activity such as fibrillation potentials and positive sharp

**FIG. 10-1.** Electromyogram with concentric needle electrode from tibialis anterior muscle

waves that are indication of acute denervation of the muscle (Fig. 10-2).

3. *Single motor unit action potentials* (MUAPs) are recorded during light voluntary contraction of the muscle and examined with respect to amplitude, duration, and number of phases of the electric potentials. An average of 20 MUAPs are commonly evaluated and can vary slightly from muscle to muscle.

4. *Motor unit recruitment* and the *interference pattern* are recorded during a gradual increase of voluntary muscle contraction and during maximal voluntary contraction to obtain a crude indication of the degree of muscle loss following denervation (Fig. 10-3).

In normal muscles, MUAPs are only seen during voluntary muscle contraction. The membranes of denervated muscle fibers become unstable and sensitive to mechanical or chemical irritation. This results in increased insertional activity and spontaneous activity that can be recorded in the absence of muscle contraction. These signs of denervation noted on EMG testing become evident at about 14 to 21 days after the nerve lesion. As the nerves to paraspinal muscles are shorter than those traveling to distal muscles, the spontaneous activity is first seen in paravertebral muscles followed by proximal and then distal muscles of the leg. These potentials represent signs of *acute* denervation of the muscle.

The analysis of single MUAPs may reveal characteristics that are typical but not specific for lower motor neuron injury that can occur in radiculopathy. The finding of increased amplitude, increased number of phases, and increased duration of the motor unit potentials are classically seen only after reinnervation of denervated muscle fibers as the result of sprouting from adjacent unaffected fibers. These changes are therefore termed signs of *chronic* denervation or reinnervation. Decreased motor unit recruitment and discharge are crude signs of the degree of neuronal loss as the result of radiculopathy.

### SENSITIVITY AND SPECIFICITY OF NEUROPHYSIOLOGIC TESTING

There are numerous problems in the interpretation of published research studies that have looked at the sensitivity and specificity of the different electrodiagnostic tests. The primary difficulty is the determination of a gold standard for comparison. The studies that have been published have attempted to correlate the tests with either clinical examination findings, imaging studies such as computed tomography (CT), magnetic resonance imaging (MRI) or myelography, or the observation of nerve root compression noted during surgery. The difficulty in attempting to correlate electrodiagnostic testing with the clinical examination is that many clinical findings such as motor and sensory changes can be equivocal and influenced by pain that the patient may be experiencing. There may also be a fair degree of interobserver differences noted in neurologic clinical findings, especially among nonneurologists, that can make it difficult to interpret these results. The difficulty in using imaging studies such as CT, MRI, or myelography as a gold standard is that virtually all findings considered abnormal on these studies, including some of the most severe lesions that appear to be causing neuronal compression, can be seen in the asymptomatic population with a normal examination. One of the primary reasons for conducting the electrodiagnostic testing is to document the significance of a suspected compressive lesion. It therefore does not make sense to use imaging studies as the gold standard. The problem with surgical observation is that there is considerable subjectivity on the part of the surgeon in documenting the presence of root compression and the sur-

**FIG. 10-2.** Summary of different typical spontaneous activity from denervated tibialis anterior muscle as shown in Figure 10-1 (1, sharp positive wave; 2, fibrillation; 3 and 4, fasciculation).

**FIG. 10-3.** Motor unit recruitment (interference pattern) during voluntary reduced contraction from denervated tibialis anterior muscle.

geon often does not have full visualization of the root or explore all potential nerve roots, especially in the newer minimally invasive procedures.

A number of studies however have attempted to address the issue of sensitivity and specificity of the neurophysiologic assessment of nerve root compression syndromes when compared to clinical, imaging, and surgical findings (13–15). The results of these studies have varied greatly from as little as 20% to as much as 90% or better correlation. The often markedly different results reported in other studies is due, in part, to the different electrodiagnostic tests used, the number of electrodiagnostic tests studied, and the basis of documenting the lesion (clinical, imaging, or surgical). The greater the number of electrodiagnostic tests used and the greater the number of tests the more sensitive the study is likely to be, but at the same time the results are likely to be less specific as each test has its own unique level of accuracy. The less precise the imaging or clinical finding the less likely that a correlation will be found.

These studies have been reviewed in detail by a number of authors and we will simply discuss a few of these papers to illustrate this point. Tullberg et al. (16), for example, looked at a series of electrodiagnostic tests in 20 patients who had undergone lumbar surgery for CT-documented disc herniations. They used a wide variety of tests including standard-needle EMG, F-wave responses on stimulation of the peroneal nerve (L5 root), and tibial nerve (S1 root) and dermatomal SEPs. They compared these studies with clinical neurologic findings such as motor, sensory, or reflex changes, CT scan results, and surgical observation of root compression. Using multiple diagnostic tools and multiple points for correlation, it is not surprising that these authors found poor reliability to predict results using electrodiagnostic testing. They noted that clinically only 4 patients with documented root compression on CT scan had motor loss and only 10 had sensory loss with very little correlation between the different findings on clinical examination. They noted that 13 of the 20 patients had abnormal electrodiagnostic test results but the correlation between tests and between tests and CT findings was low. As expected EMG was the most sensitive of these three testing methods for determining the presence of radiculopathy (45%) but it was less sensitive in determining the level of the disc protrusion (20%). The sensitivity of the F-wave to document the

presence of a root lesion noted on CT or surgery was 35%, which is in agreement with other investigations (17–20). However, the results were again unreliable in predicting the exact level. These authors concluded that there was no correlation between electrodiagnostic studies and the outcome of surgery.

The lack of correlation between electrodiagnostic studies, clinical findings, and imaging was studied by Halderman et al. in 100 patients with chronic low back and leg pain who were undergoing disability evaluations for work-related injuries (21). The most revealing part of this study was the lack of correlation between clinical findings and imaging studies. The conclusion was that, in patients with chronic persistent back pain, there is a breakdown in the correlation between the clinical presentation and pathology. This makes it difficult to use patients with chronic pain complaints as a means of determining the reliability of any test in documenting disability.

Most studies, however, that have looked at the correlation of a single electrodiagnostic test and a specific clinical or imaging finding have found a correlation of between 75% and 85% in the documentation of radiculopathy (22,23). The results of Toyokura et al. (24), who looked at patients with a well-defined lesion rather than conduct a global study, conflict markedly with the results of Tullberg et al (16). Tokoyura et al. found that there was a significant improvement in F-responses after surgery that correlated with the improvement of muscle weakness after surgery.

There has also been a fairly high correlation between electrodiagnosis and the evaluation of muscle or motor function. Carter and Fritz compared EMG findings of acute denervation in patients with MRI findings of root compression (25). They compared the findings on EMG with the findings on short-time inversion recovery (STIR) MRI of the muscles affected by the nerve roots. STIR MRI has been noted to have a strong correlation with peripheral nerve injury that causes denervation and associated muscle edema. They noted a 92% correlation between denervated muscle on EMG and that was noted on STIR MRI. Zsu et al. provided more evidence of a close correlation between different electrodiagnostic tests and gave some indication how they could be used (26). They noted that in 227 patients with signs of acute denervation on EMG due to radiculopathy 47% of patients with L5 radiculopathies had an abnormal peroneal nerve F-wave. There was an abnormal H-reflex in 73% of cases with a S1 radiculopathy. The posterior tibial F-response was less sensitive showing only a 23% abnormal rate in patients with an S1 radiculopathy. They found no false-positive results. These authors believe that the use of long latency responses is primarily to confirm the findings on EMG and more accurately define the level of the lesion, but they also believe that these tests should not be performed without EMG because of the large false-negative results of using F-waves as a freestanding test.

Tullberg et al. (16) found that dermatomal SEP showed only 15% reliability in documenting the level of a root lesion, a finding that has been observed in a number of other studies. The studies of Dermatome Sensory Evoked Potentials (DSERs), however, have given conflicting results that have fueled considerable controversy over the use of these tests. Yazicioglu et al. found that these tests were misleading in 27% of patients and predicted the presence and level of the lesion in only 7.2% of patients (27). This has led many authorities, including the American Academy of Neurology, to issue statements that DSERs do not add anything significant to the electrodiagnostic evaluation of radiculopathy (19). This has not, however, eliminated the controversy. Pape et al. recently reported a strong correlation between SERs and subsets of patients with sciatica (28). They found a strong correlation in patients with sciatica due to facet joint hypertrophy causing nerve root compression with or without disc pathology.

Studies on combining motor and sensory evoked responses that theoretically would increase reliability have also been disappointing. For example, Vohanka and Dvorak (29) correlated the neurophysiologic findings with CT or MRI findings of the lumbar spine. The quantitative analysis of motor unit potentials showed 30% sensitivity in patients with radiculopathy, but without motor deficit. The MEPs and SEPs combined reached sensitivities of 55%, but the MEPs had 75% false-negative findings.

One of the difficulties in electrodiagnostic studies has been the lack of lower extremity muscles and easily accessed peripheral nerves that can be tested for high lumbar disc herniations. Haig et al. (30, 31) has been studying the sensitivity of needle EMG of paraspinal muscles using a very precise mapping technique in fairly large samples of patients with and without low back pain and radiculopathy. They found that patients who are clinically normal have few if any EMG abnormalities in the paraspinal musculature despite a high incidence of abnormalities found on CT and MRI (32) in asymptomatic subjects. However, patients with radiculopathy as documented on pain drawings had a high degree of correlation with denervation in needle EMG of paraspinal muscles. The authors recommend EMG mapping of paraspinal muscles to rule out false-positive imaging studies. They found that the combination of paraspinal EMG mapping and lower extremity EMG showed a very strong correlation with imaging of root compression with a false-positive rate of only 8% and a false-negative rate of only 5%. In the small subset of patients with lack of correlation between imaging studies and electrodiagnostic testing it is still not possible to indicate the more reliable test for determining the presence of clinically significant radiculopathy.

Correlation between axial CT imaging and narrow spinal canal and electrophysiologic conduction studies has been prospectively evaluated in 132 patients by Vohanka et al. (33). Neurogenic claudication was initially

declared by 59% of the patients. Twenty-six patients had one level, 68 had two levels, and 37 had three levels of central stenosis. No statistically significant relationship was found among the number of levels of the stenosis and the nerve conduction studies. However a significant relationship was found between minimum sagittal spinal canal diameter and the delay of central conduction time by transcranial magnetic stimulation. A similar correlation was detected in amplitude of the H-reflex and minimum transversal diameter.

Adamova et al. (34) introduced an exercise treadmill test in patients with mild lumbar spinal stenosis. It is a simple examination that can verify walking capacity and confirm neurogenic claudication described by the patient. Unfortunately an extensive electrophysiologic testing (H-reflex, F-response, MEP) and the analysis of obtained data before and after the treadmill test did not show significant changes in comparison with control groups.

## CONCLUSIONS

There are ongoing studies that will hopefully clarify some of the difficulties clinicians have in interpreting imaging and electrodiagnostic testing. At this time, however, it is clear that it is not possible to take any one clinical finding, imaging study finding, or electrodiagnostic test out of context with other studies or findings. The most accurate method of determining the presence of a neurologic lesion is to conduct the electrodiagnostic test in conjunction with the other tests and clinical findings.

It is increasingly being recommended that the ideal approach to the study of radiculopathy is the electrodiagnostic consult by a specialist rather than the electrodiagnostic test by a technician. In this situation the electrodiagnostic specialist performs a history and examination of the patient and reviews all imaging studies. The determination of which electrodiagnostic test should be performed is based on the questions that arise from the examination of the patient.

If the clinical picture is clear, it may not be necessary to perform any testing. If there is concern as to whether an obvious radiculopathy is acute or chronic it may be sufficient to perform only needle EMG to look for signs of acute denervation or chronic reinnervation patterns. If there is concern as to whether a specific lesion on imaging is causing a radiculopathy then it may be important to include H-reflex or peroneal F-wave studies for the documentation of an S1 lesion or F-responses if polyradiculopathy is being considered. Paraspinal EMG mapping may be most appropriate when an upper lumbar radiculopathy is being considered. If there is confusion as to whether a neurologic deficit is due to a peripheral metabolic or entrapment neuropathy then it becomes necessary to consider nerve conduction studies. If there is consideration of a myelopathy or cauda equina lesion then somatosensory evoked responses, bulbocavernosus reflex

responses, or cortical motor evoked responses may be necessary. It may be necessary to consider other neurophysiologic tests such as cystometry, nocturnal penile tumescence, or specific tests of the autonomic nervous system not mentioned in this chapter in order to obtain a clear picture of the nature of the neurologic lesion causing a patient's symptoms.

It is the tailoring of the clinical neurophysiologic test to the patient and, in particular, the clinical question being asked that gives these tests their greatest value. The more qualified the specialist performing the test and the manner in which the tests are correlated with the clinical findings the more reliable the testing can be considered. The indiscriminate use of electrodiagnostic testing by technicians (even when a physician is acting as a technician) appears to be the primary reason for the variation in the results in the different studies. It is hoped that the evolution of the ordering of electrodiagnostic testing into the requesting of a consult with a clinician with the capability to examine a patient, review the imaging studies, and determine the testing approach most likely to answer specific questions will lead to the answers to questions commonly asked by surgeons and other clinicians attempting to determine whether a patient with low back symptoms has a radiculopathy, myelopathy, or other neurologic lesion.

## CHAPTER 11

# Sensorimotor Control of the Lumbar Spine

Sten H. Holm and Aage Indahl

---

### ETIOLOGY OF LOW BACK PAIN

Low back pain has probably been an integral part of most human lives through the ages. Tattoos on the back of the “Iceman” recently found in the Swiss Alps have been interpreted as a possible treatment for low back pain. At the beginning of the 20th century, the sacroiliac joint was thought of as the main pain generator of the back, and sacroiliac dysfunction was described (1). With the passing of time, other structures have come into focus. The term “facet syndrome” was coined in 1933 by Ghormley, although the meaning was different from that of today (2). It is still an undefined entity as is the “sacroiliac syndrome” (3). The major breakthrough came in 1934 when Mixter and Barr described how herniated nucleus material from the intervertebral disc, pressing on the nerve root, was the cause of sciatic pain (4). Although many details are now known about what Mixter and Barr described, it is still not fully understood why disc herniations occur. The mechanisms behind spinal disorders can either act as single variables or in combination. Derangement in the lumbar intervertebral disc and zygapophysial joints can contribute at the same segmental level or at different levels and be independently painful causing direct and referred pain. A similar situation can arise when the sacroiliac joint system itself is disturbed, or indirectly affected through derangement in the lumbar spine or its supporting structures (5–10). The relationship between pain and structural derangement is still not fully understood.

Low back pain is one of the most common medical problems of the middle-aged population, and from society’s point of view, it is the most costly musculoskeletal disease in industrialized countries today (11–13). In the majority of cases, the origin of the pain remains obscure. Much of low back pain is thought to arise from damage to the intervertebral disc or the zygapophysial joints, either directly through traumatic injuries or disc prolapse, or indirectly through degenerative processes that transmit unfavorable loading patterns onto other spinal structures

(e.g., ligaments, tendons, and supporting musculature) as well as to the sacroiliac joint (8,14–20).

In the clinical situation, the surgery rate for chronic back pain is still growing, thus indicating strong beliefs in pathoanatomic derangements. *Stability* and *instability* are terms that are fundamental in describing the function of the different back structures. Despite the lack of a working clinical definition for these terms in a biomechanical system, they are widely used. Instability of one or more spinal segments is accepted as one cause for low back pain and the growing number of spinal fusion operations supports this belief. The need for strong trunk muscles and ergonomic advice to preserve the stability and integrity of the spine have dominated conservative treatments (e.g., stabilizing exercises) for many decades. Even if there is no clear definition of instability, there seems to be a common understanding that instability is a situation where a pathologic motion occurs within the motion segment. Attempts to measure such pathologic motions using advanced techniques have not been able to demonstrate instability (i.e., hypermobility) (21). However, this appears not to have had any impact on the clinical belief regarding the existence of instability. Terms that cannot be defined, processes that cannot be measured, or exercises that have no clear criteria for being a stabilizing exercise are of little value as scientific tools. For biomechanical systems, it might be more useful to use the terms such as *motion*, *balance* or *postural control*, and *transfer of loading* with regard to the function of the spine and its motion segments. An increased insight and understanding of the sensorimotor control system that takes care of these functions may lead us closer to the nature of low back pain.

In order to understand sensorimotor control, it is necessary to have knowledge of the different structures that are involved. All clinical entities for the treatment of low back pain are unfortunately lacking a physiologic backup and verification from adequate experimentally controlled trials. Injuries and structural degeneration cannot be

**FIG. 11-1.** Neuromuscular network connecting the central nervous system to peripheral structures (shown in boxes): intervertebral disc, zygapophysial joint, skin, and spinal muscles. properly studied in the human situation because of the ongoing aging process. There remains an absolute need for interdisciplinary studies and experimental models in order to evaluate the neuromuscular interaction and the muscular control in the spine (22,23).

The peripheral part of the intervertebral disc, as well as the zygapophysial joint capsules, are richly innervated by different nerves that serve the function of pain and mechanical reception (20,24–26) (Fig. 11-1). Both injury as well as noxious stimulation of the spinal structures have been shown to cause spasm of the lumbar muscles and hamstrings (10,27), and may induce perturbations in the proprioceptive function (14). Such observations indicate possible mechanisms for long-term activation of the musculature as an important factor in low back problems.

### LUMBAR AND SACRAL STRUCTURES AND INNERVATION PATTERNS

This section contains a brief summary of important structures and mechanisms involved in control and move-

ments of the back. Also discussed is how lesions in the avascular supporting structures, depending on location, size, and degree of inflammation, can cause perturbations to the proprioceptive function of the different receptors and result in increased or prolonged muscle activation that may cause pain. Irritation of low threshold nerve endings in the sacroiliac joint, intervertebral disc, or the zygapophysial joint tissue may trigger a reflex activation of the gluteal and paraspinal muscles that may become painful over time. To come closer to a solution to many low back problems, a better understanding of muscle function and their interactions with the passive structures through the neural structures is needed.

### The Lumbar Intervertebral Disc

The intervertebral disc is a deformable connective structure that allows mobility and transfer loads between the vertebrae. A normal intervertebral disc consists of a gel-like central nucleus pulposus designed to sustain pressure. Surrounding the nucleus pulposus is a special

arrangement of layers of collagen fibers, known as the annulus fibrosus, which can resist movements in all directions due to their alternating oblique orientation. A cartilaginous end plate joins the vertebral body and the intervertebral disc, and provides a nutritional pathway to the disc, which is an avascular structure (28).

In the superficial layers of the disc, nerves form simple free endings in the fetal stage, which increase in number as the fetus matures. During the postnatal period, various types of receptors develop, and in adult material, five types of nerve terminations can be found. The complexity of the receptors on the surface of the annulus increases with age. Within a given disc, the receptors are not uniformly distributed (Fig. 11-2). After postnatal development, there is a relative decrease in the number of receptors in the anterior region. In adults the greatest number of endings are found in the lateral regions of the disc, a smaller number occur in the posterior region, and the least number occur in the anterior region. The source of the nerve endings in the lumbar disc is the lumbar sinuvertebral nerves and branches of the lumbar ventral rami and the gray rami communicantes. Each lumbar sinuvertebral nerve supplies the disc at its level of entry into the vertebral canal and the disc above. The posterolateral corner of each lumbar disc receives branches from the lumbar ventral rami that originate just outside the intervertebral foramina. This region of the disc receives a branch from the gray ramus communicantes before its connection with the ventral ramus. Branches of the gray rami communicantes innervate discs at various levels. Even though the lumbar intervertebral discs are innervated by branches of the sympathetic nervous system, it does not necessarily mean that afferent fibers from these structures return to the nervous system through the sympathetic trunk. It has been suggested that somatic afferent

**FIG. 11-2.** Schematic of the lumbar intervertebral disc showing nonuniform innervation in the peripheral part.

fibers from the discs simply use the course of the rami communicantes to return to the ventral rami (20).

The presence of nerve endings in the lumbar intervertebral disc raises the question as to their function. Malinsky (29) proposed a proprioceptive function based on its morphology; however Kumar and Davis (30) did not find any evidence to support this theory. Two studies have demonstrated that mechanoreceptors are present in the outer annulus fibrosus of the intervertebral disc (20,31). Furthermore, it has been shown that in the rat the dorsal portions of intervertebral discs from L1-L2 to L4-L5 are multisegmentally innervated by the T11-L5 dorsal root ganglions (32).

For acute pain to occur, nerves must be involved. The disc itself may be an intrinsic source of pain originating from mechanical or chemical disturbances (33) (Fig. 11-3). As previously described, it has been established that the intervertebral disc receives innervation and that there are pain potentials in the outer part of the annulus fibrosus. It is possible that discogenic pain from a single level may involve more than one recurrent branch of the spinal nerves. Free nerve ending associated with blood vessels in the disc may be considered as having a vasomotor or vasosensory function, but because the annulus fibrosus contains so few blood vessels, this is less likely to be the function for the majority of the nerve fibers in the disc. Although there is no absolute explicit evidence that disc pain can be ascribed to a particular type of nerve ending in the disc, there is abundant evidence suggesting that the disc can be painful (33,34).

### The Zygapophysial Joints

Together with the intervertebral disc, the lumbar zygapophysial joints, or more commonly called facet

**FIG. 11-3.** Schematic of a lumbar intervertebral disc showing lesions that may or may not cause pain.

joints, are responsible for mechanical guidance of the motion segment (35). The inferior articular processes of one lumbar vertebra with the superior articular processes of the lower adjacent vertebra form the lumbar facet joints. The joints exhibit features typical of synovial joints and the articulating surfaces are covered by articular cartilage. The amount of weight bearing has been difficult to calculate, but is estimated to range from 0 to 20% (36,37).

Sensory innervation of the facet joints is derived from the posterior ramus of the spinal nerves, with each joint receiving branches from the level above, the same level, and the level below. These branches supply filaments to the capsule surrounding the facet joint, which is attached to the articular cartilage. Anteriorly, the fibrous capsule of the joint is replaced entirely by the ligamentum flavum, which attaches close to the articular margin. The enclosing joint capsule is thick dorsally and is reinforced by some of the deep fibers of the multifidus muscle. The consensus is that the facet joint is a possible source of low back pain (38). Marked degenerative changes can often be demonstrated on imaging. Attempts have been made to establish the “facet joint syndrome” as a clinical entity, but this remains questionable (10).

### The Ligaments

The different ligaments provide substantial stability of the spine. The anterior and posterior longitudinal ligaments resist separation between adjacent as well as multiple vertebral bodies. Posteriorly, ligamentous structures provide resistance to flexion or axial separation between adjacent laminae (ligamentum flavum) and spinous processes (interspinous and supraspinous ligaments). The iliolumbar ligament provides a strong resistance to forward displacement between the L5 vertebra and the ilium. The intertransverse ligament, which spans between consecutive transverse processes, is considered part of the fascial system, which separates different muscular compartments within the spine (24).

Apart from ligamentum flavum, all ligaments seem to be innervated (39). The ligaments around the disc receive their innervation from the same nerves as the disc. The dorsal longitudinal ligament is more densely innervated than the anterior longitudinal ligament, receiving nerve endings from both sides. The more lateral and posteriorly located ligaments receive their innervation mainly from the posterior branch of the spinal nerve (24).

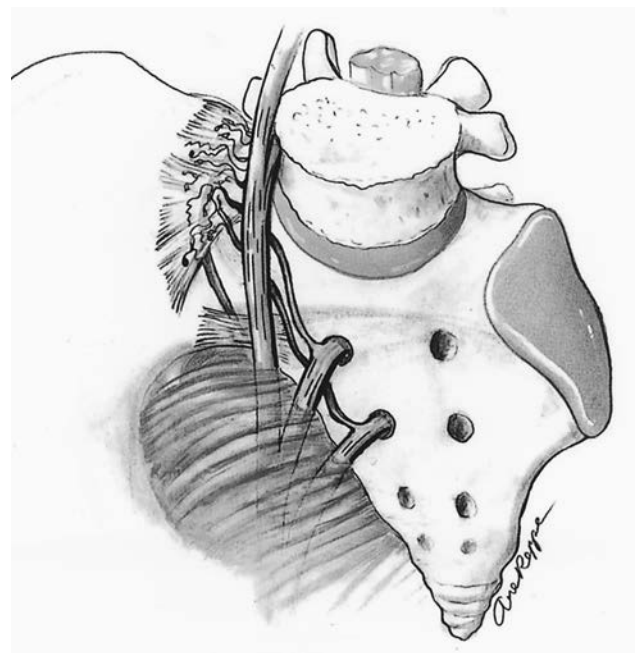

### The Sacroiliac Joint

The sacroiliac joint (SIJ) is a true synovial joint with an auricular shape and a very limited amount of motion. The joint is relatively small, considering the large forces transmitted across it. The SIJ does, however, have an extensive network of strong ligaments that helps maintain stability and is constructed in such a way that the liga-

ments are self-tightening with increasing load. Roentgen stereophotogrammetric analysis has shown the amount of SIJ motion to range from 0.5 to 1.6 mm for translation and up to 4° for rotation (40).

The SIJ appears to be richly innervated, although there seems to be some uncertainty as to the exact innervation patterns (Fig. 11-4). Solonen found the SIJ to be predominantly innervated by the L4-S1 nerve roots, with some contribution from the superior gluteal nerve, but with a lesser contribution from S2, and rarely from L3 nerve roots (41). Grob et al. (42), in a study on adult human cadavers, found the SIJ to be innervated by fine nerve branches derived exclusively from dorsal rami of the S1-S4 spinal nerves. Ikeda reported that the upper ventral portion of the SIJ was mainly supplied by the ventral ramus of the fifth lumbar nerve, while the lower ventral portion was mainly supplied by the ramus of the S2 nerve (43). Thick, thin, and unmyelinated nerve fibers have been reported, which are compatible with a broad repertoire of sensory receptors, including encapsulated mechanoreceptors (42,43).

In search of causes of low back pain, the SIJ has gained renewed interest as a possible pain generator (44,45). There is a special awareness of the SIJ as a source of pain in pregnant and postpartum women, and although the mechanism is not understood, relaxation of the SIJ before childbirth is believed to play a role (9). Instability or subluxation has most often been suggested as mechanisms behind sacroiliac dysfunction (7,46). Despite any proven clinical findings or clearly defined function of the joint,

**FIG. 11-4.** Representation showing the sacroiliac joint, stabilizing ligaments, and innervation.

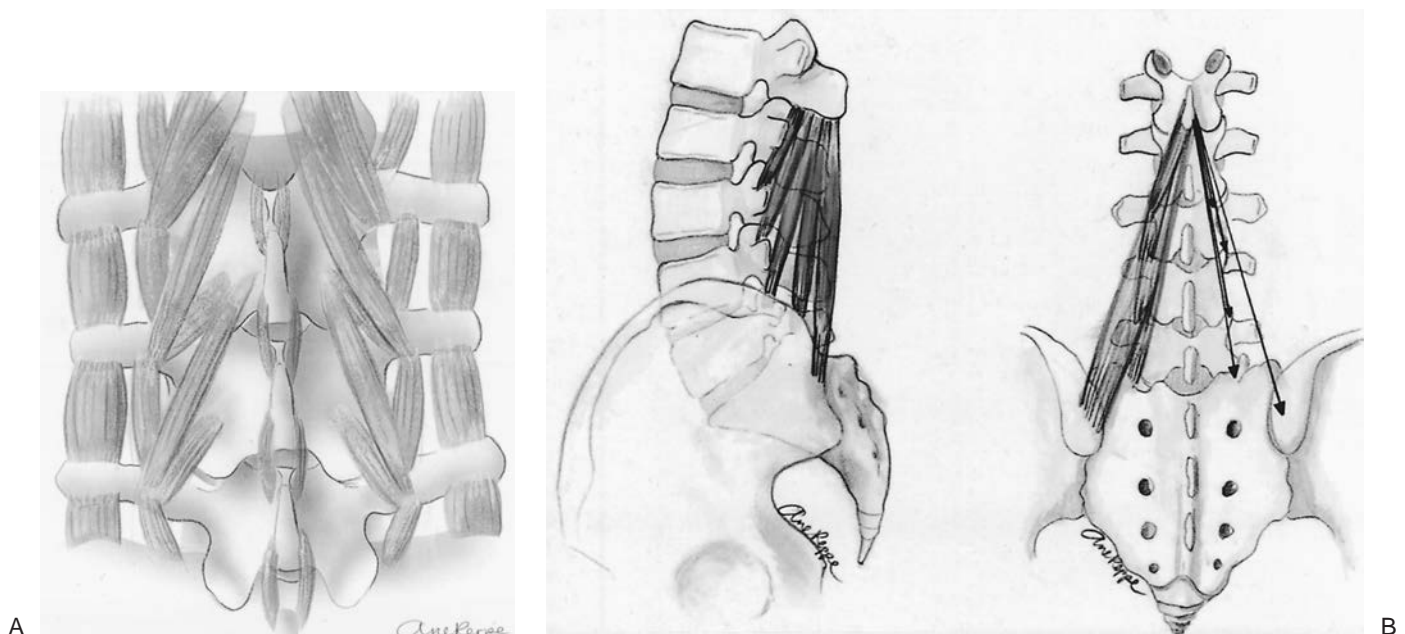

“sacroiliac dysfunction” has been established as a clinical entity (5,7,46,47).

### The Supporting Musculature

The system responsible for muscle coordination around a joint is called the “myotactic unit.” Muscle spindle afferents make direct connections to motor neurons responsible for activation of synergist muscles and to interneurons inhibiting motor neurons of antagonist muscles. Through these divergent connections to the different muscles around a joint, a strong neural network is established so that muscles do not act independently of each other. Such arrangements are responsible for joint stiffness.

Neural control on multiple levels is required to maintain normal locomotion. In order to support the body against gravity, maintain posture, and to propel it forward, muscle contractions must be well coordinated for several joints. At the same time, the nervous system must exert active control to maintain balance of the moving body, and it must adapt the locomotion patterns to the environment and to the overall behavioral goals. The spinal circuits activated by descending signals from higher centers accomplish this. Neural circuits in the spinal cord play an essential role in motor coordination. Spinal reflexes, where the “myotactic units” are the building blocks, provide the nervous system with a set of elementary patterns of coordination that can be activated, either by sensory stimuli or by descending signals from the brainstem and cerebral cortex.

The lumbar musculature exerts various forces on the spinal motion segments. Each muscle not only acts as a moment-producer, but also generates compressive and shear forces. The functions of these muscles are to stabilize the spine while providing mobility (21,48,49). The recruitment patterns for these muscles are not well established. The multifidus muscles are the longest and most medial of the lumbar back muscles. They consist of repeating series of fascicles that originate from the laminae and the spinous processes of the lumbar vertebrae and display consistent patterns of attachments caudally (24). The key feature of the morphology of the lumbar multifidus is that its fascicles are arranged polysegmentally (Fig. 11-5). Each lumbar vertebra is supplied with a group of fascicles that radiate from its spinous process, anchoring it below to mammillary processes. The fibers of the multifidus are designed to act together on a single spinous process of two to four levels. All the fascicles originating from the spinous processes of a given vertebra are innervated by the medial branch of the dorsal ramus that originates from below that vertebra. The muscles that act directly on a particular vertebral segment are innervated by the nerve of that segment (50–52). Although the paraspinal musculature has been studied quite extensively, its role in the formation of low back pain is far from clear (53). Electromyographic evaluations of various back lesions have contributed to the current understanding of low back pain (54–58). The clinical picture often seen is one of tense and painful paraspinal muscles and reduced flexibility in the lumbar spine. This

**FIG. 11-5. A:** Schematic of the interspinales, intertransversarii mediales and laterales, and parts of the multifidus muscles. **B:** Schematic showing the polysegmental attachments of the multifidus fascicles originating from L1 vertebra. is thought to be caused by reflex stabilization by the paraspinous muscles.

### SENSORIMOTOR CONTROL

The innervation patterns of the active and passive structures of the lumbar spine have, for the most part, been experimentally determined. The spinal nerve roots (dorsal and ventral), which exit from the spinal canal, connect the central nervous system and the peripheral nerves. The dorsal nerve root contains sensory fibers and the ventral root contains motor and some sensory fibers. The nerve roots join to form a spinal nerve. For each lumbar vertebra, there is an associated lumbar spinal nerve. Peripherally, each lumbar spinal nerve divides into a dorsal and ventral ramus, which branch further to provide innervation to the various passive and active structures (Fig. 11-6). Three branches stem from the dorsal ramus: lateral, intermediate, and medial. The lateral and intermediate branches innervate iliocostalis lumborum and the longissimus thoracis muscles, respectively. The medial branch provides innervation to a number of structures which lie posteriorly: muscles (interspinales, intertransversarii mediales, and multifidus), ligaments (interspinous and perhaps the supraspinous), and

the zygapophysial joint capsules. The ventral ramus provides innervation to structures that lie anteriorly: muscles (intertransversarii laterales, psoas major), the intertransverse ligament, and the lateral aspects of the intervertebral disc. The gray ramus communicans, which is an autonomic root from the sympathetic trunk, also provides innervation to the lateral aspects of the intervertebral disc and to the intervening anterior longitudinal ligament.

The control of movement depends on the sensory system working together with the motor system. Sensory information influences motor output in many ways and at all levels of the motor system. Sensory input to the spinal cord directly triggers reflex responses. The reflexes are involuntary and relatively stereotyped responses to certain sensory stimuli. Reflexes in which the sensory stimuli arise from receptors in muscles, joints, and skin, and in which the neural circuitry is entirely contained within the spinal cord are called spinal reflexes (Fig. 11-1).

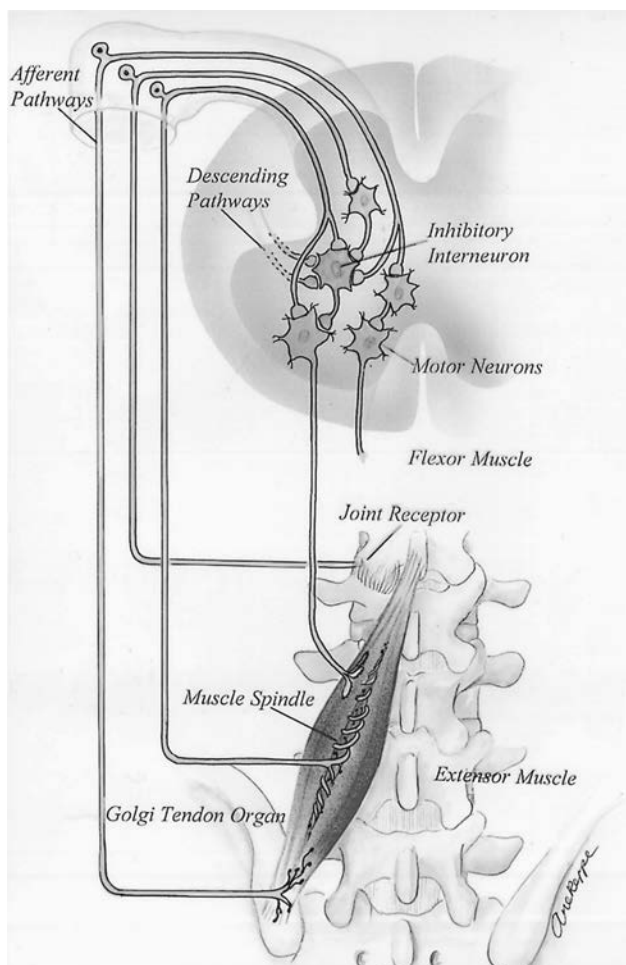

In muscle and tendon, the motor and sensory functions of the neural structures for controlling posture and movements are well established. The load-sensitive nerve endings, or mechanoreceptors, found in muscle (muscle spindles) and tendon (Golgi tendon organs), provide proprioceptive information regarding tension levels, essen-

**FIG. 11-6.** Schematic drawing of the bilateral active and passive structural arrangement and sensory innervation on the L3-L4 level. (From Holm S, Indahl A, Solomonow M. Sensorimotor control of the spine. *J EMG Kinesiol* 2002;12:219–234, with permission.)

tial for controlling muscle tone, and therefore joint stability (Fig. 11-7). Although the presence of nerve endings in passive structures (ligaments, intervertebral disc, zygapophysial joint capsule) in the spinal column has been documented, their role is not clearly defined. Regarding the articular structures, the outer annulus of the intervertebral disc and the capsules of the zygapophysial joint contain both free nerve endings and mechanoreceptors. In addition to being potential sources of pain, these structures may act as transducers for monitoring the position and movements in the motion segment. The neurologic feedback from passive structures provides sensory information needed to regulate muscle tension, and hence, the stability in the lumbar spine.

Normal locomotion requires multiple levels of neural control. To support the body against gravity, maintain posture and to transport it forward, the nervous system must coordinate muscle contractions. At the same time, the nervous system must exert active control to maintain balance of the moving body and adapt the locomotion patterns.

**FIG. 11-7.** Neuromuscular feedback system depicting the afferent sensory information from joint receptors, muscles spindles, and Golgi tendon organs for regulating muscle tension.

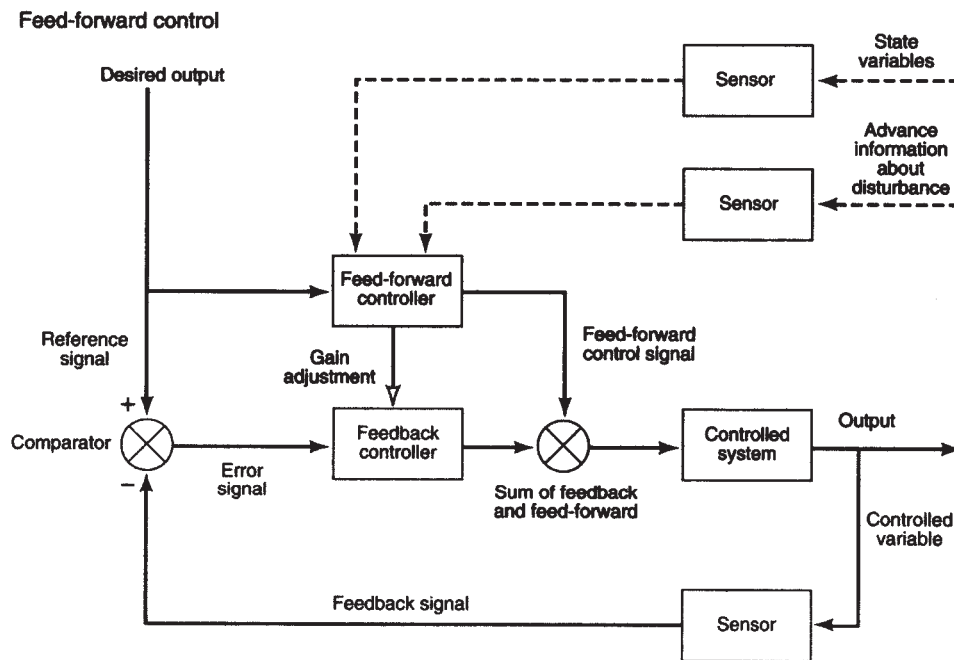

Neural circuits in the spinal cord play an essential role in motor coordination. Spinal reflexes provide the nervous system with a set of basic patterns of coordination that can be activated, either by sensory stimuli or by descending signals from the brainstem and cerebral cortex.

Functioning of the motor system is strongly related to that of the sensory system. Proper functioning of the motor system depends on a continuous inflow of sensory information. Sensory input to the spinal cord directly triggers reflexes. It is also essential for determining the parameters of programmed voluntary responses. Finally, both feedback and feed-forward mechanisms provide flexibility in the control of motor output (Fig. 11-8). Although the same sensors may provide information for both feedback and feed-forward control, the manner in which the information is processed varies. Biologic feedback processes generally operate continuously but slowly and are therefore used to maintain posture and regulate slow movements, while feed-forward systems, with an intermittent mode, operate more quickly.

## FUNCTION AND DYSFUNCTION

In low back pain, where no pathoanatomic findings can be demonstrated, the cause of the pain may mainly be a functional disturbance. In order to be able to describe possible functional disturbances, the normal function must first be described. However, this is not always the case in medicine. For example, sacroiliac dysfunction was described 90 years ago, but the function of this joint has not yet been established. The hypothesis laid out below takes into account the muscular, ligamentous, and nervous networks, and their various interactive processes (Fig. 11-1). It builds upon what is known about neural control of other joints, and it is reasonable to believe that the same mechanisms apply to the spinal motion segments.

To understand the nature of a functional disturbance and how this can occur, it is necessary to first describe normal function. The nerve endings in the outer annulus fibrosus of the disc, in the capsule of the facet joints, and in the ligaments are most likely part of a proprioceptive system responsible for optimal recruitment of the paraspinal muscles (29,31). Mechanoreceptors are thought to play an important role in monitoring position and joint movement by regulating and modifying muscle tension. These different nerve endings can record the loading on the different spinal structures. The descending signals that initiate muscle action are modified by the sensory input from the proprioceptive nerve endings. Recruitment of the paraspinal muscles may thus be coordinated in such a manner that the forces applied to the various structures are properly distributed regardless of position. In such a system, the action of the muscles can provide the different spinal structures with the support needed in order to counteract detrimental forces and avoid injury. Overload of specific structures can be detected by high threshold nerve endings, and in due

**FIG. 11-8.** Flowchart showing the functioning of the motor system involving feed-forward control in relation to feedback compensatory corrections. (From Ghez C. The control of movement. In: Kandel ER, Schwartz JH, Jessel TM, eds. Principles of neural science, 3rd ed. Norwalk, CT: Appleton & Lange, 1991:536, with permission.)

process inhibit muscle actions responsible for increasing the loading, and thereby prevent injury. This may be a reason why heavy physical loading does not seem to have the impact on degeneration of the spine as earlier assumed (59–61).

The common clinical finding of decreased range of motion of the spine in patients with low back pain points to increased muscle activity presumably caused by alterations in the recruitment system. The origin of such a change in paraspinal muscle recruitment is thought to be a lesion of some kind in one or more spinal structures. The intervertebral disc is the spinal structure where lesions are most readily detected. Even if it is not yet known exactly why disc lesions occur, since the time when Mixter and Barr demonstrated herniation of the nucleus pulposus and its effect on the nerve root as a mechanism behind sciatic pain, there has been mounting evidence for disc pathology and disc changes (4). Some of these changes can be seen on imaging, but others may only be demonstrated through histologic methods. In most cases, the likely site of the lesion is probably the annulus fibrosus of a lumbar disc. Such a lesion must occur in an innervated region of the annulus fibrosus (Fig. 11-3). Depending on the size of the lesion, the density of the neural structures, and the damage done to them, the firing patterns from these nerve endings may be altered in such a manner to cause increased activation of the paraspinal muscles. This muscle activation may occur in a “bracing” fashion and subject the muscles to static work, which is believed to be responsible for muscle pain (62).

Toward the latter part of trunk flexion, there is a spontaneous reduction in the muscle electric activity in certain paraspinal muscles. This behavior is known as flexion-relaxation and was first recognized by Floyd and Silver in 1951 (63). Paquet et al. (64) have demonstrated altered muscle activation patterns in patients with a former history of back pain compared to similar back patients without previous back pain experience. Haig et al. (65) have shown changes in the flexion-relaxation phenomenon in a patient with acute disc herniation, and Sihvonen et al. (17) have demonstrated increased muscle activation and lack of flexion-relaxation in patients with chronic low back pain. Pain, for whatever reason, lasting for some time may lead to the establishment of a more “bracing” pattern as the dominating strategy for muscle activation.

Even though it is not known which processes are responsible for muscle pain, it is a common human experience that muscles can be painful (66). There is no suitable experimental evidence supporting the hypothesis that a “pain-spasm-pain” cycle can exist in the back. Studies have shown that experimental pain in muscles does not increase the firing of  $\gamma$ -motor units, but it does increase the stretch reflex (67). Increase in such reflexes may result in inappropriate muscle activation.

## NEUROMUSCULAR REFLEX SYSTEM

A thorough description of reflex systems essential for sensorimotor control has been provided by Gordon (68).

A summary, in part, is provided in this section. The stretch reflex is the only known monosynaptic reflex in the mammalian nervous system. Because the participating afferent and efferent axons have large diameters and are among the most rapidly conducting neurons in the nervous system, the stretch reflex pathway is adapted for speed of operation. The economy of the neural circuit for the stretch reflex allows muscle tone to be regulated quickly and efficiently without direct intervention by higher centers. Descending control signals adjust the gain of the reflex loops, adapting them to the requirements of specific motor acts.

A characteristic aspect of muscle tone is that the tension produced by the muscle increases approximately in proportion to the amount of stretch. Moreover, when muscle is released from a stretch, the tension decreases progressively to its resting level. This symmetric response is present whether the muscle is stretched slowly or abruptly and is due to a combination of the mechanical properties of muscle and the neural components provided by the stretch reflex. In slowly imposed stretches, this springlike behavior occurs because of the intrinsic length-tension properties of muscle. In rapid stretches, however, the intrinsic mechanical response is an initial increase in tension followed by a transient collapse even as the muscle continues to be stretched.

The increased focus on the innervation of different spinal structures has led to a new understanding and awareness that they may play an important role in a complex regulating system (20,24–26,42). Reflexes from ligaments in many of the joints of the extremities have previously been established (69–71). Spasms and elevated activity of the lumbar paraspinal muscles are common in patients with low back pain. In the spine, several ligaments are associated with each motion segment, thus comprising a complex proprioceptive measurement system, particularly when combined with the sensory inputs from nearby discs and capsules. The existence of sensory receptors in the various spinal ligaments has been established (51,72–75). Solomonow et al. have experimentally investigated whether or not a ligament-muscular reflex exists from the spinal ligaments to related muscles (76). Furthermore, it has been demonstrated that static constant load applied to the lumbar spine through the supraspinous ligament results in spasm of the multifidus muscles, although the stretching was below the physiologic range limit and spasms were evident regardless of the loading magnitude (22). A conclusion drawn from these studies is that there exists a clear chain of events consisting of viscoelastic tissue damage, pain, and muscular spasm. The spasms are most likely triggered by nerve endings, which are found in the spinal ligamentous tissues. These receptors monitor tissue injury and trigger responses such as pain and probably its associated spasms. The finding that the viscoelastic structures were stretched, although the applied load was constant was

very interesting as this indicates that the tension developed may be a stimulus that elicits reflexive activity in the muscles (22). These two separate sensory feedback mechanisms are probably in synergy with each other to protect the spinal structures from instability and injury.

Possible muscle activation because of damage to passive viscoelastic spinal structures is difficult to detect. Painful stimuli seem to have an inhibitory effect on muscle activation. But damage done to ligaments and perhaps other passive structures does not necessarily have to result in a lot of pain. Depending on the size of the lesion, the density of the neural structures, and damage done to them, and the degree of irritation to the surrounding nerve endings, the firing pattern from these nerve endings may be altered in such a manner so as to cause increased activation of the paraspinal muscles. Studies have shown that experimental pain in muscles does not increase the firing of  $\gamma$ -motor units, but it does increase the stretch reflex (67). Increase in such reflexes may result in inappropriate muscle activation.

In muscle and tendon, the motor and sensory functions of the neural structures for controlling posture and movements are well established (77); however, until recently, this has not been the case for the spinal structures. Stimulation of the outer annulus of the disc or zygapophysial joint, both of which have been shown to contain nerve endings, causes activation of paraspinal musculature. This not only occurs on the same segmental level but also on different levels, indicating a complex interaction (15). Such an interaction is necessary in order to stabilize different segments, not only in relation to each other, but also in the process of maintaining posture. However, a lesion at one location may cause alterations in muscle activation at a location other than the actual segment and even on the contralateral side. Avramov et al. (78) have shown that loading excites three patterns of nerve discharges from the zygapophysial joints: short duration bursts during changes in loading, prolonged discharges at low levels, and prolonged discharges at high load levels. These results indicate that different units in the joint capsule have different levels of stress threshold.

The range of motion and innervation of the SIJ seems well suited for detecting various loading patterns during locomotion. In humans, the slanted position of the L5-S1 motion segment and the relative position of the SIJ appear to have physiologic importance for load detection. The afferent input from SIJ receptors, as well as mechanoreceptors in the intervertebral disc and zygapophysial joints, will contribute to different degrees of muscle activation and may constitute an integral regulatory system (79). Changes in loading on the SIJ may result in altered activation of the stabilizing muscles, and thus play an important regulatory function in stabilization and movement of the upper body during postural changes.

Instability of a spinal motion segment, as a result of degeneration of the disc or zygapophysial joints, is

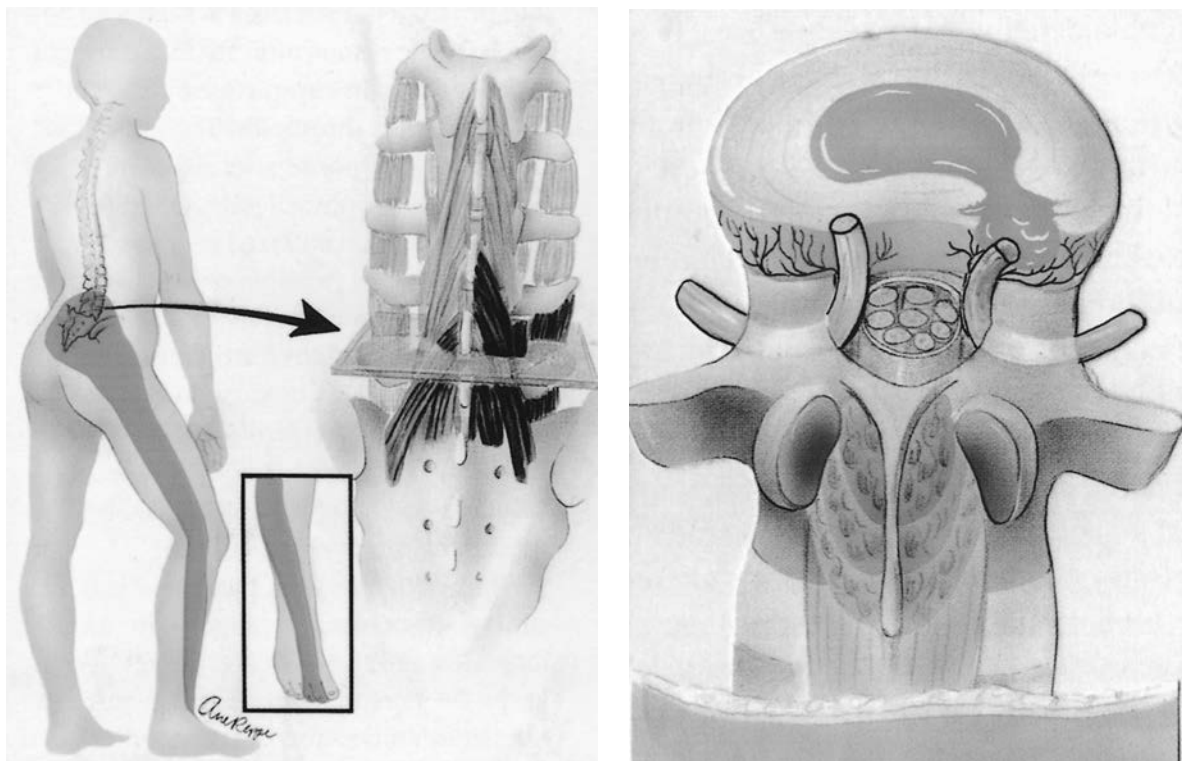

believed to be manifested as “slipping” because of laxity in the motion segment. Kaigle et al. (21) have shown that this kind of hypermobility does not seem to occur, but that the segmental motion pattern is greatly altered. The change in length and loading of the spinal ligaments may cause alterations in the firing patterns and consequently, coordination of the muscle activity. With decreased disc height as a result of degeneration, adaptation of the surrounding nerve endings may be less efficient and thus result in less optimal neuromuscular reflexes. Better knowledge of the sensory function of the passive spinal structures should influence the manner in which these structures are treated clinically.

In healthy persons, the paraspinal muscles display the flexion-relaxation phenomenon (i.e., muscle activity decreases as flexion of the trunk increases), and the muscles become silent in the fully bent posture (15,63,79). In a patient with a herniated nucleus pulposus, Haig et al. found that the flexion-relaxation phenomenon was absent (65). It may be assumed that in patients in whom the phenomenon is absent, there is an imbalance between nerve discharges to the muscles from a pathologic structure and inhibitory discharges from the zygapophysial joint capsule in forward bending. Conversely, inhibitory discharges from the joint capsule can explain why manipulative treatment and mobilization of the zygapophysial joint provide relief in some cases.

Using an experimental model, it has been demonstrated by Indahl et al. (15) that stimulation of nerve endings in the intervertebral disc and zygapophysial joint capsule elicited responses in the paraspinal muscles, thereby demonstrating neuromuscular interaction exists between these structures. Stretching on the zygapophysial joint capsule inhibited the muscular response, thus suggesting the existence of a complex reflex system that is responsible for the motion and stabilization of the lumbar spine.

Stretching of more than one joint can increase inhibition and make the treatment more effective. Muscle spasm is a common clinical feature in patients with back problems, and manipulation of the zygapophysial joints may elicit a stretch reflex from the capsule, contributing to an inhibitory action on muscle spasm, thereby relieving pain (Fig. 11-9). Thus, it appears that there is a delicate interaction between the different parts of the spinal motion segments, and proprioceptive nerve endings may play a vital part in load distribution during movements.

In addition to the lumbar motion segments, the SIJ is of great importance in stabilization of the lumbosacral area. Despite this, there have been surprisingly few experimental studies investigating SIJ function. The results of mapping studies (80), the innervation of the SIJ (41–43), its position and range of motion (81), altogether give reason to believe that the SIJ also plays a regulatory

**FIG. 11-9.** Schematic representation of patient pain and how it relates to muscle activation (**left**) and disc herniation (**right**).

function involving reflex muscle activation responsible for stabilization and movement of the upper body during locomotion. Furthermore, it was shown by Indahl et al. (15) that stimulation of nerve and nerve endings in the deep part of the ventral SIJ, as well as in the superficial part of the dorsal capsule, elicits motor action potentials in different muscles. Interesting patterns were revealed. Stimulation of nerve elements in the ventral area of the SIJ produced predominant contractions in the gluteus medius and quadratus lumborum muscles. However, stimulation of the superficial dorsal layer of the SIJ capsule elicited responses predominantly in the medially located multifidus fascicles. It is possible that the different areas of the SIJ play different roles in regulating the locomotion system and the response may therefore vary depending on the stimulation site.

## SUMMARY

Despite a pathophysiologic understanding of the involved structures, no single group of patients can, with certainty, be identified at an early stage and be given a specific treatment. This seems to support the basic notion that low back pain is multicausal, and that the prognosis depends on a variety of factors. Furthermore, this suggests that movement-related pain should be considered as a complex behavior, and not solely as a psychiatric or a neurologic problem, but rather as a problem related to the integration of nervous and biomechanical mechanisms. This involves the sensorimotor control, with feedback from muscles, discs, and joints, all in a complex interaction with the central nervous system, as well as the traditional peripheral pain mechanisms.

## CHAPTER 12

# Outcomes Assessment: Overview and Specific Tools

Kevin F. Spratt

---

Clinical outcomes were often what clinicians said they were in the days before 1982. “My doctor says I’m doing very well.” Since the early 1980s, in spine care and many other disciplines where pain and suffering are major symptoms associated with the complaints that bring the patient to health care providers, outcomes have become more strongly associated with patient self-report. The argument is clear: Who but the patient is in a position to accurately recount symptom magnitude and quality?

In spine care, the 1982 *Spine* publications of the Million et al. pain interference scale (1) (popularly called the Million Visual Analogue Scale) and the 1983 Roland and Morris Disability Questionnaire (2) signaled the beginning of legitimizing patient self-report for spine-related disease outcomes.

### THE NOTION OF CLINICAL OUTCOMES

The universe of outcome instruments potentially applicable to the spine care professional is reasonably large. Gattchel (3) edited a compendium of outcome instruments for assessment and research of spinal disorders, where he categorized such biopsychosocial measures as the following:

1. Physical or “hard” measures
  - a. Range of motion: using inclinometers or Isostation B-200 equipment (Isotechnologies, Hillsborough, NC)
  - b. Spine strength: using Cybex (a division of Lumex Corporation, Ronkonkoma, NY) or Isostation B-200 equipment
  - c. Lifting capacity functional measures: using Cybex and MedX (MedX Corporation, Altamonte Springs, FL) equipment
  - d. Other tests of human performance capacity: aerobic capacity and treadmill tolerance
2. Psychological or “soft” measures

- a. Psychological tests: depression, MMPI-2, Symptom Checklist 90-Revised (4–7)
- b. Self-report measures of pain and disability: the SF-36, Chronic Pain Coping Inventory, Coping Strategies Questionnaire, McGill Pain Questionnaire, Oswestry Disability Index, Roland and Morris Disability Questionnaire, Multidimensional Pain Inventory (MPI), Quebec Back Pain Disability Scale, Sickness Impact Profile, and Activities of Daily Living (ADL) scales (8–24)
- c. Clinical interview: the structured clinician interview for the DSM-IV (SCID) (25)
- d. Clinical ratings of overt pain behavior: the Waddell Non-Organic Signs Test (26)

The clinical outcomes chapter by Spratt and Weinstein (27) in *The Lumbar Spine*, vol. 2, provides greater detail regarding the types of outcomes as well as classification schemes for a wide variety of outcomes measures.

### RELIABILITY AND VALIDITY

For any outcome measure, whether based on patient self-report or a laboratory test, the psychometric properties of primary interest are the same: reliability or precision and validity or accuracy. Methods for evaluating reliability and validity are major topics in measurement theory and are beyond the scope of this chapter. Impressive overviews of the concepts of reliability are provided by Feldt and Brennan (28), and for validity by Cronbach (29).

As a brief primer of reliability in the clinical setting, reliability considerations are usually evaluated in two ways, internal consistence of items, and test-retest reliability. Typically internal consistency is of primary importance when considering scale construction and test-retest or stability of the score is of primary importance when considering clinical value. With test-retest reliability the object of measurement (a patient) is assessed on multiple

(usually two) occasions under the assumptions that the first assessment does not affect, or is independent of, the second or subsequent assessments. In many cases, including clinical settings, this can be problematic because: (a) a second assessment shortly after the first assessment is not likely to be independent because the patient is likely to remember what he or she said and try for consistency rather than an accurate estimate of the current state, or (b) a second assessment a few days after the first assessment may be influenced by treatments that resulted from the initial visit. Thus, the most accurate method for establishing test-retest reliability for an instrument is to have the patient respond to the instrument on separate occasions with nothing but a short natural history intervening between the events. In this situation, which is rarely evaluated in the clinical setting, low reliabilities, meaning large discrepancies within a patient across time, could reflect: (a) an instrument that does not have adequate psychometric properties, or (b) a construct under assessment (e.g., pain, function, or attitudes) that are more state-like than trait-like, meaning that the construct may not be stable. The consequence of this result is that the instrument is not useful in evaluating treatment progress because the score might vary independently of treatment effectiveness on any given day. Thus, the single most important aspect of the reliability of an instrument used in the clinical setting is that it demonstrates stability, meaning that the score measures a condition or construct that is not amenable to quick and unpredictable changes across short time increments. In practice, internal consistency reliability estimates often are used as proxies for test-retest reliability. Because instrument construction often is guided by internal consistency estimates, the general sense is that internal consistency reliabilities are positively biased estimates of test-retest reliability; therefore, the amount of error expected in a score that is most relevant to the clinical setting is often underestimated.

This notion of stability, of course, begs the issue of validity because it suggests that the specific constructs chosen to be of interest need to be reasonably stable in the short run. Strictly speaking, instruments do not have validity, but the

scores they generate have validity to the extent that those scores provide information that aids in making appropriate decisions. If a test produces a score that is likely to be interpreted as high today but low tomorrow, then the lack of stability in that score indicates that it does not provide information useful in making appropriate decisions.

Measures of reliability include Cronbach's alpha for internal consistency, kappa for categorical outcomes, and intraclass correlations or generalizability coefficients (30) when outcomes are reasonably continuous. It has been argued that generalizability coefficients are preferable to kappa coefficients under circumstances when kappa struggles, such as when the number of categories becomes large (e.g., more than four levels); when the number of raters scores being compared are greater than two (although generalized kappa statistics can be computed); and when the prevalence of one of the categories is low or the sample size is small.

The value of generalizability coefficients is that they can be developed in ways that isolate potential culprits or candidates for lack of reliability, and that they allow estimation of what some consider the most relevant form of reliability in the clinical setting: the estimate of the reliability for a single rater on a single occasion; in other words, the reliability in the classical clinical situation where one clinician is evaluating a score based on a single reading. A problem with reliability coefficients, including generalizability coefficients, always has been that the meaning of the magnitude of the coefficient is not set. A reliability of .7 in some fields is considered good to excellent, whereas .8 is considered dismal in other fields.

To better understand the relationship between the reliability coefficient and the consequent differences in assessments between raters, 100,000 pairs of random normal scores were generated, transformed to have exact reliabilities of .30, .40, .50, .60, .70, .80, .90, .95, and .99, again transformed to have the mean and standard deviation associated with selected SF-36 scores and then broken down into six mutually exclusive and exhaustive categories based on the tenth, 25th, 50th, 75th, and 90th percentiles, as summarized in Table 12-1. These six cate-

**TABLE 12-1.** Descriptive statistics and cut points for selected SF-36 scales

Statistics	PCS	MCS	SF	PF	Example: PCS
Mean	30.6	45.9	39.1	40.8	
SD	7.2	14.5	25.0	22.4	
Min	13.0	16.0	0	0	
P10	22.0	21.5	12.5	15.0	Category 1:(13–21.9) Min–P10;10% of scores
P25	26.0	35.0	25.0	25.0	Category 2:(22–25.9) P10–P25;15% of scores
P50	30.0	52.5	37.5	40.0	Category 3:(26–29.9) P25–P50;25% of scores
P75	35.0	58.0	50.0	55.0	Category 4:(30–34.9) P50–P75;25% of scores
P90	39.0	60.0	75.0	75.0	Category 5:(35–38.9) P75–P90;15% of scores
Max	58.0	63.0	100	100	Category 6:(39–58) P90–Max;10% of scores

MCS, mental component summary; PCS, physical component summary; PF, physical functioning; SD, standard deviation; SF, social functioning.

Description statistics are based on the initial visit for 376 University of Iowa patients presenting with low back troubles.

gories for each pair of ratings with the specified reliability were then crossed and the level of agreement and disagreement determined based on differences in classification group. The percentage of same and different categorization is summarized in Table 12-2 for each reliability level. This pattern is consistent for all outcome measures under the assumption of normality; therefore, separate tables for each outcome were unnecessary.

By way of interpreting the information provided in Tables 12-1 and 12-2, suppose a test-retest reliability of .8. In this situation, 42.63% of scores from that instrument are expected to remain in the score category; 45.56% are expected to be in adjacent categories; and 1.87% to differ by two categories, .915% to differ by three categories, and .026% to differ by four categories. With a test-retest reliability of .8, a miss by two or more categories is expected 11.81% of the time. Across 400 patients, just considering two category differences, this means that approximately 44 patients might have a score:

- In category 1 (13 to 21.9), but a true score in category 3 (26 to 29.9); worst case difference 16.9, best case 4.1
- In category 2 (22 to 25.9), but a true score in category 4 (30 to 34.9); worst case difference 13.9, best case 4.1
- In category 3 (26 to 29.9), but a true score in category 5 (35 to 38.9); worst case difference 12.9, best case 5.1
- In category 4 (30 to 34.9), but a true score in category 6 (39 to 58); worst case difference 28, best case 4.1

Of course, the reverse pattern is equally likely: An observed score in category 3 (26 to 29.9) might reflect a true score in category 1 (13 to 21.9). Thus, overtreatment or undertreatment might result if the observed score overestimates or underestimates severity. To the extent that overestimates of symptom severity result in a differential diagnosis suggesting a more aggressive treatment path (e.g., surgery), or underestimates of symptom severity

result in a differential diagnosis suggesting a less aggressive or immediate treatment path (e.g., watchful waiting), the lack of reliability of the diagnostic tool clearly affects quality of care.

It should be noted that a test-retest reliability estimated based on the clinically relevant generalizability coefficient of one clinician making one rating is likely to be lower than the .8 estimate used in this example. Further note that if dropping to a reliability of .7, only 36.18% of scores are expected to be in the same category if a second independent evaluation is done at the same time. Thus, the stability of many outcome measures employed at initial visits, which are often used as ancillary diagnostic tools in clinical research, may have marginal value when applied to clinical practice.

In sum, the reliability of many outcome tools used to evaluate patients presenting with low back pain have limited test-retest reliability evidence. The proxy internal consistency reliability estimates used are likely to be positively biased, suggesting that the differences between the observed and true scores are likely to be larger than expected; therefore, clinical decisions based on these scores are likely to be based on unreliable information. This may be one explanation for the often repeated, generally accepted, but not necessarily well-documented cliché that if you do not like the opinion of your clinician, get a second opinion because it will probably be different.

### GENERIC VERSUS CONDITION-SPECIFIC INSTRUMENTS

Outcomes associated with evaluating patients with low back pain employ two broad types of measures: (a) generic outcomes typically assessing general health that were developed with the general population in mind, and (b) condition-specific outcomes typically constructed by

**TABLE 12-2.** *Magnitudes of disagreement for selected reliabilities*

Reliability	Number of categories of disagreement					
	Match	1	2	3	4	5
0.30	23.40	37.99	24.34	10.63	3.06	0.586
0.40	25.65	39.55	23.41	8.966	2.079	0.348
0.50	28.24	41.35	22.00	6.957	1.293	0.158
0.60	31.62	42.99	19.79	4.890	0.663	0.052
0.70	36.18	44.73	16.12	2.765	0.201	0.010
0.80	42.63	45.56	10.87	0.915	0.026	—
0.90	54.15	42.14	3.665	0.046	—	—
0.95	65.79	33.58	0.630	—	—	—
0.99	84.45	15.55	—	—	—	—

For categories of disagreement:

- Match indicates no disagreement (i.e., 1-1, 2-2, 3-3, 4-4, 5-5, 6-6)
- 1 indicates disagreement by 1 category (i.e., 1-2, 2-3, 3-4, 4-5, 5-6)
- 2 indicated disagreement by 2 categories (i.e., 1-3, 2-4, 3-5, 4-6)
- 3 indicated disagreement by 3 categories (i.e., 1-4, 2-5, 3-6)
- 4 indicated disagreement by 4 categories (i.e., 1-5, 2-6)
- 5 indicates disagreement by 5 categories (i.e., 1-6)

practitioners in a particular field to more carefully assess the outcomes thought to be relevant to the specific condition under consideration. The SF-36 is a well-known example of a generic health outcome tool. The Roland and Morris Disability Questionnaire and the Oswestry Disability Index are well-known examples of condition-specific instruments. In practice, the title of condition-specific instrument is a misnomer because these instruments are not meant to be linked to a particular condition or diagnosis, but rather to a particular region of the body. The Roland and Morris Disability Questionnaire, for example, is a list of 24 statements associated with actions or activities, such as, “Because of my back or leg I stay at home,” and, “Because of my back or leg I sit down for most of the day.”

In practice, the differences between generic and condition-specific instruments are more in name than anything else. The intent of using both types of instruments may be to differentiate between non-back/leg and back/leg-specific symptoms. In practice, judging by the correlations in the .7 to .9 range between generic and condition-specific outcome instruments, respondents either can not or do not differentiate between the sources or causes of their pain and symptoms. These high correlations can be worse news for the researcher when considering the notion of correlational attenuation. In short, this concept of attenuation allows the researcher to estimate the true correlation between two scores adjusting for the unreliability in each measure. The logic is that the unreliability in a measure reflects random error, and random error is uncorrelated. Thus, when one correlates two scores that are not perfectly reliable, the resultant correlation is an underestimate of the true correlation because of the error in each of the two measures. The formula for correcting for attenuation is given by:

$$R_{12} = \frac{r_{12}}{\sqrt{r_{11}r_{22}}}$$

where  $R_{12}$  is the disattenuated correlation between 1 and 2;  $r_{12}$  is the attenuated correlation between 1 and 2;  $r_{11}$  is the reliability associated with instrument 1; and  $r_{22}$  is the reliability associated with instrument 2.

From this formula, as shown in Table 12-3, a consequence of a high correlation between two instruments with moderate reliabilities is a disattenuated correlation that approaches or even exceeds 1.0. This makes logical sense when one considers, for example, that two instruments with reliabilities of .7 that correlate with each other at .8, in essence, are correlated higher with each other than they are with themselves, because reliability can be thought of as the extent that a score correlates with itself. Thus, from Table 12-3, if instruments 1 and 2 both have reliabilities of .7, and the observed correlation between instruments 1 and 2 ( $r_{12}$ ) = .8, then the disattenuated correlation between instruments 1 and 2 ( $R_{12}$ ) is 1.14, indicating the unlikely event that two distinct instruments correlate higher with each other than with themselves. This situation suggests that the two instruments are not distinct. In a more common example, consider the situation where two instruments both have test-retest reliabilities of .8 and the intercorrelation between the two instruments is .7. In this case the disattenuated correlation is .88, which is higher than the reliabilities for either of the two instruments and suggests that they should not be considered distinct.

Perhaps the worst consequence of labeling instruments as condition specific when, in fact, they are region specific (i.e., the back or leg areas) is that clinicians have not tried to establish stronger links between outcome measures and specific conditions. Spratt (31), in discussing the clinical model for health care, argues that the classic Diagnosis-Treatment model should be expanded to an Assessment-Diagnosis-Treatment-Outcome (ADTO) model, which should be viewed as an iterative cycle where: (a) Assessment leads to diagnosis; (b) diagnosis leads to treatment; (c) treatment goals suggest relevant outcomes; and (d) out-

comes lead to reassessment of the patient's condition, which suggests a potential shift in diagnosis. In this framework, an outcome might reasonably be considered an extension of the assessment conducted to determine diagnosis. In this way, outcomes of interest are in fact condition specific because these aspects of the patient's health status are evaluated, presumably, because the patient's states and traits (e.g., pain or symptom location, magnitude, stability, progression, radiographic evidence of degeneration or lesions, etc.) are fundamental to determining what is wrong with the patient. Logically, effective treatment results in changes in these conditions; therefore, the very assessments and diagnostic tests done to establish a specific diagnosis seem to provide the basis for determining the condition- or diagnosis-specific outcomes of interest for evaluating a patient's health status. Within this framework, a clinically relevant change in outcome could be defined as a change in diagnosis based on changes in the assessments of the patient's health status originally used to inform the diagnosis.

### CLINICALLY RELEVANT DIFFERENCES

Currently, a concern among clinicians wishing to use outcome instruments to help understand a patient's progress is determining the minimum clinically significant difference; that is, the smallest change in a patient's score from time 1 to time 2 than can be considered a clinically relevant change. Unfortunately, a *real* change need not be synonymous with one that is greater than can be expected by chance, is clinically relevant, and reflects a meaningful amount of movement in terms of resulting clinical decisions. A real change at the group level is a simple statistical procedure. One compares the two groups' distribution of scores, determines the appropriate statistical test based on those distributions, performs the test, and obtains the probability that such a difference is likely to have occurred by chance. If the likelihood is low (<1/20 or .05), the decision is typically that the difference is too large to expect under the assumption that there was no change and the decision is to reject the notion that there was no change. If the change is for the better, the conclusion is that the patient improved over time, or if there were two treatment groups, that one group did better than the other.

However, at the clinical level, where the sample size is 1 (i.e., the individual patient), inferential statistical procedures are not of much practical value. In this case, however, the notion of a reliable difference is still quantifiable within measurement theory by estimating the standard error of measurement defined as:

$$SEM = S_x \sqrt{1 - r_{xx}}$$

where *SEM* is the standard error of measurement;  $S_x$  is the standard deviation of instrument X; and  $r_{xx}$  is the reliability associated with instrument X.

From this equation, it should be clear that the standard error of measurement (SEM) for an instrument X is smaller as the standard deviation of the scores decreases and the reliability (range, 0 to 1) increases.

Under small sample probability theory ( $n = 1$  surely qualifies as small), multiplying the obtained standard error of measurement by two and adding it to a patient's score would approximate a 95% confidence interval around that score. From Table 12-1, consider the SF-36 for the PCS outcome: Mean = 30.6, SD = 7.2, and assume test-retest reliability of .85. In this situation the SEM computes to be 2.79. Thus, a follow-up score of  $30.6 + 2 \times 2.79 \geq 36.18$  or a score  $\leq 25.03$  ( $30.6 - 2 \times 2.79$ ) indicates a reliable change in the score; that is, a score different from the initial one by more than could be expected because of unreliability. In other words, the approximate 95% confidence interval around the initial score of 30.6 is (25.03 – 36.18). If the reliability of this score was lower, say .75, this 95% confidence interval would become (23.4 – 37.8), indicating a change of around 7.2 points for the difference to be considered greater than might be expected because of lack of reliability. This analysis assumes that the underlying scores are continuous, unimodal, and reasonably symmetrical, all fairly reasonable for the SF-36 PCS and MCS scales.

However, consider the SF-36 Social Functioning (SF) scale: a two-item scale with each item effectively scored as 0, 25, 50, 75, and 100 so that possible averaged scores are 0, 12.5, 25, 37.5, 50, 62.5, 75.0, 87.5, and 100. In this case, the assumption of continuous data clearly does not hold. If one ignores the violation of assumptions and applies the SEM formula to these data, assuming a generous test-retest reliability of .7, one obtains a SEM of 13.7 and a 95% confidence interval around the mean of 39.1 of (11.7 – 66.5). However, these calculations mean virtually nothings because the changes that can occur on the SF scale are such that a single change of one level on one item will move the score 12.5 points, which is close to 1 SEM. Thus, a "reliable" difference can be obtained by consistent changes on one or more units on each of the two items making up the scale. This example should highlight the need to have a large enough number of items to allow a reasonable assumption of continuous data and range of responses to an item to allow adequate discrimination among responses.

In sum, the notion of SEM provides a coherent theoretical framework for establishing how much change in an outcome is required to be comfortable that the observed change is more than could be expected because of an inherent error in the assessment. This represents a necessary condition for establishing whether or not an observed change in outcome is clinically relevant. A second necessary condition, based on the logic provided in the previous section regarding the true concept of condition-specific outcomes guided by the ATDO clinical model is to demonstrate that the changes

observed in the outcome(s) of interest are sufficient to change the diagnostic status of the patient. It seems that these two necessary conditions for establishing the clinical relevance of changes in outcome represent a sufficient condition for establishing the clinical relevance of an observed difference.

## THE FUTURE OF OUTCOMES

In the early 1980s, when clinicians interested in studying and treating low back pain began to embrace patient self-report as an important tool in evaluating patients' health status, and by proxy treatment efficacy, I felt that clinicians had found the path to righteousness (i.e., finding the truth about treatment efficacy). More than 20 years later the path remains a long a winding road and the potential is unfulfilled.

Einstein defined insanity as doing the same thing over and over again and expecting different outcomes. Over the course of the last 20 years three common themes recur that seem to support Einstein's notion of insanity as it applies to the use of outcomes by clinicians treating patients with back troubles.

*Shorter is better.* If a set of 10 items have been identified as providing a reasonably reliable and valid score, then shortening this instrument to five items will make it twice as good. Hopefully, the potential consequences of shorting a scale on the SEM, as illustrated with the social functioning subscale on the SF-36, provide compelling reasons why shorter is not always better.

*The best way to implement an outcomes program is to start with a core set of items and expand this core as needed.* The thinking is that, in theory, it is relatively easy to establish a reasonably small information system, get the technology up and running, and train the clinician users in the system. Once this system is in operation, clinicians will demand improvements in reporting, which will expand the core. In practice, the changes in technology (e.g., additional programming and reconciling reports) required to expand questionnaires usually are perceived by those who administer the system to outweigh the potential gains to the clinician users that would result from adding to the core set. Conversely, but consistent with the aforementioned short is better bias, it is generally perceived to be easy to remove items from a core, even though this act also requires changes in programming and reconciling reports.

*The clinical community is unable to appreciate and the measurement community to clarify the distinction between outcomes as applied to groups of patients as opposed to a given patient.* In general, the current state of clinical outcomes measures is adequate in many ways when used to evaluate treatment efficacy within a randomized controlled trial. However, these tools typically are not sufficiently reliable and valid for use in clinical practice, nor does reporting at the patient level typically

provide clinicians with adequate warnings about the potential magnitude of error in the score they are using to inform their decision making. Efforts to improve the accuracy and precision of outcome instruments and the score reporting to the point that these scores would be appropriate in clinical situations would make these tools better in the aggregate sense as well, thus indicating a win-win situation. The catch? Clinically relevant outcomes require more rather than fewer items to achieve the accuracy and precision demanded at the individual patient level.

## CHAPTER 13

# The Role of Outcomes and How to Integrate Them into Your Practice

Richard A. Deyo

---

Outcomes research became a buzzword in the 1990s, although it seems to mean different things to different people. In general, it refers to a strategy of assessing clinical practices according to patient outcomes, rather than to some prespecified, often arbitrary, set of criteria for the process of care. For example, we might judge the quality of care for a patient with metastatic cancer to the lumbar spine by his neurologic function, activities of daily living, and survival, rather than by whether the patient received a particular surgical implant or a particular diagnostic test.

Several important trends have led to the increasing interest in outcome assessment. First, medical care costs are rising much more rapidly than inflation, and the employers and government agencies who pay the bills are asking if they are getting their money's worth. This seems to be an important question, because per capita costs for medical care in the United States are well above any other country in the world, and yet measures of population health, such as morbidity and mortality, are substantially worse in the U.S. than in many other developed countries (1).

A second trend has been the observation that medical practices vary widely from place to place, even among very small geographic areas (2). At an international level, the United States appears to perform roughly twice as much back surgery as most developed countries, and five times more back surgery than the United Kingdom (3). No one knows which rate is optimal, but it seems unlikely that differences in surgical rates reflect any significant differences in the prevalence of back pain or disc disease. Thus, explanations often invoke differences in training, surgeons' beliefs, public attitudes, financial incentives, imaging strategies, and professional uncertainty. Unfortunately, the differences do not seem to be based on evidence about which style of practice produces the best patient outcomes.

One implication of these findings is that some medical services may be unnecessary. Without information on

patient outcomes, however, it is impossible to know whether, and when, this is the case. Recent data from the Maine Lumbar Spine Study (MLSS) suggest that outcomes do vary from one geographic area to the next. In fact, within the state of Maine, the best surgical outcomes—in terms of pain relief, functional status, disability compensation, and patient satisfaction—all occur in the areas with the lowest surgical rates. In contrast, the region of the state with the highest surgical rates reports the worst surgical outcomes. The area of the state with intermediate surgical rates has intermediate outcomes by every measure (4). Thus, it seems clear that more is not necessarily better. Such observations have led to greater calls for accountability by the medical profession.

### TYPES OF OUTCOME MEASURES

#### The Problem of Surrogate Outcomes

Traditionally, many research studies have focused on physiologic outcomes or anatomic outcomes as indicators of success. Examples would be whether a solid fusion is achieved in a patient who undergoes lumbar spine fusion. Other examples would be spinal range of motion as a measure of improvement, spinal fluid endorphins as a measure of possible pain relief, or surface electromyography as an indicator of "muscle spasm." Unfortunately, as suggested in Table 13-1, these are all intermediate or "surrogate" outcomes, that may or may not reflect the end results in which we—and our patients—are most interested. That is, these outcomes do not necessarily correlate well with pain relief, return to work, or improvement in daily function. The implication is that if we are interested in the outcomes of pain relief, return to work, and daily functioning, we must measure them directly rather than try to infer them from these physiologic or anatomic surrogates (5).

**TABLE 13-1.** *Contrasting results for “surrogate” outcomes versus end results*

Treatment (reference)	Surrogate outcome	End result
Lumbar fusion for degenerative discs	Solid fusion achieved	Many patients with solid fusion continue to have pain; many patients without solid fusion have good pain relief
Biofeedback (28)	Reduced paraspinal EMG activity	No change in pain
Antidepressant drugs (29)	No change in spinal fluid endorphins	Better pain relief than placebo
Surgical discectomy (20)	Recovery of motor deficits equal, with or without surgery	Better pain relief with surgery

EMG, electromyogram.

### Dissociations among Outcomes

Another problem has been that, in the past, much of the research on back problems focused only on measuring pain, to the exclusion of other dimensions of outcome. However, in a modern understanding of chronic pain management, it has become apparent that both clinical and research work may need to focus more on patient functioning than on pain reports. Some clinical trials have shown that it is possible to improve pain reports without improving functional status scores, suggesting that even though pain reports diminish, behavior may not change in any significant way. This highlights the fact that even among the results most important to us, there are often dissociations among outcomes.

As one example, in the MLSS, patients treated surgically for herniated discs were compared to others treated nonsurgically. Even after statistically adjusting for many baseline characteristics to produce more nearly equivalent groups, surgical outcomes were substantially better than nonsurgical outcomes regarding pain and daily functioning. However, return to work was equivalent between the two arms (6). If one focused only on return to work, one might erroneously conclude that surgery was not helpful for herniated discs. If one focused on pain and function, however, a large advantage of surgery would be apparent.

In another example, we studied long-term outcomes in a longitudinal cohort of primary care patients seen in a managed care organization. After 2 years of follow-up, even among those with the worst pain ratings (6 to 10 on a 10-point scale), the vast majority of patients were still working. Only 11.3% were unemployed despite their high levels of pain (Table 13-2). Conversely, among those who reported no pain at all, 6.5% remained unemployed. In other words, those with the least pain had a higher employment rate, but even there, a substantial fraction remained unemployed (7). Thus, even among the outcomes that may be most relevant to doctors and patients, there are often dissociations, and these different dimensions of outcome must be measured independently.

This is one reason why the traditional outcome scale of “excellent/good/fair/poor” is often inadequate. Howe and Frymoyer noted that different definitions of these terms result in dramatically different conclusions about the

efficacy of surgical procedures, even with the same data in hand (8). Furthermore, as the examples given earlier suggest, any attempt to combine pain, function, and employment status into a single scale may be misleading, because the different outcomes can move in different directions, or one may improve while others do not.

In studying patients with degenerative spinal disorders, death and cure are generally not relevant measures of outcome. Very few patients die from back pain or disc disease. Thus, unlike the study of heart disease or cancer, death rate is a poor outcome measure for spinal degenerative conditions. Furthermore, patients are rarely cured of these degenerative conditions, because the degenerative process continues even after successful surgical intervention. In most studies of both surgical and nonsurgical treatments, a substantial proportion of patients continue to have pain symptoms, although the symptoms may be improved by the treatments under study. Unlike infectious diseases or the surgical treatment of appendicitis, it is generally inappropriate to talk about “cure.”

### Modern Outcome Questionnaires

All of these factors help to explain the growing interest in questionnaire-based measures of a patient’s pain, back-specific functioning, general health status, and work disability. Indeed, these are the dimensions of outcome recommended for routine measurement by an international working group (9) and in an update, by the participants in

**TABLE 13-2.** *Dissociations among outcomes at 2-year follow-up of patients in primary care<sup>a</sup>*

Worst pain rating (6–10): 11.3% unemployed
Best pain rating (0): 6.5% unemployed
Worst modified Roland score (37.6–100%): 11.4% unemployed
Best modified Roland score (0): 4.3% unemployed

<sup>a</sup>Excludes subjects keeping house, retired, or otherwise outside the work force.

**TABLE 13-3.** *Reproducibility of patient self-reports and physician observations<sup>a</sup>*

Test-retest reliability of patient self-reports over several weeks	Kappa <sup>b</sup>	Interobserver agreement by expert clinicians	Kappa <sup>b</sup>
Health history questionnaire	0.79	Ankle reflexes normal	0.50
Daily function: sickness impact profile	0.87	Soft tissue tenderness	0.24
Physical function: SF-36	0.89	Lumbar spine x-ray, normal or abnormal	0.51
Pain: visual analog scale	0.94	Presence of osteophytes on x-ray	0.64

<sup>a</sup>Data are from Deyo (5), Deyo, et al. (12), Deyo, et al. (13), Patrick (14), Pecoraro (15), McCombe (16), with permission.

<sup>b</sup>Kappa quantifies agreement on two measures after adjusting for chance agreements.

a “focus” issue of Spine (10). Reliable and valid measures of each of these dimensions are available because of fusing clinical expertise with social science methodology.

A common concern about questionnaire measures is that they are “soft data.” Physiologic measures are attractive in part because they seem “harder.” However, the boundary between hard and soft data is indistinct at best. Feinstein pointed out that we might judge the hardness of data by their objectivity (physician finding versus patient report); preservability (e.g., radiologic or histologic specimen); or by the ability to quantify (e.g., a hematocrit versus the observation that a patient is pale). However, he concluded that the essence of “hardness” was the reproducibility of data when measured repeatedly under the same circumstances (11). By this measure, many modern questionnaires are at least as hard as the clinical observations with which we are more familiar. For example, Table 13-3 shows the test-retest reliability of several self-report questionnaires, and contrasts these with interobserver agreement on several clinical measures (12–16). In many cases, the reproducibility of the questionnaire measures substantially exceeds that of the clinical measures.

In addition to reproducibility, these measures have demonstrable validity, as judged by comparison with other more objective measures of health. For example, in a national survey, middle-aged men responded to a single question about whether their health was excellent, very

good, good, fair, or poor. The responses to this single question predicted 10-year mortality. In fact, the survival rates fell in perfect order according to the initial self-evaluation of health, and ranged from about 60% survival among those who indicated poor health to 95% survival among those who indicated excellent health (17). Although we know little about how subjects made their self-evaluations at baseline, this simple self-rating obviously had important prognostic ability.

Questionnaires for studying back-related dysfunction have been validated against a variety of clinical measures, with reassuring results. Table 13-4 provides an example that compares the Roland Disability Questionnaire, the Short Form 36 (SF-36), and some “disability day” measures from U.S. population surveys (14). While some association is expected between a valid questionnaire and other measures of health status (e.g., opioid use, or physical examination findings), such an association would not necessarily be expected to be a strong association. In the absence of a “gold standard” for daily functioning, this sort of cumulative “construct validation” is generally the best we can do.

**Performance Measures**

Tests of patient performance have sometimes been used to evaluate physical capacity. Such tests may include, for example, computerized dynamometry, or

**TABLE 13-4.** *Construct validation of several patient self-report measures by comparison with other clinical phenomena<sup>a</sup>*

Outcome questionnaire	Opioids in past mo		Workers' comp		Abnormal straight leg raising	
	Yes	No	Yes	No	Yes	No
Modified Roland scale <sup>a</sup>	17.5	14.2	17.6	14.9	16.8	13.9
SF-36 physical function <sup>b</sup>	7.6	16.8	3.1	16.8	9.4	18.4
SF-36 pain <sup>b</sup>	19.2	33.0	21.4	28.7	23.4	32.3
Days of reduced activity <sup>c</sup>	21.3	18.1	24.3	17.4	20.2	18.7

<sup>a</sup>Mean scores at baseline for sciatica patients seen in surgical practices. All differences are significant at  $p \leq .005$ . Higher scores on the Roland scale represent worse function; range 0–2.4.

<sup>b</sup>All differences are significant at  $p \leq .005$ . Higher scores on the SF-36 represent better function, range 0–100.

<sup>c</sup>All differences are significant at  $p \leq .005$  except for those with and without abnormal SLR. From Patrick DL, Deyo RA, Atlas SJ, et al. Assessing health related quality of life in patients with sciatica. Spine 1995;20:1899–1909, with permission.

timed or measured performance on a standardized set of tasks. While this approach has the attraction of seeming objective, patient mood, motivation, and other factors affect performance. Further, they require in-person evaluation (rather than by mail or telephone) and may require special equipment, making them less practical and affordable than questionnaire measures. How these performance measures may compare with self-report measures in terms of validity and responsiveness remains unclear and is an area for further investigation.

### OUTCOME ASSESSMENT FOR QUALITY IMPROVEMENT

One application of outcome measurement is for improving clinical practices. In this circumstance, patients would use outcome questionnaires in the course of routine clinical care. The results might be used to evaluate changes in clinical practice, surgical technique, staffing patterns, or other aspects of care.

As one example, Zucherman et al. reported their experience of measuring patient outcomes with different surgical implants for performing spinal fusions. Unfortunately, they found that with successive waves of new surgical implants, their outcomes became worse rather than better (18). Only with the most recent implants at the time did their results finally improve, though they remained worse than their results using bone grafts without surgical implants. It seems unlikely that these surgeons were less technically skilled than other surgeons. Instead, they seemed to identify an important trend in their own practice that might otherwise have gone unnoticed. Even though their report did not make use of some of the newer outcome instruments, their data were sufficient for monitoring and improving their own clinical practice.

Such quality improvement efforts may have been part of the motivation for developing the Musculoskeletal Outcomes Data Evaluation and Management System (MODEMS) program by the American Academy of Orthopaedic Surgeons (AAOS). That program was designed to have surgeons implement outcome measures routinely in their own practices, with data submitted to a central database. Unfortunately, the effort was not highly successful, and this experience may point to some of the problems with outcome assessment in routine practice.

Measuring outcomes in routine care requires real resources. In addition to identifying and duplicating questionnaires, one must have some means of entering the data into a computerized database, calculating scores, and reporting the results. Some practices have succeeded in doing this at baseline for most new patients, but have found it difficult to obtain uniform follow-up. Some patients do not return to clinic, some return at unexpected intervals, and some simply do not respond to mail or telephone surveys. Obtaining a high rate of follow-up at consistent time intervals is likely to require dedicated personnel who are able to

conduct multiple mailings or phone calls, and this adds to the expense. These activities are not a part of routine care as it is currently conceived, and therefore are not reimbursed by patients or insurance companies. Thus, many practices find it difficult to collect uniform outcome data.

In part for this reason, we have proposed a simple set of outcome questions that might be used in routine care and would require minimal resources (9). This is a set of just six questions, all derived from well-validated outcome questionnaires, and covering several important dimensions of outcome: pain, back-related functioning, general health status, work disability, and satisfaction with care (Table 13-5). Even this short set of measures appears to be a substantial improvement compared with measuring pain severity alone, or by “excellent/good/fair/poor” standards. The questions were intended to be examined individually, without generating an overall score, in part to avoid obscuring the situation in which one dimension improves while others do not. A 1-week period for measuring symptoms was suggested because it allows the patient to integrate recent experience for a long enough interval to be meaningful, but short enough to avoid important problems with recall and to identify relatively short-term improvements. Many of these items are included in the lumbar cluster of the AAOS outcome instruments used for the MODEMS program.

While these outcome measures may be useful for monitoring quality improvement over time, they should be used with caution to compare individual physicians, clinics, or hospitals. Such cross-system comparisons may be misleading because of important demographic or clinical differences in the patient populations served. Thus, for example, a hospital serving low-income patients with low levels of literacy, language barriers, high levels of comorbidity, poor health insurance, and menial if any work, is likely to have worse outcomes than a health care system serving well-insured, affluent, and well-educated patients. Similarly, a physician with a reputation for excellence may have the most difficult cases referred to him or her, while a less-skilled physician may see patients with less severe problems. The patients of the more skilled physician might have worse outcomes despite higher quality care simply because of a worse initial prognosis. Comparing outcomes under these circumstances could lead to an erroneous conclusion about the quality of care. Having measures of baseline demographic and clinical characteristics for patients would help to avoid such mistaken conclusions, but may not completely adjust for all the differences in patient populations.

Furthermore, if financial incentives are tied to outcome measures, there is a substantial risk of “gaming” the results. This could occur if a health care system made only nominal efforts to collect data from patients with low literacy, limited English fluency, the most severe illness, or simply removed “outliers” from calculations or adjusted inclusion and exclusion criteria to optimize their apparent outcomes. The gaming that has been well

**TABLE 13-5.** Parsimonious routine care

Patient outcomes <sup>a</sup>					
1. During the past week, how bothersome have each of the following symptoms been? (circle one number in each row)					
	Not at all bothersome	Slightly bothersome	Moderately bothersome	Very bothersome	Extremely bothersome
a. Low back pain	1	2	3	4	5
b. Leg pain (sciatica)	1	2	3	4	5
2. During the past week, how much did pain interfere with your normal work (including both work outside the home and housework)?					
	<input type="checkbox"/> Not at all	<input type="checkbox"/> A little bit	<input type="checkbox"/> Moderately	<input type="checkbox"/> Quite a bit	<input type="checkbox"/> Extremely
3. If you had to spend the rest of your life with the symptoms you have right now, how would you feel about it?					
	<input type="checkbox"/> Very dissatisfied	<input type="checkbox"/> Somewhat dissatisfied	<input type="checkbox"/> Neither satisfied nor dissatisfied	<input type="checkbox"/> Somewhat satisfied	<input type="checkbox"/> Very satisfied
4. During the past 4 weeks, about how many days did you cut down on the things you usually do for more than half the day because of back pain or leg pain (sciatica)? _____ Number of days					
5. During the past 4 weeks, how many days did low back pain or leg pain (sciatica) keep you from going to work or school? _____ Number of days					
6. Over the course of treatment for your low back pain or leg pain (sciatica), how satisfied were you with your overall medical care?					
	<input type="checkbox"/> Very dissatisfied	<input type="checkbox"/> Somewhat dissatisfied	<input type="checkbox"/> Neither satisfied nor dissatisfied	<input type="checkbox"/> Somewhat satisfied	<input type="checkbox"/> Very satisfied

<sup>a</sup>Note: most of these items are included in the AAOS Lumbar Cluster, the Low Back Pain TyPE, and the NASS low back outcome instrument.

From Deyo RA, Battie M, Beurskens AJ, et al. Outcome measures for low back pain research. A proposal for standardized use. *Spine* 1998;23:2003–2013, with permission.

demonstrated in diagnosis coding for reimbursement suggests that this is a real concern.

Aside from quality improvement, some practices have adopted routine measurement of health outcomes for helping to inform clinical care. Thus, for example, some practices have routinely had patients complete the SF-36 or the Oswestry Disability Questionnaire, and made the results available to clinicians as they see the patients. In many cases, these have been academic practices where extramural resources, including grants, could help to support these activities. Nonetheless, some private practitioners have also adopted the strategy and find the information useful to inform their own care of individual patients.

**OUTCOME MEASUREMENT FOR RESEARCH PURPOSES**

Aside from their use in quality improvement, outcome measures might be used for comparing the effectiveness of different clinical approaches to a particular problem. In some circumstances, this might be done in the form of a randomized controlled trial. However, randomized trials are probably less common in routine practice settings than observational studies, such as cohort studies. In cohort studies, patients may receive different treatments for the same condition, but with the treatments determined by the course

of usual care rather than the dictates of a randomization schedule. Although such studies do not yield information as definitive as randomized trials with regard to treatment efficacy, outcome studies using cohort designs have sometimes added greatly to our understanding of patient experience of various outcomes, unexpected consequences of therapy, and important gaps in clinical knowledge.

An example of such work can be found in the MLSS, where we followed such patients with either herniated lumbar discs or lumbar spinal stenosis with pretreatment measures, and follow-up data collected at 3 months, 6 months, 1 year, and annually thereafter. Table 13-6 provides selected data from that study, using several state-of-the-art outcome questionnaires (19).

The MLSS collected data from the offices of orthopedic surgeons, neurosurgeons, and occupational medicine physicians. The study provided much greater detail regarding patient outcomes than was previously available from the one randomized trial of surgical versus nonsurgical treatment for sciatica (20). Like that study, the MLSS suggested that surgery offered an advantage in outcomes for several years, although the differences in outcome between surgical and nonsurgical treatment gradually narrowed over several years. The MLSS also found that return to work after 1 year and 3 years was virtually the same with or without surgery (6).

**TABLE 13-6.** Outcomes data for patients with sciatica, comparing surgical and nonsurgical therapy in a cohort study

Outcome variable <sup>a</sup>	Treatment group		P value
	Surgical (n = 219)	Nonsurgical (n = 170)	
<b>Symptoms</b>			
Low back pain compared to baseline <sup>b</sup>			<0.001
Better	75.0	54.5	
Same	16.8	29.9	
Worse	8.2	15.6	
Leg pain compared to baseline <sup>b</sup>			<0.001
Better	81.3	55.8	
Same	13.4	33.3	
Worse	5.3	10.9	
Change in predominant symptom <sup>c</sup>			<0.001
Completely gone	30.6	11.4	
Much better	40.2	31.7	
Better	9.1	13.2	
About the same or a little better	14.3	29.9	
A little worse to much worse	5.8	13.8	
Sciatica Frequency Index, mean change	-11.2	-3.4	<0.001
<b>Functional status</b>			
Roland score, mean change (1-yr baseline)	-11.1	-4.7	<0.001
SF-36 score, mean change (1-yr baseline)			
Physical function	40.3	17.5	<0.001
Bodily pain	44.0	20.4	<0.001
Disability days in past month, mean changes <sup>d</sup>			
In bed	-10.1	-3.3	<0.001
Decreased activity	-16.0	-12.5	0.04
Absent from work	-10.2	-8.0	0.06
Quality of life, ≥ moderate improvement	79.7	57.6	<0.001
<b>Patient satisfaction</b>			
Overall results of treatment, ≥ very good	61.1	46.0	0.005
Spend rest of life like now, satisfied	60.1	39.6	<0.001
If surgery, still choose back operation, yes	86.5		
<b>Employment and WC status</b>			
If receiving WC at entry	(n = 60)	(n = 63)	
Unemployed at 1-yr evaluation	30.5	44.1	0.13
Receiving WC at 1-yr evaluation	45.6	55.2	0.30
If employed at entry	(n = 113)	(n = 78)	
Unemployed at 1-yr evaluation	5.4	6.9	0.68
Receiving WC at 1-yr evaluation	4.6	7.1	0.47

SF-36, Short Form 36; WC, workers' compensation.

<sup>a</sup>All variables expressed in percentages, except where noted.

<sup>b</sup>Symptom severity was reported to be "better" if the response was "better" to "completely gone," the same if the response was "about the same" or "a little better," and worse if the response was "a little worse" or "much worse."

<sup>c</sup>Predominant symptom, either leg or back pain, at entry.

<sup>d</sup>Comparing difference of two distributions using the Kolmogorow-Smirnov statistic.

From Atlas SJ, Deyo RA, Kellar RB, et al. The Maine Lumbar Spine Study, Part II.

One year outcomes of surgical and non-surgical management of sciatica. Spine 1996;21:1777-1786, with permission.

An example of a randomized trial using similar outcome measures is the Spine Outcome Research Trial (SPORT) currently underway in the United States. This study is randomizing patients to surgical or nonsurgical treatment for herniated discs, spinal stenosis, or degenerative spondylolisthesis. The trial involves data collected from numerous clinical practices around the country. In this trial, patients usually complete questionnaires using electronic "tablets," allowing instant data entry and analysis. Outcome measures in this study include the Oswestry Disability Questionnaire, the SF-36, and symptom measures, as well as a

measure of patient satisfaction (21). For projects such as these, which enjoy extramural research funding, it is feasible to use a larger set of questionnaires than the simple measures proposed for quality improvement purposes

### RECOMMENDED QUESTIONNAIRES FOR STUDYING OUTCOMES OF LUMBAR SPINE DISORDERS

As a result of an international low back pain forum, and a subsequent focus workshop on outcome research, a core

**TABLE 13-7.** A proposed set of patient-based outcome measures for use in spinal disorders

Domain	Instrument	No. of items (response options)	Score (best to worse)	Time to complete	Dimensions
Back specific function	Roland-Morris	24 (yes/no)	0–24	5 min	Physical activities, housework, mobility, dressing, getting help, appetite, irritability, pain
	or Oswestry	10 (6 levels)	0–100	5 min	Pain intensity, personal care, lifting, walking, sitting, standing, sleeping, sex life, social life, traveling
Generic health status	SF-36 version 2.0	36 (variable)	8 dimensions: 100–0 each or norm-based: mean: 50; SD: 10	10 min	Eight dimensions: physical function, role physical, bodily pain, general health, vitality, social function, role emotional, and mental health Can be aggregated into two components: Physical and mental health
Pain	Bodily pain scale of SF-36	2 (variable)	100–0 or norm-based: mean: 50; SD: 10	2 min	Pain intensity, pain interference with work and housework
	(optional) Chronic pain grade	7 (11-point NRS) + no. of days in pain		5 min	Current, worse, and average pain, disability days, interference with usual activities, recreational, social and family activities, and work (including housework)
Work disability <sup>a</sup>	Work status	10 categories	Nominal scale	1 min	Employed at usual job, on light duty, or some restricted work assignment, paid leave/sick leave, unpaid leave, unemployed because of health problems, unemployed because of other reason, student, keeping house/homemaker, retired, on disability
	Days off work and days of reduced work <sup>b</sup>	No. of days		2 min	
	Time to return to work	No. of days		2 min	
Satisfaction: back specific	Satisfaction with care: Patient Satisfaction Scale	17 (5 levels)			Information, caring, effectiveness of treatment, and others
	Satisfaction with treatment outcome: Global question	1 (7 levels)	1–7	1 min	Extremely, very, somewhat satisfied, mixed, somewhat, very, extremely dissatisfied

NRS, Numerical Rating Scale.

<sup>a</sup>The SF-36 physical and mental role scales refer to all roles (work as well as housework). The reader specifically interested in work-related disability would need to modify these scales to refer to work roles only.

<sup>b</sup>The U.S. National Health Interview Survey asks about days off work and reduced activity both from usual work and other role activities. The reader specifically interested in work-relatedness would need to modify these questions to refer to work roles only.

From Bombardier C. Outcome assessments in the evaluation in the treatment of spinal disorders; summary and general recommendations. *Spine* 2000;25:3100–3103, with permission.

set of patient-based outcome measures for research purposes has been proposed (9,10). As shown in Table 13-7, these include measures of back-specific functioning, generic health status, pain, work disability, and patient satisfaction. Each of the instruments in Table 13-7 has been well validated, and the characteristics of the questionnaires are indicated in the table. This set of measurement instruments corresponds closely to the lumbar spine cluster proposed by the AAOS and to the North American Spine Society (NASS) spine questionnaires. The special focus issue of *Spine* contains a summary of the data relating to these questionnaires, including information about their reliability, reproducibility, and responsiveness to changes over time (10,22,23). For key elements of this recommended set, such as the Roland and Morris disability questionnaires and the SF-36, well-validated versions are available in many languages, especially European languages.

This set of instruments was intended to be a core set that might be used by most investigators studying low back problems, to help improve comparability among studies and also to facilitate formal meta-analysis of multiple studies. However, the intent was to make this core set sufficiently brief so that investigators could add additional instruments for purposes specific to the conditions and treatments they are studying. Thus, investigators may wish to add more psychological measures or disease-specific modules such as measures for spinal stenosis or scoliosis.

This is certainly not an exhaustive list of validated instruments for studying low back pain. However, it does represent a set that appears to be well validated, widely used, and at least equivalent in performance characteristics to other available instruments.

## HAZARDS IN OUTCOME MEASUREMENT

The difficulties in making fair comparisons among physicians or hospitals have previously been addressed. In general, valid comparisons of outcomes would require at least adjustment for disease severity, comorbid conditions, baseline health status, and several important demographic variables. Even with such adjustment, comparisons should be made with caution, because we do not yet know all the relevant variables for predicting patient prognosis or outcome.

Those who assess spine outcomes must be aware that many factors other than medical care can affect the results of a particular disease. Patients with multiple comorbid diseases (e.g., heart disease or diabetes) are likely to have worse outcomes than patients without comorbid illnesses. Low income or homeless patients are likely to have worse outcomes than more affluent patients. Patient compliance, genetic endowment, psychological characteristics, and environmental factors (such as workplace characteristics) may also have a major influence on patient outcomes. Thus, in comparing qual-

ity of care between providers or in comparing the effectiveness of different treatments, caution is warranted if outcomes are used. In most situations, random allocation to alternative treatments is the best way to assure that one is truly comparing equivalent groups, but this is rarely feasible in comparing health care providers or workplaces.

The optimal timing and duration of follow-up for outcome assessment may vary according to the condition or treatment under study. For example, studies of spinal manipulation have suggested that any benefits occur within a few days or weeks of treatment, and do not have long-lasting effects. In contrast, surgical intervention may result in a temporary decline in patient functioning during the postoperative recovery period, with benefits only becoming apparent in long-term follow-up. Similarly, the timing of outcome measures may vary according to whether one is studying patients with acute pain or chronic pain.

Patients' literacy and language fluency are additional potential barriers to the use of questionnaire measures such as those presented here, though these barriers can sometimes be overcome (24). Standards for developing equivalent questionnaires in different languages have been proposed (25), and oral interviews can sometimes replace self-administration.

An important caveat is that financial incentives may affect a patient's self-report. If financial gain may result from high levels of disability (e.g., disability compensation), patients may report worse functioning on standardized questionnaires. This is not being dishonest as much as it is a natural tendency to maximize symptoms and dysfunction under such circumstances. Conversely, some patients have reported fear of losing their insurance coverage if they admit to any functional problems that might be seen as "preexisting conditions" in any new insurance application. Such patients would perceive a financial incentive to report excellent functioning and no symptoms, skewing results in the opposite direction. The magnitude of such effects has not been well-quantified or studied, although it seems clear that outcomes are generally worse among patients who receive disability compensation than among those who do not, even with apparently similar levels of anatomic or physiologic disruption. Such incentives may also influence performance on standardized physical tasks.

## FUTURE DEVELOPMENTS

*Item response theory* has been well known among those who do psychological testing for many years, but its application to health status measures is relatively recent. Item response theory allows one to rate the "difficulty" of a question in comparison to other similar questions. Thus, for example, "walking one block" would be rated easier than "walking one mile". Although the ranking of these

two items is obvious, the relative rankings of other functional items may be less clear. Item response theory allows a diverse range of items to be ranked by their difficulty. Such techniques can allow the construction of a large bank of individual questions that measure the same underlying construct (such as physical function or emotional function) and calibration of every item within that bank (26).

With computer technology, adaptive testing would then become possible. The idea is that if a patient indicates he or she is able to walk a mile, then questions about less demanding activities would be avoided. Instead, a series of more difficult questions would be posed, allowing the investigator to reach a very precise estimate of a patient's physical functional ability with just a few items. Thus, after the first question, the computer selects each subsequent item from the pool of calibrated items according to the subject's responses to the initial and each subsequent item. The goal is to achieve a high level of accuracy with as few items as possible.

Item response theory models have been used for some scale validation, and the Quebec Back Pain Disability Scale was developed using this technique (27). An effort to calibrate all the items found in major scales for back pain should be encouraged, because this could lead to construction of a relevant item bank, and in turn toward computerized adaptive testing (26).

Adaptive testing aside, the Internet offers enticing prospects for the future of studying patient outcomes. If Internet access was widely available in patients' homes, patients would be able to complete questionnaires and transmit data to a central database without using pencil and paper, stamps, or envelopes. In settings where computer access is widely available, this may already be feasible.

## CONCLUSION

Variations in care and rising health care costs have led to growing calls for accountability by those who pay the bills. In many cases, studying patient outcomes in a rigorous fashion is likely to be the best way to identify effective treatments and to assess the quality of care. For low back disorders, traditional measures such as death, cure, and physiologic outcomes have only limited applicability. In many cases, patients' symptoms, function, and work status are the most important outcomes to measure. While these are subjective, modern instruments can assess these dimensions of outcome with demonstrable reliability and validity. A standard battery of instruments can be recommended for measuring several dimensions of patient outcome, generally obviating any need to "reinvent the wheel." However, improvements in such measures will inevitably be developed, and comparisons among potential outcome measures should be encouraged. Such comparisons should quantify the construct validity, reproducibility, and responsiveness of these instruments.

When comparing providers with regard to quality of care, or when comparing treatment effectiveness, extreme care is warranted to assure that the comparisons are fair, considering potential baseline differences in disease severity, health status, and demographic characteristics. A variety of logistic barriers must be overcome before these instruments are widely used in routine practice, including the resource requirements for collection, automation, analysis, and reporting of the data. Nonetheless, such efforts offer the promise of substantial improvements in quality of care and in the effectiveness of treatment approaches.

# **Alternatives to Traditional Nonoperative Treatment**

## CHAPTER 14

# Manual Therapy in Patients with Low Back Pain

Jiri Dvorak, Scott Haldeman, and Wolfgang Gilliar

---

The hands are one of the oldest tools available to clinicians for healing. References to manual treatment methods can be found in the writings of virtually all ancient and modern civilizations. This discipline, in its broadest definition and as it relates to low back pain, includes all procedures where practitioners apply their hands for diagnostic and therapeutic purposes in the hope of relieving symptoms and restoring function. Since the 1950s, and in particular since the 1970s, manual medicine has experienced unprecedented growth and acceptance, not only by the general population, but also by traditionally orthodox branches of medicine. This growing interest is due to a number of social and political forces. One of the strongest of these forces has been the failure of traditional medicine practitioners to develop treatment methods that control low back pain to the satisfaction of patients.

Despite the marked increase in diagnostic technology and improvements in both medications and surgical procedures, there is no evidence that the amount of suffering and related disability due to back pain has improved, and if anything, it appears to be increasing. There has also been a marked resurgence in interest by the public in so-called alternative and complementary medicine, or CAM approaches to health care. This may, in part, be a response to the more aggressive use of medications, injection therapies, and surgery along with the growing realization that these procedures rarely cure back pain, at least in the long term, and have significant complication rates and expenses. A recent series of publications has shown that more patients use CAM therapies to treat their low back pain than conventional medical therapies, and that satisfaction with CAM providers is markedly higher than for traditional medical providers. The most popular CAM treatment for low back pain is spinal manipulation and massage, both of which fall into the category of manual therapies, although particularly in Europe, manual medicine is integrated within the classic education of physicians. In several countries (e.g., Switzerland, Germany, Czech Republic, France) a subspecialization in manual

medicine has been established within the normal medical associations.

The initial response by the mainstream medical community to the popularity of manual therapy through the first 75 years of the 20th century was an attempt to ostracize practitioners, especially chiropractors and osteopathic physicians, and to isolate those medical practitioners who recommended and taught manual therapy. There was, however, a small group of pioneering allopathic physicians such as James Cyriax, Robert Maigne, Karl Lewit, and John Mennell, particularly in Europe, and later within North America and the rest of the world, who maintained an interest in the manual therapies throughout the 20th century. The “modern” era of manual therapy has often been attributed to the Swiss physician O. Nægeli (1843–1922), who described a series of “handgriffe” (hand applications) for cervical manipulations in 1894. It was during the same period, at the end of the 19th century and early 20th century, that Andrew Taylor Still, M.D., formulated the concepts of osteopathy and chiropractics was established as a practice devoted to spinal manipulation by Daniel David Palmer. There was a parallel growth of the three groups of practitioners of manual therapy (medical physicians, chiropractors, and osteopaths) through the 20th century that gradually resulted in communication of ideas and the teaching of techniques between these different groups of practitioners. At the same time massage and manual mobilization, which have always been part of rehabilitation and the practice of physical therapy, became more formalized within this medical profession. There is a growing body of academic physical therapists that have become very active in research in the manual therapies and are responsible for the publication of a number of clinical trials on the topic. Components of the manual medicine armamentarium are increasingly being adopted and integrated in general medical practice and are being included within the teachings of many medical specialties including neurology, orthopedics, physical medicine, rehabilitation, and rheumatology (1). In some settings the manual therapies are practiced by a med-

ical physician but in many interdisciplinary centers these therapies are performed by chiropractors, osteopathic physicians, and sometimes by physical therapists.

## DEFINITIONS

Terminology used by practitioners can be difficult to understand for many physicians who do not have formal training in the manual medicine field. The German term “manuelle medizin”, or manual medicine has become the standard term used for the manipulative therapies practiced by medical physicians in most of Europe. On the other hand, in North America 90% of the manipulative treatments are performed by chiropractors who use the term “chiropractic adjustment” to describe their procedures. Osteopathic physicians refer to specific “osteopathic manipulative therapy (OMT).” Many of the mobilization and massage techniques are generally offered by physical therapists and a growing number of massage therapists. Each of these professions, in turn, has numerous techniques or named methods of providing their form of manual therapy.

It is possible to divide the manual therapies into three major subdivisions with a fourth category representing a combination of some of the techniques. The most common procedure, and that which also requires the greatest amount of skill and training, is the classic “thrust technique.” The thrust technique is also described as “mobilization-with-impulse” technique, or “high velocity, low amplitude (HVLA) thrust” (Fig. 14-1). The second gen-

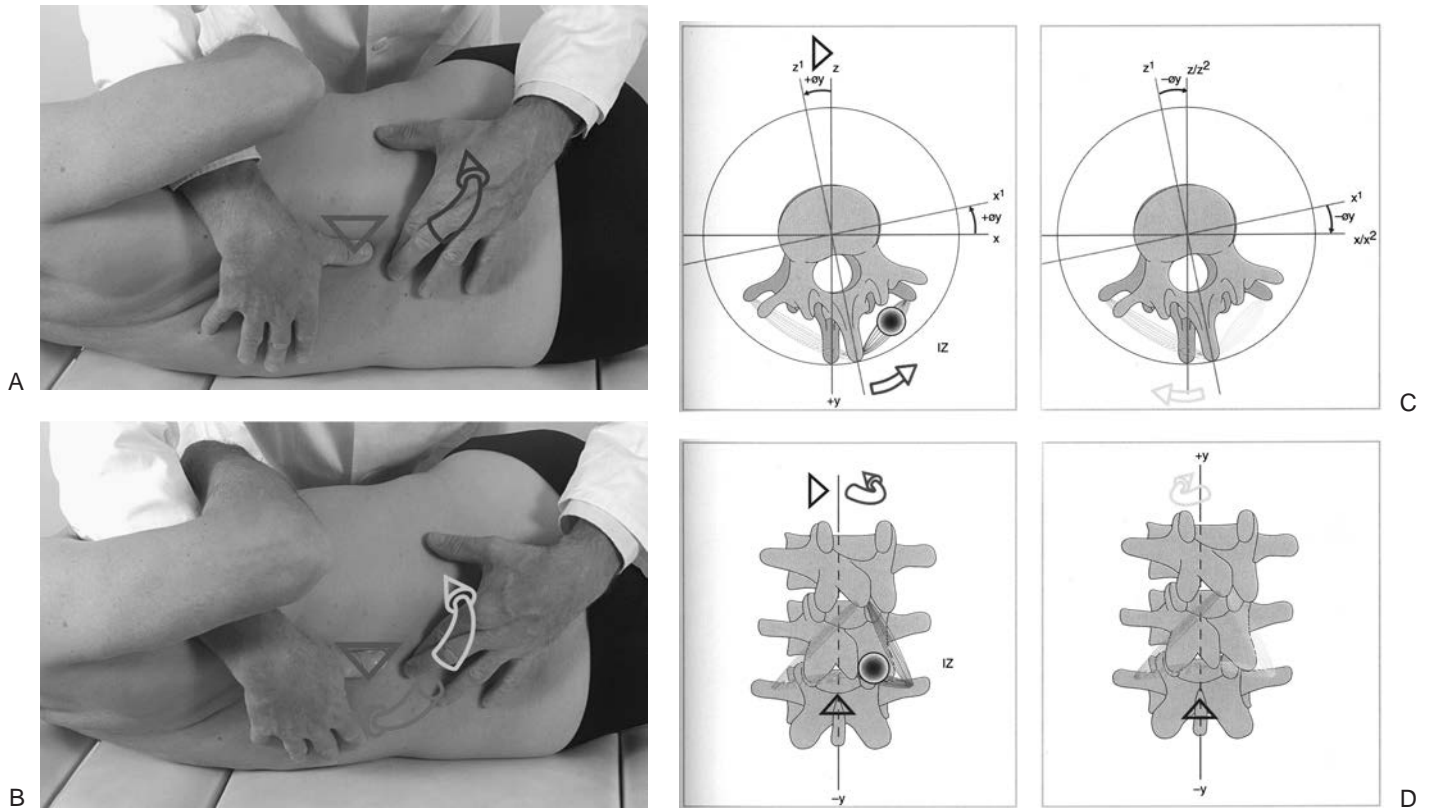

eral treatment category is represented by the nonthrust mobilization techniques, which are also known as “mobilization-without-impulse” techniques. They are easier to perform and do not take the joint beyond the normal range of motion. The third category includes the so-called soft tissue techniques, consisting of various methods of mobilization and massage applied to the soft tissues of the spine without movement of a joint.

The fourth manual technique, the “neuromuscular therapy (NMT)” is a hybrid of the classic manual techniques and includes treatment procedures that attempt to mobilize and stretch the muscles by engaging specific muscle action or invoking associated neuromuscular reflex mechanisms. These techniques rely on direct muscle force (NMT 1) in order to move the spine and stretch muscles or they include a postisometric relaxation phase (NMT 2) (Fig. 14-2). Another variation attempts to take advantage of the reciprocal innervation for inhibition of specific muscle groups (NMT 3). This form of manual therapy is based, in part, on the observation that rotation of the spine to one side is caused by the contralateral transversospinal muscular system but may be typically limited by shortened ipsilateral transversospinal muscles. Rotational motion of the superior partner of the vertebral spinal segment is initiated to one side by the rotator and multifidi muscles on the contralateral side. Thus, the right rotator and multifidi muscles function as agonists for rotation to the left side (Fig. 14-3). When the rotatores and multifidi muscles are shortened in the same spinal segment it is assumed that they diminish rotation to the

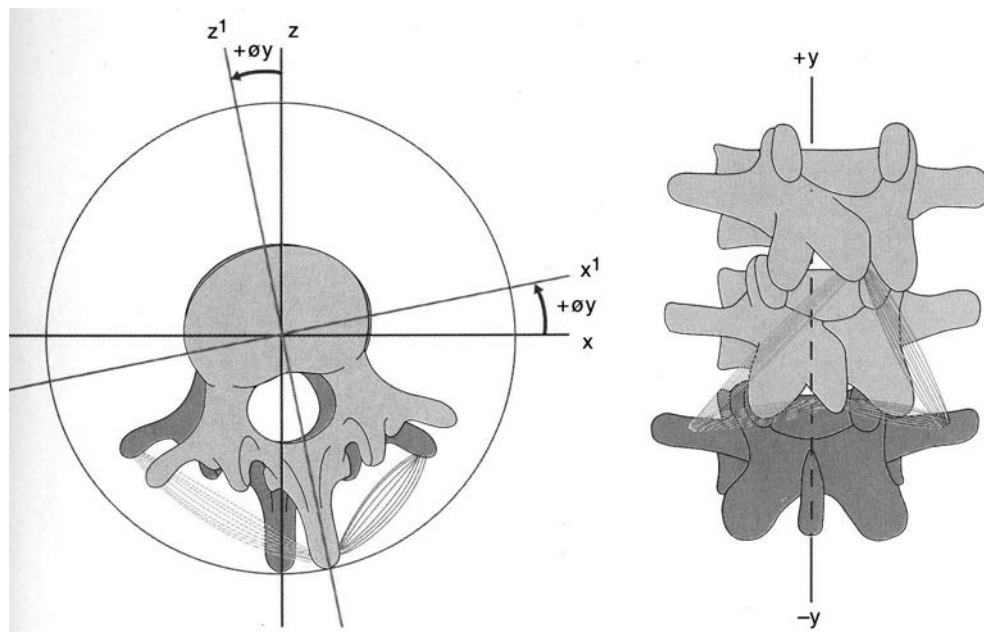

**FIG. 14-1.** Manipulation of lumbar spine in side position (mobilization with impulse). (From Dvorak J, Dvorak V, Schneider W, et al. *Musculoskeletal medicine (manual therapy)*, 3rd English ed. Stuttgart/New York: G. Thieme Verlag, 2004, with permission.)

**FIG. 14-2.** Mobilization without impulse of the lumbar spine **(A)** and mobilization without impulse using the postisometric relaxation of the antagonistic muscle groups **(B)** also described as neuromuscular therapy (NMT). **C:** Arrow indicates the direction of isometric muscle contraction. **D:** Arrow indicates the direction of mobilization. (From Dvorak J, Dvorak V, Schneider W, et al. *Musculoskeletal medicine (manual therapy)*, 3rd English ed. Stuttgart/New York: G. Thieme Verlag, 2004, with permission.)

**FIG. 14-3.** Schematic drawing of the function of intersegmental rotatory muscles. (From Dvorak J, Dvorak V, Schneider W, et al. *Musculoskeletal medicine (manual therapy)*, 3rd English ed. Stuttgart/New York: G. Thieme Verlag, 2004, with permission.)

right. These techniques then attempt to increase spinal motion by stretching the incriminated shortened muscles and restoring mobility (Tables 14-1, 14-2).

**CLINICAL MODEL FOR USE OF MANUAL THERAPY**

Rehabilitative efforts for low back pain, especially when chronic, often present both a diagnostic and therapeutic challenge. Many practitioners of manual therapy have found it useful to approach to this complex clinical presentation by addressing specific clinical parameters first. They then attempt to integrate the findings (or lack thereof) within the greater clinical context. Three major domains of decision making have been identified as important when considering manual therapy for patients with low back pain or sciatica. These domains of diagnosis, in turn, are often further subdivided into specific subcategories.

According to this diagnostic approach there are three separate but interrelated thought processes involved when formulating a diagnosis for a patient where manual therapy is being considered. The first domain, the “structural diagnosis,” refers to specific organic pathology and relies on the ability to define an objective veri-

fiable pathologic lesion (e.g., disc herniation), osteoporosis, spondylosis, spinal stenosis, spondylolisthesis, and others. The second domain refers to a “functional diagnosis” that is based on both manual and functional performance tests including such findings as muscle spasm or muscular contraction, gross range of motion, focal intersegmental restrictions in motion, spinal biomechanics, posture, and gait. The third level of information in the diagnostic process is the domain of the patient’s “pain perception” including those that exacerbate or decrease the pain and the psychosocial issues that affect pain.

This model infers that the resolution or diminution of a patient’s pain can only occur when there is improvement on all three domains. The practitioner of manual therapy, using this model, will often include specific and individually tailored rehabilitation exercises along with carefully chosen passive physical therapeutic modalities all the while being cognizant of the patient’s psychosocial situation. The unique clinical setting of the manual medicine practitioner, where there is physical contact with the patient and often multiple office visits, allows for a closer doctor-patient interaction than is commonly noted in conventional medical practices.

**TABLE 14-1.** Overview of some of the most commonly used manual therapy techniques<sup>a</sup>

Manual therapies			
Manual medicine techniques			Therapeutic massage
Mobilization with impulse	Mobilization without impulse	Soft tissue techniques	Common massage techniques
Thrust techniques 1. Chiropractic adjustment 2. Osteopathic Thrust Terminology <i>Thrust</i> is also known as: 1. High-velocity/low impulse technique or 2. Manipulation (nonspecific, general term)	Counterstrain technique Craniosacral technique Functional technique Muscle energy technique Myofascial release technique Ligamentous release technique Myofascial trigger point technique Visual techniques	Articulatory technique Deep pressure technique Diaphragmatic release Lymphatic pump technique Mesenteric release Pectoral release Stretch techniques: Lateral, linear, diagonal, etc. Traction	Swedish-type massage Effleurage (stroking) Pétrissage (kneading) Friction (rubbing) Tapotement (percussion) Acupressure Bindegewebsmassage Deep tissue massage Lymphatic massage Reflexology Shiatsu Sports massage (variation of Swedish massage)
Combined techniques			
		Neuromuscular treatment I Neuromuscular treatment II Neuromuscular treatment III	Integrating/movement approaches 1. Alexander technique 2. Feldenkrais method 3. Rolfing 4. Many others
	Remarks: The nonthrusting techniques typically take into account articular and/or soft tissue motion restrictions.	Remarks: Soft tissue techniques are used for preparation or can be used independently.	Remarks: There are numerous types of massage approaches with even more variations

<sup>a</sup>As with any classification, this table should be used as a general guide rather than a definitive one, since there is a considerable amount of overlap among the various manual medicine techniques, as well as with some of the massage techniques.

**TABLE 14-2.** Comparison of the terms “manipulation” and “mobilization” showing continental differences

	Europe	USA	Comments
Manipulation	Refers usually to the <i>thrusting</i> techniques, which are also known as high-velocity/low-amplitude techniques or the “mobilization-with-impulse” techniques.	A rather general term, which may refer to any therapeutic procedure in which the hands are used to treat the patient, including thrust techniques.  <i>Chiropractic adjustment</i> is a generic term with over 100 sub-techniques, including the high-velocity/low-amplitude (HVLA) thrust and the low-force techniques.  <i>Osteopathic manipulative treatment (OMT)</i> encompasses the entire spectrum of manual therapies from thrust to nonthrust, including the soft tissue techniques.	When possible, and in order to avoid confusion, the newer terminology of “mobilization-with-impulse” (= thrust = high-velocity/low-amplitude [HVLA] technique)  or “mobilization-without-impulse” (= nonthrust techniques) should be used.
Mobilization	Refers essentially to any type of induced tissue or joint movement which is then qualified by describing the presence or absence of impulse forces (thrust vs. nonthrust techniques, respectively).	Usually refers to the various nonthrusting and soft tissue techniques.	It is best to qualify the type of mobilization used.

## INDICATIONS AND CONTRAINDICATIONS FOR SPINAL MANIPULATION

The appropriate application of manual medicine procedures, as with any other treatment approach, requires not only theoretical knowledge and training about the indications and contraindications of a particular technique, but also a high level of technical skill and experience by the practitioner (1–3). Unfortunately the identification of the patient likely to respond to manual therapy is not yet clear. This lack of information has, as in the case of many medical procedures, led to reliance on consensus conferences to determine the indications for manual medicine.

In 1990, the RAND Corporation, which has produced appropriateness guidelines for several health care provider groups, convened two expert panels to help establish indications for spinal manipulation for back pain conditions (4). These indications, when appropriately applied, would include by far the majority of patients with low back problems (4). These panels stated that, in the absence of contraindications, a short trial of therapy using spinal manipulation for patients with lower back pain with or without sciatica was appropriate.

The absolute or relative contraindications to manual therapy identified by these panels included progressive neuro-

logic deficits from any cause, the most common of which are disc herniation, space-occupying lesions, and progressive spinal stenosis. Other contraindications include segmental hypermobility due to pathologic and traumatic fractures, acute rheumatoid inflammatory joint disease, destructive bone lesions secondary to tumor or infection, and bleeding disorders due to metabolic, congenital, or medication causes. Some of these conditions may show some symptomatic relief because of manual therapy as long as the mobilizations and the therapeutic massage techniques are carefully chosen and cautiously applied.

Major complications from manual therapy applied to the lumbar spine appear to be extremely rare. There have been a few case reports of cauda equina syndrome following lumbar manipulation (5) but it is not yet evident whether the cases would have progressed in the natural course of the disc herniation or were directly affected by a manipulation. Thus far there are no good data indicating spinal manipulation can adversely affect lumbar discs. The risk of irreversible cauda equina syndrome was estimated by Shekelle et al. (6) to be as low as 1 in 100 million lumbar spine manipulations, but this estimate was based only on reported cases and presumably there are a number of additional cases where a temporal relationship exists.

One point that is evident from both clinical practice and the scientific literature is that manual therapy is not a panacea and not all patients with low back pain respond with reduction of symptoms. Explanations for this variation in patient responses include three possibilities (7): (a) an inadequate workup of the patient's symptoms leading to a wrong diagnosis; (b) the unnecessary or inappropriate application of manual therapy (the diagnosis may have been correct but treatment was "wrong"); and (c) the probability that, for many patients with low back pain, there may be no current adequate treatment.

### **EFFECTIVENESS OF MANUAL THERAPY IN THE TREATMENT OF BACK PAIN SYNDROMES**

One of the difficulties in performing randomized clinical trials to determine the effectiveness of manual therapy is the ability to perform a double-blind study and the inability to establish a placebo treatment. This is not unique to the manual therapies, but is true of all active treatment approaches including the physical therapies and exercise. The comparison of manual medicine treatment approaches with other treatment interventions and the development of placebos based on touching the patient or performing massage, however, have allowed certain conclusions to be drawn regarding effectiveness of the manual therapies relative to no treatment and to many of the common approaches to patients with low back pain. Currently there are more than 45 randomized clinical trials, more than almost any other treatment approach to low back pain, that have attempted to evaluate the effectiveness of the manual and manipulative therapies. There are also over 50 reviews of the studies that have been published in peer-reviewed journals. It is only possible to list a few of these in a short chapter on the topic and to discuss some of the key findings and conclusions from these papers.

An example of the type of study that has been attempted to look at the effectiveness of manual therapy is a prospective randomized clinical study by Koes et al., published in 1992 (8), where 256 patients with chronic low back pain were referred for one of four categories of treatment (manipulation, physical therapy, placebo, or treatment by a general practitioner). The patients in the manipulation group and those in the active physical therapy group showed a more favorable outcome at the 3- and 6-week follow-up than those who had been assigned to either the placebo group or treatment by the general practitioner. However, by 12 weeks the differences had almost entirely disappeared. Yet, patients in the manual medicine group had received less treatment (5.4 treatment sessions versus 14.7 treatments) than those in the physical therapy group, and the authors thought that this might be regarded as a considerable advantage. The acceptance of the treatment was greater by the patients in the manual medicine group than in the other treatment groups. In a

follow-up paper, the authors noted that improvement in the main complaint was larger with manipulative therapy (4.5 times) than with physiotherapy (3.8 times) after 12 months' follow-up (difference 0.9; 95% confidence interval 0.1 to 1.7). Manipulative therapy also resulted in larger improvements in physical functioning (difference 0.6; -0.1 to 1.3). The authors concluded that manual therapy and physiotherapy are better than general practitioner and placebo treatments, and that manipulative therapy is slightly better than physiotherapy after 12 months. These observations are similar to those presented in the retrospective study by Patijn (9).

Triano et al. (10) elected to use a sham manipulation as a control group in an attempt to create a placebo. These authors reported on a prospective clinical trial of 145 patients who had experienced chronic back pain who were randomized into three groups according to specific manipulation, sham manipulation, and a group who received instruction materials. Two-week follow-up revealed that the group that had received specific manipulation showed a significantly lower visual analog pain scale value and a greater willingness to participate in rehabilitation, that is there was a greater trust in actively participating in their program. The recent study by Aure et al. (11), on the other hand, looked at the issue as to whether manual therapy was, as effective as well-established treatment approaches such as exercise. They evaluated patients with chronic low back pain randomized to either exercise or manipulation with 1-year follow-up to compare the effect of manual therapy to exercise therapy in work-disabled patients. Although improvement was observed in both groups, the manual therapy group showed significantly greater improvement than the exercise therapy group in all outcome variables. Immediately after the 2-month treatment period, 67% in the manual therapy group and 27% in the exercise therapy group had returned to work.

Reviews of the literature on the manual therapies have included meta-analyses, reviews grading the methodologic quality of the clinical trials, and the use of evidence tables and best evidence synthesis such as that done through the Cochrane Collaboration. Koes et al. have published a series of reviews of the scientific literature over the past 12 years using a described method of ranking the quality of the clinical trials. This group performed one of the earliest meta-analyses of the manipulation literature in 1991. Unfortunately 36 of the randomized clinical studies that they reviewed were thought to have low methodologic quality scores. They noted that approximately half of the studies indicated a positive result for manual medicine approaches on patients suffering from various disorders although the most favorable results were often in the studies with low methodologic scores. Similar observations were made when evaluating studies that looked at the evidence in favor of other treatments such as physical therapy and training therapy (12),

and the evidence for these common treatment approaches was often less than that for the manual therapies. In 1991, Shekelle et al. (4), in a very detailed and critical evaluation of the randomized clinical trials, came to a similar conclusion with a slightly different emphasis. These authors thought that spinal manipulation had been demonstrated to be of short-term benefit in certain patients, particularly those with uncomplicated acute lower back pain. They based this conclusion on a meta-analysis of a subset of seven clinical trials in which recovery at 3 weeks could be compared with that of other therapies. The pooled estimate showed a 17% higher likelihood of recovery in favor of spinal manipulation. Again, a substantial number of trials were excluded from the meta-analysis by these investigators because most of the published randomized clinical trials at the time had used outcomes measured on a quantitative scale, such as pain and disability, rather than dichotomous outcomes.

The most comprehensive systematic reviews involving an array of different treatments for low back pain have been performed by van Tulder et al. (13,14) on a regular basis over the past few years with regular re-analysis of the newer trials. These authors have assessed the methodologic quality of the trials and used specific evidence-based rules to determine the presence and strength of evidence of efficacy. They concluded that for acute low back pain there was evidence to suggest that spinal manipulation is better than placebo, physical therapy, exercise, and short-wave diathermy. For chronic lower back pain, they found strong evidence that spinal manipulation was better than placebo, and moderate evidence that it was better than the treatment offered by a general practitioner, massage, bed rest, and analgesics. Bronfort et al. (15) published a systematic review of the efficacy of spinal manipulation emphasizing the magnitude of treatment effects compared to other treatments in determining the strength of evidence. These authors elected to set aside the conclusions by the investigators of the individual randomized clinical trials and to focus on the data only. Their analysis reached a conclusion similar to that of van Tulder et al. in that there is evidence of short-term efficacy for spinal manipulation in patients with both acute and chronic lower back pain.

## SUMMARY

Although manual therapy is one of the oldest and most widely practiced treatments for low back pain, there has been a rapid growth over the past 20 years in its acceptance and use on an international basis. This is primarily due to the publication of a large number of clinical trials,

most of which suggest that this therapeutic approach is at least as efficacious as other established treatment approaches and is more efficacious than placebo and usual medical care.

There remain, however, numerous unanswered questions concerning manual therapy. The exact physiologic effects and mechanisms of manual therapy are not known. The relative effectiveness of the choice of manual therapy approach depends primarily on the training and experience of the clinician. Current experimental and clinical research is beginning to look at these issues and hopefully, within the near future, it will be possible to identify the patient who would most likely benefit from manual therapy and to explain the mechanism through which the treatment effect is achieved.

## CHAPTER 15

# Acupuncture and Reflexology

Marianne L. Magnusson and Malcolm H. Pope

---

### COMPLEMENTARY AND ALTERNATIVE MEDICINE IN TREATMENT OF LOW BACK PAIN

Despite the increased use and acceptance of complementary and alternative medicine (CAM), there is relatively little information available concerning efficacy. A survey of 542 patients attending 16 family practice clinics was conducted to determine patients' reasons for using CAM and the impact of CAM on health and well-being (1). Approximately 21% of the patients used one or more forms of CAM, of which the most common were chiropractic (34.5%), herbal remedies (26.7%), and massage therapy (17.2%). In spite of poor evidence for efficacy, CAM is used for low back pain (LBP) more frequently than for any other indication. Expert opinions on the use of CAM for LBP could therefore be helpful until more randomized controlled trials (RCTs) are available. Ernst and Pittler (2) sent a questionnaire to 50 clinical experts on LBP to assess the perceived clinical effectiveness of CAM for four categories of LBP. The conclusions were that expert opinion is in favor of the effectiveness of acupuncture for acute uncomplicated LBP, whereas homeopathy was perceived ineffective for LBP.

### REFLEXOLOGY

Furlan et al. (3) conducted a Cochrane Review on massage therapy. Four randomized controlled trials met the inclusion criteria. Two trials were of high and two were of low methodologic quality. None evaluated massage as the main intervention. Rather, it was the control intervention in studies evaluating manipulation, electric stimulation, and a lumbar corset. There was limited evidence showing that massage is less effective than manipulation immediately after the first session and moderate evidence showing it is less effective than transcutaneous electric nerve stimulation (TENS) during the course of sessions in relieving pain and improving activity. At the completion of treatment and at 3 weeks after discharge there was no

difference among massage and manipulation, electric stimulation, or corsets, but this evidence is limited. The reviewers concluded that there is insufficient evidence to recommend massage as a stand-alone treatment for non-specific LBP.

Reflexology has been in existence for many thousands of years and can be considered a type of massage. It was first practiced in India, China, and Egypt and then introduced to the West at the beginning of the 20th century as zone therapy (4). It was suggested that pressure on specific parts of the body could have an anesthetizing effect on a related area. The body is divided into 10 equal vertical zones, and pressure on one part of a zone is said to affect all structures within that zone. It was taught that "bioelectric energy" flowed through these zones to "reflex points" in the hands and feet. In the 1930s, the zone therapy was refined into what was termed "foot reflexology," which suggests that "congestion" or tension in any part of the foot mirrors "congestion" or tension in a corresponding part of the body (5).

Charts with organs superimposed on the foot, hand, or ear are used to map these points. The reflexologist looking for constrictions or painful areas probes the theoretical reflex points by using the charts to determine what body part corresponds to that area of the foot (or hand or ear, etc.). There are areas that are said to correspond with the lumbar spine. Several products (e.g., sandals, shoe inserts, foot massage devices) are sold based on this theory.

Jarvis (6) concluded, because of a carefully conducted trial, that reflexology could not reliably find conditions known to be present and thus was not predictive or therapeutic. Jarvis concludes that reflexology has little potential for direct harm, but can mislead people into believing that it can be used for screening or having real therapeutic value. No scientific trials were found that showed any value of reflexology for lumbar spine problems. Jarvis advises us to be skeptical of therapeutic claims beyond the ability of foot massage for relaxation.

## ACUPUNCTURE

Acupuncture, a form of Eastern medicine that has been practiced for many centuries, is the stimulation of special “points” on the body, usually by the insertion of fine needles. Originally there were 365 such points, corresponding to the days of the year, but the number identified by proponents during the past 2,000 years has increased gradually to over 2,000 (7). Acupuncture uses the meridian systems of the body (Chinese system of energy flow in the body) to promote healing and treat injury and disease. Through the insertion of needles into well-defined acupuncture sites, the nervous system is stimulated to release chemicals in the muscles, spinal cord, and brain. These chemicals will either change the experience of pain, or they will trigger the release of other chemicals and hormones that influence the body’s own internal regulating system. The improved energy and biochemical balance produced by acupuncture results in stimulating the body’s natural healing abilities, and in promoting physical and emotional well-being. The use of heat and electric stimulation at the acupuncture sites is thought to augment the therapeutic effect of needling and is used particularly in treating chronic pain (8).

The following mechanisms have been proposed to explain acupuncture’s presumed action on pain: The effects of acupuncture, particularly on pain, are partially explicable within a conventional physiologic model, which suggests that acupuncture stimulates A $\delta$  fibers entering the dorsal horn of the spinal cord. This mediates segmental inhibition of pain impulses carried in the slower, unmyelinated C fibers and, through connections in the midbrain enhances descending inhibition of C fiber pain impulses at other levels of the spinal cord. This helps explain why acupuncture needles in one part of the body can affect pain sensation in another region. Acupuncture is also said to stimulate release of endorphins and other neurotransmitters such as serotonin. This is likely to be another mechanism for the effects of acupuncture, such as in acute pain (8). Another explanation is the “gate theory”, which suggests that if pain fibers carry impulses from an acupuncture site, impulses from a painful body organ will be unable to reach the brain. Attention can be diverted from a symptom by stimulating or irritating another part of the body. Psychological mechanisms—including suggestion, operant conditioning, and other psychological mechanisms—may be involved in the placebo effect.

### Theory and Practice

Acupuncture is based on ancient Chinese medical philosophy, which views illness quite differently than contemporary science (9). In ancient China, diseases were not systematically described or classified (10). Internal organs, which were felt to be intermediaries between the body and nature, were assigned qualities representing

emotional states, colors, and seasons. Some organs, such as the “triple warmer,” were imaginary. There were no concepts of modern physiology, biochemistry, nutrition, or mechanisms of healing. There was no knowledge of the existence of cells, the circulation of the blood, the function of nerves, or the existence of hormones. Knowledge of anatomy was incomplete.

### Diagnosis

Traditional Chinese diagnosis does not correlate with modern scientific concepts. An ill person was considered out of balance with nature and its two opposing forces, yin and yang. Yin represented the feminine, passive, or accepting qualities and yang the masculine, aggressive, or forceful ones. Diseases were not described or named. Diagnoses were made from examining the pulse (of which there were supposedly six variations) and the tongue, which was said to vary in appearance with certain disease states.

### Treatment

Although the details of practice differ between schools, all traditional acupuncture theory is based on the concept of yin and yang. Illness is seen as excess or deficiency in various exogenous and endogenous pathogenic factors, and treatment is aimed at restoring balance. This reestablishing of “balance” and “harmony” supposedly occurs as symptoms improve. Since there was no formal study of diseases or description of their natural history, the ancient Chinese could rarely determine how an illness actually improved. Treatments were chosen by trial and error, and perpetuated by personal experience. Since there were no scientific criteria for success or failure, the judgment that “healing” had taken place was based on the word of the therapist or the patient.

Acupuncture points were assigned to “meridians” on the surface of the body. These supposedly represent channels through which flows the life force, “Ch’i” (or “Qi”). Insertion of needles at the designated points was said to increase or decrease the flow of Ch’i to achieve a more normal and harmonious state (7).

The life force, Ch’i, has no basis in human physiology. The meridians are imaginary; their locations do not relate to internal organs, and therefore do not relate to human anatomy. Acupuncture points are also imaginary. (Various acupuncture charts give different locations for the points.) These concepts continue to form the basis of modern acupuncture therapy even though extremely sophisticated methods are used to measure its reputed biochemical effects. Although scientific methods may be applied to biochemical studies, many published reports are based solely and uncritically on clinical anecdotes and tradition (11). In conclusion, the existence of “merid-

ians,” “acupuncture points,” or Ch’i has never been scientifically validated.

## VARIATIONS AND OFFSHOOTS OF ACUPUNCTURE

### Acupressure

Acupressure uses firm digital pressure on trigger or acupuncture points. Shiatsu, a modified form of acupressure, is a form of Japanese traditional medicine (12).

### Auriculotherapy

Auriculotherapy is based on the notion that the body and organs are represented on the ear (13). Needles are placed in the imaginary points representing the diseased organs. There is no scientific evidence that these points exist or that auriculotherapy has any therapeutic value (14).

### Staple puncture

In staple puncture, staples are placed at acupuncture points on the ear, typically to aid smoking cessation or drug withdrawal.

## PROS AND CONS OF ACUPUNCTURE

The World Health Organization recognizes the use of acupuncture in the treatment of a wide range of medical problems including neurologic and muscular disorders:

1. Digestive disorders: gastritis and hyperacidity, spastic colon, constipation, diarrhea.
2. Respiratory disorders: sinusitis, sore throat, bronchitis, asthma, and recurrent chest infections.
3. Neurologic and muscular disorders: headaches, facial tics, neck pain, rib neuritis, frozen shoulder, tennis elbow, and various forms of tendonitis, LBP, sciatica, and osteoarthritis.
4. Urinary, menstrual, and reproductive problems.
5. Smoking cessation.

The National Council Against Health Fraud (NCAHF) believes:

1. Acupuncture is an unproved modality of treatment.
2. Its theory and practice are based on primitive and fanciful concepts of health and disease that bear no relationship to present scientific knowledge.
3. Research during the past 20 years has failed to demonstrate that acupuncture is effective against any disease.
4. Perceived effects of acupuncture are probably due to a combination of expectation, suggestion, counterirritation, operant conditioning, and other psychological mechanisms.
5. The use of acupuncture should be restricted to appropriate research settings.

6. Insurance companies should not be required by law to cover acupuncture treatment.
7. Licensure of lay acupuncturists should be phased out (15).

## EVIDENCE OF ACUPUNCTURE EFFICACY

Symptom relief with acupuncture is difficult to assess because there is no objective standard of measurement. Double-blind studies comparing the insertion of needles at acupuncture points and at other points (“sham acupuncture”) are difficult to design. If an experienced acupuncturist locates the points, the practitioner’s expectations may be transmitted to the patient. If an inexperienced person inserts the points, misplaced needles may undermine the results. Moreover, practitioners may differ about the location of the points, so it may be difficult to find a patch of skin that has not been labeled an “acupuncture point.” Chronic pain is often cyclic, with periods of relief. Since people often request help when their pain is most severe, spontaneous improvement may occur, independent of the treatment (16). The natural history of most acute pain is that it improves with time and no intervention. Thus, there may be reports of improvement of symptoms from any intervention. There is general agreement that 30% to 35% of subjects’ pain improves from suggestion or placebo effect alone. Thus, measuring a small difference between placebo and acupuncture requires a large number of subjects to show as little difference as 25%. People who volunteer for acupuncture may have a conscious or unconscious bias toward the procedure and thus may be more prone to suggestion.

## RESEARCH EVIDENCE

Richardson and Vincent analyzed 28 studies on the effect of acupuncture on pain. All were published between 1973 and 1986 in English language peer-reviewed journals. Fifteen showed no difference in effectiveness between acupuncture and control groups. Thirteen showed some effectiveness for acupuncture over control groups, but not all controls were the same. (Some were compared to sham acupuncture, some to medical therapy, etc.) Overall, the differences were small (17,18).

The NCAHF Task Force on Acupuncture evaluated the above studies, as well as more recent ones, and found that reported benefits varied inversely with quality of the experimental design. The greater the benefit claimed the worse the experimental design. Most studies that showed positive effects used too few subjects to be statistically significant. The best designed experiments—those with the highest number of controls on variables—found no difference between acupuncture and control groups (15). In 1989 Dutch epidemiologists reported similar conclusions in 91 separate clinical trials of acupuncture for various disorders. They also found that the stricter the con-

trols, the smaller the difference between acupuncture and control groups (19).

Research evidence also shows that acupuncture has greater effects than placebo. Randomized trials have found that true acupuncture is more effective in relieving pain than a “sham” technique, such as inserting needles away from true points (however, the aforementioned disagreement about the localization of points should be considered). Of the numerous studies on nausea, a condition that readily lends itself to placebo controlled trials, almost all show that stimulating true acupuncture points is more effective than stimulating false points. Studies showing that acupuncture can affect anesthetized animals provide further evidence that its effects probably cannot be explained purely in psychological terms (7).

It is less clear whether acupuncture has clinically important benefits in the conditions for which it is typically used. Much of the research evidence comes from hospital-based studies of acute conditions such as postoperative pain rather than studies of chronic conditions in primary care. Moreover, most trials have had small numbers of patients and only short-term follow-up. Overall, evidence from several randomized controlled trials supports the use of acupuncture in pain conditions, particularly migraine, headache, and postoperative pain. Such trials also provide evidence of an effect of acupuncture in substance misuse, nausea, and stroke. Trials of acupuncture in asthma and hay fever have produced conflicting results. Systematic reviews and randomized controlled trials suggest that acupuncture is probably not of benefit for stopping smoking, tinnitus, or obesity.

## ACUPUNCTURE AND LBP

The use of acupuncture to treat LBP has increased dramatically in the past few decades. In spite of this, there is very sparse scientific documentation of outcomes from these treatments. In one study, 12 patients suffering chronic LBP were treated with both acupuncture and TENS. The order of treatments was balanced, and changes in the intensity and quality of pain were measured with the McGill Pain Questionnaire. Pain relief was produced in both groups and lasted between 23 hours for TENS and 40 hours for acupuncture. The difference between the treatments was not statistically significant. According to the authors, both methods could be equally effective, and probably have the same underlying mechanism of action (20). However, as there was no pure control treatment group the pain relief could be a Hawthorne effect or the two treatments were equally effective or ineffective.

Carlsson and Sjölund (21) randomly assigned 50 patients who had been suffering chronic LBP for a minimum of 6 months and had tried a variety of other therapies to a manual acupuncture group, an electroacupuncture group, or a placebo group. Treatment was delivered once per week for 8 weeks and follow-up treatments

after 6 months or longer. The placebo group was given mock stimulation. An independent and blinded-to-treatment assessment (clinical interview, physical examination) at baseline and at follow-ups at 1, 3, and 6 months classified the patient's pain as improved, unchanged, or worse. Subjectively, patients reported pain intensity at the follow-ups. At the 1-month independent assessment, 16 of 34 patients in the acupuncture group and 2 of 16 in the placebo group improved ( $p < .05$ ). There was also a significant decrease of pain intensity at 1 and 3 months in the acupuncture group. Sleep pattern was less disturbed and total intake of analgesics dropped dramatically after the treatment period in the acupuncture group, but not in the placebo patients. After 6 months, 14 acupuncture patients and two placebo patients were still improved ( $p < .05$ ). There was no difference between types of acupuncture.

Kalauokalani et al. (22) analyzed 135 patients with chronic LBP who received acupuncture or massage in a randomized trial. Before randomization, study participants were asked to describe their expectations regarding the helpfulness of each treatment on a scale of 0 to 10. The primary outcome was level of function at 10 weeks as measured by the modified Roland Disability Scale. Improved function was observed for 86% of the participants with higher expectations for the treatment they received as compared with 68% of those with lower expectations ( $p < .01$ ). Furthermore, patients who expected greater benefit from massage than from acupuncture were more likely to experience better outcomes with massage than with acupuncture, and vice versa ( $p < .03$ ). The study suggests that patient expectations may influence clinical outcome independently of the treatment itself. In contrast, general optimism about treatment, divorced from a specific treatment, is not strongly associated with outcome.

Cherkin et al. (23) randomized 262 patients with persistent LBP to receive traditional Chinese medical acupuncture ( $n < 94$ ), therapeutic massage ( $n < 78$ ), or self-care educational materials ( $n < 90$ ). Telephone interviewers masked to treatment group assessed symptoms and dysfunction. Follow-up was available for 95% of patients after 4, 10, and 52 weeks, and none withdrew for adverse effects. Treatment groups were compared after adjustment for pre-randomization covariates using an intent-to-treat analysis. At 10 weeks, massage was significantly superior to self-care on the symptom ( $p < .01$ ) and the disability scale ( $p < .001$ ). Massage was significantly superior to acupuncture on the disability scale ( $p < .01$ ). After 1 year, massage was not better than self-care but was better than acupuncture on the symptom and dysfunction scales ( $p < .002$  and  $p < .05$ , respectively). The massage group used the least medications and had the lowest costs of subsequent care ( $p < .05$ ). Therapeutic massage was effective for persistent LBP, providing long-lasting benefits. Traditional Chinese medical acupuncture was relatively ineffective.

A systematic review to assess the effects of acupuncture as treatment of nonspecific LBP was conducted by van Tulder et al. (24). Eleven studies were included, of which only two were of high quality. In the review, van Tulder et al. disagree with the original authors' conclusions in 7 of the 11 studies. According to van Tulder et al., there was no difference between acupuncture and control in seven trials. Acupuncture was superior in only two studies, whereas the results were unclear in the remaining two trials. Thus, 9 of the 11 studies could not show that acupuncture was more effective than placebo or sham acupuncture, nor with trigger-point injection or TENS. The reviewers' conclusions were that this systematic review did not indicate that acupuncture is effective for the treatment of back pain.

A meta-analysis by Ernst et al. (25), of randomized controlled trials on acupuncture for back pain involving data from nine studies, showed improvement with acupuncture compared with control intervention with an odds ratio of 2.30 (95% confidence interval 1.28 to 4.13). It was concluded that collectively, the data implied that acupuncture is superior to various control interventions, although there was insufficient evidence to prove whether it is superior to placebo.

Although both studies, which virtually used the same RCTs, conclude that there is not enough evidence to prove acupuncture more effective than any other treatment, they present contradicting results. This is due to the different methods of assessing methodologic quality and of summarizing the results that were chosen. Because of the low quality, methodologic problems, and in some trials, the use of an invalid acupuncture treatment, van Tulder et al. used a qualitative analysis, which took into account the levels of evidence rather than a statistical pooling across trials. Ernst et al. used a meta-analysis and quantitatively pooled the results from the trials.

## SAFETY OF ACUPUNCTURE

As with all CAM, the absence of a formal system for reporting adverse effects means that acupuncture's safety is difficult to assess. The definition of adverse effect varies and both under- and over-reporting occur. Most adverse effects are relatively minor events such as bruising and dizziness but more serious events have been reported such as hepatitis and pneumothorax (26,27). A prospective study of over 55,000 acupuncture treatments given in a college for medically trained acupuncturists confirms that acupuncture is probably safe in qualified hands (28). Only 63, mostly minor, adverse events were identified, and no cases of serious adverse events such as pneumothorax, infection, or spinal lesions were reported, although these have been described in the literature (27).

The adverse effects of acupuncture are probably related to the nature of the practitioner's training. A sur-

vey of 1,135 Norwegian physicians revealed 66 cases of infection, 25 cases of punctured lung, 31 cases of increased pain, and 80 other cases with complications (29). A parallel survey of 197 acupuncturists, who are more apt to see immediate complications, yielded 132 cases of fainting, 26 cases of increased pain, 8 cases of pneumothorax, and 45 other adverse results (29).

In summary, because the quality of the RCTs that evaluated acupuncture was generally poor, the effectiveness of acupuncture for treating acute or chronic back pain is unclear. However, acupuncture seems to be relatively safe (30).

## **SECTION III**

---

# **The Injured Worker**

## CHAPTER 16

# Returning Workers to Gainful Employment

Margareta Nordin

---

Returning workers to gainful employment after work absence due to low back pain has become a public health policy problem. Being unemployed or disabled from work due to low back pain of benign nature is a societal problem in industrialized and industrializing parts of the world. Compounding this problem is the fact that the reputation of low back pain and its potential incapacitating symptoms has worsened. In industrialized countries, the public still believes that low back pain is crippling, leading to serious disability and the loss of gainful employment and a satisfying lifestyle. Without great fanfare, back pain became the leading 20th century medical disaster (1), with an estimated cost of 1% to 2% of gross national product (GNP) in Organisation for Economic Co-operation and Development (OECD) countries (2) and a cost of about \$50 billion in the United States (or 0.5% to 0.6% of GNP based on data from 2001) (3). Cats-Baril and Frymoyer (4) estimated that costs for back pain in the United States were equivalent to 0.5% to 2.0% of GNP in 1991. In these and other industrialized countries, the cost structure for low back ailments is the same, with approximately 10% to 30% of being spent for direct costs and 70% to 90% on indirect costs.

It is technically difficult to estimate work loss due to back pain, however work loss due to back pain has been reported in several studies. For example, Guo et al. (5) reported in 1988 that 17.6% of the respondents ( $n < 30,074$ ) to the National Health Interview Survey lost an estimated 149 million workdays in the United States. The Office of National Statistics in the United Kingdom reports from 1993 to 1998 approximately 5% of employed individuals said they had taken time off from work for back pain over a 4-week period being questioned (6).

In Sweden about 2% to 6% of the working population experiences work loss from back pain (7). The differences in reported work loss may be due to different reporting systems, national versus non-national health

systems, and various compensation systems, among others. There are indications that sickness absence is increasing (8) and early retirement resulting from back pain is decreasing (7), however there are also indications that an increasing proportion of people receive benefits for much longer time and that the amount of benefits paid are increasing (7). This would make a strong argument to intensify the prevention of disability and encourage work ability for individuals experiencing low back pain.

### COMMONALITY OF BACK PAIN EPISODES

Prevalence of low back pain is high. International studies reveal a point prevalence (about 1 week) of 15% to 30%, a 1-month prevalence of 10% to 43%, and a lifetime prevalence of low back pain of 51% to 81% (1,7). It is important to note that study design and cultural differences in self-reporting, more so than actual differences of the populations studied, may cause the variation of these estimates (7,8). Therefore, one can reasonably state that it is more common during life to have experienced back pain than not to have experienced back pain. In fact, when conducting a study, it is actually quite difficult to find individuals who have never experienced or been out of work for back pain (9,10).

### BACK PAIN CLASSIFICATION

Pain in the lumbar spine can be classified as specific or nonspecific pain. These terms are convenience terms created to establish some sort of triage mechanism. Specific low back pain means that the pain originates from a known structure, abnormality, tumor, trauma, or systemic or established disease. All other conditions are classified and diagnosed as nonspecific low back pain (NSLBP), a diagnosis that stems from the fact that science has not yet revealed which structure in the spine generates the pain.

This classification system has been very helpful for researchers and clinicians.

One point of encouragement is that large working population cohorts using the classification of NSLBP have a good prognosis for 90% of affected individuals to return to work. Studies show that 75% of compensable back pain resolved within 4 weeks, 90% within 3 months, and 95% within 6 months (1,11,12). The probability of an NSLBP diagnosis developing into “chronic back pain syndrome” (often defined as disabling pain of more than 3 to 6 months) is approximately 5% to 6%, compared to patients presenting with a specific diagnosis of low back pain for whom about 35% to 40% will develop a chronic and disabling condition (13–15).

Although chronicity as defined by continuous pain or permanent work disability affects about 3% to 5% of patients seeking care for low back pain, recurrence of low back pain is more frequent. For example: in Canada the frequency of recurrent episodes after compensable back injury was 36% over 3 years (11). In a survey of approximately 3,800 Belgian adults, 85% of those reporting back pain at the time of interview had experienced prior episodes (16). Some authors claim that low back pain should be regarded as a persistent problem with intermittent exacerbation (Fig. 16-1) (1,17,18) that may seriously affect work ability (19).

This chapter will focus on the prevention of work-related disability in the working population with NSLBP. It will discuss the return of workers to gainful employment and the subsequent retention of that gainful employment.

### MISUNDERSTANDINGS AND A PHILOSOPHICAL SHIFT REGARDING BACK PAIN

The Paris Task Force (20) best describes the philosophical and evidence-based shift from passive to active treatment. The treatment of low back pain has not advanced beyond the outdated prescription for bed rest, because the role of activity in its treatment has been the object of three misunderstandings:

1. The first misunderstanding is related to the fact that certain activities (mainly occupational) are undeniably risk factors for low back pain and there is a natural tendency to avoid activity once an episode of back pain has begun. Although reexposure to the conditions that triggered the episode often causes pain, which may sometimes be intolerable (reinforcing the idea that it is better to avoid the conditions altogether), conditions that cause back pain are not necessarily risk factors for chronicity.

**FIG. 16-1.** Examples of concepts in studies including duration and pain in the lumbar spine. **A:** More traditional concepts where the bouts of pain are represented with a pain-free period in between. **B:** More current and debated concept in subgroups of patients where the pain over time may vary and not subside completely. (Adapted from Croft P, Papageorgiou A, McNally R. Low back pain. In: Stevens A, Raftery J, eds. Health care needs assessment. Second series: The epidemiologically based needs assessment reviews. Oxford: Radcliffe Medical Press, 1996:129–182.)

2. The second misunderstanding stems from the association many people make between “sciatica” (i.e., low back pain accompanied by spinal symptoms and signs) and low back pain unaccompanied by neurologic sequelae. However, low back pain accompanied by spinal damage only accounts for a very low percentage (approximately 5%) of all cases of low back pain, and there is no longer any consensus on the existence of a continuum linking the two types of conditions.

3. The third misunderstanding arises from current approaches to pain management. While it is common to neglect, if not disparage, specific and effective pain relief, it is nevertheless considered important to avoid anything that might trigger pain. In the absence of specific pain relief, rest becomes the only possible choice, with unfortunate results.

### APPROACH TO TREATMENT FOR NSLBP

Despite the time and effort spent preventing and treating NSLBP, the costs associated with NSLBP continue to rise (1,2,8). This may, in part, be attributed to the current management of NSLBP in which the patient is either over- or under-treated. It is often assumed that pain is due to either a specific underlying cause or that it is of a non-medical origin. Both conclusions do a disservice to the patient with NSLBP.

In the first scenario, attempting to provide a specific diagnosis to a patient with NSLBP can have deleterious consequences. For example, Abenhaim et al. (11) observed that patients given a specific spine diagnosis fared worse than patients given a diagnosis of NSLBP. The authors further discussed the possibility that medically “labeling” a condition of NSLBP with specific diagnoses may convince the patient that the pain is of a purely physical origin, suggesting that pain requires medical interventions such as medication, injections, manipulations, and even surgery. In order to relieve pain, the patient may then engage, to no avail, in negative health behaviors such as “doctor shopping,” avoidance of movement and activities, and an over-reliance on medication or other passive treatments.

In the second scenario, attributing pain to nonmedical factors such as psychological conditions alone invalidates the true nature of pain, causing serious psychological distress to the patient. Furthermore, this attribution of NSLBP to nonphysical conditions may backfire as the patient seeks validation of the physical pain by over-focusing on the pain in an effort to convince others that it is “real.” The health care provider may also grow frustrated and give up on the patient prematurely.

In the best scenario, however, the successful treatment of NSLBP requires a unique approach where the true nature and prognosis of NSLBP are shared with the patient. This is best accomplished proactively through an

evaluation and treatment program derived from the application of the biopsychosocial model (1,8,21).

### A Proactive Approach to NSLBP

A proactive approach to NSLBP includes the following:

1. The health care provider forms a partnership with the patient. Together they follow evidence-based medical practices and timelines for evaluation and treatment.
2. The health care provider must also be able to identify risk factors for chronicity as they emerge and make timely referrals when appropriate (19,22).
3. The patient is monitored on a regular basis so that changes in treatment needs may be assessed and implemented in a timely manner. For example, NSLBP may sometimes become specific as when true sciatica or a discitis develop. This can only be detected if the patient is monitored properly.

A proactive approach to NSLBP works best in the context of a biopsychosocial paradigm (8). A biopsychosocial perspective takes into consideration psychological and social factors related to pain, as well as physical factors and has been proven successful for the treatment of NSLBP. By definition, NSLBP has no identifiable known medical cause and therefore traditional medical approaches often fail. In the context of failed medical treatment approaches, as time goes on, psychological and social factors become increasingly important in determining pain and its subsequent disability. These factors must be acknowledged for successful outcomes in treating NSLBP (19,22–25).

### WORKER’S CHOICE: TO SEEK OR NOT TO SEEK TREATMENT

Pain developing in the lumbar spine may be or may not be attributed to work functions; however, the pain may still affect the work capacity and be aggravated during working hours. An individual may or may not seek help for the condition (26). The difference in action taken transpires in the predicament of the worker/employee and the system in which that individual works. Hadler described the process of predicament (27). The individual considers the pain, the restriction in function, and the options for action. There may or may not be an event that ignited the pain. All these factors influence the idiosyncratic decision to seek help based on prior experience, education, environment, and possible fear for the seriousness of the condition. Three obvious choices are relevant at this point:

1. Endure the pain and continue to work, which is not uncommon. However, few studies have focused on the individual who continues to work with low back pain.

2. Seek professional medical advice and be considered a person with an illness (i.e., a patient under medical or other care). Most studies of low back pain have focused on this group of individuals.
3. Report an occupational injury or illness and file a claim. The individual who reports a claim becomes a claimant with an injury or illness. Fewer studies have focused on treatment of work-related low back pain and claimants.

The choice an individual makes may affect the outcome of the condition. Because the environment in which the condition is treated or left untreated varies, the health care and reimbursement provided may be different. As well, the external perception of the individual with low back pain differs. For example, a person who chooses to continue to work with moderate NSLBP will probably do fine except in very physically demanding jobs such as construction, firefighting or rescue work, nursing, or jobs with exposure to whole body vibration (i.e., driving a truck) (28). An individual who seeks medical care for acute or subacute NSLBP should be advised by their health care provider to keep active and to return to work as soon as possible based on the international scientific guidelines for low back pain (19,23,29,30). The outcome for these patients, which is measured as return to work and well-being, will be far more successful than those undergoing a long-term bed rest or passive modality treatment. Finally, a claimant experiencing NSLBP who is told by the employer's physician to return to work as soon as possible will usually start to negotiate about the date to return to work. The outcome is usually very favorable if the health care provider takes the time to explain the condition and establishes trust with the claimant, and recommends continued activity, short course of active treatment, and light work duty during the next 1 to 4 weeks. The recommendation to return to the regular work is usually negotiated based on type of work, exposures to hazardous or unsafe working conditions, and tasks to be performed.

Health care providers must acknowledge and understand the options and predicaments of choice for the individual with back pain. None of the choices are wrong or right, however, they are personal and choices that are not always well understood in the scientific and medical environment. The health care provider who chooses to manage the working/employed patient should reinforce the distinction between impairment and disability, hurt and harm (1,23), and should recognize that work disability is a multidimensional problem of which clinicians and researchers have only just begun to unravel the complexity (8).

### **RULING OUT RED FLAGS**

The evaluation of low back pain should involve ruling out specific signs, referred to as "red flags" (23) and

identifying risk factors for chronicity, referred to as "yellow flags" (22). A diagnostic triage has been suggested by the Clinical Guidelines for the Management of Acute Low Back Pain from the Royal College of General Practitioners (19). Diagnostic imaging tests are not routinely indicated (31).

Red flags are signs and symptoms detected by the clinician that may indicate possible serious spinal pathology and require referral to a specialist (23). A standardized physical examination is necessary to exclude possible specific conditions. The examination must consist of a patient history that includes trauma, systemic diseases, cancer, infection, or major neurologic compromise (red flags). The patient history is followed by a physical evaluation that includes posture, gait, toe and heel walk, palpation, range of motion, the effect of trunk sagittal flexion/extension and lateral flexion on low back pain and leg pain, and a neurologic examination of the lower extremities to test motor, sensory, and reflexes (32,33). The presence of red flags or neurologic signs and symptoms (such as back pain with radiation to a leg below the knee level or sensory-motor dysfunction) will classify low back pain as specific and may require a referral to a specialist for treatment (19,23). All other patients can be classified as having NSLBP.

### **PHYSICAL AND PSYCHOSOCIAL RISK FACTORS ASSOCIATED WITH DELAYED RECOVERY**

A number of physical, personal, psychosocial, and environmental factors have been associated with the outcome of NSLBP. Physical signs that have been found to be predictors of delayed return to work in patients with acute (up to 4 weeks of duration of pain) NSLBP are altered gait and pain below the knee in a nondermatomic topography (32,34–37). Since these signs are present in both specific LBP and NSLBP, their meaning for NSLBP is still unclear. It is possible that they may reflect aspects of fear of pain and behaviors intended to communicate suffering to the health care provider rather than actual physical abnormality (38). Personal factors, such as age, affect recovery and therefore work ability (39–41). For example, it takes a person about twice as long to return to work at age 50 compared to age 30. Clinical factors such as the duration of back pain have also been associated with poor prognosis in that the likelihood of recovery diminishes steadily after as early as 4 weeks (39).

Most significantly, studies have revealed a number of psychological risk factors. For example, strong associations between delayed recovery in acute NSLBP and psychological distress have been found (38,42–44); depressive mood and somatization are consistently observed in the transition from acute to chronic low back pain (21); and high self-perceived disability and short-term changes in perceived disability have been associated with return to

work outcomes such that higher perceptions of disability are related to poorer outcome (19,38,39,41,42,44,45). Other factors have been associated with poor outcome, including the belief that back pain is harmful or potentially severely disabling; fear avoidance beliefs (the belief that certain movements or activities will exacerbate pain); perceived inability to return to work; and the belief that passive treatment is preferable to active participation in care (19,22).

These psychosocial factors can be summarized as negative beliefs about low back pain and its consequences and negative emotional states. They may be considered “yellow flags” (22) or “early predictors” (38,36) because, while they do not indicate the same urgency of treatment as red flags, there is enough evidence to recommend that they receive attention when present. Guidelines from New Zealand stress the importance of assessing psychological and psychosocial risk factors as early as 2 weeks after the onset of NSLBP (22).

In an occupational health setting, psychosocial factors such as work-related perceptions constitute additional risk factors (46). Job dissatisfaction, monotony, poor social support, high perceived stress, and high perceived job demands have all shown a strong association with NSLBP (47). Therefore, it is reasonable to evaluate these perceptions in patients with NSLBP and discuss with the patient how these factors may influence the perceived back pain.

Physical characteristics of the job (such as excessive overtime or heavy workload) may also contribute to stress (28,43,48–50). Physical characteristics may be assessed subjectively and objectively. It is less understood what impact reducing perceived or actual physical stressors at work may have on psychological distress, NSLBP, and disability.

### THE IMPACT OF COMORBIDITY ON DISABILITY IN NSLBP

There is recent information in the literature about the relationship between comorbidity and work disability from back pain. In a prospective, randomized case-controlled study Seferlis et al. (41) compared somatic and personality characteristics of acute LBP patients with healthy matched controls and found a fourfold increase in sick leave episodes in LBP patients for reasons other than spine morbidity. Fanuele et al. (51), in their prospective observational study on spine center patients, demonstrated that comorbidity affects the physical function, showing that the more comorbidities a patient has, the lower the physical functional status.

Nordin et al. (12) examined the relationship between comorbidity and the initial return to work following first episodes of work-disabling NSLBP. An inception cohort of workers with new episodes of NSLBP was identified from administratively maintained occupational health

records. A comparison of 6-month return to work rates between workers with one or more comorbid conditions to those without documented comorbidity was conducted. Workers with comorbidity were 1.3 times more likely to remain work-disabled than those with uncomplicated NSLBP, after adjusting for age, gender, lifting demands, and type of work (adjusted hazard ratio 1.31, 95% confidence interval 1.12 to 1.52). Concurrent injury (i.e., sprains or strains of the neck, upper and lower extremity, and contusions and lacerations) had the strongest association with delayed return to work (adjusted hazard ratio 1.49, 95% confidence interval 1.21 to 1.83). The authors concluded that occupational health professionals should routinely evaluate comorbidities at the first, as well as subsequent visits to better manage disability associated with NSLBP.

### ESTABLISHING AN EVIDENCE-BASED TREATMENT PLAN

Researchers and clinicians have used an additional categorization of NSLBP based on the onset and duration of pain in the lumbar spine to develop evidence-based guidelines of treatment (20). Clinical and accepted categorizations for duration of NSLBP are:

1. *Acute*: Pain with a duration  $\leq 4$  weeks.
2. *Subacute*: Pain with a duration  $\geq 4$  weeks but  $\leq 12$  weeks.
3. *Chronic*: Unremitting pain with a duration  $\geq 12$  weeks

For many individuals, however, NSLBP is not a one-time event but tends to recur (18,52). Therefore, an additional classification, *recurrent NSLBP*, signifies intermittent pain with a pain-free period in between in which the individual could resume work (7,20). Recurrent NSLBP may be acute or subacute, but since chronic pain signifies unremitting pain of more than 12 weeks, by definition, it cannot be chronic (53).

Considering the socioeconomic impact of NSLBP there is an obvious need for effective interventions, especially in occupational health care. The ultimate goal of such interventions for workers is return to work, either to a preinjury or modified work capacity. Given the favorable natural course in the acute phase of NSLBP of return to work, the challenge becomes returning an employee to work who is in the subacute or chronic phase.

A variety of treatment interventions are typically used for individuals presenting with NSLBP (54,55). Several authors have published systematic reviews of the efficacy of these interventions (19,20,53,56–58). Studies show that for subacute NSLBP exercise therapy, behavioral therapy, and intensive multidisciplinary rehabilitation with functional restoration all reduce pain and improve function in workers (20,32,59,60). Graded activity leads to earlier return to work and reduced long-term sick leave

in workers with subacute low back pain. Lindström et al. (60) described the goal of the graded activity approach as being return of an individual to the previous nonmodified workplace. Positive reinforcement to return to work is an important aspect of graded activity as well as continuous encouragement to resume work. Multidisciplinary treatment consisting of a combination of exercises, education, and a behavioral approach seems the most effective intervention in the subacute phase of NSLBP. Lindström et al. (60) conducted a randomized control trial aimed at restoring occupational function in workers in an automobile plant. The multidisciplinary intervention team included a physician, a physical therapist, and a social worker. All workers ( $n < 103$ ) participating in the study had been out of work for more than 8 weeks for NSLBP. Half of the participants were randomized to an intervention including an operant-behavioral conditioning program and the other half received what is considered "usual care." The intervention program consisted of four parts: measurements of functional physical capacity, a workplace visit, "back-to-school" education, and an individual, submaximal, gradually increased exercise program. The individually tailored exercise program was based on an operant-conditioning behavioral approach and the result of the

tests and the demands of the patient's work. No ergonomic or other changes in the work situation were needed in the study. The results were significant and positive.

The rate of return to work was significantly faster in the intervention group than in the control group ( $\kappa^2 < 4.7, p < .03$ ) (Fig. 16-2). The intervention group had 7 weeks' less sick leave in the follow-up period of 1 year than the control group receiving "usual care." Four patients in the control group went on permanent disability versus one patient in the intervention group. The study did not have an independent evaluator, causing a methodologic weakness, however it was the first randomized control trial in the industry that emphasized the importance of activity and exercise, a behavioral approach, and an individual tailored program to resume work demands. It was also a program that demonstrated the importance of full support from the employer.

One approach to augment return to work for chronic NSLBP patients is functional restoration (61–63), the goal being to restore a patient's function. This approach leads to the decrease of and control of pain through the combination of exercise with functional work simulation and behavioral support. The exercise program uses a

**FIG. 16-2.** Proportion returning to regular work. Randomized control trial from Sweden showing results from active intervention including exercise, behavioral approach and workplace visit versus usual care. (Adapted from Lindström I, Öhlund C, Eek C, et al. The effect of graded activity on patients with subacute low back pain: a randomized prospective clinical study with an operant-conditioning behavioral approach. *Phys Ther* 1992;72:279–290.)

sports exercise approach, and emphasizes mobility, strengthening, endurance, and flexibility. The functional simulation program is conducted in a specially developed occupational gymnasium and includes tasks that are commonly required in the workplace. The behavioral support consists of cognitive-behavioral treatment, relaxation, education, biofeedback, and individual and group counseling. The workers are treated in groups of up to 10 to 12 individuals (61,64).

In summary, multifactorial and multidisciplinary treatment consisting of a combination of exercises, education, and a behavioral approach seems the most effective intervention. This is especially true of graded activity (32,60) for workers with subacute low back pain and functional restoration (64) for workers with chronic low back pain. Both of these approaches offer the most promising results.

Multidisciplinary treatment is still somewhat of a gray area. It is unclear what the most effective contribution is of each of the program components. Studies are lacking and are needed to clarify the efficacy, cost utility, and cost-effectiveness of such programs. Nevertheless, literature reviews by Scheer et al. (63) and Rivier et al. (65) and one systematic review by van Tulder et al. (53) indicate favorable results for the outcome of multidisciplinary active intervention programs related to occupational subacute and chronic NSLBP, clinical improvement and well-being. The results are less explicit on return to work, work retention, and cost.

In moving forward, health care providers must simultaneously rely on and challenge evidence-based practices. Scientific evidence from clinical trials, systematic reviews, and meta-analyses on the effectiveness of interventions form a sound basis for clinical guidelines. Guidelines are efficient means to close the gap between research and practice. Good clinical guidelines, however, also consider other aspects such as side effects, costs, availability, and preferences of injured workers and clinicians (66). At present, several guidelines have been published addressing the specific issues of management of low back pain in an occupational health care setting. This includes: (a) Quebec Task Force, Canada (30); (b) Victoria Workcover Authority, Australia (67); (c) American College of Occupational and Environmental Medicine (68); (d) Dutch Association of Occupational Medicine, The Netherlands (69); (e) Accident Compensation Corporation and National Health Committee, New Zealand, 1997(22); and (f) Faculty of Occupational Medicine, United Kingdom (70). The guidelines show general agreement on numerous issues fundamental to occupational management of low back pain. The assessment recommendations consist of diagnostic triage, screening for "red flags" and neurologic problems, and the identification of potential psychosocial and workplace barriers for recovery. The recommendations for treatment of workers with low back pain include:

1. Reassuring the worker and providing adequate information about the self-limiting nature and good prognosis of low back pain.
2. Advising the worker to continue ordinary activities and working, or to return to normal activity and work as soon as possible, even if there is still some pain.
3. Most workers with low back pain manage to return to more or less normal duties quite rapidly. Consider temporary adaptations of work duties (hours/tasks) only when necessary.
4. When a worker fails to return to work within 2 to 12 weeks (there is considerable variation in the time scale in different guidelines), refer the worker/employee to a gradually increasing exercise program or multidisciplinary rehabilitation program (exercises, education about condition and prognosis, reassurance, and pain management following behavioral principles). These rehabilitation programs should be embedded in an occupational setting or occupational-related care setting.

The guidelines also recommend, on advice from health care provider, that low back pain is a self-limiting condition and, importantly, that remaining at work or an early (gradual) return to work, if necessary with modified duties, should be encouraged and supported.

### **RETURN TO WORK AS A THERAPEUTIC MODALITY**

The therapeutic value of return to work is a novel concept and some studies have looked at efficacy of restricted duty (71) and workplace modifications (72). Loisel et al. (72) states that a return to "usual" work is the only worthwhile therapeutic objective. Returning workers to modified workstations allows them to resume their work after a back injury but does not lead to therapeutic success. In fact, some companies have used a return to modified workstations to hide cases from official occupational accident statistics. The same study also clearly demonstrated that therapeutic success, measured by return to usual work, is dependent on the efficacy of workplace interventions, with medical interventions (both diagnostic and therapeutic) and graded activity programs significantly less effective. In this study, the workplace interventions consisted of workplace meetings with supervisors to discuss modifications to the organization of the patient's work. Attempts to modify workstations were relatively uncommon, but if made, they were simple (72).

Restricted work or light duty is popular among some employers and health care provider, while other organizations do not use it. It is believed to reduce indirect cost, augment work retention, and expedite the transfer of the individual from the restricted work position to full preinjury capacity duty in a more time-efficient manner. However, few studies have looked at restricted work procedures that are commonly used in industry. Hiebert et al. (71) car-

ried out a retrospective cohort study ( $n < 240$ ). The objectives were to evaluate the associations of prescribed work restrictions with work absenteeism and recurrence in cases of NSLBP. Employees absent from work because of back pain were identified from medical records of a utility company, and were placed into two groups: those who received a work restriction for back pain and those who did not. After 1 year of follow-up, the duration of sickness-related absence was compared between the two groups. Employees who returned to work within the follow-up period were followed for one additional year to determine rates of recurrence between the two groups. The Cox proportional hazards model was used to generate hazard ratios adjusted for age, gender, and job category.

Work restrictions were given to 43% of the workers reporting disabling NSLBP. Sickness-absence duration did not differ between those who received restrictions as compared to those who did not (adjusted hazard ratio  $< 1.12$ ,  $p < .41$ ). The median duration of restricted duty was 32.5 days; for 22% of workers restricted duty was never lifted. Injury recurrence appeared less likely for those who had work restrictions in their initial episode; however, it was not statistically significant (adjusted hazard ratio  $< 0.77$ ,  $p < .48$ ). The conclusion of the study was that work restriction was not associated with early return to work and thus to returning to full preinjury duty. The authors concluded that the findings of this study should be interpreted cautiously; a recommendation to discontinue the practice of prescribing work restrictions should not be made on the basis of the findings from this paper alone. This study should be interpreted as a first critical attempt to evaluate a common clinical practice and to highlight the need for further research.

### “SAFE” RETURN TO WORK

The management of low back pain in an occupational health setting should be aimed at a “safe” return to work. Current occupational guidelines are consistent regarding their recommendations to reassure the worker with low back pain, and to encourage and support return to work even with some persisting symptoms. Evidence on the effectiveness of ergonomic and workplace adaptations are lacking and guidelines do not specifically recommend this type of intervention. “Participatory ergonomics” interventions which propose consultations with the worker, the employer and an ergonomist, might be effective as the potential value of “getting all the players on one side” has been stressed (55).

The Paris Task Force (20) favors workers returning to their usual workstations or regular duty with the following conditions in place. One, several or all conditions may be used to return the employee to regular duty:

1. Management of the process by occupational physicians and the human resources department
2. Workstation assessment

3. Evaluation of workers’ physical capacity
4. Identification of workstations that are congruent with workers’ physical capacities
5. Communication between workers and supervisors
6. Regular clinical follow-up during the adaptation period.

If all of the above has failed a reclassification of the employee/worker to other type of work/duty, retraining to other type of work, or permanent disability may be considered. The most important message in this instance is to use a systematic approach to reclassify the ability or possible disability for work. The focus of this chapter is to discuss successful reintegration of the worker with low back pain episode(s) into the workplace; the reader is referred to a text by Waddell et al. (8) for further discussion of the incapacity for work and back pain in a social context, from an international point of view. Waddell et al. stress that “from a social perspective, trends of incapacity for work attributed from low back pain and social security benefits paid back for back pain form a social phenomenon which is related to the economic and labor market situation.” Most important, the text emphasizes that back pain is not simply a health problem but often raises more fundamental psychosocial issues which health care providers and social security systems are often ill-equipped to handle (73). Being ill-equipped to handle these problems or worse, refusal to recognize the problems leads to slow intervention and promotes disability.

### WORK RETENTION AFTER NSLBP

Few studies have been conducted verifying the relationship between work retention and NSLBP. Work retention is an important outcome of NSLBP as it contains information about symptom control over a period of time, medical utilization, and loss of productivity. Amick et al. (74) suggested that there are many reasons to measure work outcomes, such as evaluation of effectiveness of health services, assessment of productivity loss, and targeting injury prevention programs. Additionally, reports in the literature have shown that people who are out of work because of either disability or unemployment are more likely to develop other diseases, and ultimately their life span is reduced when compared to people who are employed (75). Work retention is therefore an important outcome of a successful intervention and workers’ well-being as a health improvement measurement.

Campello (76) studied physical and psychosocial associations and work retention. Sixty-seven patients (mean age 40, SD 12 years) with NSLBP participated in a 4-week multidisciplinary rehabilitation program. Patients returning to work were followed for 2 years. Physical and psychosocial baseline measures were collected, including performance and functional capacity tests. Psychosocial baseline measures were somatization scales, pain beliefs,

and perceived disability. Physical parameters included trunk flexibility, lifting capacity, and aerobic capacity, among others. The dependent variable, work retention, was defined as the number of days that the subject worked during the 2-year follow-up period. Survival analysis was used to establish a predictive model. The average time out of work before treatment was 9 months (SD 12). Average work retention was 362 days (range 47 to 682 days) for 18 patients that relapsed with NSLBP. Results showed that posttest trunk flexion and somatization were the strongest predictors for work retention [final trunk flexion hazard ratio 2.5 (95% confidence interval 1.26 to 4.79,  $p < .01$ ), somatization scale hazard ratio 2.5 (95% confidence interval 1.25 to 4.93,  $p < .01$ )]. The author concluded that psychosocial and physical factors are associated with work retention for NSLBP patients.

Beliefs and perceptions have also been found to be associated with work retention. Linton and Hallden (77) observed a significant difference in beliefs that one should not work with current pain levels between groups of acute and subacute NSLBP patients seeking primary care. There was a significant difference between individuals who retained work and groups that have missed work because of NSLBP problems subsequent to their return to work. Individuals who believed they should not work because of the level of pain experienced were less likely to retain work in a 6-month follow-up period. High levels of perceived disability were found to be negatively associated with work retention in a study conducted in a group of subacute and chronic NSLBP patients undergoing rehabilitation in outpatient clinics. Individuals who perceived high levels of disability were more likely to experience an interruption of work because of NSLBP in a 6-month follow-up period following completion of a treatment program and return to work (78).

High levels of anxiety were found to be negatively associated with work retention. Individuals who reported feeling tense and anxious at the time of intervention were less likely to retain work after they returned to work (77). Changes in depression and anxiety were also found to be predictive for work retention in a study conducted of patients with chronic NSLBP enrolled in an intensive rehabilitation program (79). Individuals who showed a decrease in anxiety and depression levels (from high to low levels) were more likely to retain work than individuals who did not show a decrease in levels of distress after multidisciplinary intervention. In conclusion, physical and psychosocial factors affect work retention after an episode of disabling low back pain.

## CONCLUSIONS

The probability of returning to work decreases very rapidly with increasing duration of work absence in every study reviewed by the Paris Task Force (20). The risk of

chronicity and work incapacity increased very rapidly in the first weeks of the episode of back pain, and the prognosis is greatly compromised well before the third month of disability. This chapter has focused on the prevention of work disability and the different possibilities a worker might undergo to return to gainful employment after an episode of NSLBP. Perhaps the most important message to the health care provider is to accept that the diagnosis of NSLBP is an accurate and a "good" diagnosis with a good prognosis. Scientific studies may change this concept in the future when scientists discover the cause(s) of NSLBP.

A working person is at great risk for delayed recovery and long-term disability from 6 to 12 weeks following the onset of symptoms of NSLBP and work incapacity. At this time there are successful interventions to return a person to gainful employment. Based on scientific evidence these interventions must be active, include exercises, and take into account psychosocial and workplace interventions after a careful multidisciplinary evaluation of the work-disabled patient.

## CHAPTER 17

# Occupational Ergonomics

William S. Marras

---

Ergonomics has been defined as “a multidisciplinary activity dealing with the interactions between man and his *total* working environment” (1). Ergonomic design attempts to create workplaces to accommodate or “fit” the workers. The goal of ergonomics is to create a work environment that is efficient, productive, and optimizes worker health. Inherent in this definition is the idea that ergonomics deals with not only the physical components of the workplace, but addresses the mental or cognitive components as well. Among the scientific disciplines employed to achieve these goals are biomechanics, biochemistry, psychology, cognitive science, physiology, physical anthropometry, organizational design, and medicine.

The science of ergonomics is primarily concerned with the *prevention* of problems in the workplace. Over the past several decades, ergonomics has been employed with increasing frequency by organizations of all sizes. Many large as well as small companies have permanent ergonomic programs in place that have derived significant benefits from these efforts (2). There are several motivations for the incorporation of ergonomic principles in the design of the workplace. These motivations are associated with the direct and indirect costs associated with musculoskeletal disorders in the workplace. Direct costs are associated with the rapidly increasing health care costs associated with a work-related musculoskeletal disorder. Indirect costs associated with work-related musculoskeletal disorders include the training of new workers that replace the injured worker, employee turnover costs including administrative costs, loss of productivity, lower product quality, and the cost of the injury investigation. Many businesses have discovered that the prevention of injuries is much more economically advantageous than rehabilitating a musculoskeletal disorder that has already occurred.

Ergonomic approaches alter the work environment to control risk exposure and optimize efficiency and productivity. Two types of risk controls or ergonomic inter-

ventions are used in the design of the workplace. First, engineering controls are used to physically change the orientation of the work environment relative to the person. Engineering controls ideally alter the workplace and create a work environment where the risk has been minimized so that the work-person interface is optimal. Second, administrative controls are often employed when it is not possible to provide engineering controls. Administrative controls do not eliminate the risk. Instead they attempt to control risk by managing the time of worker exposure to the risks in the workplace. This is often accomplished through rotation of workers exposed to a risk or ensuring that workers have adequate time to recover from exposure to workplace risks through appropriate scheduling of days off work.

While ergonomics typically addresses all aspects of musculoskeletal disorders as well as performance issues, the discussion of ergonomics in this chapter will be limited in scope to issues and principles associated with the prevention of low back disorders (LBDs) due to physical work activities (not related to whole-body vibration).

### **MAGNITUDE OF THE LOW BACK PAIN PROBLEM AT WORK**

It should be acknowledged that since most people work, workplace risk factors and individual risk factors are difficult to separate (3). However, potential patterns can be identified through surveys of working populations. In the United States back disorders are associated with more days away from work than those related to any other part of the body (4). Recent studies of 17,000 men and women of working age population in Sweden (5) indicated that 5% of workers sought care for a new low back pain episode over a 3-year period. They also found that many of these cases became chronic. Evaluations of data from a large sample of U.S. households collected by the National Health Injury Survey (NHIS) found that back pain accounts for about one-fourth of the workers’

**FIG. 17-1. A:** Number and distribution of back cases with days away from work in private industry by industry division during 1997. **B:** Number and distribution of back cases with days away from work in private industry by source of the disorder during 1997. (Data for both **A** and **B** from National Institute for Occupational Safety and Health. Worker health chartbook. Cincinnati, 2000.)

compensation claims in the United States (6). Two-thirds of the low back pain cases were attributed to occupational activities. Prevalence of lost workdays due to back pain was found to be 4.6% (7). Certain occupations were also found to be significantly linked to greater rates of low back pain reporting. Risk appeared to be highest for construction laborers (prevalence 22.6%) and nursing aides (19.8%) (6). Figure 17-1 summarizes the findings of a National Institute for Occupational Safety and Health (NIOSH) analysis of work-related LBDs (4). This figure indicates that, in terms of prevalence, the service industry followed by manufacturing account for nearly half of all occupationally related LBDs. The analysis also indicates that handling of containers and worker motions and position assumed during work are most often associated with LBDs in U.S. industry. Hence, these data strongly suggest that occupational factors appear to be related to risk of LBDs.

### EPIDEMIOLOGY OF WORK RISK FACTORS

Several reviews have identified specific risk factors that increase the risk of LBDs in the workplace. The NIOSH performed a critical review of the epidemiologic evidence associated with musculoskeletal disorders (8). Five categories of risk factors were evaluated. The critique concluded that strong evidence existed for an association between LBDs and lifting/forceful movements and LBDs and whole-body vibration. Significant evidence was found for the associations between heavy physical work and awkward postures and back problems. The review concluded that insufficient evidence was available to make any conclusions between static work postures and LBD risk. In a methodologically rigorous review Hoogendoorn et al. (9) were generally able to support these conclusions. They found that manual materials

handling, bending, twisting, and whole-body vibration were risk factors for back pain.

Several studies have been in search of a dose-response relationship among work risk factors and low back pain. Two studies (10,11) suggest that cumulative loading of the spine might be associated with risk of LBD at work. However, Videman et al. (12) suggested that the relationship might not be as straightforward as the linear relationships suggested. When examining the relationship between back pain, history of physical loading, and occupation in cadaveric specimens, Videman et al. concluded that the risk relationship between LBD risk and loading was “J-shaped” with sedentary jobs being associated with moderate levels of risk, heavy work being associated with the greatest degree of risk, and moderate exposure to loading being associated with the lowest level of risk. Seidler et al. (13) have recently suggested that the combination of occupational lifting and trunk flexion, and duration of the activities significantly increased risk.

Over the past decade, studies have also assessed the impact of psychosocial factors in the workplace in relation to the risk of LBDs (14–17). Studies often show that monotonous work, high perceived workload, time pressure, low job satisfaction, and lack of social support are related to LBD risk. However, Davis and Heaney (18) found that the impact of psychosocial factors was diminished, yet still significant, once biomechanical factors were accounted for in the study designs.

Secondary prevention studies of LBD have begun to explore the interaction between LBDs, physical factors, and psychosocial factors. Frank et al. (19) as well as Waddell (20,21) have pointed out that much of low back pain treatment is multidimensional. Epidemiologic studies of the role of variables in primary prevention of work-related low back pain have suggested that

**TABLE 17-1.** Summary of epidemiologic evidence with risk estimates (null, positive, and attributable fraction) of associations with work-related factors associated with low back disorders

Work-related risk factor	Risk estimate					
	Null association <sup>a</sup>		Positive association		Attributable fraction (%)	
	<i>n</i>	Range	<i>n</i>	Range	<i>n</i>	Range
Manual material handling	4	0.90–1.45	24	1.12–3.54	17	11–66
Frequent bending and twisting	2	1.08–1.30	15	1.29–8.09	8	19–57
Heavy physical load	0		8	1.54–3.71	5	31–58
Static work posture	3	0.80–0.97	3	1.30–3.29	3	14–32
Repetitive movements	2	0.98–1.20	1	1.97	1	41
Whole-body vibration	1	1.10	16	1.26–9.00	11	18–80

*n*, Number of associations presented in epidemiologic studies.

<sup>a</sup>Confidence intervals of the risk estimates included the null estimate (1.0). In only 12 of 16 null associations was the magnitude of the risk estimate presented.

multiple dimensions, such as physical stressors and psychosocial factors, play a role in low back pain risk (22). Tubach et al. have recently shown that low social support at the workplace and bending at work are strongly associated with extended work absence due to low back pain (23).

Recent rigorous epidemiologic reviews of the literature performed by the National Research Council (3) have concluded that there is a clear relationship between back disorders and physical load imposed by manual material handling, frequent bending and twisting, physically heavy work, and whole-body vibration. The risk attributable to these risk factors is summarized in Table 17-1. This analysis indicates that the vast majority of high quality epidemiologic studies have associated LBDs with these risk factors and up to two-thirds of risk can be attributed to materials handling activities. As a result of these epidemiologic analyses, it was concluded that preventive measures may reduce the exposure to risk factors and reduce the occurrence of back problems.

### OCCUPATIONAL BIOMECHANICS LOGIC

The epidemiologic literature helps to understand what factors might be associated with work-related LBDs but the body of literature is problematic in that it has great difficulty prescribing an optimal level of exposure in order to minimize risk. The National Research Council's review of epidemiologic evidence and LBDs concluded that "epidemiologic evidence itself is not specific enough to provide detailed, quantitative guidelines for design of the workplace, job, or task. This lack of specificity results from the absence of exposure measurements on a continuous scale, as opposed to the more commonly used dichotomous (yes/no) approach. Without continuous measures, it is

not possible to state the 'levels' of exposure associated with increased risk of low back pain" (3). In order to more fully understand "how much exposure is too much exposure" to risk factors, we must develop an understanding of how work-related factors might lead to LBDs. This causality pathway is typically addressed through biomechanical and ergonomic analyses. If one views the biomechanical literature as a whole, it is clear that these analyses represent a promising approach to controlling low back injury risk in the workplace.

Biomechanical logic presents a format to help us understand the mechanisms that might effect the development of a LBD. At the heart of this logic is the idea that risk is associated with a load-tolerance relationship. Figure 17-2 shows this relationship graphically. As explained by McGill (24), when work is performed the structures and tissues of the spine undergo a loading pattern with each repeated job cycle. If the magnitude of the load imposed upon a structure or tissue exceeds the structural tolerance of this tissue, damage occurs and this damage might be capable of setting off the sequence of events that could lead to LBD. If the magnitude of the imposed load is below the structural tolerance, the task is safe. The magnitude of the distance between the structure loading and the tolerance is considered the safety margin (Fig. 17-2A). If the load exceeds the tolerance then risk is present (Fig. 17-2B).

Biomechanics can also be used to describe the processes believed to be at work during exposure to cumulative trauma disorders. As shown in Fig. 17- 2C, when exposed to repetitive exertions, one would expect the tolerance to be subject to degradation over time. As the work is performed repeatedly, we would expect that the loading pattern would remain relatively constant, however, with overuse we would expect the tolerance limit to decrease over time. This makes it more probable

**FIG. 17-2.** Biomechanical load-tolerance relationships. **A:** When the tolerance exceeds the load, the situation is considered safe with the distance between the two benchmarks considered a safety margin. **B:** When the load exceeds the tolerance, risk of injury exists. **C:** Cumulative trauma occurs when the tolerance decreases over time.

for the load to exceed the tolerance and thus trigger a potential disorder.

### PAIN AND BIOMECHANICAL TOLERANCE

It is believed that there are numerous pathways to pain perception associated with LBDs. It is important to understand these pathways since they are the basis for the structure and tissue limits employed in ergonomic logic. One can consider the quantitative limits above which a pain pathway is initiated as a tolerance limit for ergonomic purposes. While none of these pathways have been defined definitively, these pathways are appealing since they represent biologically plausible mechanisms that complement the view of injury association derived from the epidemiologic literature.

In general, three broad categories of pain pathways are believed to exist that may affect the design of the workplace. These categories are associated with: (a) structural and tissue stimulation, (b) physiologic limits, and (c) psychophysical acceptance. Each of these pathways is expected to have different tolerance limits to mechanical loading of the tissue. Thus, in order to properly design a workplace one must design tasks so the ultimate limit within each of these categories is not exceeded.

#### Pathways between Tissue Stimulation and Pain

The literature suggests that there are several structures in the back that when stimulated are capable of pain perception. Both cellular and neural mechanisms can lead to pain and both laboratory and anatomic investigations have indi-

cated neurophysiologic and neuroanatomic origins of back pain (25–29). These pathways often involve pressure on a structure that can directly stimulate pain receptors or trigger the release of pain-stimulating chemicals.

Pain pathways have been identified for joint pain, pain of disc origin, longitudinal ligaments, and mechanisms for sciatica. Facet pain mechanisms are associated with an extensive distribution of small nerve fibers and endings in the lumbar facet joint, nerves containing substance P, high-threshold mechanoreceptors in the facet joint capsule, and sensitization and excitation of nerves in the facet joint and surrounding muscle when the nerves are exposed to inflammatory or algescic chemicals (30–32). The pathway for disc pain has been suggested through an extensive distribution of small nerve fibers and free nerve endings in the superficial annulus of the disc and small fibers and free nerve endings in the adjacent longitudinal ligaments (25,28,33,34). Sciatic pain can be associated with mechanical stimulation of spine structures. Even moderate pressure on the dorsal root ganglia results in vigorous and long-lasting excitatory discharges that might explain sciatica. Additionally, sciatica might be explained by excitation of dorsal root fibers when the ganglia were exposed to the nucleus pulposus. Stimulation and nerve function loss in nerve roots exposed to phospholipase A<sub>2</sub> might also explain sciatica (27,35,36). Recent work is showing the importance of proinflammatory agents such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-1 (IL-1) (37). These agents up-regulate under certain conditions and set the stage for pain perception. It is possible that mechanical stimulation of tissues can initiate this sequence of events and thus

become the initiator of pain. Thus, it may be possible to consider the role of these agents in a load-tolerance model where tolerance may be considered the point at which these agents are upregulated.

These studies provide the framework for an established and logical link between the mechanical stimulation of spinal tissues and structures and the sensation of low back pain that is the foundation of occupational biomechanics and ergonomics.

### Functional Lumbar Spinal Unit Tolerance Limits

The tolerances of the individual structures of the functional lumbar spinal unit are often considered collectively as part of the structural support system. The vertebral body can typically withstand large loads when compressed. The tolerance limits are often considered along with those of the end plate. A review by Jager (38) indicated the compressive tolerance reported in the literature could be large (over 8 kN) especially in an upright posture, but highly variable with some specimens indicating failure at 2 kN. Damage to human vertebral cancellous bone is typically a result of shear stress and the ultimate strength is correlated with tissue stiffness when exposed to compressive loading (39). Bone failure often occurs along with disc herniation and annular delamination (40). Thus, damage to the bone itself appears to be part of the cascading series of events associated with low back pain (29,41,42).

There is a debate in the literature as to the pain pathway associated with vertebral end-plate microfracture. One line of thinking maintains that health of the vertebral body end plate is essential for proper mechanical functioning of the spine. Damage to the end-plate nutrient supply can result in damage to the disc and disruption of spinal function (43). Traditionally, the literature has supported the idea that the disruption of nutrient flow is capable of initiating a cascading series of events that can lead to low back pain (29,41,42,44). Tolerances of the vertebral end plate have been studied in several investigations. These studies suggest that the end plate is the first structure to be damaged when the spine is loaded, especially at lower load rates (43,45–47). End-plate failure commonly occurs with compressive loads of 5.5 kN (47). End-plate tolerances have been observed to decrease by 30% to 50% with exposure to repetitive loading (45) which suggests the disc is affected by cumulative trauma. Integrity also appears to be influenced by anterior-posterior shear loading. Shear limits tolerances of 1290 to 1770 N for soft tissue and 2000 to 2800 N for the hard tissue have been reported for the spine (48,49).

Activity-related damage might also be indicated by the presence of Schmorl nodes. Some have suggested that Schmorl nodes might be remnants of healed end-plate fractures (50,51) and might be linked to trauma (51,52).

Position or posture of the spine appears to strongly influence end-plate tolerance during loading. Flexed

spine postures can greatly reduce loading tolerance (40,53). Hence, trunk posture is an important consideration for occupational risk assessment. Industrial surveillance studies by Punnett et al., Marras et al., and Norman et al. (10,54–56) all suggest that LBD increases as trunk postures during work deviate from an upright posture.

Individual factors can also influence end-plate integrity. Age and gender have been found to greatly influence the biomechanical tolerance of the end plate (57). Brinkmann (45) has shown that bone mineral content and end-plate cross-sectional area can explain much of the variance in tolerance (within 1 kN).

The disc can be subject to damage with sufficient loading. Disc herniation can occur when the spine is subject to compression and positioned in an excessively flexed posture (53). Repeated flexion under moderate compressive loading can also produce disc herniations (46). Excessive anterior-posterior shear may produce avulsion of the lateral annulus (58,59). The torsion tolerance limit of the disc can occur at loads as low as 88 Nm in an intact disc and 54 Nm in the damaged disc (60,61). The literature indicates that when the spine assumes complex spinal postures such as hyperflexion with lateral bending and twisting, disc herniation is likely to occur (62,63).

The biomechanical tolerance of the disc may also be associated with the time of day when the lifting is performed. Snook et al. (64) found that flexion early in the morning was associated with greater risk of pain. Fathallah et al. (65) reported similar results and concluded that risk of injury was greater early in the day when disc hydration was at a high level. Thus, the temporal component of risk associated with biomechanical exposure must be considered when assessing risk.

This discussion has indicated that the tolerance limits of the functional lumbar spinal unit may vary considerably. Adams et al. (66) has described how repeated microfractures of the vertebrae and scarring of the end plate can lead to an interruption of nutrient flow to the disc. This event can result in weakening of the annulus which may permit protrusion into the surrounding structures or spinal instability. The end plate and much of the annulus are not capable of sensing pain. However, once protrusion occurs or instability results in the application of loads of surrounding tissues, inflammatory responses can occur and nociceptors of surrounding tissues can be stimulated, thus initiating a sequence of events associated with pain. Quantitative ergonomics attempts to design work tasks so that these tolerance limits are not exceeded. Thus, although a wide range of tolerance limits are reported for the functional lumbar spinal unit, most authorities have adopted the NIOSH lower limit of 3400 N for compression as the protective limit for most male workers and 75% of that limit for female workers (67). This is the limit at which end-plate microfracture is believed to begin for some workers. Similarly, a limit of 6400 N represents the limit at which 50% of workers

would be at risk (68). Contemporary quantitative assessments are recognizing the complex interaction of spine position, frequency, and complex spine forces (compression, shear, and torsion) as more realistic assessments of risk. However, these contemporary ergonomic assessments have not resulted in best practices or standards by governmental agencies to date.

### Ligament Tolerance Limits

The literature suggests that ligament tolerances are affected by the load rate (69). Avulsion occurs at low load rates and tearing occurs at high load rates. Hence load rate may explain the increased risk associated with bending motions (velocity) that have been observed in surveillance studies (70) as well as injuries from slips or falls that may be a result of injuries at greater load rates (24). Posture can also play a role in tolerance. Under load, the architecture of the interspinous ligaments can result in significant anterior shear forces on the spine when flexed in a forward bending posture (71). This result is consistent with the recent field observations of risk (10,54–56, 72,73). Studies have identified 60 Nm as the point at which damage begins to occur (74). This finding is consistent with the field observations (55,56) that have found exposures to external load movements of at least 73.6 Nm as associated with high risk of occupationally related low back pain reporting. Similarly, Norman et al. (10) reported nearly 30% greater load movement exposure in those jobs associated with risk of LBP. Mean movement exposure associated with the LBP cases in this study was 182 Nm of total load movement (due to the load lifted plus body segment weights).

Lordic spine curvature may also affect the loading and tolerance of the spinal structures. The research team at the University of Waterloo has shown that when lumbar spinal curvature is maintained during bending the extensor muscles support the shear forces of the torso. If the spine is flexed during bending and posterior ligaments are flexed, then significant shear can be imposed on the ligaments (75–77). Other studies have indicated that shear tolerance (2000 to 2800 N) of the spine can be easily exceeded when the spine is in full flexion (49).

A strong temporal component to ligament recovery appears to exist. Solomonow has found that ligaments require long periods to regain structural integrity and compensatory muscle activities are recruited (78–84). Recovery time has been found to be several-fold the loading duration and can easily exceed the typical work-rest cycles observed in industry.

### Facet Joint Tolerance

Failure of the facet joints can occur in response to shear loading. Investigations by McGill have concluded that much of the tissues that load the facets have signif-

icant horizontal loading components and thus place these structures at risk from occupational tasks (85). Cripton et al. have estimated a shear tolerance for the facet joints of 2000 N (86). These findings are consistent with industrial observations that have shown that exposure to lateral motions and shears is associated with increased risk of LBD reporting (10,55,56). Laboratory assessments have confirmed that exposure to high lateral velocities can result in significant lateral shear forces (87).

Torsional forces can also cause the facet joints to fail (60). Exposure to high torsional movements, especially when combined with high velocity, have been associated with increased loading (88–91). Field studies have also shown that these movements are associated with high-risk jobs (10,55,56). Loading when exposed to torsional moments also depends upon the posture of the torso, with greater load observed with more deviated postures from neutral (89). Specific structure loading depends upon specific posture and curvature of the spine since load sharing occurs between the apophyseal joints and the disc (74). Therefore, spine posture dictates both the nature of spine loading and whether damage might occur to the facet joints or the disc.

### Adaptation

An important consideration in the load-tolerance relationship is that of adaptation. Wolff's law dictates that tissues adapt and remodel in response to load. In the case of the spine, adaptation in response to load has been acknowledged for bone (92), the ligaments (93), the disc (94), and the vertebrae (95). Adaptation may explain the observation that the greatest risk has been associated with jobs involving both high loading and very low levels of spinal loading, whereas job demands associated with moderate spine loading have the lowest levels of risk (96,97). Hence, there appears to be an ideal zone of loading that minimizes risk of exceeding the tolerance limit.

### Psychophysical Tolerance Limits

The tolerance limits of tissue are typically derived from cadaveric studies. While these mechanical limits of performance may be adequate for the analysis of tasks that may lead to an acute trauma event, their application to tasks that may lead to cumulative trauma disorder may be less clear. Since adaptation may play a role, such quantitative analyses of the load-tolerance relationship becomes difficult. In addition, some dynamic tasks such as pushing and pulling may be difficult to characterize through quantitative biomechanical analyses and their injury pathway may be poorly understood.

When mechanical tolerances are not known such as in these circumstances, one approach used to establish tol-

erance limits has been the psychophysical approach. The psychophysical approach is a means of strength testing where subjects are asked to progressively adjust the amount of load they can push, pull, lift, or carry until they subjectively feel the load is of a magnitude that would be acceptable to them over an 8-hour work shift. Task variables such as lift origin, height, load dimensions, frequency of exertion, push/pull heights, carrying distance, and so forth are all systematically altered so that a database of conditions and the acceptable exertion range is cataloged for a spectrum of male and female subjects. These data are typically presented in tables that indicate the percentage of subjects who would find a particular load acceptable for a given task. Snook et al. have produced extensive description of these tolerances (98–103). An example of this information for pushing activities is shown in Table 17-2.

Few investigations have explored whether the design of work tasks through psychophysical tolerance limits is

protective and minimizes low back pain at work. However, Snook (99) has observed that low back-related injury claims were three times more prevalent in jobs exceeding the psychophysically determined strength tolerance of 75% of men compared with jobs demanding less strength.

**Physiologic Tolerance Limits**

Work tasks requiring high energy expenditure are thought to limit the ability of the body to deliver oxygen to the muscles. When oxygen debt occurs, insufficient release of adenosine triphosphate (ATP) occurs within the muscle and prolonged muscle contractions cannot be sustained. Hence, under high-energy expenditure work conditions, aerobic capacity may be considered as a physiologic tolerance limit for low back pain.

Physiologic criteria for limiting low back pain due to heavy physical work requiring high levels of energy

expenditure have been defined by the NIOSH (104). This document considers an energy expenditure rate of 9.5 kcal per minute as a baseline measure for maximum aerobic lifting capacity. Seventy percent of this baseline is considered the aerobic tolerance limit for work that is defined primarily as “arm work”. Of the baseline energy expenditure, 50%, 40%, and 33% are considered the tolerance limits for lifting task durations of 1 hour, 1 to 2 hours, and 2 to 8 hours, respectively.

Minimal epidemiologic evidence is available to support these limits, although Cady et al. have demonstrated the importance of aerobic capacity in back injury for a large sample of firefighters (105,106).

### PSYCHOSOCIAL PATHWAYS

A body of literature exists that has attempted to explain how psychosocial factors might relate to the risk of suffering an LBD. Reviews have implicated psychosocial factors as associated with risk (14,107) and some have dismissed the role of biomechanical factors. However, few studies have properly evaluated biomechanical exposure along with psychosocial exposure in these assessments. A recent study by Davis and Heaney (18) has shown that no studies have been able to adequately assess both risk dimensions concurrently.

Recent biomechanical studies (108,109) have indicated that psychosocial stress does have the capacity to influence biomechanical loading. These laboratory studies have demonstrated how individual factors such as personality can interact with perception of psychosocial stress to increase trunk muscle coactivation and subsequent spine loading. Hence, these studies provide evidence that psychosocial stress may influence risk through a biomechanical pathway.

### SPINE LOAD ASSESSMENT

An important component of evaluating the load-tolerance relationship, and the potential risk associated with work is an accurate assessment of the loading experienced by a tissue. The review of the tolerance literature suggests that it is important to understand the specific nature of the tissue loading including factors such as compression force, shear force in multiple dimensions, load rates, positions of the spine structures during loading, frequency of loading, and so forth. Thus, accurate and specific information about loading is essential if one is to use this information to assess potential risk associated with occupational tasks.

Presently it is not feasible to directly monitor the loads imposed upon the spine structures and tissues while workers are performing an occupationally related task in the workplace. Instead, indirect means such as biomechanical models are typically used to estimate loading. All biome-

chanical models attempt to understand how exposure to external loads results in internal forces that may exceed a tolerance limit. External forces reside outside the body (e.g., gravity or inertia) and must be overcome by the worker to do work. Internal forces are the structures inside the body (e.g., muscles, ligaments, etc.) that must supply counterforces to support the external load. However, since the internal forces are typically at a biomechanical disadvantage, these internal forces can be very large and result in large force applications on spine tissues. Several approaches to biomechanical modeling have been used for these purposes resulting in different trade-offs between their ability to realistically assess spine loading associated with a task and ease of model use.

The first models used to assess spine loading during occupational tasks were reported in the 1970s. Early models of spine loading made assumptions about which trunk muscles supported the external load held in the hands during a lifting task (110,111). These models assumed that a single muscle vector within the trunk could summarize the internal supporting force (and spine loading) required to counteract an external load lifted by a worker. The model assumes that a lift could be represented by a static equilibrium-lifting situation and that no muscle coactivation occurs among the trunk musculature during lifting. The model employs anthropometric regression relationships to estimate body segment lengths representative of the general population. Two output variables are predicted that can be used in a load-tolerance assessment of work exposure. The first model output is spine compression that is typically compared to the NIOSH compression limits of 3400 N and 6400 N. The second model output is population static strength of six joints. L5/S1 joint strength is used to assess overexertion risk to the back. The model has evolved into a computer-based model (3-dimensional static-strength prediction program [3DSSPP]) and is typically used for general assessments of materials handling tasks involving slow movements where excessive compression loads are suspected of contributing to risk. An example of the computer program is shown in Fig. 17-3. The model can be linked to field observations by videotaping a lifting task and recording the weight of the object lifted. Early risk assessments of the workplace have used this method to assess spine loads on the job (112).

During the 1980s, biomechanical models were expanded to account for the contribution of multiple internal muscles' reactions in response to the lifting of an external load. Much of the spine tolerance literature was beginning to recognize the significance of three-dimensional spine loads as compared to only compression loads in defining potential risk. Thus, biomechanical models were developed that predicted compression forces as well as shear forces imposed upon the spine. The first functional multiple muscle system model proposed for mate-

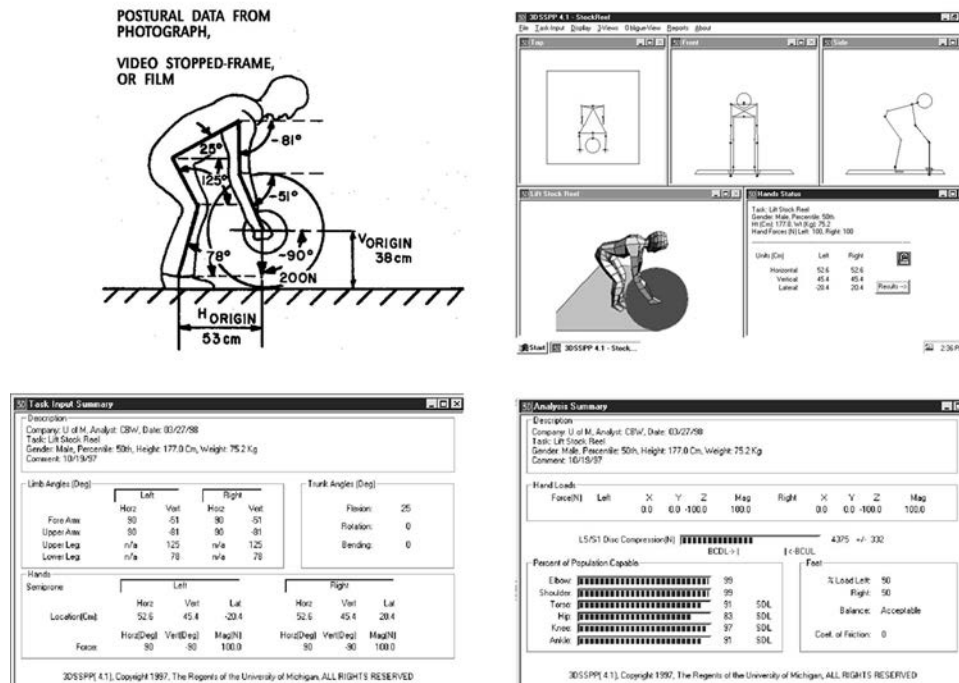

FIG. 17-3. Example of three-dimensional static strength prediction program. (Courtesy of D. Chaffin.)

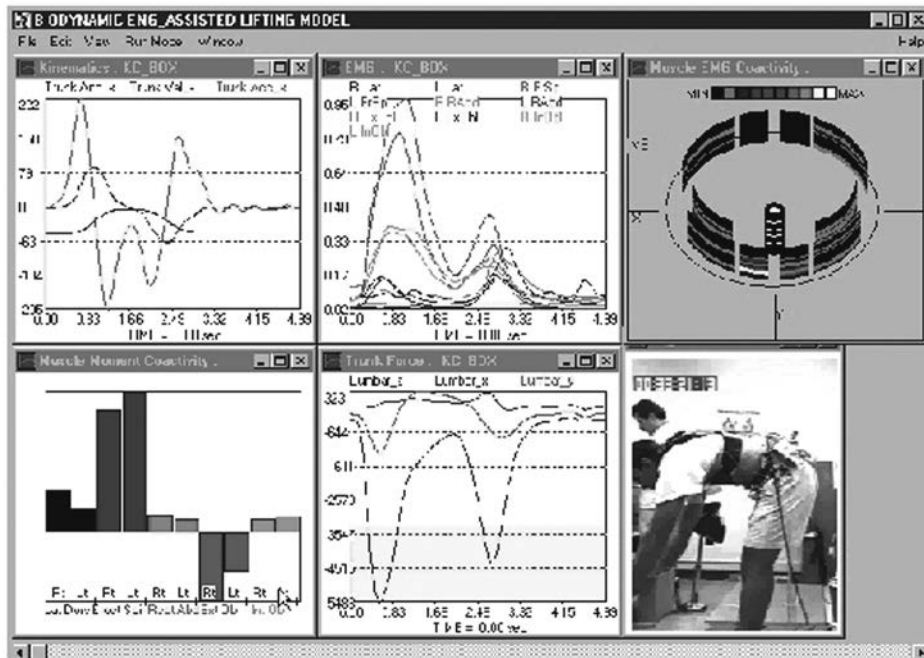

rial handling assessments was developed by Schultz and Andersson (113). This model demonstrated how loads manipulated outside the body could impose large spinal loads due primarily to the coactivation of trunk muscles necessary to counteract this external load. The modeling approach represented much more realism than previous models, however, the approach resulted in indeterminate solutions (since there were more muscles' forces represented in the model than functional constraints unique solutions became difficult). In order to overcome this problem, modeling efforts attempted to determine which muscles would be active (114–116). These efforts resulted in models that worked well for static representations of a lift but not necessarily for dynamic lifting situations (117).

In order to better account for spine loads under dynamic, complex lifting situations, later efforts attempted to directly monitor muscle activity using electromyography (EMG) as an input to multiple muscle models. EMG eliminated the problem of indeterminacy since specific muscle activities were uniquely defined through the neural activation of each muscle. These biologically assisted models were not only able to accurately assess compression and shear spine loads for specific occupationally related movements (88,89,118–129) but are also able to predict differences among individuals so that variations in loading among a population

could be assessed (87,108,130–133) (Fig. 17-4). Validation measures suggest that these models have excellent external as well as internal validity (133,134). Granata and Marras (135) demonstrated the importance of accounting for trunk muscle coactivation when assessing spine loading and found that not accounting for coactivation could result in miscalculations of spinal loading by up to 70%.

The disadvantage of biologically assisted models is that they require EMG recordings that are often not tolerated well in the workplace. Therefore many of the studies of loadings associated with the spine during work have been performed under laboratory conditions and have attempted to assess specific aspects of the work that may be common to many work conditions. Several efforts used EMG-assisted models to assess three-dimensional spine loading during materials handling activities (87,118,123,136–138). There are many examples of information provided from these in-depth analyses using biologically assisted models. Figure 17-5 shows the difference in spine compression as subjects lift with one hand versus two hands as a function of lift asymmetry (118). This figure indicates that compressive loading of the spine is not simply a matter of load-weight lifted. Significant trade-offs occur as a function of asymmetry and the number of hands involved with the lift. The concept of trade-offs among workplace factors was reinforced in a study that evaluated order-selecting activi-

**FIG. 17-4.** Electromyography (EMG)-assisted model used to evaluate spine loading during simulated work activities. ties in a laboratory setting (139). Some of the results from this study are displayed in Table 17-3. This table shows the interaction between load weight, location of the lift (region on the pallet), and presence of handles on spine compression (benchmark). This analysis indicates that all three factors significantly affected the loading on the spine. Another study indicated the trade-offs between spine compression and shear loads as a function of how many hands were involved in the lift, whether both feet were in contact with

the ground, lift origin, and height of a bin from which subjects were lifted (140) (Table 17-4). Similar studies have also helped to understand spine loading trade-offs associated with team lifting (141), patient lifting (Table 17-5) (142), the assessment of lifting belts (77,143–146), and while using lifting assistance devices (147). Efforts have also been made to apply the in-depth knowledge obtained from these biologically assisted models through regression models of workplace characteristics (148,149). Recently,

**FIG. 17-5.** Mean peak compression force as a function of lift asymmetry [clockwise (CW) versus counterclockwise (CCW)] and hand(s) used to lift load. Results derived from electromyography-assisted model simulation of tasks (118).

EMG, electromyogram; N, Newton.

efforts have also employed these models to assess the role of psychosocial factors, personality, and mental processing on spine loading (108,109).

Efforts have also attempted to use stability as criteria to govern detailed biologically assisted biomechanical models of the torso (84,150–157). One potential injury pathway for LBDs suggests that the unnatural rotation of a single spine segment that may create loads on passive tissue or other muscle tissue can result in irritation or injury (85). Much of the work performed in this area

to date has been directed toward static response of the trunk as well as sudden loading responses (151,152,154,155,158,159).

#### ASSESSMENT METHODS AND THE IDENTIFICATION OF LBD RISK AT WORK

Previous sections have introduced methods used in studies of the assessment of spine loads in response to various work-related factors that are common to many

**TABLE 17-4.** Spine forces (means and standard deviations for lateral shear, anterior-posterior shear, and compression) as a function of the number of hands used, the number of feet supporting the body during the lift, the region of a pallet and the height of a bin when lifting items from an industrial bin (140)

Independent measures	Condition	Lateral shear force (N)	Anterior-posterior shear force (N)	Compression force (N)

workplaces (e.g., one-hand versus two-hand lifting). These studies have resulted in a rich body of literature that can be used as a guide for the proper design of many work situations. However, a need still exists for assessing unique work situations that may not have been explored in these laboratory studies. The more robust methods for assessing spine loads (e.g., EMG-assisted models) may not be usable for assessment on the job since they require extensive instrumentation. This section reviews the methods and tools available for the assessment of LBD risk at the work site along with a review of the literature that supports their usage.

### Three-Dimensional Static Strength Prediction Program

The three-dimensional static strength prediction program (3DSSPP) has been described previously. This program considers the load-tolerance relationship from two aspects. An estimate of spine compression is generated and compared to the generally accepted tolerance limits of 3400 N. In addition, the load imposed by the task on six joints is compared to the static strength of the muscle groups. This last relationship has been defined as a lifting strength rating (LSR) and was used to prospectively assess low back injuries in an industrial environment (97). The LSR is defined as the weight of the maximum load lifted on the job divided by the lifting strength measured in the same lifting posture for a large, strong man. The study concluded that “the incidence rate of low back pain [was] correlated [monotonically] with higher lifting strength requirements as determined by assessment of

both the location and magnitude of the load lifted.” This was one of the first quantitative ergonomic studies to conclude that not only was load lifting potentially hazardous, but it was also important to consider the load location when assessing risk. The study also suggested that exposure to moderate lifting frequencies appeared to be protective, whereas, high or low rates of lifting were common in jobs with greater reports of back injury.

An industrial study using both the LSR and estimates of back compression forces observed jobs over 3 years in 5 large industrial plants where 2,934 material handling tasks were evaluated (112). The results suggested a positive correlation between the lifting strength ratio and back incidence rates. The study also reported that musculoskeletal injuries were twice as likely for predicted spine compression forces that exceeded 6800 N. However, this was not true for back incidents specifically. The study also suggested that prediction of risk was best associated with the most stressful tasks (as opposed to indices that represent risk aggregation).

### Job Demand Index

A similar concept to the LSR was reported by Ayoub et al. (160) in terms of a job severity index (JSI). This index considers the ratio of the job demands relative to the lifting capacities of the worker. Job demands include factors such as the weight of the object lifted, the frequency of lifting, exposure time, and lifting task origins and destinations. A comprehensive task analysis is required to assess job demands. The worker capacity includes the strength and body size of the worker. Strength is deter-

mined through psychophysical testing. A prospective study using the JSI was performed by Liles et al. (161). Results suggested a threshold of a job demand relative to worker strength above which the risk of low back injury increased. The authors suggest that this method could identify the more costly injuries.

### NIOSH Lifting Guide and Revised Lifting Equation

The NIOSH has developed two tools to help industry assess the risk associated with materials handling jobs. The objective of both tools was to “prevent or reduce the occurrence of lifting-related low back pain among workers” (162). Both tools considered biomechanical, physiologic, and psychophysical limits in their development.

The first tool was a guide based upon biomechanical, physiologic, and psychophysical information (68). This method assessed job characteristics and assessed the magnitude of the load that must be lifted for spine compression to reach 3400 N (the action limit, or AL) or 6400 N (the maximum permissible limit, or MPL). The AL was defined as the tissue tolerance where damage begins to occur in the spine. In theory, to be protective, work tasks should be designed so that the load lifted by the worker was below the calculated AL limit. The AL was determined through a functional equation that considered four discounting factors multiplied by a constant. The constant (90 lbs or 40 kg) was assumed to be the magnitude of the weight lifted under ideal lifting conditions that would result in a spine compression of 3400 N. The four discounting factors consist of: (a) horizontal distance of the load from the spine, (b) the vertical height of the load off the floor, (c) the vertical travel distance of the load, and (d) the frequency of lifting. These discounting factors were governed by functional relationships that reduced the magnitude of the allowable load (constant). An MPL was determined by multiplying the AL by 3. It was assumed that if the load lifted by the worker exceeded the MPL, more than 50% of the workers were at risk and engineering controls were needed. If the load lifted by the worker was between the AL and the MPL then the task placed less than 50% of the workforce at risk and either engineering or administrative controls were required. The guide was designed to be used for primarily sagittally symmetric lifts that were slow and smooth. Only one evaluation of the guide’s effectiveness could be found in the literature (73). Comparing the predictions with historical data of back injury reporting in industry, this evaluation indicated an odds ratio (OR) of 3.5 with good specificity but low sensitivity.

A revision of this method was published in 1993 and has become known as the “revised NIOSH lifting equation” (162). The revision was intended to consider asymmetric lifting situations as well as tasks with various types of coupling (handles). The revised equation was similar in form to the 1981 guide in that it included a load

constant that was mediated by several work characteristic “multipliers.” However, several components of the equation were different. First, the value calculated was a recommended weight limit (RWL). If the load lifted by the worker was below this value the load was considered safe. Second, the load constant was reduced to 23 kg or 51 lbs (from the 40 kg or 90 lbs in the 1981 guide). Third, the form of the multipliers was changed and the functional relationship between discounting and the workplace measure was slightly more liberal for the four factors originally contained in the 1981 guide (horizontal distance, vertical distance, vertical travel distance, and frequency). This was done to compensate for a lower load constant. Fourth, two new multipliers (task asymmetry and coupling) were added to the equation. Once the RWL is calculated for a given work situation, it is compared (as a denominator) to the load lifted by the worker to form a lifting index (LI). If the LI is less than the value 1, the job is considered safe. If the LI is greater than 1, then risk is present. LI values above 3 are thought to place nearly all workers at increased risk (104).

Two assessments of the revised equation to injury reporting have been performed. One assessment compared the ability of the tool to identify high- and low-risk jobs based upon a historical database (73). This assessment yielded an OR of 3.1. Further analyses indicated higher sensitivity than the 1981 guide but lower specificity. A second analysis using a different data set assessed ORs as a function of the LI. For LIs between 1 and 3 the ORs ranged from 1.54 to 2.45, indicating an increasing OR with increasing low back pain reporting. However, the OR for LIs over 3 was lower (OR of 1.63) indicating a nonmonotonic relationship between the LI and risk.

### Video-Based Biomechanical Models

Norman et al. (10) used a quasi-dynamic two-dimensional biomechanical model to assess cumulative biomechanical loading of the spine in 234 automotive assembly workers. This study identified four independent factors for LBD reporting consisting of integrated load movement (over a work shift), hand forces, peak shear force on the spine, and peak trunk velocity. They concluded that workers in the top 25% of loading exposure on all risk factors were at about six times the risk of reporting back pain than those in the bottom 25% of loading.

### Lumbar Motion Monitor Risk Assessment

In an attempt to consider the contribution of trunk dynamics as well as the traditional biomechanical factors in workplace assessment of risk, Marras et al. (55,56) biomechanically evaluated over 400 industrial jobs (with documented LBD risk history) by observing 114 workplace and worker-related variables. Of the variables ex-

plored, exposure to load movement (load magnitude × distance of load from spine) was found to be the single most powerful predictor of LBD reporting. This study also identified 16 trunk kinematic variables that resulted in statistically significant ORs associated with risk of LBD reporting in the workplace. None of the single kinematic variables were as strong a predictor as load moment, however, when load moment was combined with three kinematic variables (relating to the three dimensions of trunk motion) along with an exposure frequency measure, a strong multiple logistic regression model resulted that described reporting of back disorder well (OR of 10.7). The analysis indicated that risk was multivariate in nature and that exposure to the combination of the five variables described reporting well. This information was incorporated into a functional risk model (Fig. 17-6) that accounted for trade-offs between risk variables. For example, a job task that exposes a worker to low magnitude of load moment can represent a high-risk situation if the other four variables in the model were of sufficient magnitude. The model has been validated in a prospective workplace intervention study (72). The risk model has been linked with a lumbar motion monitor (LMM) (Fig. 17-7) in a computer program to document trunk motion exposure on the job.

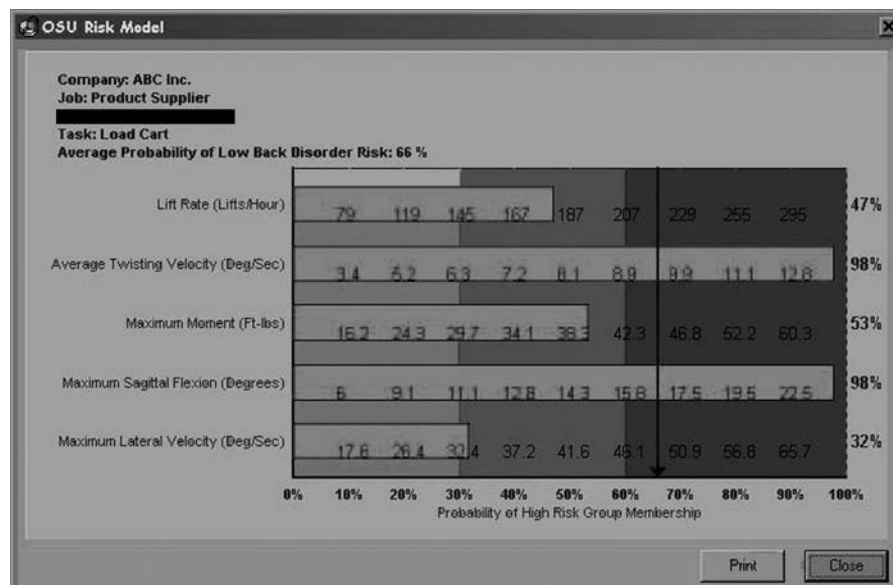

When the findings from these studies are considered in conjunction with previous epidemiologic studies in the workplace (54), it is clear that work associated with activity performed in nonneutral postures increases the risk to the back. Collectively these studies indicate that as trunk posture becomes more extreme or the trunk motion becomes more rapid, reporting of back disorder is greater.

These results suggest that occupational risk of LBD is associated with mechanical loading of the spine and suggest that when tasks involve greater three-dimensional loading, the association with risk becomes much stronger.

A database of 126 jobs including LMM information was evaluated by Fathallah et al. (70) to precisely quantify and assess the complex trunk motions of groups with varying degrees of LBD reporting. They determined that groups with greater reporting rates exhibited complex trunk motion patterns involving high magnitudes of combined trunk velocities, especially at extreme sagittal flexion, whereas the low-risk groups did not exhibit these patterns. This study suggested that elevated levels of complex simultaneous velocity patterns along with key workplace factors (load moment and frequency) were unique to those with increased LBD risk.

### Workplace Assessment Summary

The findings of recent quantitative studies used to assess workplace LBD risk using available workplace assessment tools are summarized in Table 17-6. The studies are consistent in that even though these studies have not evaluated spinal loading directly, the exposure measures included were indirect indicators of spinal load and suggest that as these risk factors increase in magnitude the risk increases. Load location or strength ratings both appear to be indicators of the magnitude of the load imposed upon the spine. The exposure metrics (load location, kinematics, and three-dimensional analyses) are important from a biomechanical standpoint because they

**FIG. 17-6.** Lumbar motion monitor risk model. The probability risk of high risk (of low back pain) group membership is quantitatively indicated for a particular task for each of five risk factors indicating how much exposure is too much exposure for a particular risk factor. The vertical arrow indicates the overall probability of high-risk group membership due to the combination of risk factors.

**FIG. 17-7.** The lumbar motion monitor used to track trunk kinematics during occupational activities.

mediate the ability of the trunk’s internal structures to support the external load. As these metrics change they can change the nature of the loading on the back’s internal structures.

Collectively, these studies demonstrate that when meaningful biomechanical assessments are performed

at the workplace, associations between biomechanical factors and risk of LBD reporting are evident. Several common components of biomechanical risk assessment can be derived from these studies. First, increased LBD reporting is associated with work primarily when the specific load location relative to the body (load moment or load location) is quantified in some way. Most studies have shown that these factors are closely associated with increased low back pain reports. Second, many studies have shown that increased reporting of low back pain can be well characterized when the three-dimensional kinematic demands of the work are described. Finally, nearly all of these assessments have demonstrated that risk is multidimensional in that there is a synergy among risk factors that is often associated with increased reporting of low back pain. Several studies have also suggested that some of these relationships are nonmonotonic. In summary, these efforts have suggested that the better the lift characteristics can be characterized in terms of biomechanical demand the better the association with risk.

**THE PROCESS OF IMPLEMENTING ERGONOMIC CHANGE**

Recent findings have shown that there are substantial links between biomechanical loading of the spine and psychosocial factors (108,109). Hence, ergonomic changes to the work environment must consider biomechanical loading as well as the psychosocial environment. A review of ergonomic interventions (163) has shown that such interventions can reduce workers’

**TABLE 17-6.** Summary of recent field evaluations of low back disorder risk factors and strength of association with risk (odds ratio). The more precisely the lifting requirements (e.g., load location, moment, etc.) are specified the better the association with risk

CI, confidence interval; OR, odds ratio.

compensation costs if they are implemented correctly. However, experience has also shown that unless workers are accepting of workplace redesign, the interventions will not be effective.

A proven method to maximize the effectiveness of workplace interventions is through the implementation of an ergonomics process. These processes are designed to address occupational health issues in a timely manner and create an environment that fosters worker acceptance of engineering interventions. Ergonomics processes grew out of efforts to control musculoskeletal disorders in meat packing facilities (164). The logic behind this approach is to develop a system or process to identify and correct musculoskeletal problems associated with work. It is considered a process instead of a program since it is intended to become an ongoing surveillance and correction component of the business operation instead of a one-time effort.

The process is intended to encourage management and labor to communicate and work as a team to accomplish a common goal of worker health. In order to address the psychosocial issues in the workplace, a key component of an ergonomics process is worker empowerment. Workers are encouraged to take an active role in the process and take control and ownership of work design suggestions and changes. Thus, the process encourages a participatory approach. Benefits of such an approach include increased worker motivation, job satisfaction, and greater acceptance of change. The goal is to create an environment where the success of the operation is the objective as opposed to the interests of any given individual.

There are several functions of a successful ergonomics process. These functions include: management leadership and commitment, employee participation, job analysis leading to injury prevention and control, training, medical management, program evaluation, and documentation. A successful process begins with the creation of an ergonomics committee. The committee composition should be balanced between management and labor to encourage a balanced effort to work toward the common goal. Committee members should include those involved with the design of work layout as well as those empowered to dictate scheduling. In addition, labor representatives to the committee should include those employees who have broad experience with many of the jobs in the facility as well as those employees who can communicate well with the majority of the other workers. This committee then becomes the center of all ergonomic-related activities within the facility.

The ergonomics process is actually a system where the different components of the system interact to produce the desired effect. The interactions within this system are shown in Fig. 17-8. This figure indicates that the ergonomics committee is at the heart of the interactions with all the components of the process. The process begins with management involvement. Ergonomics processes must be driven from the top down. Thus, management

FIG. 17-8. The interaction of elements within an ergonomics process.

must initiate the process and visibly demonstrate commitment to the process. In addition, management must provide resources to the committee. These resources should include financial resources so that physical interventions can be implemented as well as access to information such as injury records, production schedules, and so forth.

As indicated in Figure 17-8, the fundamental responsibilities of the ergonomics committee are threefold. First, the committee must monitor the workplace to determine where clusters of work-related musculoskeletal injuries are located. Techniques for surveillance include injury reports as well as surveying workers for symptom recording. In order that ergonomic efforts become preventive rather than reactive it is important to solicit the cooperation of all workers in this effort. Medical personnel can help facilitate this effort by helping the committee interpret the trends in an objective fashion. The second responsibility of the committee is the prevention and control of occupationally related musculoskeletal disorders. For the purposes of LBD, the techniques discussed earlier can be employed to help isolate the nature of any potential problems associated with the design of work. The issue of interest here is often “how much exposure to risk factors is too much exposure?” Thus, quantitative methods can be used to help determine which changes are needed and their likely impact. As indicated in the figure, ergonomic experts can be useful in assisting the committee in performing these assessments. The third responsibility of the committee is the training and education of the workers. Several levels of training are typically necessary. All workers should receive short duration awareness training to inform them that an ergonomics process is in place, familiarize them with risk factors, and explain to them how to interact with the process. In addition, workers should receive training as to the types of symptoms that need to be reported to the committee for prevention to be successful. Higher level training should also

be provided to engineers and supervisors. In general, training should be of sufficient detail so that management understands the functioning of the process and so that they do not become an impediment to the process success. Both medical professionals and ergonomic specialists can facilitate these activities.

Medical management and the ergonomic experts serve as resources to the committee for the process responsibilities. The goal of a process is not to make the ergonomics committee into ergonomics experts, but to encourage them to actively involve experts to accomplish the goals of the process. These experts can be valuable in terms of advising the committee as to how and when to perform surveillance activities as well as suggesting appropriate interventions for a given situation.

It is imperative that the program be evaluated regularly to justify its continuation. Issues such as the achievement of program goals, reductions of musculoskeletal disorders, hazard reduction, and employee feedback should be considered. Corrective actions should be taken in response to the evaluation. Finally, documentation is an important part of a successful program. Records should be kept that document the changes made to the workplace and that can serve as justification of expenditures. These records can also be used to transfer knowledge to new team members.

Ergonomics processes can have a significant impact on musculoskeletal risk, but only if the process is performed correctly and maintained. Keys to process maintenance include strong direction, realistic goals, establishment of a system to address employee concerns, early intervention success, and publicity for the intervention.

## CONCLUSIONS

This review has shown that LBDs are common in the workplace and associated with occupational tasks when the risk factors of manual materials handling, bending and twisting, and whole-body vibration are present. The load-tolerance relationship represents a sound biomechanically plausible avenue to support the epidemiologic findings. Sophisticated biologically assisted biomechanical models have been developed that have been used to quantitatively assess many situations (in the laboratory) that are common to workplaces. There are also a host of quantitative workplace assessment tools available to assess risk directly at the work site. These tools appear to be most sensitive if they are multifactorial in nature and assess the load movement exposure and torso kinematic responses to work situations in three-dimensional space. The more precisely these job requirements are documented the better the association with risk. Finally, the implementation of ergonomic change in the workplace must consider psychosocial issues in the workplace in order to foster worker acceptance of change. The imple-

mentation of an ergonomics process can be useful for these purposes.

# Surgery

## CHAPTER 18

# Preparation for Surgery

Orso L. Osti, Simon Macklin, and Hiroaki Nakamura

---

### PREOPERATIVE ASSESSMENT

Significant changes have occurred over the last 30 years in the way patients are counseled before surgery. It is paramount that plainly written information on the relevant surgical procedure, containing appropriate illustrations, be available to patients before surgery. Audiovisual equipment can be used; however, in view of the emotional implications of surgical intervention for pain, a face-to-face preoperative discussion between the surgeon and patient is advised. The surgeon needs to ensure that all appropriate imaging is available at the time of the surgery and that a recent body pain drawing is available to confirm the site and pattern of distribution of preoperative symptoms. Obtaining informed written consent, which should include financial details of the surgery, is mandatory before the operation. The consent form should be signed by the surgeon and patient at the same time and, preferably, within days of the operation. Consent should be obtained immediately before scheduling the patient for surgery and one should reappraise the consent form with the patient on the day of the operation.

### PREANESTHETIC ASSESSMENT

A detailed preanesthetic assessment is an essential prerequisite to safe anesthetic practice. It offers the anesthetist the opportunity to identify the presence of comorbid medical conditions, arrange for optimization of those conditions if required, identify other confounding factors (e.g., difficult venous access or airway), discuss options for preoperative medication and postoperative analgesia, and obtain informed consent for the anesthetic. It is important to discuss the possible requirement for blood transfusion at this point and explore potential strategies for blood conservation. This may be particularly relevant in those with a religious objection to the use of homologous blood products.

A number of specific questions should be considered: Is there a previous anesthetic history? If so, were there any complications? Are there cardiac, respiratory, or endocrine comorbidities? Is airway management expected to be difficult?

Most institutions have guidelines for appropriate preoperative investigations based on the patient's age and comorbidities. Table 18-1 shows the guidelines currently in use at the Royal Adelaide Hospital.

### PREOPERATIVE MEDICATIONS

With few exceptions, therapeutic drugs taken for concurrent diseases should be continued up to the time of surgery (1). The notable exceptions to this rule are: aspirin and other nonselective nonsteroidal antiinflammatory drugs (NSAIDs), hypoglycemic agents, and monoamine oxidase inhibitors. Aspirin and nonselective NSAIDs (which act on both cyclooxygenase 1 and 2 enzymes) should be discontinued for 7 to 10 days before surgery to allow recovery of platelet aggregation. The newer cyclooxygenase 2 inhibitors (e.g., rofecoxib and celecoxib) are free from platelet aggregation inhibition and can be continued up to the time of surgery without a risk of increased bleeding because of platelet dysfunction.

A range of new specific platelet aggregation inhibitors, clopidogrel (Iscover [Bristol-Myers Squibb Pharmaceuticals, Australia] and Plavix [Sanofi-Synthelabs, Australia]) or ticlopidine (Ticlid [Roche Products, Australia]), recently have been introduced for use in patients with acute coronary syndrome or for use in thromboembolic prophylaxis. These should be stopped at least 5 days prior to surgery to prevent excess bleeding owing to platelet dysfunction.

Monoamine oxidase inhibitors are associated with a high incidence of CNS side effects if piperidine-based opioids are used for analgesia. These side effects may be

**TABLE 18-1.** *The current guidelines for preoperative investigations in use at the Royal Adelaide Hospital*

Investigations	Clinical Indications	Investigations	Clinical Indications
Electrocardiogram (ECG) <sup>a</sup>	Men aged 45 years and over Women aged 50 years and over Hypertension Current or past significant cardiac disease Current or past significant circulatory disease Current or past significant pulmonary disease Diabetes mellitus; person aged 35 years and over Renal disease Thyroid or other metabolic disease Morbid obesity Sleep apnea History of alcoholism Cardiac drug therapy Radiation or chemotherapy Other clinical indications	CBE, <i>continued</i>	History of alcoholism Severe chronic disease History of current infection Other clinical indications (e.g., platelet count for regional anesthesia)
Chest x-ray (CXR) <sup>b</sup>	Current or past significant pulmonary disease Asthma or COAD that is debilitating or with a change of symptoms Ongoing pulmonary infection (productive cough with colored sputum or a change in nature of sputum) Cardiovascular disease Current or past significant disease, <i>or</i> A change in symptoms Cardiothoracic procedure since last CXR Cardiac pacemaker or implanted defibrillator Thyroidectomy for information on trachea Malignancy Sleep apnea Radiation or chemotherapy Other clinical indications	Biochemistry (Urea and electrolytes) <sup>e</sup>	Aged 65 years or over and when clinically indicated Renal disease Diabetes mellitus Cardiovascular disease Hypertension Adrenal and other endocrine disease Liver disease Cardiac drugs Diuretics Steroids Chemotherapy

<sup>a</sup>An ECG is valid for 6 months unless there has been a change in symptoms or clinically indicated.<sup>b</sup>If a CXR is clinically indicated, obtain a CXR if none was obtained in the last year or if symptoms have changed since the last CXR.<sup>c</sup>A hemoglobin level +/- platelet count may suffice in the majority of cases.<sup>d</sup>A CBE is valid 6 months unless clinically indicated.<sup>e</sup>Valid for 6 months if last set of results is normal unless clinically indicated.<sup>f</sup>Valid for 6 months unless clinically indicated.<sup>g</sup>Specify tests required (i.e., spirometry, blood gases, or carbon monoxide diffusion factor)<sup>h</sup>Valid for 1 year unless clinically indicated.<sup>i</sup>Valid for 1 year unless symptoms have changed or clinically indicated.

either excitatory or depressive and are most commonly seen when meperidine (pethidine) is coadministered (2). Other opioids with a piperidine base (e.g., fentanyl) have been used without complications. The assumption is that alfentanil and sufentanil are probably safe (3,4). No literature addresses the safety of remifentanyl.

The current recommendations are that the newer reversible monoamine oxidase inhibitors (MAOIs) should be discontinued 24 hours before anesthesia. The older irreversible MAOIs should be continued because of the high risk of uncontrolled depression in the weeks leading up to surgery. Under these circumstances, all opioids may display an exaggerated depressant effect and smaller doses should be used in the first instance. Meperidine (pethidine) should be avoided.

Most institutions, and all anesthetists, should have a management plan for the diabetic patient. Ideally the diabetic should appear as early as possible on the theater list (operating schedule). Management should be directed to avoid dangerous hypoglycemia and excessive hyperglycemia. An intravenous dextrose infusion, combined with a sliding scale of actrapid insulin, is often used to facilitate perioperative glycemic control.

The use of specific analgesic or anxiolytic medication in the immediate preoperative period is a matter of personal choice and can be tailored to the individual patient's requirements.

## CONSENT FOR ANESTHESIA

In the current climate with the drive for increased day of surgery admissions, a strong argument can be made for the anesthetic assessment and consent to be performed before admission to the hospital for surgery. This allows time for appropriate investigations to be organized and the results to be reviewed before admission to the hospital. This is particularly pertinent for those with cardiorespiratory disease, in whom modification of therapy may be required for optimization of the medical condition before anesthesia. It also enables the risks and complications to be explained to the patient in a nonthreatening environment.

## POSITIONING

Enough emphasis cannot be placed on the care that must be taken in positioning the patient under anesthesia to minimize the risk of pressure injury. Surgery on the lumbar spine may be undertaken in the lateral or prone position. For combined anterior and posterior stabilization, the patient needs to be rotated part way through the procedure.

The patient in the prone position is at particular risk. Appropriate padding and supports should be used to prevent pressure injury to soft-tissue structures (e.g., breast

and penis) and bony prominences (e.g., iliac crest, knees, and elbows). Special attention should be given to protecting the orbital structures from trauma. The eyes should be taped closed to prevent corneal abrasions and the head should be supported to prevent pressure on the supraorbital nerves. There is little evidence to suggest that use of ophthalmic lubrication confers any benefit. Pressure on the globe must be avoided at all costs because of the danger of retinal vein occlusion or retinal ischemia. The latter is of particular concern if hypotensive anesthesia is employed. Both of these complications may lead to blindness.

Before positioning in the prone position, it is worth identifying limitations in cervical spine movement and assessing the range of shoulder movement. The arms may be positioned with the arms flexed at the elbow, externally rotated and abducted at the shoulder and placed on a support. This has the advantage of allowing easy access to peripheral veins, arterial monitoring, pulse oximetry, and neuromuscular monitoring. However, the ulnar nerve and brachial plexus must be protected to avoid pressure or overextension leading to neuropraxia. An alternative is to place the arms alongside the torso if there are physical limitations that prevent the former position. Access to monitoring devices is limited in this position.

Regardless of the position, the ulnar nerve is at high risk of damage, which may occur in spite of one's best efforts to protect it. The mechanisms behind the damage are not altogether clear, and preventative measures cannot be implemented without definitive causation. Nevertheless, it is imperative to avoid pressure or excessive stretching of the ulnar nerve at the elbow (5).

A number of devices are commercially available for surgery in the prone position. These range from the simple (e.g., firm blocks to be placed under the hips and chest) to the sophisticated (e.g., the Andrew's table). These devices are designed to avoid pressure on the abdomen and thereby avoid splinting of the diaphragm and minimal epidural bleeding from abdominal compression. As intra-abdominal pressure increases, the vertebral venous pressure raises in parallel with raising pressure of the inferior vena cava (IVC) (6–8). Appropriately designed surgical frames have been proved to reduce the pressure within the IVC compared with more conventional chest rests (9). Reduction of intra-abdominal and IVC pressure lower blood loss (10). The spinal frame used in our institution is shown in Figure 18-1. The iliac crest padded supports are modifiable to accommodate different patient sizes. The frame is radiolucent to allow biplanar fluoroscopy.

Approximately 20% of patients operated in the prone position using iliac crest support frames complain postoperatively of symptoms linked to neurapraxia of the lateral cutaneous nerve of the thigh. This is more common in obese individuals and where the surgery is prolonged

**FIG. 18-1.** Spinal frame. The iliac crest padded supports are modifiable to accommodate for different patients' sizes. The frame is radiolucent to allow biplanar fluoroscopy.

(over 2 hours). In most cases, the neurapraxia fully resolves within 6 weeks.

### KNEE-CHEST POSITION

One of the potential advantages of the knee-chest position over iliac crest support frames for lumbar spine surgery is the greater opening of the interlaminar space compared to the iliac crest support frame. However, it is possible that the dural sac and individual nerve roots may be under increased tension in this position; therefore, safe retraction of the neural tissue may be more difficult to achieve. Potential circulatory disturbance in the legs should be carefully monitored in view of the significant bend at the knees. It is common for older individuals to complain after the surgery of increased knee pain, especially if patello-femoral osteoarthritis is present preoperatively.

Intraoperative preservation of the physiologic lumbar lordosis may become critical when stabilization procedures are performed. A decrease in the lordosis angle has been correlated with increased symptoms and gait abnormality following lumbar fusion (11–13). The hip flexion angle relates to lumbar lordosis (14–16), and it appears that iliac crest support-type frames may lead to better maintenance of physiologic lumbar lordosis compared with knee-chest devices because they involve less flexion of the hip joint.

### LATERAL DECUBITUS

This position may be used when the upper lumbar spine is approached retroperitoneally. In most cases, the approach is carried out through the left side with the patient lying onto his or her right side. The right (bottom) knee is flexed to approximately 90° with the left (upper) knee extended. An axial pad is placed just underneath the waistline, and the pelvis and head of the fibula are protected with adequate padding. The patient's right upper extremity is placed on the operating table with the left

side in a padded gutter arm support. An axillary roll may be used to take pressure off the brachial plexus to avoid disabling postoperative neurapraxia.

### BLOOD CONSERVATION

The requirement for blood transfusion depends on a multitude of factors, not the least of which is an agreement on the threshold hemoglobin before transfusion. Most departments of transfusion medicine have guidelines for transfusion that have reduced the threshold level from a previously accepted level of 100 g/L (10 g/dL). In the absence of confounding comorbid disease, there is little indication for transfusion unless the hemoglobin concentration has fallen below 80 g/L (8 g/dL) in the absence of ongoing blood loss.

A number of strategies have been proposed to reduce the incidence of homologous transfusion. These include autologous predonation, isovolemic hemodilution and perioperative cell salvage. Autologous predonation can be logistically difficult and costly to institute; it may result in a relaxation of the transfusion trigger and result in inappropriate transfusion; it does not remove the risk of clerical error; and it does not remove the risk of transmission of bacterial infection. If the blood is harvested but not reinfused, it is not suitable to be used in the general blood pool and therefore becomes an expensive and useless commodity.

Isovolemic hemodilution refers to the practice of harvesting a quantity of blood at the beginning of a procedure and replacing it with a crystalloid or colloid solution to prevent a fall in circulating volume. This has the effect of immediately reducing the hemoglobin concentration and therefore reducing the amount of hemoglobin lost per volume of shed blood. Providing the blood has been harvested correctly, it will contain fresh platelets and coagulation factors not usually present in stored blood. In addition, the harvested blood can be processed to extract a platelet concentration rich in growth factors, which may be of benefit to osteogenesis at the surgical site. The har-

vested blood can then be reinfused during the later stages of the operation.

Perioperative cell salvage has been extensively used as a blood conservation technique. Despite the equipment becoming increasingly sophisticated, its application is still limited to those procedures where blood loss is anticipated to be excessive, such as more extensive and lengthy spinal procedures.

## BLOOD LOSS AND THE SURGICAL FIELD

It is important to realize that the second arm of blood conservation techniques are directed at reducing blood loss to optimize the surgical field. A number of basic strategies should be employed; these are summarized in Table 18-2. Remember that bleeding can be venous or arterial.

Venous bleeding occurs predominantly from the epidural veins, which are in communication with the IVC. Therefore, strategies to reduce IVC pressure reduce epidural venous pressure. Positive pressure ventilation tends to reduce venous return and increase IVC pressure. Consequently, efforts to limit the positive inspiratory pressure while maintaining appropriate gas exchange should be made. This can be achieved by maintaining an adequate level of neuromuscular blockade, together with adjustments of inspiratory time, pressure, and flow rate. Appropriate use of bronchodilating drugs may help in the bronchospastic patient. Positive end expiratory pressure (PEEP) should be avoided (17). Careful positioning on a suitable support system avoids abdominal compression. This has been shown to reduce IVC pressure with reduction in epidural venous pressure. This position also avoids diaphragmatic splinting from abdominal compression, which would otherwise cause a rise in ventilatory inflation pressure and increase IVC pressure (18).

Avoiding vasodilatation and reducing the perfusion pressure can reduce arterial bleeding. Vasodilatation can be minimized by controlled hyperventilation to produce hypocapnia. The perfusion pressure can be reduced by a number of pharmacologic interventions that come under the broad heading of hypotensive anesthesia. A wide range of drugs has been used to induce hypotension under anesthesia; a full discussion on the relative merits can be found elsewhere (19). However, hypotensive anesthesia is

not without its complications and consideration must be given to the risk-benefit assessment for each individual patient. The risks of hypotensive anesthesia are hypoperfusion of vital organs, principally those organs whose function is not conventionally monitored. The CNS is of prime concern. Cerebral hypoperfusion may lead to a range of postoperative complications from short-term confusion and disorientation to massive cerebral infarction. Although cerebral autoregulation maintains cerebral blood flow through a range of blood pressure variations, blood flow is pressure dependent beyond the extremes of these variations. Volatile anesthetic agents may offer some cerebral protection by reducing cerebral metabolic oxygen consumption. A more scientific method of determining adequacy of cerebral blood flow is to monitor jugular bulb oxygenation or cerebral blood flow by means of transcranial Doppler. These techniques are becoming recognized as having a role to play in carotid vascular surgery and neurosurgery, but their role in hypotensive anesthesia outside of these domains has yet to be determined. In addition, spinal cord ischemia may occur if blood flow through the anterior spinal artery is compromised. The effects of hypoperfusion of the CNS may be exacerbated by hyperventilation and consequent hypocarbia leading to vasoconstriction deliberately induced to reduce bleeding.

Modern volatile anesthetic agents are an attractive option to induce hypotension. Agents, such as isoflurane and sevoflurane, with relatively low blood-gas solubility coefficients cause depression of medullary cardiac centres while depressing myocardial contractility directly. This leads to a reduction in cardiac output and a fall in blood pressure. Because of their low solubility, changes in inspired volatile agent concentration lead to rapid changes in blood concentration. This offers a level of titratability that makes them useful agents for inducing hypotension without a prolonged recovery time.

A special mention should be made regarding perioperative  $\beta$ -blockade. In addition to its advantageous effects on slowing heart rate and reducing force of contractility and thereby reducing blood pressure, evidence is becoming available that the use of perioperative  $\beta$ -blockade may reduce the all-cause mortality in high risk surgical patients undergoing noncardiac surgery (20–22). Their potential benefit to patients who are not considered high risk is yet to be determined (23).

A conservative approach to hypotensive anesthesia for surgery on the lumbar spine would be to use  $\beta$ -adrenergic blockade with atenolol for a target heart rate of 60 to 70 beats per minute and a volatile anesthetic agent 0.5 to 1.5  $\mu\text{g}/\text{kg}$  clonidine to provide a modest fall in blood pressure but maintain a mean arterial pressure above 70 mm Hg. By using a drug such as clonidine with a long half-life (compared to agents such as sodium nitroprusside), the problems of rebound hypertension or rapid return to normotension are avoided.

**TABLE 18-2.** Strategies for minimizing blood loss

Prevent venous bleeding	Reduce arterial bleeding
Avoid abdominal compression	Control heart rate
Avoid diaphragmatic splinting	Hyperventilate to hypocapnia
Minimize peak inspiratory pressure	Induce hypotension
Avoid positive end expiratory pressure	

Finally, two additional concerns must be addressed. First, the negative impact of perioperative hypothermia on the incidence of wound infection has been investigated (24,25). Hypothermia leads to increased shivering in the immediate postoperative period, which increases the basal metabolic rate. This increases respiratory and myocardial work and can be relevant in patients with impaired cardiorespiratory function to the point of precipitating cardiorespiratory failure. In addition, hypothermia has an adverse effect on normal hemostatic function. Although major blood loss is uncommon in most surgery on the lumbar spine, the impact of moderate hypothermia, below 35°C, on platelet function and the coagulation cascade must be considered (26,27). If efforts to create a bloodless surgical field are to be successful, meticulous attention to detail is required. This should include the avoidance of hypothermia by the use of appropriate warming devices. The introduction of forced air warming devices, which direct warmed air through an inflatable blanket to provide body surface heating, has been a huge advance in this field (28). Most of the work on the effects of hypothermia and coagulation has been done on either trauma or cardiopulmonary bypass patients. Further work needs to be done on patients undergoing elective noncardiac surgery. Nevertheless, it seems prudent to minimize hypothermia for the reasons mentioned in the preceding.

Finally, what is the role of the serine protease inhibitor, aprotinin, and the lysine analogs, tranexamic acid and aminocaproic acid? Both of these groups of agents have been shown to be beneficial in cardiac surgery or knee arthroplasty (29–31). Tranexamic acid has been shown to be beneficial in pediatric scoliosis surgery (32). The emphasis has been on the reduction in blood transfusion. The role of these agents in reducing bleeding to improve the surgical field has yet to be determined.

## ANTIBIOTICS

Infection rates with spinal surgery vary widely among published series and according to the type of surgery performed. Wimmer et al. reported on 22 cases out of 850 clean spinal procedures with an overall infection rate of 2.6% (33). In that study, it was suggested that extended preoperative hospitalization, large intraoperative blood loss, and prolonged operating time were correlated with increased risk of postoperative infection. The authors also suggested that routine prophylactic antibiotics may not be necessary, although parenteral postoperative antibiotic should be administered when segmental instrumentation is used.

The overall risk of infection is higher in acute trauma than in elective surgery. Patients with significant preoperative neurologic deficit are also at higher risk. It has been shown that penetration of antibiotics into the disc is poor and that a critical relationship exists between serum

antibiotic concentration and disc antibiotic levels that may have a prophylactic effect on infection. It has been suggested that antibiotic concentration within the disc is highest between 15 and 80 minutes following intravenous administration (34).

Prophylactic administration of antibiotics should be considered mandatory for all procedures that may violate the intervertebral disc. In experimental studies where lumbar intervertebral discs were inoculated with staphylococcus epidermidis cultures, no discitis developed with prophylactic intravenous or intradiscal administration of cephalosporins, whereas large doses of antibiotics administered following the inoculation of bacteria into the disc did not prevent disc infection (35,36).

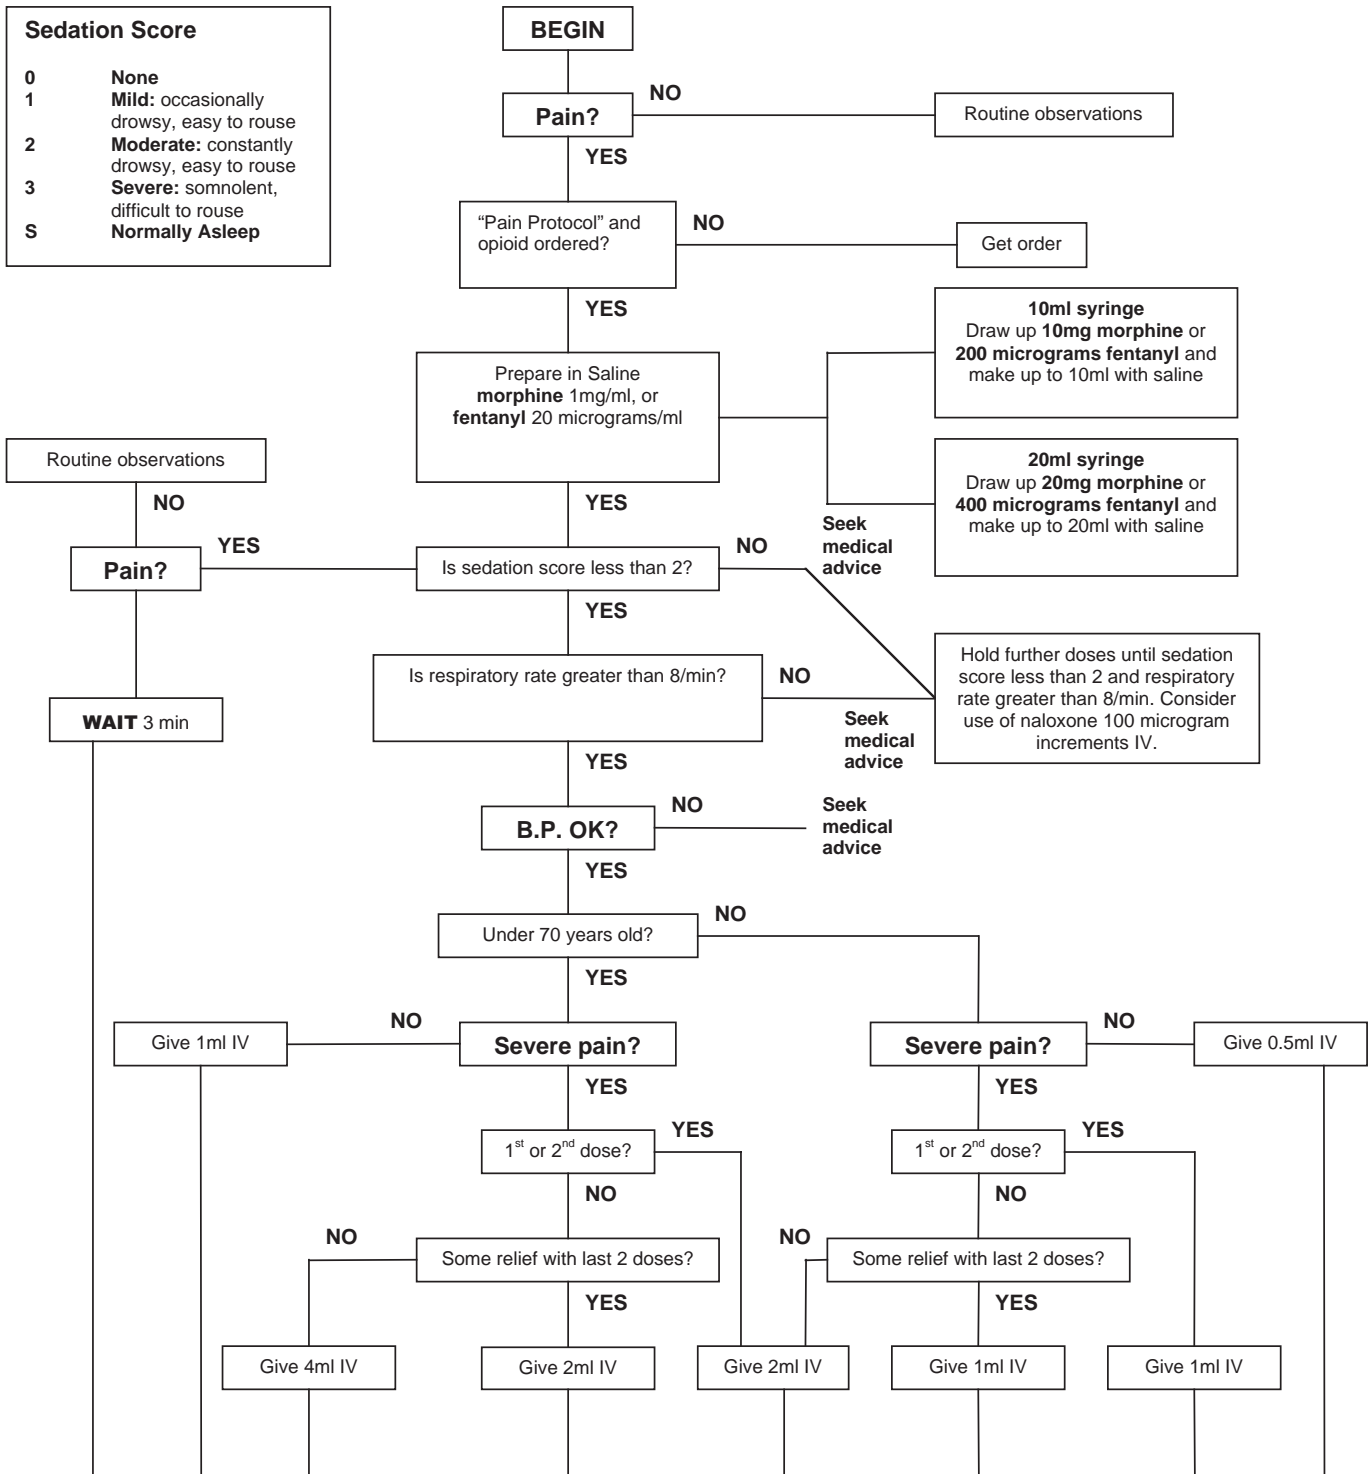

Different classes of antibiotics have been demonstrated to penetrate the intervertebral disc at different rates. Aminoglycosides and glycopeptides appear to penetrate into the nucleus pulposus well, whereas penicillins and cephalosporins have been proven to enter the disc at much lower concentrations. Prophylactic antibiotics are even more critical when percutaneous disc procedures are performed. The administration of antibiotics should be planned so that the highest intradiscal concentration may be achieved when the surgical insult to the disc is likely to occur. Maximal antibiotic concentration in the disc, as indicated, occurs 15 to 80 minutes following parenteral antibiotic administration; the likely average time for broad-spectrum antibiotics is 30 to 45 minutes.

## POSTOPERATIVE PAIN MANAGEMENT

The mainstay of acute pain management is opioid analgesia. Postoperative analgesia should be administered by a route that offers rapid onset and the ability to titrate the dose to achieve optimal effect. The intravenous route is the most suitable in the recovery unit, where the patient can be closely monitored for the adverse effects of opioids. Central nervous system depression is initially manifest and may then present with more serious effects, such as respiratory depression. A simple sedation score can be used as an early warning sign for the clinician before more significant CNS depression occurs. Figure 18-2 gives the protocol for intravenous opioid loading used at the Royal Adelaide Hospital. Once therapeutic plasma concentrations of opioid analgesics have been achieved, it is appropriate to convert to a patient controlled analgesia (PCA) system. Most institutions have a protocol for drug concentration, bolus dose, and lockout time to be used for PCA. A simple protocol for the fit patient under 65 years of age is the following:

- Morphine: 1 mg/mL
- Bolus dose: 1 mg
- Lockout time: 5 minutes

The bolus dose can be increased if analgesia is inadequate and decreased if excessive sedation occurs. It is

**FIG. 18-2.** Guidelines for intravenous opioid administration. These guidelines are/should: (1) Only to be used by staff in recovery wards who have been instructed in this technique; (2) NOT appropriate for routine maintenance of analgesia in general wards; (3) Note that the peak effect of an intravenous dose may not occur for over 15 minutes, therefore all patients should be observed closely during this time; (4) All patients receiving repeated doses of IV opioids should be ordered oxygen; and (5) "Pain Protocol" should cease when the patient is comfortable (they will not necessarily be pain free). From The Acute Pain Service, Royal Adelaide Hospital, with permission.

generally accepted that a background infusion ordinarily should not be prescribed because it appears not to improve the analgesia but may increase the incidence of side effects (38).

Morphine should be the first line agent of choice, but fentanyl can be used as an alternative. Meperidine (pethidine) should be avoided if feasible because of the possibility of CNS toxicity associated with its metabolite, normeperidine (norpethidine). Normeperidine plasma concentrations can be achieved with PCA pethidine and can lead to CNS excitability, and manifest as agitation and even convulsions (39,40).

It is worth considering the use of adjuvant analgesic agents that do not specifically target opioid receptors. Use of nonspecific cyclooxygenase inhibitors may increase intra and post-operative bleeding and should be avoided. However, the more recently released selective cox-2 inhibitors (celecoxib and parecoxib) may have a role to play and further investigation of these drugs is warranted. Similarly, centrally acting drugs that are  $\alpha$ -adrenergic agonists stimulate the descending spinal inhibitory pathways. These pathways originate in the periaqueductal gray matter and reticular formation, to run in the dorsolateral fasciculus. They synapse in the substantia gelatinosa of the dorsal horn where norepinephrine and serotonin are released. They are involved in the highly complex system of interneurons, which modify nociceptive input to the spinal cord. Clinical data do not support the use of clonidine by the epidural or intrathecal route with conflicting data on its analgesic efficacy. However, its sedative effects may be beneficial in patients with a high preoperative opioid intake. Similarly, tramadol may be beneficial by preventing reuptake of norepinephrine and serotonin at the spinal cord level. It has only weak intrinsic opioid activity and is thought to exert its effects at a supraspinal or spinal cord level.

Finally, if pain control in the immediate postoperative period is difficult, ketamine by intravenous infusion of 2 to 8 mg/hour (depending on age and comorbid disease) can be used. Ketamine is the only clinically available NMDA (N-methyl-D-aspartate) receptor antagonist and provides analgesia at the spinal cord level where NMDA is an excitatory neurotransmitter.

## CHAPTER 19

# Surgical Approaches to the Thoracolumbar Spine

Scott D. Daffner and Todd J. Albert

---

The thoracolumbar spine offers numerous challenges in treatment, particularly with regard to anterior surgical approaches. The unique biomechanics of this region, particularly the transition from thoracic kyphosis to lumbar lordosis, put it at increased risk for degeneration. In addition, a wide variety of traumatic and neoplastic conditions may also affect the thoracolumbar spine.

Two basic surgical approaches exist for surgery in this region—anterior and posterior. Posterior approaches are most frequently used for procedures involving the posterior elements, although modifications of the posterior exposure may allow access to the anterior portion of the spine. Anterior approaches are generally required for access to the vertebral body itself. In addition, combined anterior and posterior approaches are occasionally used, depending on the type of pathology, the extent of the injury, and the judgment of the physician.

### **BONY ANATOMY OF THE THORACOLUMBAR SPINE**

The thoracolumbar region represents the transition from one type of vertebral body to another. Thoracic vertebrae are generally smaller than those of the lumbar region. Their facet joints are oriented more frontally, the spinous process is longer and angled more distally, the pedicles are narrower and shorter, and the articulations with the ribs distinguish the thoracic vertebrae. The short transverse processes are angled posterolaterally, articulating with the ribs (1,2).

The lower thoracic vertebrae begin to resemble lumbar vertebrae. Their facet joints change from a frontal orientation to one that more closely resembles those of the lumbar vertebrae in which the superior articular facets are anterolateral to the inferior articular facets of the vertebra above and are directed dorsomedially. From L1 to

L5, the pedicles become larger in diameter and become more medially oriented (1,2).

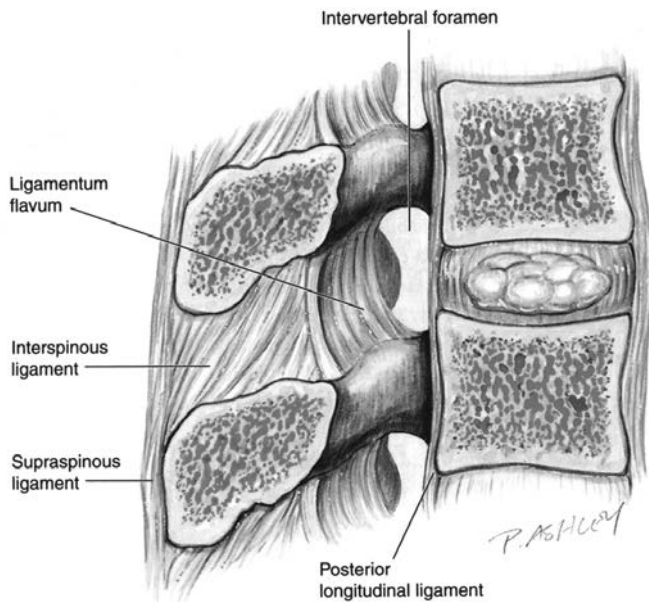

Several ligamentous structures stabilize the bony elements of the vertebrae (Fig. 19-1). The supraspinous and interspinous ligaments connect the spinous processes, while the intertransverse ligaments segmentally connect the transverse processes. The ligamentum flavum passes between the ventral side of the lamina to the superior lip of the next caudal lamina. The ligamentum flavum has a midline raphe, providing a convenient plane through which the canal may be entered. The broad anterior longitudinal ligament runs the length of the spinal column, intimately integrated with the periosteum of the anterior vertebral body, while the posterior longitudinal ligament lies along the posterior aspect of the vertebral body, adhering strongly to the intervertebral discs.

### **POSTERIOR APPROACH**

The most commonly used approach to the spine is the posterior approach (3). This approach differs little along the entire length of the spine, and is used for laminectomy and posterior, transpedicular, or posterolateral fusion.

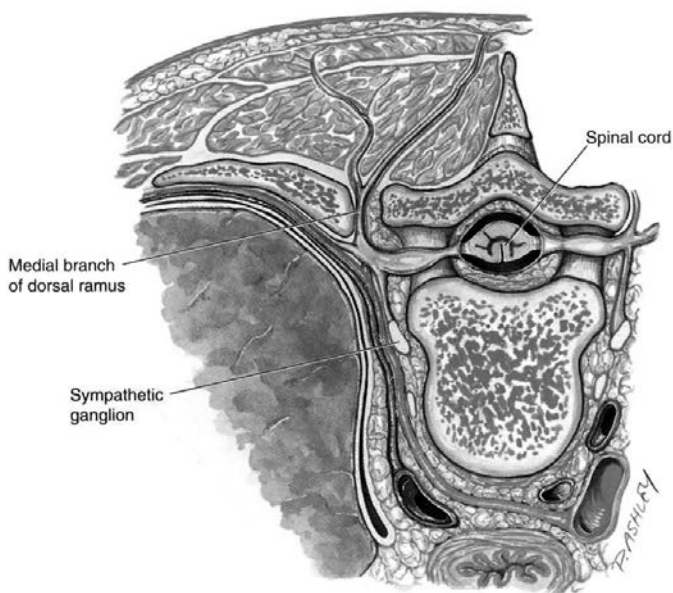

#### **Posterior Anatomy**

To fully appreciate this approach, one must understand the anatomy (Fig. 19-2). The muscular layers of the back can be divided into three distinct layers (Fig. 19-3). The *superficial layer* consists of the trapezius, which inserts on the T12 spinous process most caudally, and the latissimus dorsi which arises from the spinous processes and inserts onto the humerus. The *intermediate layer* is composed of the serratus posterior inferior, while the *deep layer* includes the erector spinae group (spinalis, longissimus, and iliocostalis) lying superficial and lateral to the

**FIG. 19-1.** Ligamentous stabilization of the vertebra and ribs. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

transversospinalis group (rotatores, multifidus, and semispinalis). These latter muscle groups are often detached as a single mass during this approach. The bony structures revealed during this approach include the spinous processes, laminae, and transverse processes. The facet joint capsules are also visualized from this approach.

**FIG. 19-2.** Axial view demonstrating posterior exposure of the thoracolumbar spine. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

### Surgical Technique

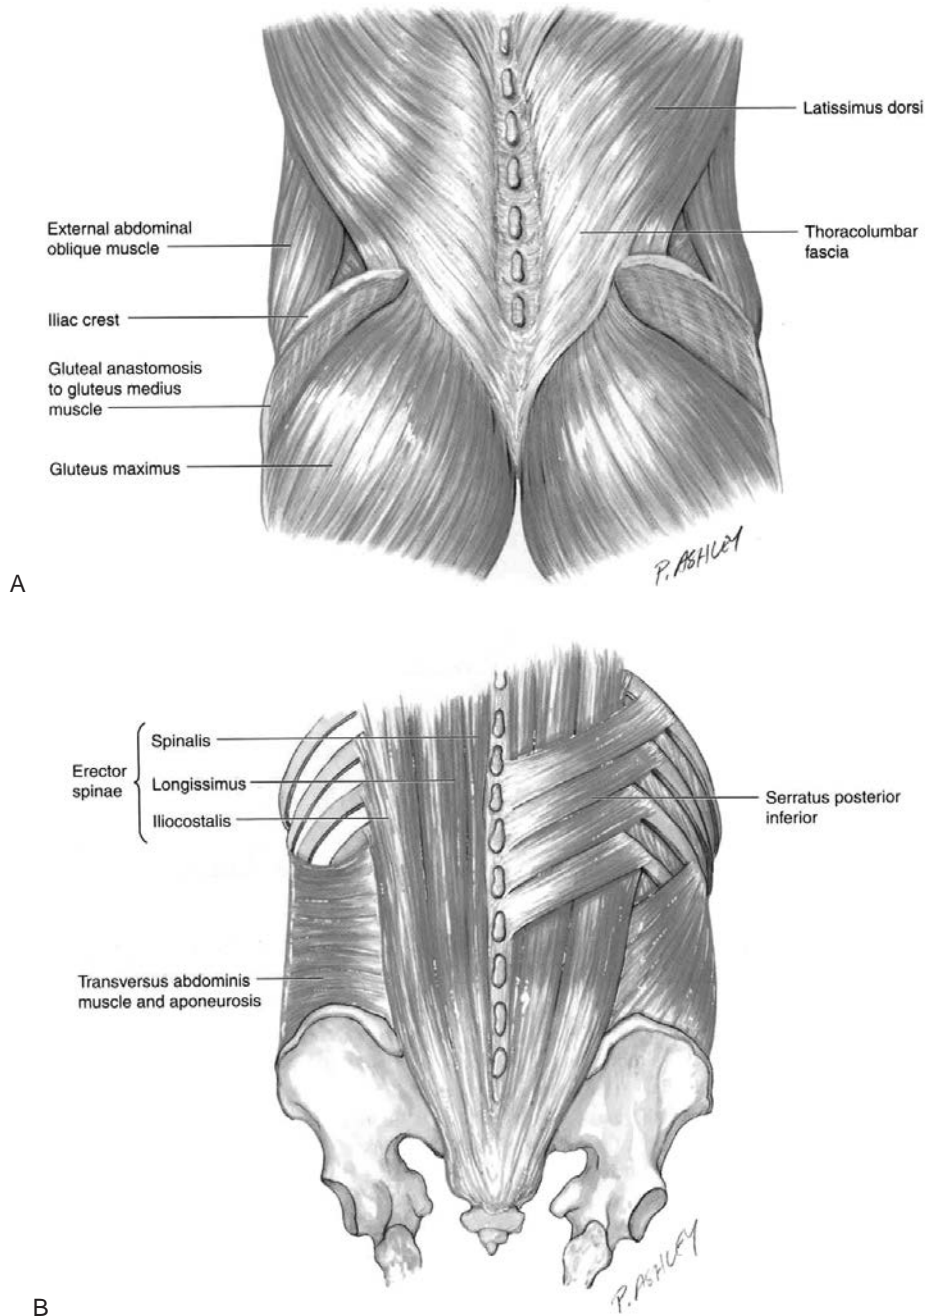

The patient is placed in either the prone or kneeling position with the abdomen hanging free to reduce pressure on the abdomen and thereby reduce epidural venous pressure and decrease intraoperative bleeding (Fig. 19-4). It is important to pad all bony prominences (2,3).

The skin incision is made in the midline over the spinous processes at the appropriate level. The incision is carried down through the subcutaneous tissue to the deep fascia. By dissecting the deep fascia subperiosteally from the spinous processes, one can preserve the attachments of fascia and can avoid bleeding from intramuscular blood vessels. The erector spinae muscles should be gently retracted with a Cobb elevator, helping to avoid straying into the musculature (Fig. 19-2). Subperiosteal dissection should be carried out in a caudal to cephalad direction. The dissection may be extended laterally to facilitate posterolateral fusion or pedicular instrumentation. Unless a facet fusion is planned, care should be taken to avoid subperiosteal dissection into the facet joint (2). Transverse processes may be palpated inferolateral to the facet joint by following the base of the superior articular process out laterally. After defining the superior and inferior borders of the transverse process, electrocautery may be used to continue the subperiosteal dissection of the segmental musculature, taking care to preserve the intertransverse ligament.

This approach may be extended to allow exposure of the posterior and anterior spinal elements. The extended posterior approach is primarily used for tumor resection and for osteotomies. The extensive nature of this approach may increase the risk for neurovascular damage, including spinal ischemia. The skin incision is extended three or four levels proximal and distal to the desired level of resection. The contents of the spinal canal may be visualized by performing a complete laminectomy. In the low thoracic region, ribs may be divided lateral to the costotransverse joints. If the pleura is entered, a chest tube may need to be inserted. Mobilizing the vascular structures may require ligation of the segmental vessels. The vertebral bodies may then be excised through the disc space above and below the pathology. Posterior stabilization should be performed before the anterior vertebral body resection to avoid neurologic compromise resulting from a completely destabilized spine (1).

Complications associated with the posterior approach may be minimized by careful planning and meticulous surgical technique. Identification of the appropriate level should be verified by taking an intraoperative radiograph. Neural elements, including nerve roots, must be clearly identified and protected. Excessive bleeding may be minimized by performing a subperiosteal dissection. Identification and cauterization of the segmental facet artery lateral to the pars will minimize bleeding as the dissec-

tion is carried out laterally. Epidural bleeding may be controlled by using Gelfoam or thrombin-soaked pledgets and bipolar cautery (2).

**ANTERIOR APPROACHES**

Two basic anterolateral approaches to the thoracolumbar spine may be used. These are the transpleural

retroperitoneal and the retropleural retroperitoneal approaches. While the transpleural approach provides excellent exposure of the anterior vertebral column over a number of segments, it involves extensive soft-tissue dissection and the rib head may impair visualization. In addition, bleeding from the epidural veins may be difficult to control. The retropleural approach is more lateral than the transpleural approach. Because the rib head and

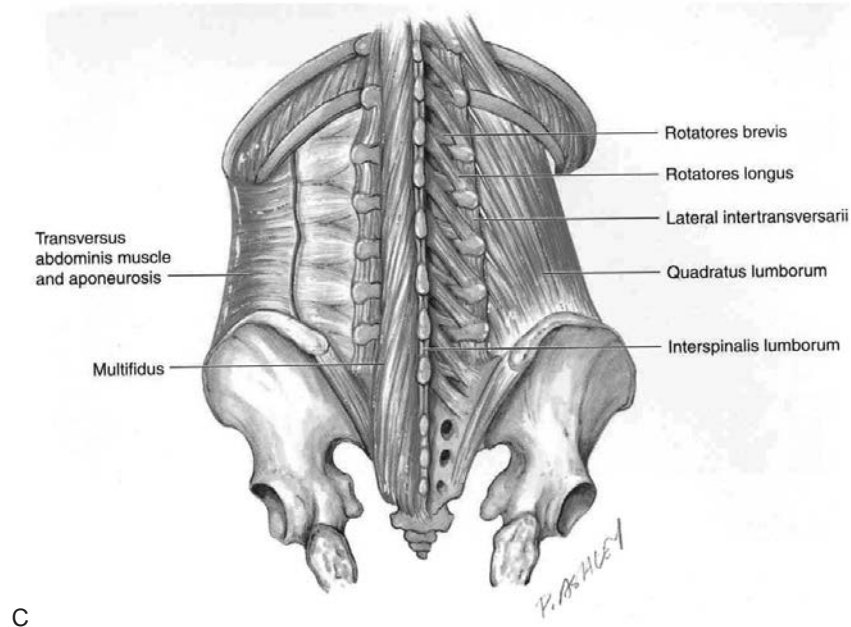

FIG. 19-3. (continued).

pedicle are resected, this approach offers better visualization of the anterolateral spinal canal during decompression, although it may be associated with a great deal of bleeding (1,4,5).

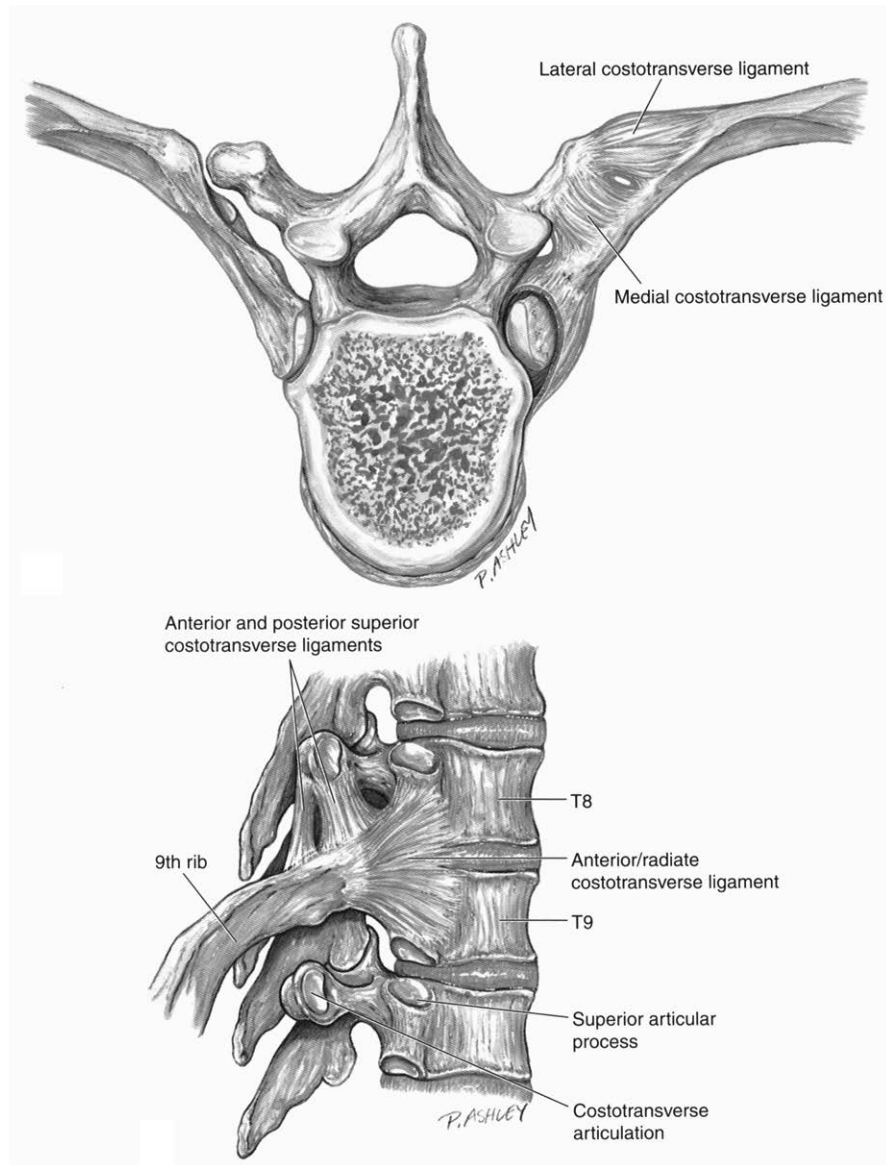

#### Anterior Anatomy

Anterior approaches to the thoracolumbar junction require a solid understanding of the associated anatomy of the chest and abdominal walls, the diaphragm, and the retroperitoneal contents. Within the chest wall, the ribs

articulate with the spine at the level of the disc space above (e.g., the 9th rib articulates at the level of the T8-9 disc space) and the transverse process of the same level. Caudally, the 11th and 12th ribs lack costovertebral articulations. The ribs are stabilized by a number of strong ligamentous attachments, particularly the costovertebral and costotransverse ligaments (Fig. 19-5). The superior costotransverse ligament runs from the inferior aspect of the transverse process to the superior aspect of the rib below. The medial (capsular) ligament attaches the posterior neck of the rib to the anterior border of the

FIG. 19-4. Patient positioning in the kneeling posture on an Andrews table. Note the rolls allowing for decompression of the abdominal contents, which decreases intraoperative blood loss. Alternatively, the patient may be placed on a posted frame. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

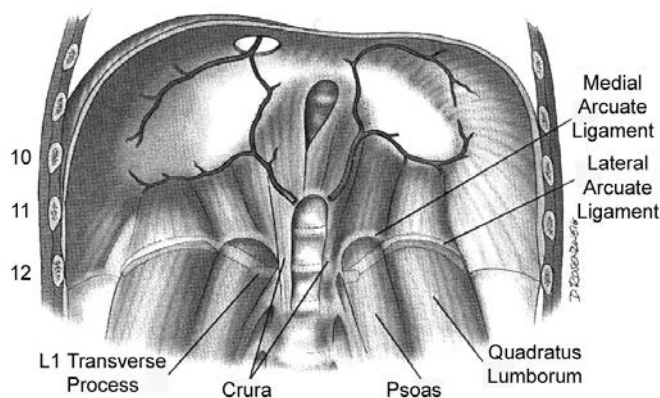

**FIG. 19-5.** Ligaments stabilizing the ribs. **A:** Axial view. **B:** Sagittal view. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

transverse process. The lateral costotransverse ligament connects the posterior tubercle of the rib to the tip of the transverse process. The anterior costotransverse (radiate) ligament connects the head of the rib to its respective vertebral body. The intercostal neurovascular bundle runs along the inferior surface of the rib in the costal groove. The endothoracic fascia lies deep to the intercostal muscles. Beneath this lies the pleura, which extends to the 10th rib in the midaxillary line and to T12 or L1 in the midline posteriorly (6).

The muscles of the anterior abdominal wall represent a continuation of the layers of the intercostal muscles, with the external, internal, and innermost intercostals muscles continuing as the external oblique, internal oblique, and

transversus abdominus muscles, respectively. The transversalis fascia, which lies deep to the transversus aponeurosis, represents the abdominal equivalent of the endothoracic fascia and adheres loosely to the parietal peritoneum.

The diaphragm attaches anterolaterally to the lower six costal cartilages, lower four ribs, xiphoid process, and the thoracolumbar vertebral bodies posteriorly. The crura of the diaphragm insert on the lumbar spine between L1 and L3, and the aorta passes through the crura at the T12 level. The medial arcuate ligament spans the psoas muscle at L1 or L2, and the lateral arcuate ligament bridges the quadratus lumborum from the transverse process of L1 to the 12th rib (Fig. 19-6) (6).

**FIG. 19-6.** The crura and arcuate ligaments of the diaphragm's insertion on the posterior abdominal wall. (Modified from Birch BD, Desai RD, McCormick PC. Surgical approaches to the thoracolumbar spine. *Neurosurg Clin* 1997;8 (4):471–485.)

Vascular structures encountered in the anterior approach include the aorta, diaphragmatic arteries, celiac trunk, superior renal artery, and the left renal artery on the left and the inferior vena cava on the right. The aorta is essentially tethered to the spine by the segmental arteries, which run toward their respective foramina. The artery of Adamkiewicz usually arises from the aorta in the lower thoracic or upper lumbar level along the left side (3).

The ilioinguinal and iliohypogastric nerves course inferolaterally over the quadratus. The genitofemoral nerve emerges from the body of the psoas, lying on its

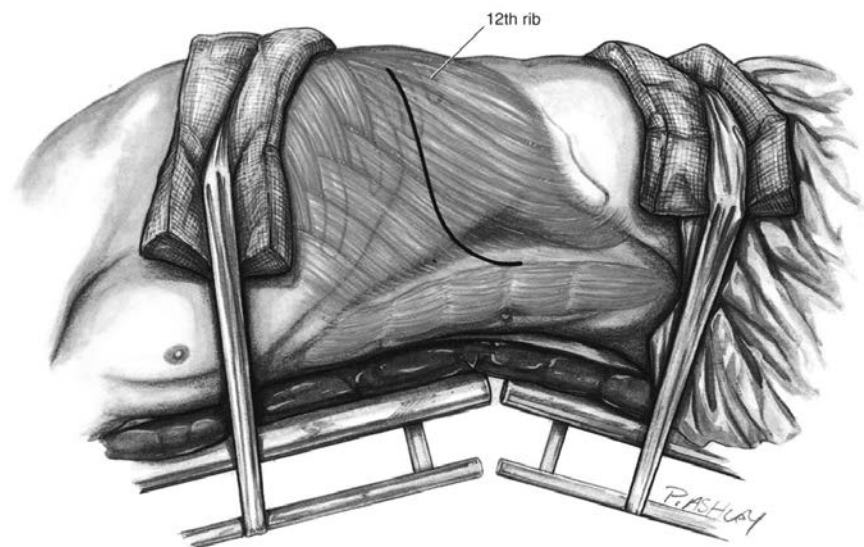

anterior surface in the lower lumbar region. The sympathetic trunk lies anterior to the psoas along its junction with the spinal column and may need to be divided (unilaterally) during an anterior approach.

The retroperitoneal space contains the kidneys, adrenal glands, and the ureters, which course inferomedially along the ventral aspect of the psoas toward the bladder between the peritoneum and the psoas fascia. Because the ureters adhere loosely to the peritoneum, they are usually safely retracted with the peritoneum and its contents during anterior surgical approaches.

### Surgical Technique

The spine is usually approached from the left side, since it is much easier to mobilize the aorta than the vena cava. The patient should be positioned in the lateral position with the area of interest over the break in the table. An axillary roll and sufficient padding should be used to prevent neurovascular compression injuries (Fig. 19-7). The patient may be rolled slightly posteriorly by 45° to 60° (1,3,5).

At our institution, we prefer the transpleural retroperitoneal approach. The incision is made over the rib one or two levels proximal to the level of spinal pathology. The incision extends anteroinferiorly from just lateral to the paravertebral musculature over the rib (10th, 11th or 12th), toward the anterior superior iliac spine. The subcutaneous tissue and musculature are divided with electrocautery to help control bleeding. The periosteum of the rib is then dissected free, taking care to preserve the intercostal neurovascular bundle inferior to the rib. After stripping the periosteum from the rib to within 1 or 2 cm of the costotransverse joint, the rib is resected using rib cut-

**FIG. 19-7.** Patient positioning for the anterior approach to the thoracolumbar spine. The level of interest should be placed over the break in the table and the incision should be made over the rib two levels above the level of interest in the midaxillary line. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

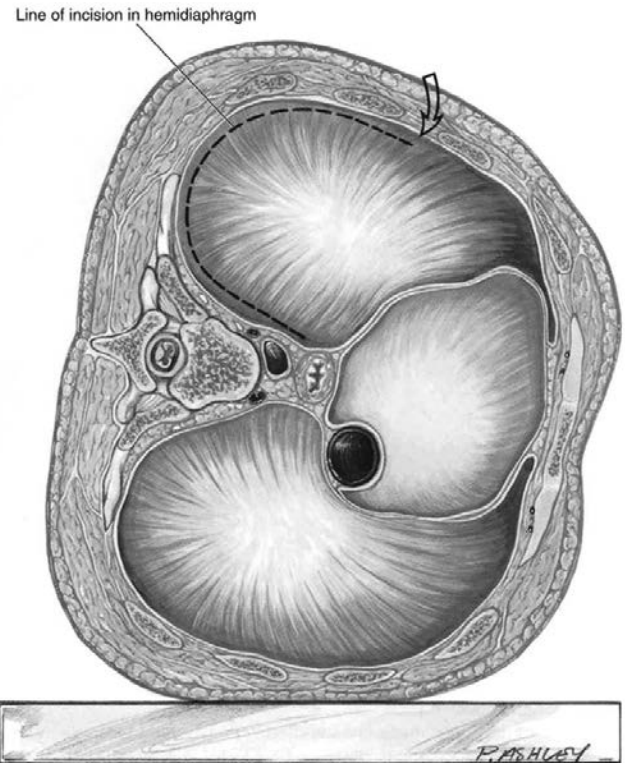

ters and is saved for possible future bone grafting (Fig. 19-8). The pleura is then incised (3-5).

The diaphragm may be released from its lateral insertions in the thoracoabdominal wall (Fig. 19-9). The peritoneum is then gently mobilized away from the posterior abdominal wall with blunt dissection. Dissection of the diaphragm then proceeds medially, elevating the medial and lateral arcuate ligaments from the underlying musculature. The medial attachment of the lateral arcuate ligament and the lateral attachment of the medial arcuate ligament are divided at their insertion on the L1 transverse process, taking care to retain sufficient tissue to permit reattachment of the diaphragm. Finally, the left crus of the diaphragm is divided approximately 2 cm from the vertebral body, allowing communication between the thoracic and abdominal cavities (1,4-6).

The lung is then retracted medially along with the diaphragm and peritoneum. The intercostal and lumbar vessels should be ligated close to the aorta to mobilize the great vessels (3). Elevation of the psoas muscle laterally to the pedicles allows for adequate exposure of lumbar segments. Occasionally, the sympathetic chain, which lies along the anterior spine, may need to be transected during this approach. If this is done, the patient should be told that the foot on the side of the sympathectomy will become warmer (5). The periosteum of the vertebral body is incised and dissected away. Care is taken not to cauter-

**FIG. 19-8.** Removal of the rib 1 to 2 cm distal to the costovertebral joint. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

**FIG. 19-9.** Line of incision to detach the diaphragm from the posterior and lateral abdominal wall. One should leave a cuff of approximately 1 cm for reattachment. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

ize blood vessels around the intervertebral foramen. Once exposed, decompression and stabilization may be performed (Fig. 19-10).

Closure begins with reattachment of the diaphragm to the psoas, L1 transverse process, quadratus, and the cuff of tissue remaining along the anterior and lateral chest wall from which it was initially dissected. A chest tube and retroperitoneal drain are inserted, and the abdominal and chest walls are then closed in layers.

A retropleural retroperitoneal approach may also be used to expose the thoracolumbar spine (1,5,6). This approach is similar to the one described previously, with the incision made along the rib, two levels above the spinal pathology, from the paraspinal muscles to the midaxillary line. The rib that crosses the midaxillary line on the lateral chest radiograph should be resected. The rib is dissected subperiosteally and removed, taking care not to damage the underlying pleura. The endothoracic fascia, which lies deep to the rib periosteum, may then be incised with scissors in line with the incision. The parietal pleura is then carefully freed from this fascial layer by blunt dissection with either a finger or a sponge on forceps beginning anteriorly and progressing posteriorly.

**FIG. 19-10.** Axial section demonstrating the anterior retroperitoneal exposure of the thoracolumbar spine. The lungs and abdominal contents are retracted medially, providing excellent exposure. (From Albert TJ, Balderston RA, Northrup BE, eds. *Surgical approaches to the spine*. Philadelphia: WB Saunders, 1997, with permission.)

The abdominal muscles are divided and the peritoneum is carefully mobilized. The costal cartilage may then be divided allowing the peritoneum and abdominal contents to be swept laterally from the undersurface of the diaphragm. The diaphragm is then incised, leaving a 1 cm cuff of tissue for reattachment. The vertebral column is then approached as described earlier. The diaphragm is reattached, and if the pleura was violated during the approach, a chest tube should be placed at the time of closure.

Complications associated with the anterior approach include vascular and visceral injuries, chyle leak, dural tears, neurologic injury, and hernias (1,5). At our institution, somatosensory evoked potentials (SEP) and motor evoked potentials (MEP) are routinely used. Blood loss is best controlled by carefully cauterizing or ligating small bleeding vessels during the approach. Bone wax or Gelfoam pledgets may be used for dissection adjacent to the neural elements; as monopolar electrocautery should be avoided here, only bipolar cautery should be used. A thorough knowledge of anatomy is the key to identifying and ligating blood vessels (especially veins) during this approach.

A dural tear may occur during decompression. Anterior dural tears are difficult to repair, and may be treated alternatively by application of Gelfoam. Direct suturing of the tear or application of fat or muscle patches may also be tried. Additionally, placement of a subarachnoid drain may be considered if closure cannot be obtained.

As mentioned previously, the sympathetic chain is often sacrificed or injured during the anterior approach with no long-term effects. Patients must be forewarned, however, that a temperature difference between the limbs may be experienced, with the leg on the sympathectomized side feeling warmer.

Finally, because the diaphragm is incised for this approach, care must be taken to securely reattach it to the chest wall to avoid herniation of abdominal contents into the thoracic cavity. Postoperative pulmonary toilet must be employed, and close attention should be paid to chest tube protocol if one is used.

### COMBINED ANTERIOR AND POSTERIOR APPROACH

Occasionally, the degree and complexity of pathology is best treated with a combined anterior and posterior approach. This is most often used for tumorous or traumatic injuries resulting in three-column instability and neural compression. The sequence of the surgical approach—anterior followed by posterior, posterior followed by anterior, or simultaneous—depends upon the pathology and the patient, and should therefore be determined on a case-by-case basis (7).

An anterior, followed by a posterior, procedure is useful in situations where the use of anterior instrumentation is contraindicated, or when anterior instrumentation alone may not adequately stabilize the spine, but the coronal

alignment of the spine is satisfactory. In these instances, an anterior decompression and fusion is followed by a posterior stabilization procedure. For deformity surgery, the anterior approach is generally done to decompress and release a kyphotic deformity with the use of structural graft for fusion. Additional correction may be attempted by the posterior procedure.

A posterior, followed by an anterior, procedure may be indicated in patients with significantly displaced fracture dislocations. The initial posterior procedure restores realignment of the spine in the coronal and sagittal planes. In patients with loss of anterior column support, an anterior procedure may be necessary. Finally, the posterior reduction and decompression may not adequately decompress the spinal canal, in which case an anterior procedure should also be performed.

The inherent instability of injuries requiring combined anterior and posterior procedures increases the risk of complications. Careful electrophysiological monitoring can help avoid intraoperative neurologic injuries. Blood loss is increased in these combined procedures due to the extended operative time needed. An operating table which allows

axial rotation of the patient's body without the need for repositioning can help decrease the potential for complications by reducing procedure time as well as avoiding any potential injuries which may occur from patient movement (7).

## CHAPTER 20

# Surgical Approaches to the Lumbar Spine: Anterior and Posterior

Anthony P. Dwyer

---

This chapter discusses the surgical anatomy of the anterior and posterior approaches to the lumbar spine, including the advantages, disadvantages, risks, and complications of each approach. It does not discuss specific anatomic detail, which can be reviewed in many excellent surgical anatomy textbooks (1–5).

Surgical anatomy consists of surface anatomy, radiologic anatomy, and the surgical approach anatomy (4,6). There must be an understanding of the principle of the internervous plane and the steps to expand the approach of surgical dissection (7). Such anatomic knowledge helps the surgeon anticipate the complications of each approach and assists in potential disaster planning, such as injury to a major vessel, the spinal cord, nerves, or viscera.

Finally, it is important to remember the principles of all surgical approaches (4).

1. Each surgical layer must expose the margins of the wound.
2. Exposure of each surgical layer must be completed before the next layer is exposed.

These principles avoid a conical exposure, whereby the exposure is narrow with deeper dissection.

The decision to use the anterior or posterior approach to the lumbar spine is based on the site of the pathology and the best approach to that pathology afforded by each. It is also important to know and understand the vital structures that are encountered with each approach. Each pathology must be considered, as well as its location. Such pathologies include: coronal or sagittal deformity, neurologic compression, infection, primary and metastatic tumors, nonunion, and instability of the spinal column.

The surgical management of these pathologies must be easily and safely attainable with the selective surgical approach.

There are general indications, contraindications, and specific risks for each approach. Ideally the lumbar spine should be approached from the left side because the arterial structures are more resistant to surgical trauma than are venous structures, but a right-sided retroperitoneal approach can be used if there has been a previous left-sided approach, which may produce significant scarring and fibrosis. Other examples of conditions that might alter the choice of surgical approach include: excessive subcutaneous fibrosis following burns or radiation therapy that prevent a safe posterior approach to the lumbar spine, or the potential for an anterior approach to the lumbar spine to cause retrograde ejaculation from damage to the hypogastric plexus (8).

Each surgical approach has its own advantages and disadvantages, and at times both must be used in a single stage (9). For example, the anterior approach may require the presence of a general or vascular surgeon, but the reduced surgical trauma associated with the minimized muscular cutting of the new approaches may result in a shorter hospital stay and quicker rehabilitation. On the other hand, the posterior approach is more common and routine, but is associated with more surgical trauma from ischemia and denervation of the muscles. In addition, the prone position may be associated with cardiopulmonary problems in the older patient, injury to the peripheral nerves, and ophthalmic complications.

### **ANTERIOR SURGICAL APPROACH TO THE LUMBAR SPINE**

This discussion covers the retroperitoneal approach to the lumbar spine, as popularized by Hodgson and others (10–12). Both the antero-lateral approach (with the patient in the lateral or semilateral position), and the direct anterior midline approach (via the rectus abdomi-

nus muscle and the transversalis fascia muscle, with the patient in the supine position) are discussed. This section does not cover the transperitoneal approach to the lumbar spine, because this is generally used only for exposure of the lumbosacral junction and is discussed in a separate section.

The retroperitoneal approach to the lumbar spine has the advantage of being readily expanded to provide access to the anterior and middle columns of the lumbar spine. Also, it allows ready access to the vertebral bodies, the annulus and intervertebral disc, the anterior aspects of the transverse process and lateral pedicle, the neural foramen, and the anterior epidural space.

It is useful for surgical access for vertebral body and disc space infection, primary and secondary tumors, decompression of the vertebral canal from anterior pathology, correction of lumbar deformity, reconstruction of the anterior column, and stabilization and fusion of a symptomatic unstable segment.

## DIRECT ANTERIOR APPROACH

### Surface and Radiologic Anatomy

The surface landmarks for the anterior approach to the lumbar spine consist of the iliac crest, anterior superior iliac spine, pubic symphysis, the coastal margin and the umbilicus (6).

In a thin patient the lumbar sacral junction and the aorta can be readily palpable through the midline.

The surface anatomic landmarks need to be compared with a careful study of the antero-posterior (AP) and lateral views of the lumbar spine, noting the relationship between anatomic landmarks and X-ray anatomy in order to properly plan the skin incision and surgical approach.

Usually the intercrystal line on top of the iliac crest passes through the L4-5 disc, but this varies among individuals and may be altered with lumbosacral anomalies such as sacralization of the fifth lumbar vertebrae or lumbarization of the sacrum.

Inadvertent operating at the wrong level of the lumbar spine may be prevented by "signing your site" and confirming the specific level with intraoperative X-rays.

### Patient Position

For the direct anterior approach to the lumbar spine, the patient is positioned in the supine position with a padded support under the prominence of the sacrum and the lumbar spine centered over the break in a radiolucent operating table to allow for adjustment in the degree of extension of the lumbar spine. The direct anterior approach is ideal for an average-sized patient but a large patient may require the antero-lateral approach to allow the abdominal contents to conveniently fall away from the lumbar spine. The head and neck are in the neutral posi-

tion with the upper extremities partially abducted. Compression stockings to the lower extremities should be used and an indwelling urinary catheter inserted.

### Incision

There are four choices for the skin incision:

1. Horizontal paramedian
2. Vertical paramedian (Fig. 20-1)
3. Pfannenstiell or horizontal incision above the pubic symphysis
4. Oblique

The horizontal and vertical paramedian incisions are most commonly used. The Pfannenstiell incision may be used for cosmetic reasons and the oblique incision is rarely used for the direct anterior approach because the anatomy is the same as in the antero-lateral approach.

The level of a transverse incision depends on the specific level of pathology. As mentioned, the surface and radiologic anatomy need to be correlated with each other to make sure that the intercrystal line does indeed go through the L4-5 disc. With that determined, the L3-4 disc generally is at the level of the umbilicus, and the L5-S1 disc is usually halfway between the umbilicus and pubic symphysis.

Access to more than two lumbar levels usually requires the use of a vertical paramedian decision, with the length determined by the specific number of levels required. Access is through the rectus-abdominus muscle to the posterior rectus sheath above the arcuate line, or by mobilization of the rectus laterally. Incision of the anterior rectus sheath in line with the skin incision or it can be enlarged by making a vertical incision at both its medial and lateral margins as described by Henderson (8) and Fraser (13,14). The specifics of this are described in the following.

**FIG. 20-1.** Vertical paramedian incisions. (Modified from Henderson, R.J. Anterior approach for lumbar fusions and associated morbidity. In: Spine care. St. Louis: Mosby, 1995:1112-1134, with permission.)

### Surgical Anatomy

The key muscle in the direct anterior approach is the rectus abdominus with its anterior and posterior sheaths above the arcuate line. Division of the anterior rectus sheath exposes the rectus muscle (Fig. 20-2). The underlying transversalis fascia is defined and carefully incised to gain entry into the retroperitoneal space. The peritoneal fat is gently freed with a finger from the transversalis fascia. The freed peritoneum, with its contents, is retracted medially (Fig. 20-3). The psoas is encountered posteriorly and medially with the genitofemoral nerve located on its surface and the sympathetic trunk located medially.

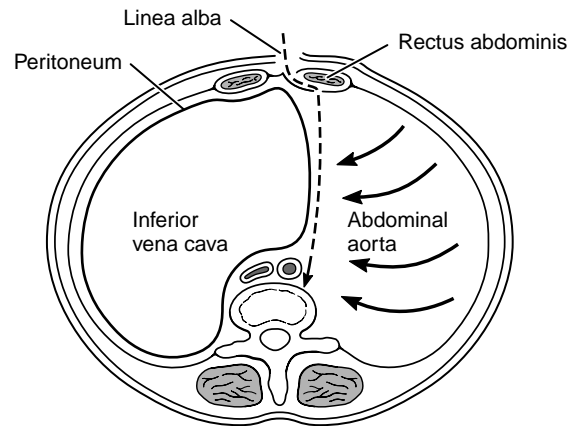

The ureter is identified by its peristaltic movements and accompanying blood vessels. The ureter usually stays with the posterior peritoneum as it is moved forward. The major blood vessels are identified: the aorta and common iliac and iliac arteries anteriorly and to the left of the corresponding veins.

The left iliolumbar vein may have several different configurations and should be doubly ligated before it is incised and mobilized (Fig. 20-4) (2).

The presence of the hypogastric plexus coming off the aorta can be at risk of damage as it courses over the anterior aspect of the lumbosacral disc (Fig. 20-5). Electrocautery should not be used in this area in males in order to avoid damage to the hypogastric plexus, which could result in retrograde ejaculation.

### Contraindications and Disadvantages of the Anterior Approach

Contraindications to the direct anterior approach to the lower lumbar spine include the presence of pathology in

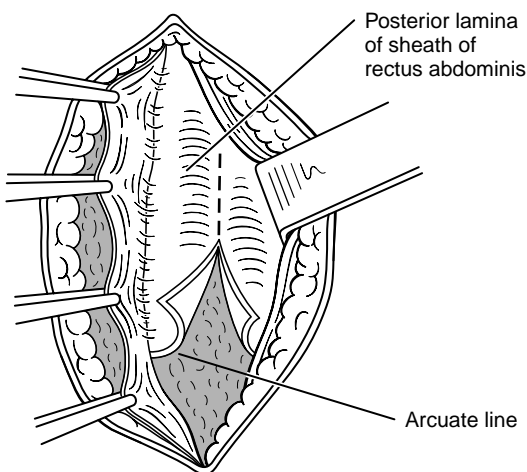

**FIG. 20-3.** Direct retroperitoneal approach. (Modified from Nakano N, Nakano T. Anterior extraperitoneal lumbar discectomy without fusion. In: *The lumbar spine*. Philadelphia: WB Saunders, 1990:987–989, with permission.)

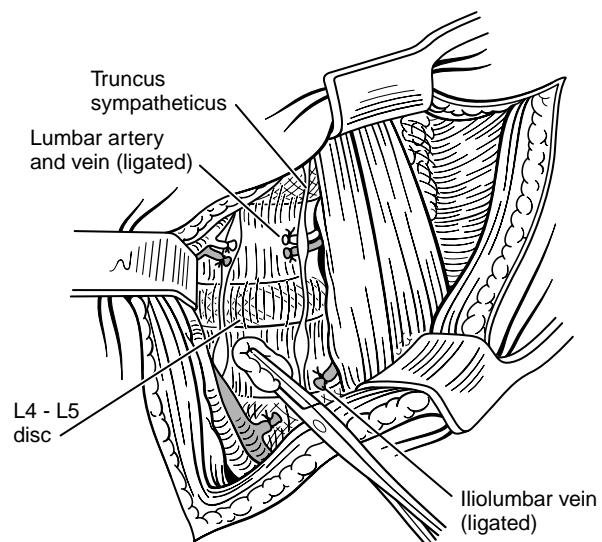

the posterior column, and situations where the anatomy does not allow safe access to the anterior and middle columns. This includes low bifurcation of the aorta that may prevent safe access to the L5-S1 or L4-5 disc or the presence of significant retroperitoneal scarring from previous surgeries.

Disadvantages include the technical challenges of dissecting and manipulating major arteries and veins; namely, the iliolumbar vein, vena cava, common iliac vein, and accompanying arteries.

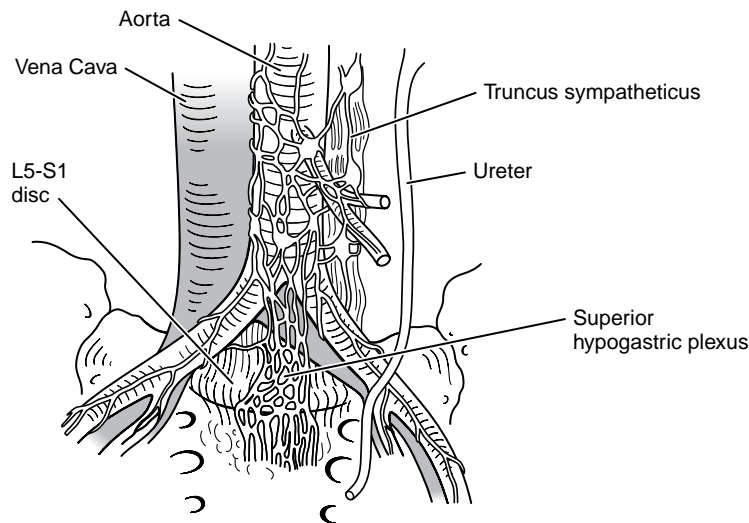

As indicated, the arterial structures are more resistant to manipulation than veins, so the approach to and the

**FIG. 20-2.** Rectus abdominis. (Modified from Nakano N, Nakano T. Anterior extraperitoneal lumbar discectomy without fusion. In: *The lumbar spine*. Philadelphia: WB Saunders, 1990:987–989, with permission.)

**FIG. 20-4.** Retroperitoneal structures at the L4-5 disc level. (Modified from Henderson, R.J. Anterior approach for lumbar fusions and associated morbidity. In: *Spine care*. St. Louis: Mosby, 1995:1112–1134, with permission.)

**FIG. 20-5.** Hypogastric plexus, vessels, and ureter. (Modified from Henderson, RJ. Anterior approach for lumbar fusions and associated morbidity. In: Spine care. St. Louis: Mosby, 1995:1112–1134, with permission.)

dissection of the lower lumbar spine should be done from the left. This approach also minimizes the potential damage to hypogastric plexus over the lumbosacral disc, minimizes the risk of injury to the ureter and the genitofemoral nerve and other nerves that lie within and on the psoas muscle.

The surgeon should be aware that anterior and lateral vertebral osteophytes can cause adherence of venous structures to the spine and make their dissection and manipulation difficult and dangerous because of the potential of injuring one of the veins. The assistance of an experienced vascular surgeon is invaluable to minimize this occurrence and help manage it if it occurs.

### ANTEROLATERAL APPROACH

Indications for the anterolateral approach are similar to those for the direct anterior approach. It is particularly helpful in the obese patient, where the lateral decubitus position permits the viscera and abdominal wall to fall out of the way.

#### Patient Position

The patient is positioned in the decubitus position with the left side up over a beanbag on a radiolucent operating table. The patient must be positioned over the break in the table so that flexion of the table will permit lateral flexion of the patient. This lateral flexion increases the interval among the costal margin, iliac crest, and pubic symphysis to facilitate exposure. An auxiliary role is placed under the dependent axilla and the upper arm is placed in a relaxed neutral position over a pillow or armboard. The hips and knees are flexed and padded to protect the peripheral nerves, particularly the lateral popliteal nerve at the knee. Flexion of the hips relaxes the psoas muscle, which aids in its dissection from the lateral aspect of the lumbar bodies and the transverse process.

Once the patient is properly positioned, a beanbag is inflated to provide support. The bean bag must not come higher than the umbilicus anteriorly and the spinous process posteriorly in order to avoid limitation of the surgical exposure. The patient is secured with strapping around the shoulders and over the greater trochanter, to stabilize the patient when the table is rotated.

It is very important to keep the posterior cortex on the vertebra in a direct vertical alignment when decompressing the spine anteriorly in order to avoid disorientation and potential neural injury by penetration through the posterior cortical wall into the anterior epidural space of the vertebral canal.

### Incision

As with the direct anterior approach to the lumbar spine, the incisions for the antero-lateral approach to the lower lumbar spine depend on which levels require exposure (Fig. 20-6). Usually the lateral edge of the incision is

**FIG. 20-6.** Variation in oblique incision for specific lumbar level. (Modified from Watkins RG. Surgical approaches to the spine. In: The lumbar spine. Philadelphia: WB Saunders, 1996:1263–1271, with permission.)

in the midaxillary line proceeding medially and curving inferiorly to the midline anteriorly. The surface and radiologic anatomy must be checked to be sure that the intercrystal line passes through the L4-5 disc and appropriate adjustments in the incision should be made if necessary. For exposure of the L3-4 level the medial aspect of the incision should be in the midline at or below the umbilicus. For access to the L4-5 disc, the medial aspects of the incision should be in the mid- to upper third of the way between the umbilicus and pubic symphysis. Access to the L5-S1 disc should be midway between the umbilicus and pubic symphysis.

### Surgical Anatomy

Knowledge of the muscles of the lateral abdominal wall is the key to this approach. The fascia and fibers of the external oblique usually run along the line of the incision, and the fibers of the internal oblique run at nearly 90 degrees to the external oblique fibers. The transversus abdominus muscle runs nearly horizontally above the transversalis fascia. After blunt dissection between the fibers of the external and internal obliques, the transversalis fascia is defined and reflected laterally to gain access to the retroperitoneal space. The peritoneum is carefully swept off the transversalis fascia and the retroperitoneal fat is encountered in the retroperitoneal space. The dissection is bluntly carried down to the psoas muscle. The mobilization, dissection, and manipulation of the psoas laterally are important to obtain access to the lateral aspect of the lower lumbar spine. Care must be taken to avoid injury to the sympathetic trunk lying along its medial aspect, the nerves of the lumbar plexus in its substance, and the genitofemoral nerve along the surface of the psoas. The ureter is identified by its peristaltic movement and usually moves with the posterior peritoneum as the peritoneum and its contents are reflected anteriorly.

The relationship of the major blood vessels, iliolumbar vein, and hypogastric plexus are the same as with the direct anterior approach.

### POSTERIOR APPROACH

This discussion covers the posterior approach to the lumbar spine through the following incisions and dissections: direct midline, paramedian muscle splitting, and far lateral or oblique.

The posterior approach provides access to the posterior column, including the pedicle, transverse process, facet joint lamina, and spinous process; the vertebral canal; the middle column, including the disc, posterior longitudinal ligament, and posterior vertebral body; and limited access to the anterior column.

The posterior approach is commonly used for the following surgical procedures: decompression of the verte-

bral canal, nerve root canal and foramen; posterior fusion and instrumentation for management of deformity and instability; excision of primary and secondary spinal tumors; and débridement of spinal infections.

### Surgical and Radiologic Anatomy

The surface anatomic landmarks include the midline lumbar spinous processes, intercrystal line, and posterior superior and inferior iliac spines. Usually the sacral dimple area is at the level of the lumbosacral disc.

The radiologic anatomy must be checked on the AP and lateral X-rays, taking care to ensure that there are no lumbosacral anomalies such as lumbarization of the sacrum, or sacralization of L5, spina bifida occulta, or prior laminectomy defect. The intercrystal line must be checked on both the AP and lateral views to see its exact location with respect to the 4-5 intervertebral disc. Care must be taken to assure the appropriate level and confirm this with cross-table lateral X-rays if necessary. The key to orientation within the spinal canal is the pedicle: medial to the pedicle is the nerve root and superior to it is the intervertebral disc.

### Patient Position

The patient is placed prone on a suitably padded spinal frame that provides the required position and posture of the lumbar spine. This may be in lumbar flexion for a simple laminotomy and disc prolapse or in extension and lordosis for decompression of spinal stenosis. The lordotic position is mandatory if instrumentation and fusion is required to assure that lumbar lordosis is achieved. This minimizes the risk of developing a “flat back” position.

The spinal frame must allow the abdomen to hang free to avoid compression of the abdominal contents, which can cause excessive epidural bleeding by shunting of blood from the vena cava through Batson’s plexus into the epidural veins. Epidural bleeding also can be minimized by having the anesthesiologists avoid overinflation of the lungs and overdistention of the diaphragm, which can increase abdominal pressure and shunt blood from the vena cava into the epidural veins.

The patient also can be placed in the kneeling position, which also avoids abdominal compression. Care must be taken to avoid pressure on the knees and other bony prominences.

### Incisions

#### Midline

The midline incision is centered over the appropriate level and is the most commonly used incision in gaining access to the posterior lumbar spine. It provides ready access to unilateral or bilateral pathologies. The length of

the incision can be minimized by taking a cross-table X-ray beforehand to accurately identify the level or levels in question.

The incision is taken directly down through the superficial and deep subcutaneous fascia to the middle of the posterior tip of the spinous process and the lumbo dorsal fascia. Stripping and dissection of the subcutaneous tissue from the lumbar dorsal fascia avoids producing a dead space that can fill with serous fluid and blood.

### *Paramedian Incision*

The paramedian incision is used for the paraspinous approach popularized by Wiltse that involves splitting of the sacrospinous muscle in the sagittal plane, two or three fingerbreadths from the midline (15,16). Wiltse recommended bilateral skin incisions, whereas others have advocated a midline skin incision with bilateral incision of the thoracolumbar fascia and splitting of the sacrospinalis muscle (Fig. 20-7). This provides access to the facet joint and transverse processes, and for lateral pathology such as a far lateral disc prolapse.

A midline incision for the bilateral paramedian approach has the advantage of a single skin incision but requires a longer cut than a bilateral skin incision. A bilateral incision also provides adequate access for pedicle screw and instrumentation insertion.

### *Far Lateral Incision*

This incision is placed over the lateral edge of the erector spinae muscle, usually between the junction of the medial spinalis muscle and the intermediate longissimus muscle portion of the erector spinae muscle. This approach provides access to the transverse process and is the least used incision or approach to the posterior lumbar spine.

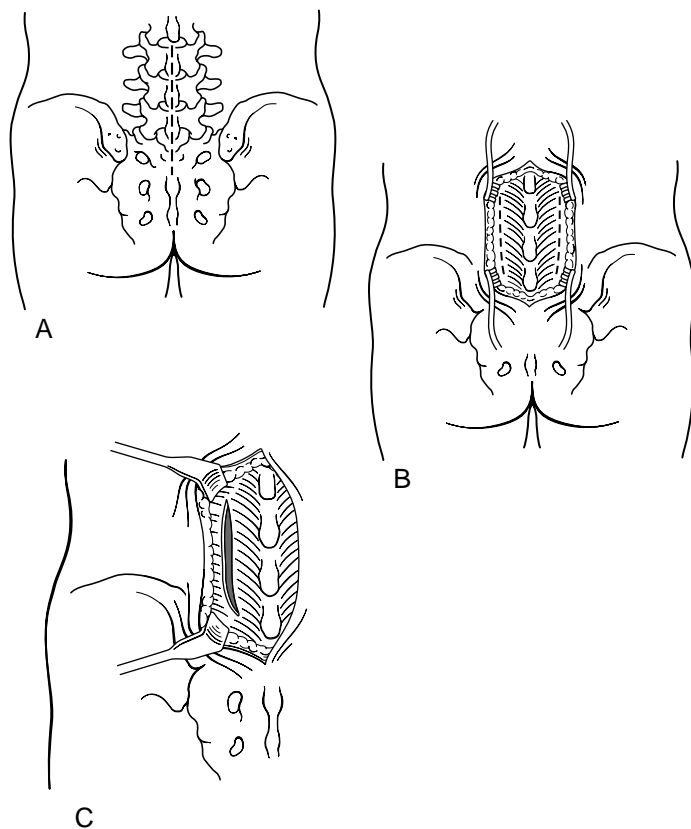

### *Surgical Anatomy*

The lumbar dorsal fascia is detached from the tips of the spinous process and is followed by subperiosteal dissection of the paraspinous muscles from the spinous process, lamina, and posterior facet joint. If necessary, this can be carried out all the way to the transverse processes.

### *Posterior Lumbar Muscles*

The lumbar musculature can be grouped into the following types:

- short intersegmental muscles, which include interspinales and intertransversarii mediales;
- short polysegmental muscles, which include multifidus and the lumbar portions of longissimus and iliocostalis (the lumbar erector spinae); and

**FIG. 20-7.** Midline incision for paraspinous approach. (Modified from Wiltse LL, Bateman GI, Hutchinson RH, et al. The paraspinous sacra spinalis splitting approach to the lumbar spine. *J Bone Joint Surg* 1968;50A:919; Wiltse LL. The paraspinous sacra spinalis splitting approach to the lumbar spine. *Clin Orthop* 1973;91:48, with permission.)

- long polysegmental muscles, which include thoracic portions of longissimus and iliocostalis(1).

#### Short Intersegmental

*Interspinalis.* There are four pairs of lumbar interspinalis, each pair lying lateral to the interspinous ligament and connecting the adjacent spinous processes.

*Intertransversarii Medialis.* These arise from the accessory and mamillary processes and from the mamillo-accessory ligament between the processes, and are innervated at each level by the lumbar dorsal rami.

#### Short Polysegmental

*Multifidus.* Multifidus is invariably encountered in posterior midline approaches to the lumbar spine, as it is the most medial and the largest of the posterior lumbar musculature.

There is a constant pattern of fascicles, either short thin fascicles arising from the caudal portion of the dorsal aspect of each lumbar and inserted into the mamillary process of the vertebra two levels caudal, or larger longer fascicles arising from the spinous process radiating out in five overlapping groups that form the bulk of the multifidus. The fascicles arise either from the base of the spinous process or from the common tendon at the caudal tip of the spinous process and are inserted three levels caudal into the mamillary process—the posterior superior iliac spine, the posterior iliac crest, or the sacrum.

*Lumbar Erector Spinae.* The lumbar erector spinae is made up of two named muscles—the longissimus thoracis and iliocostalis lumborum—that are separated by the lumbar intermuscular aponeurosis. Each has two named portions: *lumbar* fascicles arising from the lumbar vertebrae and *thoracic* fascicles arising from the thoracic vertebrae.

The longissimus thoracis pars lumborum has five fascicles, each arising from the mamillary process and the adjacent transverse process of each vertebra and inserted into the medial aspect of the posterior superior iliac spine.

The iliocostalis lumborum pars lumborum has four overlapping fascicles arising from the tip of the transverse process of L1, L2, L3, and L4 vertebrae as well as the adjacent middle layer of the thoracolumbar fascia, and insert into the iliac crest lateral to the posterior superior iliac crest.

The thoracic portions of these muscles make up the long polysegmental muscles, arising from the ribs and transverse processes, and attach to the sacrum and iliac crest, as well as the tendinous portions forming the erector spinae aponeurosis that are attached to the ilium, the sacrum, and the sacral and lumbar spinous processes.

The thoracolumbar fascia is made up of three layers— anterior, middle, and posterior—that separate the poste-

rior lumbar and trunk muscles into separate compartments and has significant biomechanical functions.

The posterior layer is the most significant surgically and consists of superficial and deep laminae forming a retinaculum over the lumbar muscles. The posterior layer is attached medially to the midline and laterally to the lateral raphe, arising vertically from the iliac crest.

Other anatomical works list these lumbar muscles into layers:

*Superficial:* the thoracic portions of longissimus thoracis and iliocostalis lumborum.

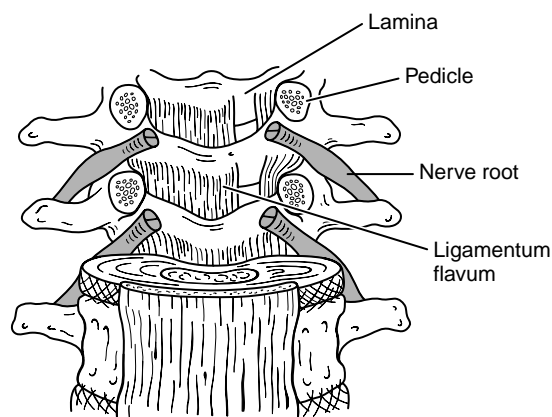

*Intermediate:* the multifidus and the lumbar portions of longissimus thoracis and iliocostalis lumborum.

*Deep:* the interspinales and intertransversarii.

#### Ligamentum Flavum

Knowledge of the ligamentum flavum, and understanding its attachment at each level, aids in its safe dissection and removal. The ligamentum flavum runs in a vertical direction attaching to the cephalic tip of the distal lamina and halfway up the ventral surface of the proximal lamina (Fig. 20-8) (18). The ligamentum flavum also attaches laterally to the undersurface of the facet joint, and its fibers blend with those of the anterior capsule of the facet joint.

The facet joints are innervated by the posterior rami of the spinal nerves, which gain access to the posterior compartment at the lateral edge of the pars interarticularis and are accompanied by the intertransverse artery, which supplies the muscles of the deep layer. These vessels frequently are breached during posterior exposures and bleed during routine dissection of the pars, particularly during dissection out to the lateral tip of the transverse process at each level.

**FIG. 20-8.** Ligamentum flavum, nerve root, and pedicle. (Modified from Watkins RG. Surgical approaches to the spine. In: The lumbar spine. Philadelphia: WB Saunders, 1996:1263–1271, with permission.)

### The Pedicle

The superficial landmarks, entry point, length, breadth, and direction of each lumbar pedicle are important. The pedicle is the key landmark to safely find the lateral edge of the nerve root and the intervertebral disc immediately above it. Pedicle fixation requires thorough knowledge of the pedicle entry point, which usually is located at the junction of the lateral edge of the facet and the midpoint of the transverse process.

Usually the pars of L5 is in line with the lateral portion of the L5 pedicle. Proceeding proximally, the lateral portion of the pars moves medially, so in the upper lumbar spine the medial edge of the pars is in line with the medial border of the pedicle.

### Erector Spinae Muscle

The paravertebral approach of Wiltse exposes the spine in the interval between the multifidus and lateral muscles (longissimus and iliocostalis) (Fig. 20-9). The posterior and lateral aspect of the facet joint is palpated and the lateral muscles are retracted and dissected off the transverse process. The transverse process is identified and followed medially to pedicle, which can be palpated and used to identify the exiting nerve root. This approach provides access to a far lateral disc.

### Indications and Advantages

The direct posterior approach to the lumbar spine provides safe access to posterior pathology and limited access to anterior column pathology through the pedicle or by gentle cauda equina retraction.

### Contraindications

Potential contraindications to the posterior approach include anterior column pathology and significant skin or

post-subcutaneous scarring and fibrosis related to previous radiation therapy or significant burns.

### Disadvantages

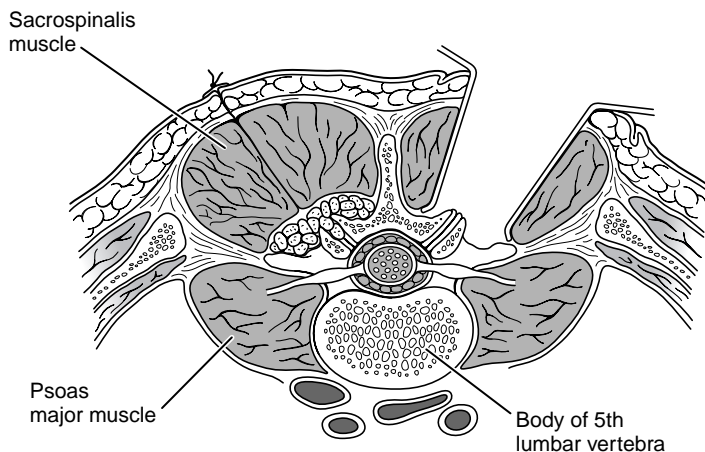

One disadvantage to the posterior approach is the stripping of the paraspinal musculature, which can be associated with impairment of its nerve and blood supply and the formation of thick scar tissue, which can contribute to development of the postlaminectomy syndrome. Long and wide muscle stripping can be associated with prolonged recovery and postoperative pain and disability that can persist despite extensive postoperative rehabilitation.

Postlaminectomy scarring can occur as the muscle grows back into the laminectomy site and into the exposed dura and nerve roots. This also can produce difficulty in obtaining safe exposure for a redo posterior decompression. The scarring is often associated with dural tear and nerve root damage during repeat decompression.

There have been reports of injury to the aorta, vena cava, and retroperitoneal viscera with inadvertent placement of the instruments through the anterior longitudinal ligament. Therefore, it is imperative to know the length of the instruments being used and the depth to which it can be safely inserted into the disc space. It is also recommended that the pituitary rongeur be placed through the annulotomy with the jaws closed and then opened to avoid inadvertent grabbing of neural structures.

Intraoperative ophthalmic complications are uncommon but catastrophic. These include postoperative blindness and visual field defects. Contributing etiologies include an underlying vascular diathesis, diabetes, and direct pressure to the globe.

Prolonged positioning in the prone position also can result in cardiopulmonary shunting, which can be problematic in the elderly population undergoing multilevel decompression and fusion.

## CHAPTER 21

# Posterior and Anterior Surgical Approaches to the Lumbosacral Junction

Peter A. Robertson

---

### SEGMENTATION

Normal segmentation at the lumbosacral junction is frequently assumed, yet abnormal segmentation has been described in 33% of a cohort of patients (1). The presence of a transitional vertebra at the lumbosacral junction confuses nomenclature. Failure to recognize abnormal segmentation may cause incorrect interpretation of pathology, incorrect recognition of anatomic features at surgery, and increased risk of operating at an incorrect level.

Segmentation variations include extra or missing vertebrae within the spinal column (2); supernumerary or absent ribs; transitional lumbosacral segmentation with L5 transverse process articulation with the sacral ala; and incomplete coalescence of S1 and S2 with a well-formed S1-2 intervertebral disc. A wide variety of combinations may make it difficult to define levels with certainty. Options include classification of the whole spinal segmentation from proximal to distal, or counting from the sacrum up, to define levels. The former gives accurate labeling of the whole spine yet requires cumbersome total spinal X-rays and unwarranted exposure to radiation. The latter is more practical when dealing with the lumbosacral spine.

A practical approach to the nomenclature of atypical lumbosacral segmentation is to identify the transitional vertebra and describe it based on its most salient characteristics. A transitional vertebra that has all the appearances of an L5 vertebra, apart from a unilateral articulation between a transverse process and the sacral ala, is described as a sacralized L5. Conversely, if the upper sacral segment has all the hallmarks of an S1 segment, yet there is a significant rudimentary disc between S1 and S2, it is regarded as a lumbarized S1 (Fig. 21-1). Clear identification of a transitional lumbosacral segment requires lateral and special antero-posterior (AP) radiographs. The lateral allows definition of the vertebral

body and sacral shape and the degree of formation of the abnormal disc. The AP views must include a view so that the X-ray beam is parallel to the lumbosacral disc. The beam should be centered on the disc. The lordosis thus requires the beam to be angled cephalad by approximately 20°, although this angulation varies dependent on the lordosis and should be judged from the lateral view. This is to accurately define the anatomic relationship between the transverse processes of L5 and the ala of the sacrum.

Once the transitional vertebra characteristics are defined and clarified, the adjacent segments can be numbered. When the number of lumbar vertebrae differs from normal (as defined by the absence of articulating ribs), some refer to the lumbosacral segment as the L4-S1 level or the L6-S1 level. Alternatively, the lumbar vertebrae may be numbered above an L5 segment to maintain familiarity with traditional segment numbering.

Because of the potential for confusion, it is essential that the treating doctors recognize any segmentation abnormalities and label the segments consistently. Consistent vertebral numbering and close correlation between preoperative and intraoperative lateral radiographs offer the best chance of avoiding incorrect levels.

### POSTERIOR SURGICAL APPROACHES TO THE LUMBOSACRAL JUNCTION

The midline posterior approach to the lumbosacral junction, through a longitudinal incision, is an extensile approach that allows access to the posterior elements, the canal and the foramina, the posterolateral gutters, and the intervertebral disc space. It is the most frequently used approach and obviously can be extended to link with proximal dissection.

Identification of the level of incision is by relationship to the iliac crests (approximately L4 body level), palpa-

**FIG. 21-1. A:** A lateral X-ray of a transitional lumbosacral junction. The rudimentary disc space is between the upper sacral segment and the remainder of the sacrum. **B:** The anteroposterior radiograph angled parallel with the disc demonstrates the transitional vertebra with lateral articulation between the vertebra transverse processes and the sacral ala.

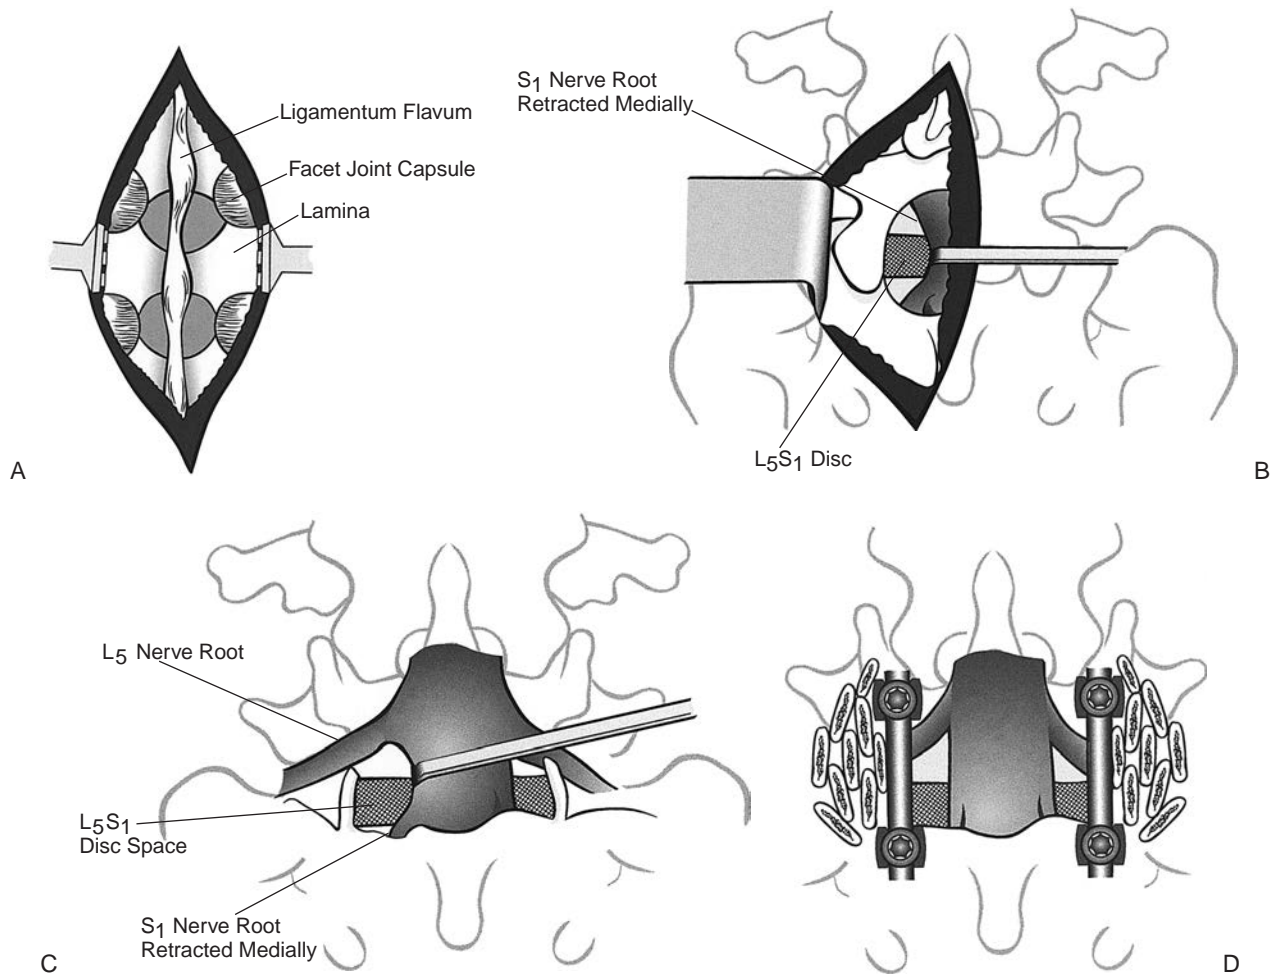

tion of the lumbosacral spinous process gaps, or use of skin markers and radiology.

Longitudinal division of the skin and subcutaneous tissue displays the deep fascia. This is a double-layered sheet that attaches to the spinous processes medially, and encloses the multifidus, the most medial of the paraspinal muscles. Although subperiosteal dissection is possible in children and adolescents, adults require division of the deep fascial attachment to the spinous process. The multifidus muscle attachment to the spinous processes and laminae of L5 and S1 is easily swept aside with a Cobb or Harrington periosteal elevator. The tendinous attachment of the multifidus is to the midline structures at the level of the supraspinous and interspinous ligaments. This attachment requires sharp division. Preoperative identification of any spina bifida is mandatory to allow cautious dissection of the upper sacrum—preventing inadvertent canal entry. Self-retaining retractors hold the multifidus muscle laterally and allow midline access to the canal by midline laminectomy or unilateral laminotomy. The parasagittal muscles can be swept further laterally, to display the glistening white lumbosacral facet joint capsule. The Taylor pointed retractor can then be placed lateral to the facet joint and levered laterally to retract the paraspinal muscles. This retraction technique is ideal for unilateral posterior lumbosacral approaches. Dissection proximal to the lumbosacral facet joint displays the pars interarticularis of L5. Definition of the lateral aspect of the pars is necessary to allow sufficient pars preservation when performing L5 laminectomy (Fig. 21-2).

More lateral development of this approach allows exposure to the posterolateral gutters, where bone grafting is performed in a posterolateral fusion. The multi-

fidus muscle has a further attachment to the posterolateral facet capsule and superior articular facet, which, when divided in a longitudinal direction, reveals loose fatty tissue that can be swept laterally to reveal the superior ala of the sacrum. Display of the transverse process of L5 requires detachment of multifidus from the posterolateral facet capsule of L4-5. Again, loose fatty tissue covers the transverse process of L5 and is easily swept laterally.

Troublesome bleeding may occur with exposure of the posterolateral gutters. The segmental vessels that accompany the nerve roots as they enter the foramen also give branches that course lateral to the pars interarticularis and supply the paraspinal muscle complex. These posterior vessels give off small, but occasionally troublesome, vascular branches that pass distally, lateral to the facet joint capsule and superior articular facet of the joint below (3). They frequently bleed as the transverse process or ala of the sacrum is displayed. Direct visualization can be difficult because of the paraspinal muscle mass that prevents retraction, so that it is difficult to see lateral to the facet joint capsule and superior articular facet. Useful tricks to prevent troublesome bleeding lateral to the facet joints include preemptive use of bipolar coagulation forceps in the loose fatty tissue lateral to the facet joint capsule (before sweeping the fatty tissue aside to display the transverse process or sacral ala), or bending the tip of the unipolar diathermy and sweeping that diathermy tip up the lateral aspect to the superior articular facet superior to the sacral ala or the lumbar transverse process. Troublesome bleeding is controllable with lateral gutter packing. More constant vascular ooze from the lateral gutter occurs after the transverse process and the lateral aspect of

**FIG. 21-2.** Diagrammatic representation of the posterior approach to the lumbosacral junction. **A:** Posterior approach to the lumbosacral junction demonstrating laminae, ligamentum flavum, and facet joint capsules. **B:** Unilateral flavectomy, laminotomy, and approach for discectomy after retraction of the S1 nerve root. **C:** Extensive facetectomy to demonstrate the transforaminal “window” for access to the disc space. **D:** Posterolateral fusion with pedicle screws and rods after wide destabilizing facetectomy at the lumbosacral junction.

the superior articular facet are decorticated, before bone grafting and fusion procedures. For this reason decortication should be deferred until as late as possible in the procedure. Minor degrees of initial bleeding can occur with dissection around the S1 posterior foramen. This is best controlled with bipolar diathermy.

Attempts to coagulate the posterior branch of the segmental vessels, lateral to the pars interarticularis, threaten the posterior primary rami that accompany these vessels. At L4 and L5 these nerves do not have cutaneous sensory function (4), but the damage has implications for muscle function.

In unilateral posterior lumbosacral approaches effective retraction can be obtained with a Taylor pointed retractor, placed lateral to the facet joint, and retained by a weight and chain.

Bilateral approaches obtain best visualization with Travers (straight) or Adson (curved) self-retainers. Difficulty

with retraction is alleviated by proximal and distal release of the erector spinae from the midline structures. Careful use of self-retaining retractors and hand-held retractors gives adequate exposure to all posterior structures. Powerful crank type retractors can give wide exposure to the posterior structures, but can damage the paraspinal muscles, particularly if the retractor blades are forced hard up against the posterior iliac crest laterally. Muscle atrophy, weakness, and electromyographic changes occur following surgery, and these changes should be minimized (5–7). The crank retractor bulk can also limit access to the correct oblique pathway for pedicle screw placement at L5 and S1 (Fig. 21-3).

As an alternative to bilateral multifidus dissection off the spinous process and laminae for decompressive procedures, a unilateral multifidus strip combined with a spinous process osteotomy (at the base) allows midline access for decompression. This approach may limit mus-

**FIG. 21-3.** Magnetic resonance imaging scan (axial) of the lumbosacral junction of an achondroplastic dwarf presenting for decompression of spinal stenosis. Note that the posterior iliac crests are very medial, causing herniation of the paraspinal muscle mass posteriorly. A posterior approach to this level is technically difficult because of muscle bulk and difficulty with retraction owing to the iliac crests. A limited amount of muscle excision may be required to access the spinal canal.

cle damage, preserve midline structures, and improve cosmesis, yet risks problems from spinous process nonunion, and cannot be applied if bilateral wider posterolateral exposure is needed (8).

### SPINAL CANAL DISSECTION AT THE LUMBOSACRAL JUNCTION

Entry to the spinal canal at the lumbosacral junction requires removal of the ligamentum flavum on one or both sides of the midline. This can be achieved with either cautious sharp dissection in the midline or detachment of the ligamentum flavum at its periphery (easiest distally) using a small curved sharp curette. Once the epidural space is opened, it is explored and expanded with a dissector. A Kerrison up-cutting rongeur can be used to remove the ligamentum flavum and display the epidural space from the midline out to the facet joint.

The extent of dissection within the canal is determined by the pathology. Flavectomy alone gives adequate access to most posterolateral disc herniations. Partial laminectomy of either L5 proximally or S1 distally may be required for migrated disc fragments. Medial facetectomy is required where facet hypertrophy causes lateral recess stenosis at the entrance to the nerve root canal. Facetectomy can be performed with either rongeurs or osteotomes. Occasionally, more radical or complete facetectomy is required to decompress the L5-S1 foramen

and to allow access to the L5-S1 disc space to provide a working channel for interbody dissection and surgery. More proximal and lateral dissection is required if the L5 root needs decompression under the pars interarticularis, such as when there is a pars defect filled with hypertrophic fibrocartilage in association with a spondylolysis or spondylolisthesis (Fig. 21-2).

Once inside the canal it is essential to appreciate the position of the roots and dura at all times. A small layer of fat may cover the dura dorsally. The dural sac and traversing S1 root are medial to any working zone for discectomy or interbody work. The exiting L5 root has passed superiorly and laterally to the lumbosacral disc. If pathology about the exiting L5 root requires treatment at the lumbosacral junction, it is both superior and lateral to the flavectomy site for entry to the lumbosacral canal.

Epidural veins may be bountiful to the lateral and anterior regions of the canal, adjacent to the medial wall of the pedicle, and also to the posterior intervertebral body of L5 and S1. The vertebral body venous plexus communicates with the epidural veins anterior to the dural sac. The most effective way to prevent troublesome venous bleeding is to carefully position the patient before surgery, leaving the abdomen free from pressure, thereby avoiding engorgement of the epidural plexus.

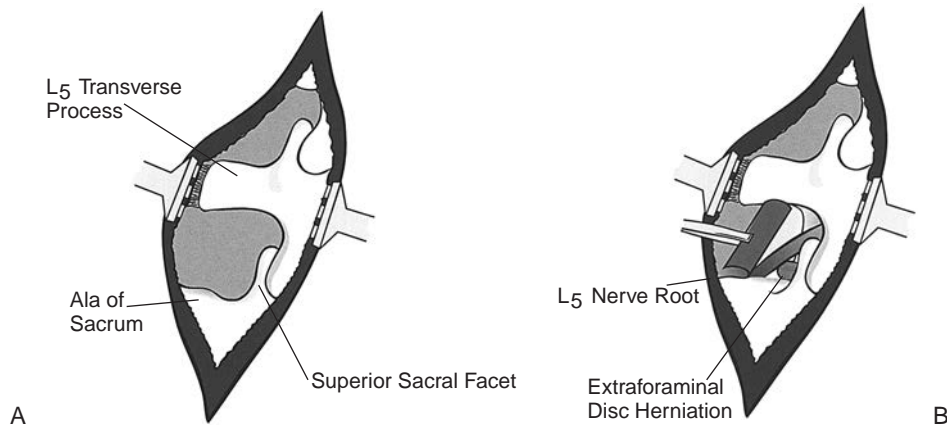

If epidural venous bleeding is troublesome during canal dissection, careful packing with Gelfoam soaked in thrombin or with neurosurgical patties is useful. Larger veins may be cauterized with bipolar diathermy after careful retraction of neural structures. Occasional venous ooze from a cut bone at the edge of a laminectomy field may require the use of bone wax.

### PARASAGITTAL APPROACH TO THE LUMBOSACRAL JUNCTION

Wiltse described the parasagittal approach to the lumbar spine (9), primarily for intertransverse fusion. It is particularly advantageous if surgery involves only posterolateral fusion without canal exploration. At the lumbosacral junction, in the presence of a high-grade spondylolisthesis, it can be very difficult to find and display the L5 transverse process in its forward slipped position. The Wiltse approach allows direct dissection on to the posterolateral structures with the minimum of muscle dissection (Fig. 21-4). Pedicle screws can be placed without excessive muscle retraction, a particularly helpful step at L5 where the pedicle is obliquely directed (10). This approach is also useful to treat the relatively uncommon far lateral disc herniation at L5-S1 and for excision of anomalous transverse processes that articulate with the sacrum and cause pain (Fig. 21-5) (11,12).

The approach is longitudinal and parasagittal between the multifidus muscle group medially and sacrospinalis laterally. Skin incision options include a midline longitudinal skin incision approach with bilateral parasagittal

**FIG. 21-4.** Diagrammatic approach of the Wiltse parasagittal approach to the spine. **A:** The Wiltse parasagittal approach demonstrating the lateral aspects of the superior articular facets and the L5 transverse process and ala of the sacrum. **B:** Removal of the intertransverse membrane demonstrates the nerve root and the site of a far lateral (extraforaminal) disc prolapse.

fascial incisions two fingers breadth lateral to the midline; bilateral skin parasagittal incisions over the intermuscular interval; and a transverse skin incision at the lumbosacral junction with vertical fascial incisions over the parasagittal muscle interval. Bone graft may be harvested through any of the skin incisions by subcutaneous dissection. The latter incision may be cosmetic, avoiding a longitudinal lower lumbar incision.

The intermuscular interval is 2 to 3 centimeters lateral to the midline, and allows a direct approach to the lateral aspect of the superior articular facets of L5 and S1 and the transverse process of L5 and the ala of the sacrum. The lateral border of the L5 pars interarticularis is tra-

versed by the posterior primary ramus of L5 and the posterior branch of the segmental vessels. The latter frequently require coagulation.

The parasagittal approach gives excellent visualization of the posterolateral fusion bed and the lateral superior articular facet and the transverse process. Far lateral disc herniations may be resected after the intertransverse membrane is removed from its attachment to the adjacent transverse processes. The L5 nerve root traverses obliquely over the posterolateral aspect of the disc before forming a lumbosacral trunk.

This parasagittal approach can be used to access the spinal canal with multifidus retraction, hemilaminectomy on the surgical side, and then dissection beneath the lamina on the contralateral side so as to perform medial facetectomy and root decompression on that contralateral side (13).

A posterolateral approach lateral to iliocostalis has been described as an alternative approach to the far lateral disc prolapse (14). This approach develops a plane between iliocostalis and the flank muscles, and then follows the most lateral branch of the posterior primary rami down to the nerve root in the foramen. It is an approach perhaps more useful in the proximal lumbar spine, above the posterior iliac crest, yet has been used at L5-S1.

**FIG. 21-5.** Axial magnetic resonance imaging scan of a right far lateral disc prolapse (arrow) at the lumbosacral junction causing L5 root symptoms. This herniation can be approached surgically via a Wiltse parasagittal approach with minimal bone resection. Attempts to approach this from within the canal require destabilizing facet joint excision.

#### ANTERIOR APPROACHES TO THE LUMBOSACRAL JUNCTION

Anterior approaches to the lumbosacral junction require an approach between the great vessels to the lumbosacral disc. Retraction of the iliac arteries and veins laterally gives the broad expanse of the lumbosacral disc, with only the median sacral artery and the presacral autonomic nerves coursing inferiorly across the lumbosacral disc. Decisions as to the approach to this disc depend on

a preference for a transperitoneal or retroperitoneal approach to the disc, and any requirement for dissection to include more proximal discs.

If only the lumbosacral disc requires surgery, then the transperitoneal approach offers a very direct approach and straightforward route to this disc. Division of the posterior parietal peritoneum allows direct display of the bifurcation of the great vessels, and the fine vessels and nerves that cross the disc (15). Obvious contraindications to this approach include acquired conditions resulting in extensive peritoneal adhesions.

The bifurcation of the aorta and inferior vena cava usually lie at the level of the L5 vertebral body, so the lumbosacral disc is approached between the bifurcations. Because the vena cava bifurcation is below and to the right of the aortic bifurcation, the vascular structure most at risk for injury is the left common iliac vein (16). Considerable variation exists in the relationship between the bifurcations and the body of L5 (17). When the bifurcation is proximal in relation to the spine there are occasions when the lower two lumbar discs can be approached through the bifurcation. At the other extreme, a low position of the vessels may result in a need to approach the lumbosacral disc lateral to the iliac vessels. In this latter situation, the iliolumbar vein should be divided to assist mobilization of the vessels.

The median sacral artery must be divided. Most surgeons advocate avoiding the use of diathermy about the presacral plexus over the front of the lumbosacral disc, for fear of the complication of retrograde ejaculation in male patients (15). Review has suggested that this complication is rare (18,19), yet it is prudent to cautiously isolate the presacral plexus and mobilize it to the side before approaching the lumbosacral disc (Fig. 21-6).

The lumbosacral junction also can be approached by a retroperitoneal method, with development of the retroperitoneal space, usually on the left side, allowing retraction of the viscera and display of the great vessels and spine. This is the approach required if the lumbosacral disc surgery is part of a combined procedure that involves surgery to the proximal discs.

The transperitoneal approach is best made through a vertical incision between the recti, with the incision located between the umbilicus and the symphysis. The parietal peritoneum is divided longitudinally, and with the patient in the Trendelenburg position, the abdominal contents are packed out of the way. This approach presents the posterior wall of the abdomen. Division of the posterior parietal peritoneum reveals the bifurcation of the aorta and inferior vena cava, and the lumbosacral disc between these structures. If the anterolateral disc region is to be exposed, the vessels must be carefully retracted to each side. The surgeon should make the incision low in the abdomen so that any instrumentation required for access to the lumbosacral disc can be performed with a direct view of the inferiorly directed L5-S1 disc space.

Approaches to the lumbosacral disc through a retroperitoneal route generally require a more lateral entry to the abdominal cavity. Approaches are either muscle-cutting or -splitting (19). Multiple descriptions of approach options exist, aiming to preserve abdominal wall muscle function (19–22). Incisions are horizontal or oblique along the line of the external oblique muscle, and placed at levels appropriate to allow access to the relevant discs. The deeper layers are either split or divided lateral to the recti. Most authors advocate avoidance of extensive longitudinal dissection lateral to the rectus abdominus, because of the risk of denervation of this muscle, yet this approach may yield a useful extensile approach that incorporates access to the lumbosacral disc along with several more proximal discs when extensive procedures are performed (20). In order to prevent possible denervation of the rectus, we have combined a paramedian longitudinal skin incision with a midline vertical incision between the recti, and a left-sided retroperitoneal dissection giving access to the lumbosacral junction, and combining this with access to the lumbar discs as high as L1.

Careful vascular retraction allows display of the lumbosacral disc. The adherent relationship between the great vessels and the lower lumbar vertebrae mean that

**FIG. 21-6.** Diagrammatic representation of the great vessel bifurcations overlying the lumbosacral disc, and the access to the disc with vessel retraction. **A:** Great vessels and presacral plexus overlying the lumbosacral disc. **B:** The lumbosacral disc after retraction of the presacral plexus and the great vessel bifurcations, and division of the median sacral artery.

**FIG. 21-7. A:** Lateral radiograph of a 20-year-old woman with a delayed diagnosis and presentation (because of pregnancy) of a posttraumatic lumbosacral dislocation. **B:** Postoperative lateral radiograph after anterior transperitoneal approach, extensive mobilization of the great vessels, resection of anterior sacral callus, discectomy, inferior L5 hemicorpectomy (to avoid distraction during vertebral reduction), and subsequent posterior approach with transforaminal interbody fusion with titanium mesh cages and posterior pedicle screw instrumentation. The anterior approach was transperitoneal, with extensive mobilization of the great vessels to allow display of the L5 and S1 vertebral bodies.

greater anterior displays of the L5 body or upper sacrum require much greater mobilization of the vascular structures. Although this is infrequently required, a vascular surgeon can provide a very good working area for more extensive anterior surgery (Fig. 21-7).

# Endoscopic Anterior Lumbar Procedures

Ensor E. Transfeldt and John N. Graber

---

Contemporary surgery of the lumbar spine is evolving into less invasive methods in an effort to decrease morbidity and hospital stay and speed up recovery and return to activity and work. The spine is enveloped by a variety of organs and muscles and traditional exposures alone have been frequently associated with a greater morbidity than many of the surgical procedures on the spine itself. Endoscopic techniques and image-guided surgery provide an exciting opportunity to provide minimal access to the spine. It is not intended to change the surgery, although many of the instruments and techniques have been modified to accommodate the endoscopic access. The indications for endoscopic access include surgery for trauma, tumor, infections, deformity, and degenerative conditions.

Laparoscopic- or endoscopic-assisted surgery is an alternative surgical approach to the spine rather than the development of a new operation. The development of this technique grew out of an interest in minimally invasive surgery. Initially, the approach was used for single-level anterior interbody fusions that evolved for use of interbody cage fixation and now has application for decompression, including corpectomies, débridement, and complex multilevel fusions and fixation. The indications for endoscopic procedures and the operation itself are the same as for any open procedure.

The laparoscopic technique requires an anatomic approach and the same attention to detail of the surgical technique and biology of fusion and healing as is needed with open approaches. Laparoscopic techniques are technically more demanding and present a different view of the anatomy than the conventional open approach. If the surgeon is unable to perform the operation through a conventional open technique, it is unlikely that he or she will be able to do it using an endoscope. The procedure requires a team approach with skill and experience, as well as a steep learning curve. Benefits include minimally invasive dissection of tissues, preservation of paraspinous musculature, decreased blood loss, shorter

hospital stay, and faster recovery. This needs to be weighed against potential disadvantages, including the need for different instrumentation with unfamiliar tactile sensations and indirect visualization.

The endoscopic exposure can be done with either gas insufflation or “gasless” technique. Each has its proponents. Gas insufflation techniques require gas seals and special trocars as well as special instruments to maintain intra-abdominal pressure. This changes many aspects of the surgical procedure. The gasless technique allows standard instruments, but has other limitations. Once access is achieved, specialized equipment may be required to perform the surgery and insert implants. These instruments frequently are expensive. They have longer shafts and less tactile feedback and are more difficult to control; thus, the procedure takes longer. As newer equipment, including motorized equipment is being developed this will be improved. Gasless approaches allow the use of conventional instrumentation. Anatomic considerations are different, too. Experience helps to determine where to retract and where pressure can cause injury.

Visualization is made possible by fiberoptics, allowing illumination and magnification through a camera. Display is usually on a flat two-dimensional screen, thus losing some three-dimensional perception. The technology does offer the advantage of magnification.

Minimally invasive open techniques, such as the mini anterior lumbar interbody fusion (ALIF), have been described and developed and offer an attractive alternative to endoscopic techniques. They have the advantage of being able to perform the procedure with standard instruments, more rapid exposure of the spine, and with comparable morbidity and benefit to laparoscopic access. Stand-alone anterior fusion and instrumentation, especially with cages has waned in popularity. Laparoscopic surgical approaches appear to offer less advantage if a more expensive posterior operation is also required. All of these factors need to be considered when planning one's approach to spine fusion.

## CLASSIFICATION OF ENDOSCOPIC ANTERIOR PROCEDURES

The major categories of laparoscopic surgery are:

- I. Transperitoneal
  - Gas insufflation
  - Without insufflation
- II. Retroperitoneal
  - Gas insufflation
  - Without insufflation
  - Endoscopic-assisted mini open

Anterior lumbar endoscopic surgery developed originally as an extension of the techniques of laparoscopic surgery for the abdomen by general surgeons. The two methods of endoscopic access used more widely for anterior lumbar surgery are transperitoneal with insufflation and retroperitoneal gasless approaches.

## TRANSPERITONEAL APPROACH

### History

Obenchain (1) described a laparoscopic approach for anterior L5-S1 fusion without instrumentation. Zuckerman et al. first described instrumented anterior lumbar fusions through a transperitoneal approach with insufflation in 1995 (2). Matthews et al. (3) and Regan et al. (4) reported the technique and preliminary results.

Subsequently, the clinical effectiveness of laparoscopic ALIF has been reported extensively (3–13).

Regan et al. (14) described 249 patients undergoing laparoscopic ALIF and compared these to a cohort of 591 consecutive anterior fusions, using the same device. It basically showed that there was a decreased hospital stay, decreased blood loss, increased operative time, but operative time improved with time and experience.

Lieberman (15) did a prospective study and found that the laparoscopic technique resulted in decreased operative time with experience. Mean blood loss was 105 cc and the operative time was 2 hours, but was reduced to 1.5 hours with experience. The postoperative stay was 4 days. Postoperative functional outcomes assessment clearly needs to be done in these types of studies.

Kleeman and Hiscoe (16) described a prospective study comparing laparoscopic ALIFs to traditional posterolateral fusions with pedicle screws. He found that the fusion and complication rates were similar. In the laparoscopic group, blood loss was reduced by 90%, the hospital stay reduced by 50%, and the patients had an earlier return to work with a faster functional recovery. All the studies do show that there is a steep learning curve.

The transperitoneal approach with insufflation does provide direct anterior midline access to the L4-5 and L5-S1 levels and occasionally to the C3-4 level. It becomes increasingly more difficult to employ transperitoneal endoscopic techniques for more superior levels because

of the sigmoid colon and inferior mesenteric artery. The major advantage of air insufflation is that it allows fairly rapid exposure of the lumbar spine, as well as assistance in “organ retraction” by the increased intra-abdominal pressure, which helps keep the loops of the bowel out of the working field. Visual interference by loops of bowel still occurs and must be dealt with by use of retractors. The working field is also larger and there is less bleeding with this technique than that of the gasless transperitoneal approach. This approach requires trocars with specialized diaphragms to prevent air leaks. Specialized instruments and implants are needed to adapt to the use of the trocars.

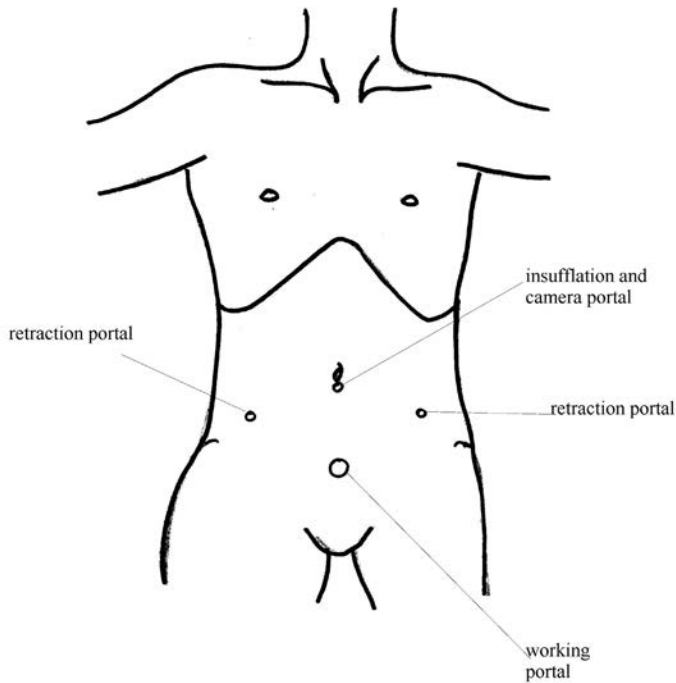

Instruments for the insertion of interbody cages were easily adapted to this technique. Trephine discectomies are used for removal of a cylindrical core of disc and a bone fold cage replaces the space. The disadvantage of this technique is that it results in a smaller surface area for exposure for bone fusion. Complete discectomy and preparation of the end plate is more tedious and difficult through trocars under conditions of insufflation. This approach has possible benefits for anterior-only surgery (e.g., stand-alone anterior cages). The addition of a more invasive posterior approach (e.g., for posterior fixation) eclipses the minimal invasiveness of the laparoscopic technique.

## TECHNIQUE OF TRANSPERITONEAL APPROACH WITH INSUFFLATION

### Positioning and Pneumoperitoneum

The patient is placed in the supine position with the arms by the side. The operating table is then placed in the steep Trendelenburg position. A lumbar roll under the patient's pelvis and lumbar spine is also placed in order to maintain lumbar lordosis, but also to facilitate use of a C-arm fluoroscope. The standard laparoscopic equipment used for this procedure includes a 0°, 10 mm telescope, camera lightsource, and insufflator. However, the use of angled viewing scopes offers advantage for more experienced surgeons. A 5 mm, 30° viewing scope has been our choice. The Trendelenburg position allows the bowels and the abdominal contents to fall in a cephalad direction.

A Veress needle is introduced supraumbilically into the abdomen in order to create a pneumoperitoneum. Pneumoperitoneum is created with carbon dioxide (CO<sub>2</sub>) gas insufflation. Alternatively, a supraumbilical or infraumbilical incision is made with the introduction of a Hasson trocar for use of the endoscope. In this technique, all trocars have special valves to seal the escape of gas from the peritoneum. Through the umbilical trocars, the pneumoperitoneum can also be created. The other portals are then made under direct vision. The location of the working portal, which is usually through an 18 mm trocar, is dependent upon the trajectory of the intervertebral space being fused, and this assessment is made from preoperative X-rays (Fig. 22-1).

**FIG. 22-1.** Typical port placements for transperitoneal access to the lumbar spine. Camera access through this site is typical and a working portal is made on the midline lower abdominal wall in the trajectory of the desired interspace. The lateral portals are used for dissection and retraction.

A 5 mm trocar is then inserted on each side, midway between the umbilicus and the pubis and lateral to the epigastric vessels. During the procedure, additional portals can be introduced if needed. The loops of small bowel are then placed into the epigastrium using special graspers. The location of the bifurcation of the great vessels is identified. The working portal is placed at a site on the abdominal wall in the interspace to be fused (Fig. 22-2).

### Exposure of L5-S1 Disc Space

Having identified the bifurcation of the great vessels, the posterior peritoneum is incised longitudinally below the bifurcation and blunt dissection is used to visualize the L5-S1 disc space and median sacral vessels. The median sacral artery and vein are then clipped and divided. The iliac vein and artery must be swept off the lateral aspect of the interspace with laparoscopic Kittner dissectors. Ongoing retraction of these vessels can be done through trocars or by passing Steinmann pins through the abdominal wall. Dissection should generally be done without the use of monopolar cautery to avoid retrograde ejaculation in males. The approach for discectomy will then depend upon the individual preference of the surgeon. Special instruments for doing discectomies, as well as special metallic working portals with reamers

**FIG. 22-2.** The location of the working portal on the abdominal wall is determined by the trajectory of the interspace as seen on lateral spine films.

for insertion of cages and bone material have also been designed (Figs. 22-3, 22-4A, B).

Fluoroscopy is used at this point to visualize depth of the discectomy and reaming, as well as insertion of implants. The laparoscope allows simultaneous visualization to ensure that vascular and other structures are not damaged and remain out of the working site.

### Technique for L4-5 Approach

The L4-5 disc space uses a similar approach, but the exact location of the dissection does depend on preoperative magnetic resonance (MR) images and computed tomography (CT) scans, which will help determine the location of the bifurcation. In the unlikely setting where the bifurcation of the great vessels is located above the L4-5 interspace, then the same dissection as already described will be used.

**FIG. 22-3.** Two sites of trephine partial discectomy are done on each side of midline on the L5-S1 disc space.

**FIG. 22-4.** **A:** Postoperative anteroposterior radiograph demonstrating side-by-side cage placement in the L5-S1 interspace. **B:** Lateral radiograph showing the cages in the L5-S1 interspace.

In most cases, the bifurcation is below or at the L4-5. The iliac artery and vein are first identified. Segmental vessels will also be identified, clipped, and divided and it is strongly recommended that the ascending iliolumbar vein be identified, clipped, and divided. These steps are important in mobilizing the aorta and the vena cava across the right side of the spine for adequate exposure of the L4-5 interspace. Percutaneous Steinmann pins can be placed to the vertebral bodies in order to assist with retraction or specialized retractors can be used through one of the working portals. Imaging with the C-arm of fluoroscope in two planes is necessary to ensure that implants are inserted centrally in the disc and to the correct depth.

#### **TECHNIQUE OF TRANSPERITONEAL APPROACH WITHOUT INSUFFLATION**

Maintaining a pneumoperitoneum requires the use of expensive special gas-sealing ports, as well as special instruments. The instruments need round shafts in order to accommodate the diaphragms. Albert Chin introduced the concept of a mechanical retraction device, the Laparolift (Origin Medsystems, Menlo Park, CA), which displaces the anterior abdominal wall and holds it up like a tent (17).

As a substitute for pneumoperitoneum, this system has a fan retractor that is inserted into the abdomen in a closed configuration through a 15 mm minilaparotomy incision and is then opened up. This fan retractor is attached to a powered hydraulic table-mounted device that provides the vertical lift and creates a working space.

The remainder of the portals, including the working portals and lateral portals, are similar to those described in the transperitoneal approach with insufflation. No gas seal however, is required. This allows use of conventional instrumentation and implants.

Before deploying the fan and applying lift, a finger should be introduced through the infraumbilical incision into the abdominal cavity and swept around to ensure no intra-abdominal adhesions are present. The fan retractor is then inserted and advanced in a plain parallel to the anterior abdominal wall. The fan blades are then opened and locked. Next, the retractor is attached to a sterile-draped lifting arm, which has previously been attached to the side rail of the operating room table. The retractor is then elevated using the hydraulic system of the lever arm, creating a "tent effect" by elevating the abdominal wall (Fig. 22-5A, B).

The endoscope is then inserted into the abdominal cavity through the fan insertion incision between the fan arms. This provides also provides an opportunity to visualize the arms of the fans to ensure that they have not entrapped any bowel or omentum. A force-limiting device is incorporated into the motor of the lifting arm to avoid excessive forces. The ancillary portals are then placed under direct visualization of the endoscope. The working portal is again strategically placed based on the trajectory of the interspace to be fused and gauged from preoperative X-rays. The ancillary ports are simple, rigid or flexible valveless sleeves, which are used simply to guide the insertion of instruments. It is possible with the flexible sleeves to introduce conventional curved and odd-shaped instruments into the abdominal cavity (Fig. 22-6A, B, C).

**FIG. 22-5. A:** Schematic drawing showing Laparolift (Origin Medsystems, Menlo Park, CA) with hydraulic arm, which is table-mounted and made to apply variable pressure to the anterior abdominal wall in a lifting fashion so as to create a space for visualization. **B:** Clinical photograph showing Laparolift (Origin Medsystems, Menlo Park, CA) in place with laparoscopic cannula placed through same portal as the Laparolift device. This is typically used for passage of the laparoscope.

**FIG. 22-6. A:** The L5-S1 interspace following complete discectomy. **B:** A femoral ring allograft has been prepared and passed through a working portal and is being placed into the L5-S1 interspace. **C:** The femoral ring allograft has been placed and appropriately recessed.

## RETROPERITONEAL APPROACH

### History

The retroperitoneal is a potential space that can be created by dissection in natural anatomic and fascial planes. Retroperitoneoscopy was first described in the literature for straightforward smaller urologic and gynecologic procedures (18).

Introduction of CO<sub>2</sub> insufflators improved visualization and working space in the retroperitoneum. Fibrous bands limited the usefulness of CO<sub>2</sub> dissection. Balloons were introduced in the 1990s as an alternative for retroperitoneal dissection (19–22). The retroperitoneal approach is more versatile (1,23). McAfee has used a combination of video-assisted thorascopic and laparoscopic methods.

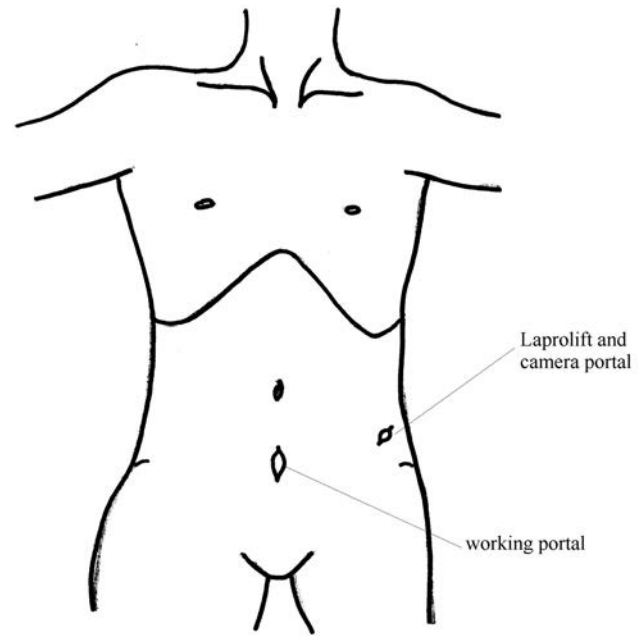

### TECHNIQUE FOR RETROPERITONEAL APPROACH WITHOUT INSUFFLATION

The spine lies in the retroperitoneal space, which is only a potential space that can be created by retracting organs. This potential space is created by manual dissection and by the use of the balloon dissection of tissue planes. The cavity is then maintained with a mechanical lifting arm, as well as a specialized retractor. The dissecting balloon has a core cannula for placement of the endoscope so that the balloon dissection is performed under direct vision. The abdominal peritoneum is dissected off the abdominal wall and acts as an envelope containing the abdominal organs out of the view of the spine. A strategically placed working portal allows access for standard open surgical instruments, thus simplifying the endoscopic access (Fig. 22-7).

The patient is placed in the supine position with a sandbag under the left flank. Two incisions are made. The left flank incision for the balloon dissector and endoscope is placed halfway between the 11th rib and the iliac crest in the anterior auxiliary line. The second incision for the working portal is strategically placed, depending on the level and trajectory of the interspace that is to be fused. This approach allows fusion of any of the interspaces from T12-S1.

The flank incision is approximately 15 mm in length and dissection is carried out to the lateral abdominal musculature. The external oblique, internal oblique, and transverses muscles are bluntly separated to expose the extraperitoneal pararenal fatty tissue. A finger is again introduced into this space as a blunt dissector.

The elliptical-shaped preperitoneal dissecting balloon cannula (PDB) (Medsystems, Inc., Menlo Park, CA) is then introduced into the retroperitoneal space and once the balloon is within the incision, the endoscope is introduced into the core of the dissection cannula. The balloon is then deployed and expanded using an inflation bulb. Through the inflated balloon it is possible to identify the line of the peritoneum and observe its dissection on the

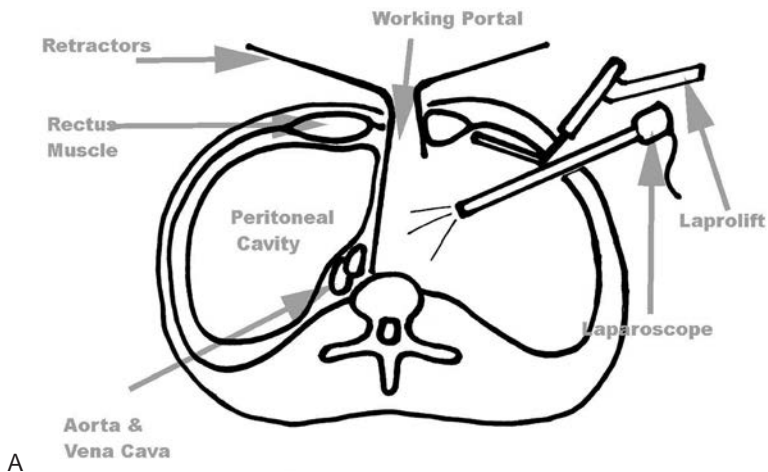

**FIG. 22-7.** Typical port placements for retroperitoneal access to the anterior lumbar spine. There are two portal sites. A midline site for access provides the working portal and a lateral site for a camera, Laparolift (Origin Medsystems, Menlo Park, CA), and retractors.

anterior abdominal wall. This line should be extended as close to the midline as possible to allow placement of the anterior working portal (Fig. 22-8A, B).

Once the retroperitoneal space has been developed and the peritoneum has been reflected from the undersurface of the anterior abdominal wall, the Laparolift retractor is inserted and a 10 cm long fan retractor (Laparofan, Medsystems, Inc., Menlo Park, CA) is inserted through the left flank incision and the arms of the fan are deployed under direct endoscopic visualization. The fan retractor is then attached to the mechanical lifting arm, which is then elevated again increasing the cavity. A flexible nonvalve trocar is then inserted behind the arms of the fan retractor, through which the endoscope is passed. A specialized balloon retractor can also be inserted through the same port or through the working port in the anterior abdominal wall. This retractor is only inflated once it has been introduced into the retroperitoneal space and is helpful in providing retraction of the peritoneum with its gastrointestinal contents.

The working portal is made through a 12 mm paramedian incision on the anterior abdominal wall, approximately 2 cm lateral to the midline. The level of the incision and the exact location may again depend on the level and trajectory of the interspace to be exposed. Through the para-midline skin incision, the anterior rectus sheath is identified and incised. The rectus muscle is retracted laterally, and the posterior rectus sheath is then incised and the peritoneum with its contents should have been

**FIG. 22-8. A:** Diagram demonstrating the concept of the retroperitoneal endoscopic approach with exposure of the anterior lumbar spine. A small skin incision is made anteriorly and the rectus muscle retracted laterally and after exposure of the preperitoneal space, the peritoneum bluntly dissected laterally and posteriorly and retracted to the right side. A Laparolift (Origin Medsystems, Menlo Park, CA) is placed anterolaterally through a small incision and a laparoscope is inserted through the same portal. The aorta and vena cava are identified and mobilized by clipping and diving the segmental vessels and then bluntly retracting them to the far side as well. **B:** Operating room photograph during retroperitoneal gasless exposure.

reflected across the midline, but this can additionally be assisted through this direct approach. Blunt dissection with the finger can again be used to sweep the peritoneum further off the abdominal wall if balloon dissection has not provided sufficient exposure.

The peritoneum contains the bowel, which can be retracted with inflatable or fan retractors. A supplemental balloon retractor may be introduced through the working portal as well, if necessary. The remainder of the procedure is then similar to that described in the transperitoneal technique. Exposure of the great vessels is necessary, and again isolation and retraction of these vessels will depend on the level of the interspace to be exposed. The L5-S1 interspace is again exposed below the bifurca-

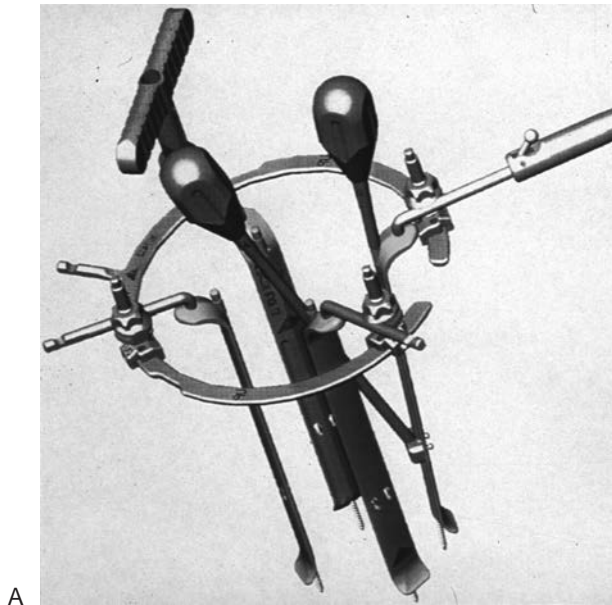

**FIG. 22-9.** Demonstrating the use of Steinmann pins to hold vessels and organs retracted. This technique can be employed in any of the endoscopic procedures discussed in this chapter. It could also be used for a mini anterior lumbar interbody fusion.

tion of the great vessels and the L4-5 and more proximal levels will require a retraction of the aorta and inferior vena cava to the right of the spine. Percutaneous Steinmann pins may then be used to maintain retraction of the great vessels (Fig. 22-9). Flexible endoscopic ports are introduced through the working portal. It is important to identify all the great vessels as well as the ureter to prevent injury. The sympathetic and parasympathetic presacral plexus are frequently approached from the side and elevated anteriorly with the great vessels. Lumbar segmental vessels should be clipped for more proximal lumbar spine dissection and at the L4-5 level the recurrent iliolumbar vein should also be identified and clipped. Conventional techniques for lumbar discectomy and preparation of the end plates can then be performed through this working portal.

Osteotomies and curettes of any shape or size can generally be used as well. In addition, a variety of intervertebral implants can be used, including screw-in cages, tap-in cages, cortical allografts, and prosthetic implants.

#### TECHNIQUE FOR RETROPERITONEAL WITH INSUFFLATION

There have been a few reports of a retroperitoneal exposure with insufflation dissection, but these were generally not widely embraced. In the anterior abdominal wall in the midline after exposure of the anterior abdominal wall, the section is carried down through the anterior and posterior sheath of the rectus muscle after retraction of the muscle itself. The posterior rectus sheath is then divided, exposing the extraperitoneal layer at the level of

A

B

**FIG. 22-10.** **A:** Endo-Ring (Medtronic Sofamor Danek, Memphis, TN) in which Steinmann pins and retractors are used. The Endo-Ring is stabilized to the table. **B:** Clinical use of an Endo-Ring.

the arcuate ligament. Dissection with a finger is used to free up the peritoneum from the abdominal muscle wall. An inflatable balloon may be used for dissection and a 10 mm scope introduced bilaterally.

#### **ENDOSCOPIC-ASSISTED MINI-OPEN APPROACH**

Videoscopic-assisted open surgery with an enlarged working portal is an option. Essentially, this opening could employ a mini ALIF exposure, which is enhanced with an endoscope (Fig. 22-10A, B). An endoscope may be used through a separate portal. The newer technology of flexible fiberoptics allows the use of a camera and light source through a thin, flexible scope passed through the mini ALIF approach itself. The working portal may be small so that the only person having direct visualization of the surgical field is the operating surgeon. The addition of a videoscope allows the assistant to provide assistance or retraction.

#### **COMPLICATIONS OF ENDOSCOPIC SPINE SURGERY**

Complications can be divided into those caused by the technique of laparoscopy and those caused by the dissection necessary to expose the spine. Typical laparoscopic injuries include intestinal or other organ puncture caused by port placement, port site bleeding or hernia, cardiovascular dysfunction due to the increased intra-abdominal pressure, and CO<sub>2</sub> subcutaneous emphysema (23).

Intraoperative complications include major vessel injuries, distal arterial embolus, bowel injuries, and bladder and ureter injuries. Postoperative complications

include deep vein thrombosis, ejaculatory dysfunction, and ileus.

The safest way to decrease complications in endoscopic spine surgery is to use an experienced laparoscopic general surgeon and to do careful preoperative planning. It is important to maintain good visualization, orientation, a maximum working space, and appropriate instrumentation.

It is vitally important to have an “emergency set” in the operating room for conversion to open procedures to minimize blood loss when vessel injuries occur (24). Conversion should not be considered a failure of the operation.

Specific complications are primarily related to exposure of the anterior lumbar spine, and usually include damage to vascular structures and the sympathetic plexus. Regan et al. (24) compared 249 laparoscopic patients to 591 open patients undergoing the same operation. Complications were comparable in both groups: 4.2% complications in the open group, 4.9% complications in the laparoscopic group. Device-related complications were increased in the laparoscopic group and these included disc herniations and no root irritation. Laparoscopic-related complications occurred in 4.7% of patients in the laparoscopic group and 2.3% in the open group. The authors point out that the laparoscopic procedures associated with a learning curve, but once mastered they believe this is an effective and safe procedure.

In Regan’s series (25), there was a reoperation for nerve root compression or irritation in four patients, retrograde ejaculation occurred in 4.8% of males, and conversion to open procedure for excessive bleeding occurred in two patients. Major complications occurred in 13.4% of the first 40 cases.

## VASCULAR INJURIES

The occurrence of vascular injuries should definitely be a primary concern for the use of the endoscopic approach. The literature seems to show a higher incidence of vascular injuries with endoscopic surgery than with the open approach. With the transperitoneal video-assisted approach the following vascular injury rates have been reported: McAfee (26) (1/22; 4.5%), Mathews et al. (3) (1/6; 17%), Zuckerman et al. (2) (2/17; 12%), Mahvi and Zdeblick (9) (2/20; 10%), Regan et al. (14) (5/58; 9.5%), Lieberman et al. (15) (1/47; 2.1%), Regan et al. (4) (6/24; 25%), and Escobar et al. (23) (2/34; 5.9%). In the video-assisted retroperitoneal gasless approach, reported vascular injury rates were as follows: Escobar (23) (0/30 patients), Onimus et al. (24) (0/20), and Thalgott et al. (27) (8/98; 8.1%).

Mini-laparotomy, an alternative minimal access approach has also been associated with vascular injuries. Escobar et al. (23) report two vascular injuries in 51 patients (4%), Mayer (28) reported none in 25 patients, Baker et al. (29) reported 18.4% in 19 patients. Vascular injuries have also been reported in traditional open approaches; however, the incidence appears to be much lower. Faciszewski et al. (30) reported only one major vessel injury in 350 anterior lumbar procedures (0.08%); Baker et al. (29) reported a 7.7% rate in 26 patients for this approach.

Vascular injuries may involve bleeding from small vessels or injury to the major vessels. It is important to ligate all bleeding vessels. Specialized equipment has been made for clipping vessels in surgeries where transperitoneal with insufflation approach is used. In the gasless approach, the conventional hemo-clips can be used. Injury to the major vessels requires immediate control of bleeding and if any difficulty is encountered, it is recommended to proceed with conversion to a conventional open approach as quickly as possible.

Anatomic variations increase incidence of vascular injuries and these occur most frequently at the L4-5 level. Zdeblick has described the incidence of vessel injuries and retrograde ejaculations at the L4-5 level. It is thought to be related to the vascular anatomy, especially the bifurcation of the aorta and the inferior vena cava (9,10,29, 31–34). Most often, the aorta and vena cava divide on the L5 vertebral body and exposure of the L4-5 disc is made above. However, at times the bifurcation is high and the L4-5 exposure more difficult. Sometimes it is easier to expose from below the bifurcation, but tears to the left common iliac vein are more common. We use the tenet that “it is easier to avoid bleeding than it is to stop it.” In this case bleeding is best avoided by gently retracting the vein and observing sites of fixation by large branches that will tear with further retraction. Preemptive clipping and dividing of the L4 segmental lumbar artery and vein and the ascending iliolumbar vein is prudent if not necessary.

## Retrograde Ejaculation

In Regan’s series (35) in which he compared open techniques with laparoscopic techniques, the authors report that retrograde ejaculation occurred in 9.4% of laparoscopic cases compared to 4.7% of open cases. Complications of retrograde ejaculation vary between 0.42% and 45% of cases (12,34,36,37).

Retrograde ejaculation results from injury to the superior hypogastric plexus, which controls bladder-neck closure during ejaculation. The incidence reported varies between 0.42% and 45% of cases (13,14,34,38). The majority of these are thought to be transient. Retrograde ejaculation has been reported with open ALIF in 0.42% to 22% of cases (13,14,34,39,40). In Flynn’s series (4,500 cases), 25% of patients reported retrograde ejaculation and had spontaneous resolution (39).

The superior hypogastric plexus lies in the retroperitoneal connective tissue anterior to the distal aorta and aortic bifurcation. It lies slightly to the left of the midline before dividing into the left and right hypogastric plexus. It is therefore most vulnerable with direct dissection from anterior and left-sided dissection. The retroperitoneal approach is usually done from the left side and is usually more posterior to the hypogastric plexus. This would explain why they are fewer patients with retrograde ejaculation (41).

Kleeman (16) recommends careful analysis of the vascular anatomy, especially at the L4-5 level and has classified the vascular anatomy at this area so that appropriate surgical approaches can be planned. This would reduce exposure on the side of the aorta and thus the hypogastric plexus. It is also recommended that bipolar cauterization be used.

## Loss of Orientation

Loss of orientation regarding the center of the disc and the midline has been described in laparoscopic transperitoneal techniques and it is more difficult to identify during the procedure under visualization of a scope due to limitation of the exposure and orientation of the camera.

Loss of orientation can lead to asymmetric graft/cage placement. If placement is too lateral, then foraminal encroachment or vessel injury is a risk. It is therefore important to use X-rays in two planes.

## Pseudoarthrosis

The most common cause for reoperation of interbody fusion cages is pseudoarthrosis. Salvage includes instrumented posterolateral fusions and frequent removal of the interbody device and replacement with autograft or allograft (42). This complication of pseudoarthrosis is seen more commonly in procedures where a trephine cylindrical core of disc was removed and it is recommended that a

complete discectomy would decrease the chances of nonunion. Studies using bone morphogenetic protein (BMP) have shown remarkably high fusion rates.

### **Iatrogenic Nerve Root Impingement**

This complication occurs due to disc herniation or retropulsed bone although it is not unique to endoscopic techniques, as described (23, 26). Neurologic problems including the radicular type of pain appeared to be unique to the transperitoneal insufflation technique. Regan et al. (14) reported six such cases in among 215 patients (2.8%), and a reoperation rate of 2.3% for nerve root decompression. Escobar et al. (23) reported six patients, all with transperitoneal insufflation approach for an incidence of 18% (6/34). All of these had undergone cylindrical trephine discectomies and insertion of a screw-in cage device. One of the six patients had an acute cauda equina syndrome secondary to an acute disc herniation requiring emergent posterior decompression, which resulted in full neurologic recovery. Four of the six patients with new onset radicular symptoms had spontaneous resolution of the symptoms within 6 months after the index procedure.

### **Postoperative Ileus**

Some degree of postoperative ileus is normal and to be expected after any surgery and anesthetic, even nonabdominal procedures (43). The degree of ileus is generally proportional to the extent of surgery, the amount of intestinal manipulation, the quantity of residual intraperitoneal blood or hematoma, the severity of physiologic disruption or infection, and the specific sensitivity of the individual patient. Paying strict attention to all these matters is important in avoiding extensive ileus. It has been shown that typical laparoscopic surgery is associated with less postoperative ileus than with comparable open procedures. The difference in ileus between mini-open spine access and the endoscopic exposure has not been specifically investigated. Unless the length of laparoscopic procedures can be decreased to that it compares with open procedures, it is unlikely to be much different.

### **Hernias**

Hernias at the trocar site are a rare complication and occur more commonly in transperitoneal than in retroperitoneal endoscopy (26). This can be avoided by placing a stitch in the fascia of all ports greater than 10 mm in size.

### **Ureteral Injuries**

The ureter is at risk for injury during anterior exposure of the lumbar spine and this may be higher with minimal access approaches. Escobar et al. (23) reported two

(2/135; 1.5%) injuries: one with video-assisted extraperitoneal approach and one with a mini-laparotomy approach. There have been numerous single case reports regarding ureteral injuries with anterior lumbar surgery. Faciszewski et al. (30) has reported one case in a series of 350 traditional open approaches for an instance of 0.3%.

### **Laparoscopic Conversion**

Conversion to an open approach may be due to vascular injury, abdominal adhesions, organ injury, or technical difficulties. Conversion should not be considered a failure.

### **COMPARISON OF MINI OPEN TECHNIQUE TO ENDOSCOPIC OPEN ALIF**

The advantages of minimally invasive techniques are intended to reduce postoperative morbidity and decrease hospital stay. There should be no increase in complications of the approach and the outcomes should be comparable to traditional open approaches. The mini open technique offers many of the same advantages as the laparoscopic techniques. Mayer (28) has been credited for describing this approach. In contrast to standard laparotomy, this technique uses a muscle-splitting approach, separating muscles in the direction of the fiber orientation.

Another technique or approach is a vertical midline incision and division of the left rectus sheath in a vertical direction. The rectus muscle is retracted laterally and the posterior sheath is incised vertically as well. The preperitoneal plane is developed bluntly, first laterally and then posteriorly. Thereafter, the operation continues as with standard lateral open approaches.

Zdeblick and David reported a comparison of 25 anterior laparoscopic approaches with 25 mini open techniques for L4-5 fusion. Paired threaded cages were used in both cases. Operating time, blood loss, and length of hospital stay showed no statistical difference. There was a lower rate of complications in the mini open group (4%) versus a higher rate (20%) in the laparoscopic group. This study shows that even in technically competent hands laparoscopy has no advantage to a mini approach (34). There was significant increase in surgical time in the laparoscopic group when two-level procedures were evaluated (180 minutes versus 160 minutes).

Escobar et al. (23) reported on a retrospective review comparing 135 patients undergoing four different approaches: transperitoneal video-assisted surgery with insufflation, retroperitoneal endoscopic video-assisted surgery, mini laparotomy, retroperitoneal approach, and traditional oblique retroperitoneal surgery. There was onset of new radicular pain or numbness not experienced by the patient prior to surgery in six patients (18%); all with transperitoneal video-assisted surgery using insufflation. Vascular problems occurred in five patients (3%

overall); two in the transperitoneal video-assisted group (5.9%) and three in the mini-laparotomy group (8.7% of the group). Retrograde ejaculation occurred in four of 50 male patients (8%); three in the transperitoneal video-assisted group (25%) and one in the mini-laparotomy group (2%). Two patients had ureteral injuries (1.5% overall); one each in the retroperitoneal endoscopic and mini-laparotomy groups. Conversion to open procedures was performed in seven patients (11% of the video-assisted procedures).

The reasons for conversion included two major vessel lacerations and five peritoneal tears in the retroperitoneal video-assisted group. Overall, the incidence of complications in the endoscopic group was consistent with the literature for video-assisted techniques; it was thought to be higher than for open techniques. Reports in the literature do not show any advantage of laparoscopic versus mini-open for anterior lumbar surgery (34, 40).

In reviewing the literature, it would appear that the laparoscopic insufflation technique is associated with a higher rate of vascular injuries. These injuries usually require conversion to an open procedure, thus prolonging surgical time. However, vascular injuries occur with all approaches and successful vascular repair was the standard outcome for the aforementioned cited literature.

## CONCLUSION

Minimizing access to the spine will remain a goal in spine surgery. Current techniques have some drawbacks, but should be regarded as a stepping stone to the future. There are good studies using prospective randomized controls, but no good outcome studies are described for fusion outcomes. These studies are necessary to establish superiority of any technique. The need for more minimally invasive techniques will always be there. The use of BMP and other materials to substitute for the patient's own bone have already reduced the need for harvesting of bone graft and lend themselves to easy implantation, thus making endoscopic techniques more attractive.

Evaluation of fusion by standard radiographs is unreliable. Thin section CTs with three-dimensional reconstruction are more reliable. CTs are usually performed when there is a suspicion of pseudoarthrosis or nonunion, or for evaluation of pain. There are few studies reporting CT evaluation of all patients in a laparoscopic cohort. Pellise et al. described a 16.6% fusion rate in patients fused with carbon fiber cages using laparoscopic techniques with complete discectomy (44). There was significant improvement in clinical outcomes however at a minimum follow-up of 2 years.

Fusion surgery comprises a large volume of spine surgery, and interbody fusions have become widely popular. The access for interbody fusions can be performed anteriorly or posteriorly. Interbody fusions through a posterior approach include a conventional posterolateral

interbody fusion (PLIF) or the recently popularized translumbar interforaminal fusion (TLIF) and should be considered less invasive if they save the need for additional anterior access. Dural injury and epidural scarring however are a high risk. Image-guided interbody fusions and instrumentation have been a further development of the minimally invasive posterior approach.

Malberg et al. (45) have described a direct lateral approach to the spine employing minimal access. A small incision is used and a working channel is docked on the disc space after a series of dilators have prepared access through a psoas muscle-splitting approach. A guide frame coupled with X-rays provides image guidance to accurate placement of the dilators and working channel. An electromyogram neuromonitoring system is used to provide increased safety from nerve injury to the lumbar plexus. However, there have been no extensive reports on the clinical experience with this approach.

We have found many of the techniques and limitations of endoscopic approaches to be cumbersome and most often use mini open procedures. This has been especially true in multilevel fusions. The balance of benefits and drawbacks will continue to tip in favor of endoscopic approaches as technological advances continue to eliminate the problems.

## CHAPTER 23

# Biology of Bone Grafting: Autograft and Allograft

Robert Gunzburg and Marek Szpalski

---

Spinal fusion is a well-accepted procedure for the treatment of disorders such as trauma, deformity, tumor, inflammation or infection, and common degenerative pathology. The aim of a spinal fusion is to eliminate the instability of the spine caused by these pathologies. By definition, spinal fusion means the achievement of a bony union between the involved vertebrae. In this chapter, the two types of bone grafts that are derived from natural bone (i.e., autograft and allograft) and are commonly used to achieve this goal will be discussed.

Far from being an inert structure, bone tissue can modify its mass and morphology in response to local and hormonal factors, thereby meeting the functional demands posed by various stimuli. Bone tissue also has the capacity for repairing itself without scarring. Bone grafting makes use of these core characteristics. In order to make optimal use of the clinically available graft options, the biology of bone, including its capacity for remodeling and self-repair, must be understood.

### BONE STRUCTURE AND PHYSIOLOGY

#### Bone Cells

*Osteoprogenitor cells* are derived from mesenchymal cells and line the internal and external surfaces of bone. These cells have the capacity for differentiation into osteoblasts and related cells (e.g., fibroblasts) that comprise connective tissue.

*Osteoblasts* are active secretory cells derived from osteoprogenitor cells. Osteoblasts form the extracellular bone matrix by secreting osteoid (unmineralized matrix) and regulate its mineralization through the exocytosis of alkaline phosphatase-containing vesicles. Osteoblasts form a tight cell layer at the bone surface and have a life span of up to 8 weeks. The production of matrix proteins by osteoblasts decreases considerably with time, yet osteoblasts remain in communication with each other and

with related cells (e.g., osteocytes) by elaborating cytoplasmic processes that penetrate surrounding osteoid and terminate in gap junctions, creating an extensive intercellular communication network.

*Osteocytes* are derived from osteoblasts and comprise 90% of all cells in the mature skeleton; however, these mature cells differ significantly from osteoblasts in their biochemical, morphologic, and functional characteristics. Osteocytes are smaller, contain fewer organelles and have a higher ratio of nucleus to cytoplasm. They elaborate numerous filopodia, enabling interconnections and cellular communication. Occasionally, osteoblasts become trapped in the extracellular matrix, resulting in stimuli sufficient for their transformation into mature bone cells. Ongoing studies of the mechanosensory properties of osteocytes suggest that they are the primary regulators of bone remodeling, orchestrating the formation and resorption of bone in response to mechanical demands (1).

*Osteoclasts* are multinucleated, highly migratory, phagocytic cells derived from monocyte/macrophage precursors. Osteoclasts are responsible for the resorption of fully mineralized bone through acidic decalcification of bone matrix, followed by lysosomally mediated hydrolysis of its organic components. An activated osteoclast can resorb bone matrix at the rate of 200,000  $\mu\text{m}^3$  per day. Interestingly, 7 to 10 generations of osteoblasts are required to form this same amount of bone matrix (2).

#### Molecular Basis of Bone Remodeling

The regulation of osteoblastic and osteoclastic activities is dependent on a complex network of signaling molecules, including steroid hormones, prostaglandins, and cytokines; the molecular basis of osteoblast-osteoclast interactions is the subject of intensive research. The differentiation of osteoclast precursors into osteoclasts requires the expression of osteoclast differentiation factor

(ODF; also known as RANKL, TRANCE, and OPGL), a membrane-associated cytokine produced by osteoblasts in response to osteotropic factors such as parathyroid hormone, vitamin D, and cytokines such as tumor necrosis factor (TNF) and interleukins (3–5). Osteoclast precursors express the cell-surface receptor RANK, which binds ODF through cellular interaction with osteoblasts, in turn leading to osteoclast differentiation. ODF also plays a key role in the activation of osteoclasts into mature bone-resorbing cells (3). On the other hand, a number of cell types have been shown to secrete a soluble decoy receptor, known as osteoclastogenesis inhibitory factor (OCIF, also known as osteoprotegerin, or OPG) that competes for binding with RANK, thereby inhibiting osteoclast formation and subsequent bone resorption (5,3,6). The balance of molecular-signaling events, such as those touched upon in this chapter, most likely determine the outcome of stimuli leading to either net bone formation or net bone resorption.

### Extracellular Matrix

Mineralization of osteoid, which consists primarily of collagen and ground substance, begins 10 to 15 days after its formation (7). Initially, mineral content rises rapidly to approximately 70% of its final amount; the remaining 30% being deposited over a period of several months. Even after mineralization is complete, bone still contains 25% organic matrix, including cells. Hydroxyapatite  $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_3]$ , the bone mineral, accounts for 70% of the final weight, while water accounts for the remaining 5%. Proteins, such as bone morphogenic proteins (BMP), growth factors, and cytokines, are embedded in the remaining extracellular matrix and play an important role in the mineralization process.

### Bone Architecture

The matrix of mature cortical and cancellous bone has a lamellated structure. The lamellae run parallel to the trabeculae of cancellous bone or concentrically surround the Haversian canal in cortical bone, forming the so-called osteon, or functional unit of cortical bone. Typically, the long axis of the osteon runs parallel to the long axis of the bone. Osteons evolve into secondary osteons or haversian systems by resorption of preexisting bone. Modeling is the process whereby bone is laid down onto a surface without necessarily being preceded by resorption. Osteoblastic activity that fills voids following osteoclastic activity is referred to as remodeling. In the adult skeleton, remodeling is the more active process and gives bone the capacity to adapt to changes in loading and metabolic stimuli. Indeed, bone tissue adapts to mechanical stimuli (compression and bending movements) according to Wolff's law, which states, bone is laid down

where stresses require its presence, and bone is absorbed where stresses do not require it.

### Osteoinduction

In addition to differentiated bone cells such as osteoblasts, osteoclasts, and osteocytes, bone and adjacent tissue contain a number of less differentiated cells. Osteoinduction is the process by which these less differentiated, yet pluripotent cells are stimulated to develop into the bone-forming cell lineage (8). A great deal of research has focused on BMPs as inducing agents. BMPs are soluble glycoproteins (9) released in response to trauma, such as a fracture, or physical stimuli, such as mechanical, electrical, or magnetic alterations. Although osteoblasts present at the site of injury participate in the healing of a fracture, bone and soft tissue injuries are the primary trigger for the transformation of undifferentiated cells into osteoblasts. The response to injury involves the coordinated involvement of vascular and nervous tissue, as well as the sensitization of precursor cells, leading to the production of growth factors by these cells and their differentiation into actively remodeling cell types (8,10). Insofar as bone formation necessitates an adequate blood supply, bone growth factors are also angiogenic (11).

### Osteoconduction

Osteoconduction is the appositional growth of bone on the three-dimensional surface of a suitable scaffold (12). This includes the ingrowth of capillaries, perivascular tissue, and osteoprogenitor cells and follows a highly organized, predictable spatial pattern (13).

### Osteogenesis

Osteogenesis is the process of bone formation through cellular osteoblastic activity. Osteogenesis is dependent upon osteoconduction as a matrix for the delivery of the osteoinductive factors needed for the differentiation of osteoprogenitor stem cells.

## SPINAL FUSION

Osseous spinal fusion remains the ultimate goal in the treatment of numerous spinal conditions. In spite of improvements in surgical techniques and instrumentation, failure (nonunion) has been estimated to occur in 5% to 35% of patients undergoing single-level fusions, and more frequently in patients undergoing multilevel fusions (14). The rate of clinical success does not necessarily parallel the rate of fusion. Numerous factors, such as mechanical stability, type of instrumentation, type of bone graft material, and individual biological factors, influence fusion rates.

Spinal arthrodesis can be achieved anteriorly by the fusion of vertebral bodies. This became a standard procedure in the cervical spine soon after Cloward first advocated this approach as a treatment for ruptured discs (15). At the levels of the thoracic and upper-lumbar spine, the approach is more difficult due to the presence of the rib cage and diaphragm; nonetheless, spinal interbody fusion can still be accomplished at these levels. Below the level of the conus, interbody fusion can be achieved either through an anterior or posterior approach.

Spinal arthrodesis can also be achieved posteriorly by bone bridging between the transverse processes and facet joints of the vertebrae involved in the fusion. All these fusion techniques are often combined with a variety of internal fixation devices. The choice of approach and technique depends on the type and location of the pathology and the surgeon's experience and knowledge.

## BONE GRAFTS

Bone is a commonly transplanted tissue. Bone grafts have to promote osteogenesis and, in some applications, may need to provide mechanical support. The morphology of the required graft depends on the type of fusion being sought. Cortical bone is typically used for fixation and support, whereas cancellous bone provides osteogenic potential (16). For cervical interbody fusion or reconstruction or for thoracic and lumbar interbody fusions and reconstructions, corticocancellous grafts are required to provide structural support. However, when stabilizing devices such as cages are being used, cancellous bone chips (particulate grafts) may be preferred. Particulate graft materials may also be preferred for posterior and posterolateral intervertebral fusions. Cancellous bone grafts have been used to stimulate bone regeneration under a variety of pathologic circumstances, including trauma, infection, congenital defects, tumor invasion, and degenerative diseases. For optimal remodeling of bony tissue, these grafts need to mimic the properties of cancellous bone, providing the interrelated characteristics of osteoconduction, osteoinduction, and osteogenesis.

Revascularization occurs more rapidly with particulate grafts than with structural grafts. Particulate bone grafts tend to remodel entirely with time, whereas structural (cortical) grafts have a tendency to retain their shape and contain a mixture of necrotic and viable bone (17). The process of creeping substitution, "the temporal and spatial repair activities whereby viable new bone replaces necrotic old bone" (18), is also thought to differ between cancellous and cortical allograft (17). Whereas creeping substitution of cancellous bone involves appositional bone formation followed by resorption, this order of events is reversed for cortical bone, with osteoclastic activity initiating the repair process (17,18). Such differences in the biology of remodeling between different

types of grafts may lead to significant differences in their clinical applications (17).

## Autograft

Autografts are grafts harvested from the patient at the time of surgery. The autograft is the "gold standard" by which the success of other grafting techniques is assessed. Spinal fusion is the most common reason for the harvest of autogenous bone (19). The main source of autograft is the iliac crest, yet other sources, such as the proximal tibia, the fibula, or a rib, can be used if the iliac crest is not an option. Iliac crest bone can be harvested in the form of cancellous bone chips, respecting the inner and outer tables of the crista, or as tricortical strut grafts, providing bone capable of structural support (Fig. 23-1).

Cancellous bone autografts offer a number of positive features including histocompatibility, which precludes the risk of graft encapsulation and associated inflammation. Moreover, autografts maintain viable osteoblasts and osteoprogenitor cells, and also confer osteoconductive and osteoinductive potential (19,20). The calcified matrix of mature bone and its organic components (e.g., collagen and ground substance) supply the graft with biocompatible, osteoconductive properties (19). Noncollagenous growth factors, the most thoroughly investigated of which are the BMPs, are primarily responsible for the osteoinductive capacity of autograft (21). The highly porous, trabecular structure of autogenous cancellous bone permits the ingrowth of blood vessels needed for bone growth and reduces the risk of complications from hypoxia. Finally, autograft does not pose a risk of disease transmission. Autograft procedures show a high rate of success for certain spinal fusions, such as posterior-cervical arthrodesis.

**FIG. 23-1.** Common types of iliac crest bone grafts. (From Sandhu HS, Grewal HS, Parvataneni H. Bone grafting for spinal fusion. *Orthop Clin North Am* 1999;30:686, with permission.)

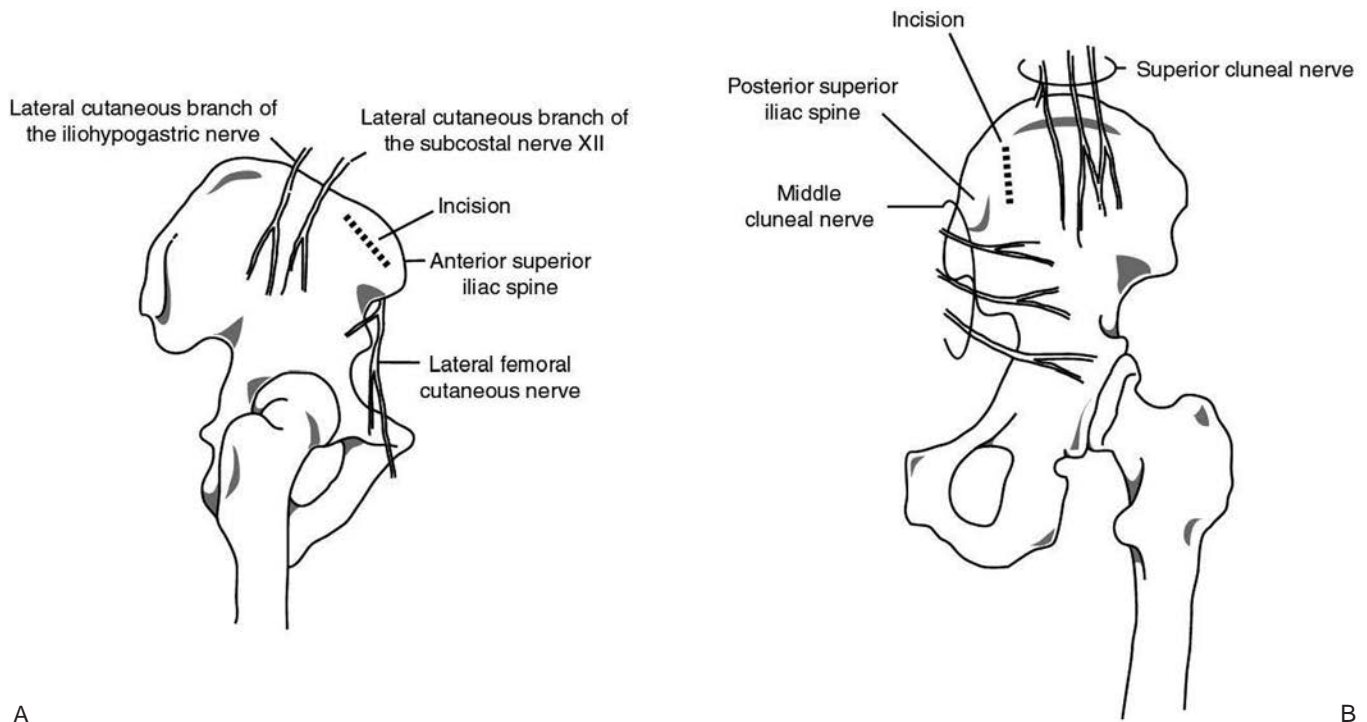

Autograft, however, has several drawbacks, including both surgical complications and its limited supply. Although transplanted donor cells most likely contribute to new bone growth, most of the osteogenic cells that repopulate the graft are thought to migrate from the fusion bed (12,19). Although transplanted cells are initially alive, graft viability is diminished when the graft tissue is separated from its blood supply (19), leading to ischemic or apoptotic cell death (12) and leaving behind only a bone mineral scaffold (22). Although morselization may increase bone graft surface area, leading to increased accessibility of osteoinductive and osteogenic factors (19), additional processing of autogenous bone may contribute to further decreases in cell viability. The surviving cells receive their oxygen and nutrients by diffusion only; thus, cells are likely to die from ischemia before the graft is vascularized. Rapid vascularization of the graft site may be impeded by fibrin formation in the autograft and by the packing procedure used to place the graft into the surgical site; this is particularly of concern within the innermost region of the graft. Autogenous bone viability is further complicated by donor variables such as the age, gender, genetic makeup, and physical health of the patient.

Harvest of autogenous tissue is associated with high donor-site morbidity and is estimated to occur in 10% to 39% of patients (23). Donor-site morbidity is dependent upon the surgical approach; for example, sacroiliac sub-

luxation and dislocation occur more frequently with the posterior approach, while infection occurs more frequently following the anterior approach (24). Minor complications are common and include superficial infections, temporary sensory impairment, and mild or transient pain. Acute and chronic pain at the donor site is commonly reported, but chronic pain may occur in over 25% of patients who undergo autograft procedures for spinal fusion (25,26). Although the precise cause of pain following iliac crest harvest is unknown, such pain is probably muscular or periosteal in origin and is often resistant to conventional treatment (26).

Major complications associated with the harvest of tissue from the iliac crest have been reported at rates of 0.7% to 25% (19). These include severe bleeding, herniation, serious infection, scarring, hematoma formation, injury to nervous or vascular tissue, pelvic fracture, and chronic pain at the procurement site (20,26–30). Skaggs et al. reported that after autogenous bone harvest, 15% of pediatric patients had complications that affected daily living activities (31).

Skillful surgical technique is essential to avoid injury to neurologic or vascular tissue during the harvest of iliac crest bone. Structures that often lie in the dissection path include the sciatic, iliohypogastric, lateral femoral cutaneous, and cluneal nerves, as well as the superior gluteal vessels (32) (Fig. 23-2). Damage to nervous and vascular

**FIG. 23-2.** Nervous tissue that can be damaged during harvest of bone from the iliac crest. **A:** Proximity of anterior incision (*dotted line*) relative to critical neurologic structures. **B:** Proximity of posterior incision (*dotted line*) to cluneal nerves.

tissue has been correlated with the amount of soft tissue dissected during the procedure (23). The superior gluteal vessels or the sciatic nerve may be damaged by dissection too close to the sciatic notch (33). In addition, chronic procurement-site pain may result from removal of bone in the sacroiliac region due to disruption of the sacroiliac joint (32). Since these iatrogenic complications may prolong recovery and increase disability, the surgeon should be thoroughly familiar with all anatomic structures that can be damaged during the harvest procedure (32).

Certain conditions require a relatively large amount of autogenous bone, limiting the applicability of autograft procedures. For example, obtaining adequate bone stock for multilevel spinal fusions may not be possible. Conversely, harvesting sufficient autogenous bone may be impractical in certain patient populations (i.e., older adults, children, or patients with metastatic carcinoma). Alternatives to autograft (e.g., allograft or composite materials) should be considered in these patients as well as in severely osteopenic patients (30). In patients with paralytic scoliosis and pelvic obliquity, posterior spinal fusion typically requires additional instrumentation to the pelvis, precluding harvest from the posterior ilium (34,35). An inadequate quantity of autogenous bone in a graft procedure may result in failure to fuse (36); supplementation of autograft with alternative graft materials should therefore be considered in cases that may lack sufficient autogenous bone stock.

## ALLOGRAFT

Allografts are grafts previously harvested from another patient, or from the patient undergoing surgery at the time of surgery. Allografts were originally used only when the amount of bone-graft material required for a procedure exceeded the amount of autogenous bone that could be harvested. Recent improvements in the quality, safety, and availability of allogeneic materials have resulted in substantial increases in the use of allograft; in the mid-1990s, allograft comprised nearly 35% of all bone grafts performed in the United States (37). The advantages of allograft include avoidance of donor-site morbidity, the potential for providing immediate mechanical support, and availability in a variety of forms and shapes for customized applications. Allograft can be used as a particulate or structural material. As mentioned, the histology of bony incorporation differs significantly between these two preparations.

Although the rate of success for anterior spinal-lumbar arthrodesis with allograft has been reported to be similar to that of autograft, the two methods do not produce equivalent results (38). Allografts can have variability in bone quality and pose a small, but definite risk of disease transmission and immunogenic reactions (39). Processing techniques to reduce these risks result in a loss of osteogenic potential due to the lack of donor cells (40)

and reduced osteoinductive potential (19), presumably due to the inactivation or removal of osteotropic factors such as BMPs. The risk of disease transmission is related to the rigor with which allograft tissue is processed. For example, transmission of human immunodeficiency virus (HIV) has been documented in fresh-frozen allograft, but not in freeze-dried allograft (38,41). Transmission of HIV and hepatitis are also dependent on how carefully donors are screened. For orthopedic applications, freezing, freeze-drying, and irradiation, sometimes followed by demineralization, are commonly employed methods for processing and preserving allograft materials (17,40). Although freeze-drying reduces immunogenicity and lengthens shelf life relative to fresh-frozen allograft, freeze-drying also reduces mechanical strength by up to 50% (19,38,42). In addition, freeze-dried grafts are incorporated into host tissue less completely and retain BMPs less efficiently than fresh-frozen grafts. In summary, graft strength, immunogenicity, risk for transmission of disease, and capacity for incorporation into the host site can vary widely with the technique used for allograft preparation. One additional disadvantage of allograft is its expense.

## Demineralized Bone Matrix

Brief mention should be made of demineralized bone matrix (DBM), a cortical allograft that is further processed by decalcification, leaving collagen, noncollagenous proteins, and growth factors (43). The resultant matrix lacks weight-bearing capacity (44) but has improved osteoinductive potential due to the presence of low-molecular-weight glycoproteins including BMPs (45). Decalcification of cortical bone increases the accessibility of these growth factors sequestered within the bone matrix (1,19,39). In addition, DBM is less immunogenic than conventionally processed allograft (43). Although DBM has been used clinically with proven success, the osteoinductive potential of DBM can vary, depending on the method of processing (46). Moreover, the effectiveness of DBM in promoting new bone formation is also related to the particle size of the matrix and to the method used for its sterilization (37).

## Autograft and Allograft in Combination

As mentioned earlier, allograft may be needed to supplement autograft when the volume of the latter is not sufficient for a given procedure. Munting et al. used freeze-dried, cortical allograft for the repair of large, anterior segmental defects of the spine involving at least one vertebral body and its two adjacent discs (47). In 41 of 67 cases, autogenous bone, obtained from either the resected vertebral bodies or the ribs, was used to fill the medullary cavity. None of the patients experienced infection, transmission of disease, or long-term mechanical

graft failure over the follow-up period, which averaged 31 months. Fusion was reported to have been obtained reliably. The authors noted that the use of autograft in the medullary cavity promoted successful fusion by providing a large surface area for load transmission at the graft-host interface.

### Comparison of Autograft and Allograft

Successful incorporation of bone graft depends on the quality and quantity of graft material as well as host physiological responses. The graft material requires osteoconductive, osteoinductive, and osteogenic elements in order for successful new bone growth to occur. Since autogenous bone supplies all three of these items, it is generally considered superior to that of allograft. Moreover, autograft has produced less variability in clinical results. As observed by Ehrler and Vaccaro, two primary indications exist for the use of allograft bone: insufficient autograft and the requirement for immediate structural support (38).

In addition to being only weakly osteoinductive and devoid of osteogenic cells, allograft typically induces an inflammatory reaction in the host, thus producing an inflammatory response that may be an important contributor to graft failure (38,48,49). Indeed, allograft may induce a robust inflammatory reaction immediately after transplant, resulting in capillary thrombosis, thus further slowing revascularization and osteoinduction (38). This leads to tissue necrosis, comprising up to 50% or more of the graft (38). Animal studies suggest that the host immune response is specific to donor antigen and consists of killer/suppressor T cells, which are likely mediators of graft rejection (48). The human immune reaction to allograft bears resemblance to the immune reaction in animals (50), resulting in a rate of sensitization (67%) that is higher than that seen after blood transfusion (12% to 50%) (51). Immunologic factors that mediate rejection of foreign material share common bone-marrow-derived precursors and cytokines with the factors responsible for remodeling of bone; this may help explain the deleterious interaction between the two systems (48). In a study of 29 patients who received allograft, those who lacked sensitization to class II antigens achieved a more satisfactory clinical outcome compared with patients who exhibited such sensitization (50). This result provides evidence for a causal relationship between immunogenicity and less satisfactory outcome.

The rate of incorporation of graft material is determined by several factors, including anatomic site, size of the graft area, and size of the graft (12,22). Incorporation of allograft is qualitatively similar to that of autograft but occurs at a slower rate and with more variable results. The variable amount of inflammation arising from allograft procedures may be largely responsible for these differences. However, the weak osteoinductivity of allograft

may also be a contributing factor to its slower rate of incorporation relative to autograft. Demineralization of allograft material improves osteoinductivity. Pals and Wilkins have reported excellent functional outcomes with DBM in treating giant bony tumors (52); other authors, however, have reported variable efficacy in promoting bone induction (43).

Autograft has been used successfully in posterior cervical, thoracic, and intervertebral fusion procedures (e.g., achieving adequate fusion in over 90% of patients receiving posterior cervical fusions) (19), but less successfully in posterolateral lumbar fusion procedures, with some studies reporting adequate fusion in less than 60% of such surgeries (19). The success rate for posterolateral lumbar fusion is even lower when allograft is used alone or in combination with autograft (38). Success rates for anterior spinal lumbar fusions with allograft are comparable to autograft (38). High rates of success have also been reported for allograft posterior lumbar interbody fusion procedures (38).

Allograft has been shown to be useful as bone-void filler since it provides early structural support without donor-site morbidity (50). Perhaps the best indication for allograft is in adolescent patients undergoing scoliosis correction and fusion (19). In one study, 40 patients with idiopathic scoliosis who underwent corrective surgery were treated with either femoral head allograft or autograft from the iliac crest. Successful unions were obtained for all patients in both groups. Interestingly, the group treated with allograft experienced reduced postoperative pain relative to the group treated with autograft (53).

### CONCLUSION

Spinal fusion is a common procedure for treating trauma, infection, congenital malformations, tumor growth, or degenerative diseases that threaten bone integrity. The vast majority of spinal fusion procedures rely on bone grafting techniques that support bone remodeling by providing osteogenic potential and, in some cases, mechanical support. Autogenous cancellous bone is the "gold standard" for bone graft materials, providing a matrix for osteoconduction, growth factors for osteoinduction, and osteoprogenitor cells for new bone formation. Autograft has several disadvantages, however, including limitations in the quality and quantity of bone available, and, most significantly, morbidity associated with the procurement site, usually the iliac crest. Complications of iliac crest harvest can occur in up to 25% of patients and may lead to prolonged recovery time and long-term morbidity.

The popularity of allograft has increased over the past few years due to improved safety, availability, and the potential for customizing allograft materials to specific applications. However, allograft has several drawbacks. Like autograft, allograft exhibits variations in the quality

of tissue used for transplantation. Allograft also has a finite risk of transmitting disease and producing an immunogenic response in the host. In order to avoid these risks, allograft is extensively processed, resulting in reduced mechanical strength and osteoinductive potential. These characteristics probably affect clinical results obtained with allograft, resulting in less consistent surgical outcomes than are obtained with autograft. In spite of improvements in modern technology and instrumentation, the rate of failure (nonunion) of spinal arthrodesis remains relatively high, particularly in cases involving multilevel fusions. Insofar as fusion rates are related to factors such as mechanical stability and type of bone graft material, improvements in fusion rates may depend on further innovations in bone graft technology, including the use of autograft/allograft combinations and the development of composite materials that provide the scaffold and biologic stimuli necessary for successful bone remodeling.

# Bone Graft Substitutes in Spinal Surgery

Anis O. Mekhail and Gordon R. Bell

---

Bone grafting is a prerequisite to obtaining a solid spinal fusion. Bone grafting can also be used for reconstruction of spinal defects caused by infection, trauma, or tumors. Autogenous bone graft is still the gold standard for augmenting spinal fusion. However, autogenous bone graft has significant limitations, including donor site morbidity and limited supply (1–5). The limitation in providing functional shapes, the increased operative time, the blood loss, and the possible need for transfusion are additional problems to be considered.

Although allograft is sometimes an attractive alternative to autograft, it has its own limitations and problems. These include loss of biologic and mechanical properties during its processing (6–8), the risk of disease transmission (9–13), immunogenicity (14,15), cost, and religious concerns. In general, allograft is associated with slower fusion rate, greater graft resorption, and increased infection rate when compared to autograft. This is especially true in lumbar intertransverse fusions and multiple-level anterior cervical fusions (16,17).

Despite the advances in spinal instrumentation, the incidence of nonunion has remained unacceptably high (10% to 40% without instrumentation, 10% to 15% with instrumentation) (18–25). Because of the limitations of autografts and allografts, scientists have sought to develop bone graft substitutes. In order to understand the value of the different bone graft substitutes, it is important to appreciate the different properties of graft materials that contribute to fusion (26,27). The ideal bone graft substitute should possess all the properties of autogenous bone graft, which include osteogenicity (the ability to directly produce bone by viable osteogenic cells), osteoinductivity (the ability to stimulate undetermined osteoprogenitor stem cells to differentiate into osteogenic cells and to induce the osteoblastic pathway even in a nonbony location), and osteoconductivity (the ability to provide a passive porous scaffold to support and direct new bone formation by allowing ingrowth of neovasculature and the infiltration of osteogenic precursor cells) (28). Bone graft substitutes should also be biocompatible,

bioabsorbable, be easy to use clinically, be cost-effective, provide the appropriate structural support required depending on the clinical situation (block form as well as granular), and be without risk of disease transmission. A composite graft (a mix of two or more graft materials) combines an osteoconductive matrix with bioactive agents that provide osteoinductive or osteogenic properties in order to closely replicate or supersede autograft properties. The bone graft substitute can be used as an extender if less bone graft is co-mixed and it can be used as an expander if the total volume of the mixture is increased, in an effort to increase the likelihood of bone healing. The bone graft substitute can replace bone graft if it can affect bone healing without adding bone.

Attaining spinal fusion does not only depend on the type of graft material used but also on several local and systemic factors, which include biomechanical stability and loading, blood supply, graft recipient site preparation, recipient bone pathology, nutrition, radiation, drugs, smoking, and several systemic diseases. These factors are discussed, for the most part, in Chapter 23. With all these factors taken into consideration, the basis of spinal fusion is simply bone formation, in an osteoconductive medium, by osteoprogenitor cells, which are induced by osteoinductive agents. However, for this scenario to occur, optimal local and systemic factors need to be present. The success of spinal fusion also varies depending on the location of the arthrodesis itself along the spine, and the biomechanical environment influencing the spinal fusion (posterolateral intertransverse process, anterior interbody, anteroposterior combined, presence or absence of internal fixation).

Differences in species used may also play a role, as they may heal differently and their spines are subjected to different loads. Animal models of spinal fusion should be evaluated with great caution. Structural grafts used for obtaining interbody fusion are located between two flat bones and are subjected to compressive loads, whereas graft materials used for posterior and posterolateral fusions are not structural, are surrounded mostly by soft

tissue, and heal under tension loads. Also, the addition of instrumentation plays an important role in the success of fusion. Instrumentation adds to biomechanical stability and can affect the type of load applied, such as allowing a facet joint fusion to occur under compression rather than tension (29).

## OSTEOCONDUCTIVE MATERIALS

### Ceramics

The mineral phase of bone comprises approximately 60% to 70% of its dry weight (28). This carbonated calcium phosphate apatite mineral, termed *dahllite*, contains 4% to 6% carbonate by weight and small amounts of sodium, magnesium, and other trace elements (30). The structural integrity of bone, especially its compressive strength, directly depends on the state of the mineral phase. It has been demonstrated that the chemical structure of the substrate is vital to its observed osteoconductive properties. Ideally, a bone graft substitute would have a similar mineral composition and structure.

Because ceramics do not normally exhibit osteogenic or osteoinductive properties, when used alone they are dependent on local host tissues for osteoprogenitor cells and osteoinductive factors. When loaded with a source of osteogenic cells, such as autogenous bone or bone marrow, ceramic scaffolds facilitate cellular adhesion, support vascular ingrowth, and promote new bone formation (31).

The advantages of biodegradable osteoconductive ceramic bone graft substitutes include the availability in unlimited quantity and no donor site complications or infection risks. For synthetic materials to be useful *in vivo*, they must be compatible with surrounding tissues, be chemically stable in body fluids, have compatible mechanical and physical properties, be able to be produced in functional shapes, be able to withstand the sterilization process, have reasonable cost, and have a reliable quality control (32). Calcium phosphate, for the most part, possesses these properties (33–36). Although some inert metals, such as titanium and cobalt chrome, and some ceramics, such as aluminum oxide, can provide passageways for bone incorporation, bone does not directly bond to and proliferate along their surfaces. On the other hand, bone forms directly on the surface and chemically binds to bioactive osteoconductive ceramics. Moreover, the bone grows three-dimensionally along the ceramic's surface.

The most commonly used ceramics in bone surgery are calcium phosphates, which include coral-based or synthetic hydroxyapatite (HA) and tricalcium phosphate (TCP). They have a high degree of biocompatibility with host tissue (33,37) and they are brittle materials with low fracture resistance and variability in their chemical and structural (crystalline) composition (27). Optimal interconnection between pores (connective porosity

greater than 100  $\mu\text{m}$ ) and a pore size of 100 to 500  $\mu\text{m}$  have been demonstrated to be essential for osteoconductivity (38,39). This is based on the three-dimensional interconnection between the lacunae in the bone that provide intercellular communication. Different preparative methods of ceramic bone graft substitutes lead to either a compact or a porous material. Greater crystalline formation and material density result in greater mechanical strength and resistance to dissolution with long-lasting stability. The poorly interconnected porosity created in artificially created ceramics retards normal rate of bone healing and remodeling required to obtain optimal mechanical strength. In contrast, an amorphous ultrastructure and greater porosity enhance interface activity and bone ingrowth, but they also enhance biodegradation of the implant (33).

Commercially available HA is relatively inert and biodegrades poorly (33,40,41). Nonresorbing materials may interfere with remodeling, create a stress riser, and impede the accretion of strength of the fusion mass (33). Conversely, ceramic TCP undergoes biodegradation within the first 4 to 8 weeks of implantation, which may be too early for optimal fusion mass healing (33,42). Biphasic ceramics, with an optimized ratio between HA and TCP may increase the mechanical strength or the degree and speed of resorption (43–47).

Natural ceramics derived from sea coral were first recognized by Chiroff et al. to have morphologically better interconnective porosity than artificially created HA, and with a structure similar to bone (48). Because the implant material is not coral but is derived from the mineral content of coral, the implants are called coralline. Coral is composed of 97% calcium carbonate in the form of aragonite. Coralline implants can be manufactured using one of two processes. The first is using natural coral in the calcium carbonate form (Biocoral; Inoteb, Saint-Gonny, France) after removing the organics and sterilizing with radiation. Biocoral is available as blocks and in granular form. The other process is replamineform (involving a hydrothermal exchange reaction), which converts delicate coral calcium carbonate into mechanically superior HA (39,49). Because this is a solid-state reaction, the inter-connected porosity is perfectly preserved (50). Two genera of stony corals are used: *Porites* and *Goniopora*. The exoskeleton of genus *Porites* is similar to cortical bone while that of *Goniopora* is similar to cancellous bone. Pro Osteon or Interpore porous HA (Interpore Cross International, Inc., Irvine, CA) are trade names for coralline HA. The number following the trade name designates the nominal pore diameter. Pro Osteon 200 HA is derived from *Porites* and has a pore diameter of 200  $\mu\text{m}$ , while Pro Osteon 500 HA is derived from *Goniopora* and has a pore diameter of 500  $\mu\text{m}$  (50).

Coralline implants are extremely biocompatible with promising results as a bone graft substitute to augment or replace autogenous bone graft (33,51–54) or as a part of

a composite with an osteoinductive bone protein (55). However, the poor bioabsorbability of the HA can still effect poor bone remodeling. The alteration of the coral processing with a partial thermoreaction, where only 20% of the calcium carbonate is converted into HA, has been found to improve its bioresorbability (18,56). The HA layer delays the resorption of the underlying calcium carbonate to achieve a controlled rate of graft resorption. Bucholz et al. have noted that for invasion to occur, the coralline implants must be rigidly stabilized and in close apposition to the host bone (51).

Endobon (Merck, Darmstadt, Germany) and Pyrost (Stryker Howmedica Osteonics, Rutherford, NJ) are macroporous HA products derived from exposure of cancellous bovine bone to high temperatures. OsSatura porous-coated HA (IsoTis NV, Bilthoven, The Netherlands) is a porous calcium phosphate scaffold with a biomimetic coating: a first generation tissue-engineered product (57). Its surface structure resembles that of natural bone, which makes it osteoconductive. It is in the form of small granules with favorable handling characteristics.

Generally, TCP has inadequate porosity with a small grain size, and rapid dissolution that makes it a poor bone graft substitute. However, Vitoss (Orthovita, Malvern, PA) is an ultraporous formulation of  $\beta$ -TCP, with a broad range of pore size (1  $\mu$ m to 1 mm) and interconnected porosity. The pore structure wicks blood, marrow, and cells. The material mimics human cancellous bone and is supplied as morsels or dowels that can be used as graft extenders in spinal surgery (58–60).

Emery et al. studied anterior interbody fusion in the thoracic spine of dogs, using autologous tricortical iliac crest bone graft, HA ceramics, calcium carbonate and a mixture of HA and TCP (45). All fusions were performed using anterior spinal instrumentation. Autologous bone graft was the most effective biomechanically and histologically. The same authors, in another study, found that autologous bone graft was also significantly better than calcium carbonate ceramics when combined with internal fixation (29). Although fixation did not statistically improve the biomechanical properties of ceramic fusion segments, it had a profound beneficial effect on the ability of the ceramic to be revascularized and remodeled.

Toth et al. assessed the effect of porosity of ceramic in a goat anterior cervical spine fusion model (61). Autograft was compared to 30%, 50%, and 70% porosity implants of 50:50 HA: $\beta$ -TCP. All of the tested ceramic implants performed equal to or better than autograft iliac crest bone at 3 and 6 months. The more porous implants had a higher union rate early on, but also had a higher incidence of graft fracture. Overall fusion rates were 67% for the ceramic implants and 50% for autograft. The relatively low fusion rates in all groups were likely due to excessive neck motion in the goat; however, these low fusion rates put into question

the ability of this model to be validly extrapolated to human anterior cervical fusions.

Posterolateral intertransverse lumbar fusion has been studied mainly in sheep (62). Some authors demonstrated better results with autologous bone when compared with different ceramics (43,56), others found similar results in terms of fusion rate when using coral *Porites* (calcium carbonate), a combination of HA and TCP, or resorbable coralline HA (46,63).

Baramki et al. evaluated the efficacy of porous HA granules in achieving posterolateral lumbar fusion in a sheep spine fusion model (56). Bisegmental instrumentation was performed using either no graft material, autologous bone, HA alone, or an HA/autograft composite in a 1:1 ratio. The radiographic images were difficult to interpret because of the radiodense interconnected porous HA granules. According to mechanical stability criteria, the fusion rate for the different groups was as follows: 100% (14/14) for the autologous bone group, 72% (10/14) for the bone/interconnected porous HA group, 50% (7/14) for the pure interconnected porous HA group, and 15% (2/14) for the sham group.

Delecrin et al. showed the influence of the fusion site microenvironment on incorporation of ceramic and new bone formation in a canine posterior lumbar fusion model (64). They evaluated bone growth into a macroporous ceramic implant in an interlaminar fusion site and a posterolateral intertransverse fusion site, using block HA/TCP (60%/40%) composite as a graft material. The percentage of newly formed fusion bone was significantly higher at the interlaminar fusion site compared to the intertransverse site, where decorticated bone in the fusion bed was scarce. For both locations, the highest amount of newly formed bone was observed in the area of close contact between ceramic and decorticated bone, and the lowest was observed in central areas. These results demonstrated the deficiency of osteoinduction properties of the graft, and a consequent reliance on bone growth induction, with the decorticated bleeding bone in the fusion bed serving as a source of stem cells and osteogenic factors.

Zdeblick et al. evaluated the efficacy of porous coralline HA as a substitute for autogenous or allogenic bone graft following multilevel anterior cervical discectomy in a goat cervical spine fusion model (65). They noted significant rates of implant collapse with bone graft substitute at 12 weeks but there was excellent biologic compatibility with good early creeping substitution of the graft by host bone. The concomitant use of an anterior cervical plate with the graft prevented extrusion and led to graft incorporation rates comparable to the autogenous bone group and superior to the allograft bone results. Mechanically, however, while the HA and allograft groups were comparable, they were significantly inferior to the autogenous graft group, leading to the early collapse of the fusion mass.

Clinically, ceramics have been mainly used as bone graft extenders with autologous bone, especially in fusion with long instrumentations (66–68). Ceramics are regulated by the Food and Drug Administration (FDA) as devices. Pas-sati et al. used a combination of HA and TCP with autolo-gous bone in 12 adolescent patients. All patients fused clin-ically and radiologically (68). Histologic analysis performed on specimens from two of these patients showed *de novo* bone ingrowth into ceramic pores. How-ever, because these cases were instrumented posterior tho-racic spines for adolescent deformities, the healing envi-ronment might have been less challenging than posterior lumbar intertransverse fusions in adults. Similarly, Rans-ford et al. compared 170 cases of posterior spinal fusion to treat idiopathic scoliosis using a synthetic porous ceramic (Triosite [Zimmer S.A.S., Cedex, France]) with 171 cases of autogenous bone graft in a prospective randomized study (69). Their results indicated no significant differ-ences between the groups. In a prospective study of 32 patients treated with single-level posterolateral fusion using a biphasic calcium phosphate ceramic implant mixed with locally harvested bone, the overall rates of solid con-struct were 97% with clinical improvement in all but one case (70). However, there was a high rate of graft resorp-tion, and poor fusion mass was evident on radiographs. The authors believed that the reason for a small fusion mass could be attributed to the tensile forces placed across the graft and the inferior supply of osteogenic factors as com-pared with massive autologous graft.

In patients undergoing anterior cervical interbody fusion using cages filled with coral HA, Thalgott et al. demonstrated a high fusion rate (71). McConnell et al. compared tricortical iliac crest bone graft to Pro Osteon 200 (coralline HA) in a prospective randomized study, of 29 patients, for anterior cervical interbody fusion with plating (72). There was no significant difference in clinical outcome and fusion rate. However, significant graft settling occurred in 50% of the HA grafts and 11% of the autografts ( $p < .009$ ).

Other potential applications for ceramics is their use as mineral bone cement to augment osteoporotic vertebral compression fractures or pedicle screw fixation (73). The Norion Skeletal Repair System (Norion Core, Cupertino, CA) is a resorbable calcium phosphate cement that is composed of a combination of monocalcium phosphate, calcium carbonate, and  $\beta$ -TCP in a powder form and a solution of sodium phosphate, mixed into an injectable paste. Under physiologic conditions, the material hardens within 10 minutes, through precipitation, into dahllite (carbonated HA) in a nonexothermic reaction. The chem-ical composition and crystallinity of the material are sim-ilar to that of the mineral phase of bone. It also undergoes the same *in vivo* remodeling as normal bone.

Alpha-Bone Substitute Material (ETEX Corp, Cam-bridge, MA) is a poorly crystalline (mimics mineral phase of bone) calcium phosphate cement with favorable absorp-

tion and osseointegration characteristics and easy intraop-erative handling characteristics (74–76). It is hydrated with saline to form a workable paste that hardens within 20 min-utes at physiologic body temperature and can be prepared to harden to a variety of compressive strengths (5 to 40 milli-Pascals [mPa]). The setting reaction is endothermic, avoiding thermal damage. This substance appears to be suited to incorporation of antibiotics or other proteins, such as bone morphogenetic proteins (BMPs).

### Calcium Sulfate

The first internal use of calcium sulfate as gypsum (plaster of Paris), to fill bony defects was reported in 1892 by Dressmann (77). Calcium sulfate is biocompatible and when it dissolves it produces an acidic microenvironment (pH 5.6) that may help limit bacterial activity. Despite this local dissolution, on a systemic level, the breakdown of the graft material does not lead to any appreciable increase in serum calcium levels (78). Sidqui et al. found that osteoblasts can attach to calcium sulfate (79). In addi-tion, osteoclasts can actively resorb the calcium sulfate, forming lacunae in a manner similar to natural bone. When mixed with water, calcium sulfate initiates an exothermic reaction that leads to recrystallization of the calcium sulfate into the solid form. Recrystallization occurs randomly and thus produces crystals of varying size and shape as well as multiple defects within the struc-ture. This variability in the crystalline structure causes sig-nificant variability in solubility, mechanical properties, and porosity. In addition, it may resorb too rapidly, lead-ing to fibrous ingrowth instead of bony substitution.

Medical grade calcium sulfate is in the form of regu-larly shaped crystals of similar size and shape. It pos-sesses a slower, more predictable solubility and resorp-tion. Medical grade calcium sulfate has been shown to possess an osteoconductivity equal to that of autogenous iliac crest marrow/bone with a rate of absorption that is equal to the rate at which new bone is formed (80–82). OsteoSet (Wright Medical Technology, Arlington, TN) is available in 3- and 4.8-mm pellets that dissolve *in vivo* within 30 to 60 days. The pellets are packaged in vials and are sterilized by gamma irradiation. Cunningham et al. showed that OsteoSet was comparable to autograft in a sheep posterolateral spinal fusion mode (83). OsteoSet is also available in a powdered form, thus maximizing the surgical options for adding antibiotics and filling defects with custom-molded beads or shapes. The chief advan-tage is that it can be used in the presence of infection (84–86).

Hadjipavlou et al. compared the effectiveness of cal-cium sulfate to other graft materials (autogenous iliac crest, frozen allogeneic bone, Pro Osteon 500 coralline graft, osteoinductive demineralized sheep bone prepara-tion, and admixtures of autogenous iliac crest bone with calcium sulfate and coralline graft) in achieving lumbar

interbody fusion in mature sheep (87). The substrates were placed into titanium mesh cages, which were implanted intervertebrally and recovered after 4 months. The histomorphometry suggested that the different graft types were equally effective at producing bone and were not different from the outcome of the empty control cages. Biomechanically, however, the behavior of the control fusion masses (with no graft material) was inferior to that of the fusion masses with other graft materials. The demineralized sheep bone preparations proved the least effective of the different substrates in achieving a solid interbody fusion. In terms of torsional strain, tensile failure, and volume of bone formed within the titanium cages, the effects of calcium sulfate and autogenous bone were indistinguishable from each other and similarly, that of calcium sulfate was indistinguishable from Pro Osteon and 1:1 admixtures of those substrates with autogenous bone. Elkins and Jones also noted no difference in the degree of bone healing between autogenous cancellous bone, calcium sulfate, and a composite of calcium sulfate and autogenous cancellous bone (88).

Calcium sulfate can also be used as a carrier for the local delivery of antibiotics. The elution of calcium sulfate is 17% at 24 hours; at 3 weeks, trace amounts are still detected. This profile compares favorably to polymethylmethacrylate, which releases 7% of its load by 24 hours, with trace amounts detected at 14 days (89).

Allergy to calcium sulfate, although rare and related to minor additives, should be considered when assessing the risk/benefit of using it as bone graft substitute. In a series of 15 implantations of calcium sulfate pellets (OsteoSet) used for bone reconstruction after resection of bone tumors, three cases of inflammatory reactions were noted (90). However, other investigators have noted that calcium sulfate is innocuous in terms of producing a local soft tissue chemical or pyogenic inflammatory reaction (80,81,88,91).

### Collagen

Type I collagen, which is the most abundant protein in the extracellular matrix of bone, has a structure that is conductive for mineral deposition, vascular ingrowth, and growth-factor binding, and provides both a favorable physical and chemical milieu for bone regeneration (92). It binds the noncollagenous matrix proteins, which initiate and control mineralization. By itself, collagen functions poorly as a graft material, but when combined with bone morphogenetic proteins, osteoprogenitor precursors, or HA, it may enhance the incorporation of the grafts (57). Although it has potential immunogenicity, no significant adverse reactions have been shown with bovine collagen implanted in skeletal sites (93).

Collagraft (Zimmer, Warsaw, IN) is a composite of suspended fibrillar collagen (from bovine dermis) and a porous calcium phosphate ceramic (65% HA and 35%

TCP), in a ratio of 1:1 (93–96). It can be used as a paste or in strips and does not provide any structural support by itself. It is usually mixed with autologous bone as a bone graft extender or with autologous bone marrow aspirate. Collagen serves as a carrier for the ceramic and the autogenous marrow. Appositional new bone is formed directly on the calcium phosphate surfaces. The results of using this composite in spinal fusion in animal studies are mixed. The results from a study by Walsh et al., evaluating the use of the composite in a posterolateral intertransverse lumbar fusion in a sheep model, support the use of Collagraft (95). Zerwekh et al. showed that the use of Collagraft and autogenous bone mixture (3:1) for lumbar interbody fusion in a canine model provides a suitable osteoconductive alternative to the use of autogenous bone and results in the formation of a mechanically competent fusion mass not significantly different from that obtained with autogenous bone alone (97). On the other hand, Muschler et al. found collagraft to be inferior in union score when compared to autograft in a posterior segmental canine spinal fusion model (96). However, the material was applied in onlay fashion, which inhibits its incorporation.

Healos (Orquest, Mountain View, CA) is a mineralized collagen sponge, launched in Europe for clinical use in spine surgery in 2000. Each microscopic type I collagen fiber is coated with HA. By itself it is osteoconductive, but it can be mixed with bone marrow aspirate to provide osteogenic and osteoinductive potential. In a study of posterolateral intertransverse lumbar spine fusion in a New Zealand white rabbit model, Tay et al. concluded that Healos could be used in combination with an osteoinductive or osteogenic agent to ensure reliable fusion rates (98).

### Nonbiologic Osteoconductive Materials

Degradable polymers, bioactive glasses, and various metals have been studied. The advantages of nonbiologic materials include the ability to control all aspects of the matrix, avoidance of immunologic reaction, and excellent biocompatibility. They provide structural support and can be used as spacers.

Polylactic and polyglycolic acid polymers slowly degrade by hydrolysis. Although well tolerated, these polymers may incite an inflammatory response in the surrounding tissues, especially with bulk implants. The materials can be assembled in various forms and can be integrated with growth factors or other compounds to create multiphase delivery systems. Porous foams of these polymers can be produced with optimum pore sizes for bone ingrowth. However, these materials by themselves have little osteoconductive potential, and bone ingrowth into them is not optimal (99). They are mainly used as growth factor delivery vehicles. Degradation of the polymer releases the factor locally.

Immix (Osteobiologics Inc., San Antonio, TX) is a synthetic bone graft scaffold, tissue engineered from amorphous D, L-poly(lactide-co-glycolide), and is designed to resorb within 12 to 20 weeks following implantation. It has been developed as granular particles, resembling allograft bone chips. It provides a porous architecture for the ingrowth of new bone and then fully degrades.

## OSTEOINDUCTIVE MATERIALS

Demineralized bone matrix, which was first shown by Marshal Urist to induce ingrowth of connective tissue cells and differentiation of cartilage and bone, has been a great breakthrough in the advancement of biologic bone graft substitute technology (100,101). Advances in protein isolation technology yielded evidence of a series of osteoinductive glycoproteins, including BMP, transforming growth factor- $\beta$  (TGF- $\beta$ ), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and others. Extracts of bone containing these growth factors produce new bone in ectopic sites in animal trials (102,103). The interaction of these factors with cytokines involves the regulation of chemotaxis and proliferation and differentiation of osteoprogenitor cells culminating in new bone formation. Of all these osteoinductive proteins, the most critical to bone formation are the BMPs, which have been shown to stimulate osteoblastic differentiation of pluripotent stem cells *in vitro* and are the only bioactive molecules capable of inducing ectopic bone production *in vivo* (104).

### Demineralized Bone Matrix

Demineralized bone matrix (DBM) is an osteoconductive scaffold that is produced by acid extraction of banked allograft bone. It provides no structural support and contains noncollagenous proteins, osteoinductive growth factors, and type I collagen (105). DBM is a mixture of BMPs and immunogenic, noninductive proteins. It has greater osteoinductive potential than allograft due to enhanced bioavailability of growth factors secondary to the demineralization (106,107).

A great deal of variability in the osteoinductive potential of DBM products depends on a number of factors, such as processing solution, demineralization time, temperature extremes, DBM particle size, and method of terminal sterilization (108,109). Since the method of sterilization can reduce the activity of DBM, many suppliers prefer sterile procurement and processing. The variability in the DBM osteoinductive potential may reflect differences in the BMP content (110), although the absolute concentration of BMP within a particular DBM preparation does not necessarily correlate with its clinical efficacy. Another factor that may influence the efficacy of DBM is age. DBM acquired from young donors has been

shown to have greater osteoinductive properties than those taken from older donors (111).

DBMs are usually suspended within a distinct carrier to modify their consistency and facilitate their use. A number of DBMs are associated with a glycerol carrier, and large amounts of these preparations have proven to be toxic when administered to athymic rats, eventually leading to death in a dose-dependent manner (112,113). However, there have been no reported cases of glycerol toxicity related to the implantation of these DBM products after years of use in humans. DBMs are currently available in a variety of configurations, and it appears that different configurations of the same DBM may perform differently, which can be the result of their different osteoconductive properties. A putty and flexible sheet form of a particular DBM was found to enhance spinal fusion to a greater extent than the gel form of the same DBM, most likely because these fiber-based preparations were thought to possess increased osteoconductivity compared to the particle form (114).

Because of the lack of an osteogenic potential of DBMs, they are most effective when implanted in environments that offer sufficient vascularity and an adequate supply of osteoprogenitor cells. DBMs have been found to promote successful arthrodesis of the spine when used alone or in conjunction with autograft, bone marrow, or ceramics (115–121). In humans, DBMs are mainly indicated as bone graft extenders when used in spinal fusion and are not thought to be sufficient for complete substitution for autogenous bone graft in the more challenging healing environments.

Several DBMs are now available commercially. Grafton (Osteotech, Inc., Eatontown, NJ) consists of DBM combined with a glycerol carrier and is available in the form of gel, malleable putty, or flexible sheets. Opteform (Medtronic Sofamor Danek, Memphis, TN), a moldable bone paste, contains cortical bone chips. Osteofil (Medtronic Sofamor Danek) is an injectable bone paste that combines DBM with thermoplastic, collagen-based hydrogel carrier matrix. This nonwater-soluble composite is easily extruded through a syringe when warmed to 46° to 50° but becomes firm when cooled to body temperature. Dynagraft (Regeneration Sciences, Inc., Irvine, CA) combines DBM with a pleuronic reverse-phase copolymer carrier that becomes firmer as it warms to body temperature. Both Dynagraft and Osteofil were reported to contain greater amounts of DBM per unit volume than the glycerol-containing composites (106).

### Bone Morphogenetic Proteins

The BMPs are soluble, low-molecular-weight noncollagenous glycoproteins that belong to an expanding TGF- $\beta$  superfamily of growth and differentiation factors. Unlike DBM, pure BMPs are nonimmunogenic and non-species-specific. BMPs are multifunctional; they regulate

growth, differentiation, chemotaxis, and apoptosis, and play a pivotal role in the morphogenesis of a variety of tissues and organs (122). Different BMPs have different functions including extracellular and skeletal organogenesis and bone regeneration. Osteogenic BMPs act locally by binding to specific receptors present on the surface of mesenchymal stem cells. These receptors then transduce the signal through a group of proteins called Smads, which in turn activate particular genes. BMPs *in vivo* cause mesenchymal cells to differentiate into chondrocytes, which create a cartilage matrix that mineralizes and then is replaced by bone (endochondral ossification) which ultimately remodels. In higher concentrations, BMPs can result in direct (intramembranous) ossification. The relative amounts of endochondral and intramembranous ossification induced appear to be associated with the concentration of BMP implanted, the site of implantation, and the nature of the carrier and matrix material (123). The bone formed, as a result of the BMP induction, appears to be physiologically normal in all the species tested. The bone induction is observed only locally at the site of BMP and matrix implantation and is limited temporally only to the time when the BMP is present. The activity of BMPs is tightly controlled at many levels. Outside the cell, soluble inhibitory proteins such as noggin, chordin, and follistatin can bind certain of the BMPs and inhibit their binding to cell surface receptors. Inside the cell, the activity of BMPs is controlled through the combination of signal-transducing and inhibitory Smad proteins.

Human BMP is a rare and very expensive product. It comprises only 0.1% by weight of all bone protein, and is most abundant in diaphyseal cortical bone. It exists in the extracellular matrix, and is not accessible until the bone matrix has been demineralized (101,124). Mixtures of BMPs are available as purified bone extracts for clinical studies. Although these preparations may have the advantage of containing many potent osteogenic factors, including BMP heterodimers, they have lower BMP concentrations, contain other biologically inactive or inhibitory proteins, and may elicit a host immune response. A highly purified extract from a mixture of bovine bone morphogenetic proteins (bovine BMP extract or bBMPx) has demonstrated promising preclinical efficacy results (125). Using molecular cloning technology, it has been possible to produce recombinant human BMP (rhBMP) as a singular molecular species in unlimited quantities and without immunogenetic properties (126,127). In summary, this process involves inserting the human BMP DNA coding sequence (gene) for each protein into an expression vector. This vector is transfected into a mammalian cell host in order to produce a stable cell line that expresses that particular BMP. The rhBMPs extensively studied are rhBMP-2 (128) and rhBMP-7 (osteogenic protein-1, or OP-1) (129), which have similar osteoinductive activities *in vivo*.

Recombinant human BMPs are soluble factors and tend to diffuse away from the fusion site when used alone. Therefore, in larger animal models and human clinical trials, these factors are combined with a carrier matrix that serves to contain the BMPs and release them gradually. These carriers may also act as osteoconductive scaffolds (130). The ideal carrier system will retain and release the BMP in a controlled fashion, be biocompatible, not interfere with normal bony healing, be porous to promote osteoconductivity, be biomechanically suited for the site of implantation, be easy to apply, and be easy to manufacture. Once these BMPs are released, appropriately responding osteogenic cells must be present in the area for any significant bone formation to occur. In animal models, such as rabbit, dog, sheep, goat, and nonhuman primate, researchers have performed posterolateral intertransverse spinal arthrodesis or interbody arthrodesis with cages containing rhBMP-loaded carriers (collagen sponges, autogenous bone graft, DBM, ceramics, degradable polymers) (131–138). Uniformly, these studies have reported a dose-dependent increase in bone formation, consolidation, and remodeling with the rhBMP-loaded scaffolds compared to unloaded controls. Multiple animal studies have shown that rhBMP-mediated fusions rates were equivalent or superior to those obtained with autogenous bone graft and may generate fusion masses that are biomechanically stronger and stiffer (43,131, 138–141). The use of BMPs has been shown to obviate the need for decortication of the posterior elements that is usually required to provide endogenous osteoinductive growth factors that are necessary for obtaining posterolateral fusion (142). The osteoinductive activity of BMPs may even compensate for the inhibitory effects of nicotine and nonsteroidal antiinflammatory medications on spinal fusions (143–145).

Boden et al. conducted a multicenter trial to test the efficacy of rhBMP-2-mediated spinal arthrodesis (146). Fourteen patients were randomly treated with tapered titanium fusion cages containing either rhBMP-2 (1.5 mg/mL) soaked bovine collagen sponges or morselized autogenous iliac crest bone graft. The authors showed that this concentration of rhBMP-2 consistently resulted in spinal fusion. All of the 11 patients who received rhBMP-2 had solid fusions by 6 months compared with 2 out of 3 control patients. The Oswestry Disability Questionnaire scores of the rhBMP-2 group improved sooner (after 3 months) than those of the autograft group, with both groups demonstrating similar improvement at 6 months. There were no adverse events related to the rhBMP-2 treatment. The patients who received rhBMP-2 collagen sponges had shorter operative times, less blood loss, and shorter hospital stays.

Before embarking on the use of BMPs in humans on a big scale, certain issues have to be addressed. These issues include the cost-effectiveness, the optimal carrier systems, appropriate dose for the different spinal applica-

tions, and safety. It is important to realize that certain carrier materials that prove successful in one location may not be efficacious in another. Both rhBMP-2 and OP-1 appear to be safe, provided they are used appropriately, placed accurately, not allowed to come into contact with decompressed areas, and remain contained in the region of fusion (147). In some patients, transient antibody responses to the BMPs or carrier materials have been observed without clinical untoward effects. New bone formation may occur if rhBMP-2 or OP-1 comes in contact with laminectomy sites or decompressed neuroforamina, and may lead to restenosis. In a canine lumbar spine fusion model, the placement of OP-1 over a dural tear stimulated new bone formation in the subarachnoid space, resulting in mild spinal stenosis at the site of dural decompression (148). Adequate hemostasis should be performed to avoid the absorption of BMP by a hematoma at the decompression site. It is not advisable to leave collagen-based hemostatic agents in contact with the BMP implant where decompression has been performed, because BMP may elute from its collagen carrier into the collagenous hemostatic agent and thus enter the region of decompression. Leakage of rhBMP-2 or OP-1 outside the fusion area may lead to adjacent-level fusion. Appropriate carriers should adequately retain the BMP within the fusion area. Irrigation of the surgical site should not be performed after implantation of the BMP. Suction drains should not be placed directly in contact with BMP implants.

In a study by Ackerman et al., an economic analysis was performed comparing the total direct medical costs of BMP with autogenous iliac crest bone graft in single-level anterior lumbar fusion (149). Their preliminary results suggest that from a payer perspective, the upfront price of BMP is likely to be entirely offset by reductions in the use of other medical resources. That is, BMP appears to be cost neutral. The reason for these cost offsets was largely due to the prevention of pain and complications associated with iliac crest bone graft and reduction of costs associated with fusion failures. When considering the costs associated with an unsuccessful fusion as well as the cost offsets associated with obviating the need for autogenous iliac crest bone graft (e.g., iliac crest backfill, autograft extenders, and autograft harvesters), elimination, the associated donor site pain, and morbidity (e.g., infection, hematoma, neuroma, and vascular injury), a 9.3% increase in fusion success rate was required to achieve cost neutrality at a BMP price of \$4,000. These analyses did not consider the health-related quality-of-life impact of eliminating donor site pain and complications. Since, at the present time, there are no large prospective randomized trials comparing the use of BMP to autologous bone graft, it is difficult to conclude that either graft material is more cost-effective.

### Autologous Platelet Concentrate

Platelet  $\alpha$ -granules contain several locally active factors, including PDGF, TGF- $\beta$ , insulin-like growth factor, and epidermal growth factor, as well as important osteogenic substances like osteocalcin, all of which play specific roles in stimulating bone formation by promoting mesenchymal stem cell chemotaxis, proliferation, and other cellular processes (150,151). The clinical use of PDGFs to enhance bone healing involves extracting autologous growth factors (AGFs) from the patient's blood and mixing the AGF concentrate with a bone graft or a bone graft substitute. The AGF gel is obtained from the platelet-rich plasma (buffy coat) of the blood collected in the cell saver during surgery through centrifugation. The buffy coat is ultraconcentrated to a density of 1 million platelets/ $\mu$ L. This platelet-rich plasma, which is concentrated in a fibrinogen matrix, is combined with thrombin to form a fibrin clot (AGF gel). Approximately 20 mL of AGF is derived from 500 mL of blood in 10 minutes. The AGF gel also acts as a constraining gel, thus minimizing bone graft migration. In a retrospective study, 39 patients undergoing anterior or posterior fusion of the lumbar spine were treated with AGF concentrate, autogenous bone graft, and coralline HA in conjunction with stable internal fixation (152). After an average follow-up of 13 months, no pseudoarthroses were noted clinically or radiographically. Like DBMs, platelet gels are classified as minimally manipulated tissues and are therefore not closely regulated or subjected to rigorous testing.

### BONE MARROW ASPIRATE

Autologous bone marrow contains both osteoprogenitor cells as well as growth factors that may enhance bone formation. Compared to autogenous bone graft harvesting, bone marrow aspiration is a much less aggressive technique with almost no donor site morbidity. Bone marrow is usually aspirated from the iliac crest but can be aspirated from any cancellous bone rich in bone marrow including vertebral bodies (through pedicles, before pedicle-screw placement). Bone marrow aspirates are usually combined to a carrier before application to the arthrodesis site in order to avoid its diffusion away from the area in need of repair.

Because the extent of osseous regeneration is dependent on the number of osteoprogenitor cells able to produce new bone, unfractionated bone marrow exhibits only moderate osteogenic potential, because it possesses only a limited quantity of mesenchymal stem cells. The bone marrow of healthy adults contains only one mesenchymal stem cell for every 50,000 nucleated cells, and this population is even further diminished in older patients and in those with metabolic diseases such as osteoporosis (153,154). Moreover, as bone marrow is

aspirated from the iliac crest, it undergoes dilution with peripheral blood. Consequently, it has been recommended that no more than 2 mL of bone marrow should be aspirated from any single site (153). Centrifugation of the aspirated bone marrow separates the marrow cells from plasma and preserves the osteogenic potential of the cells, decreasing the volume of material injected (155). The proliferation and rate of differentiation of stem cells can be enhanced by the addition of growth factors (156) or by combining them with collagen (94).

Using special purification and subcultivation techniques, mesenchymal stem cells may be separated from other bone marrow elements and expanded *in vitro* without any loss in their multilineage potential (157). When supplied with the appropriate regulatory molecules in cell culture, these mesenchymal stem cells have the capacity to develop into mature osteoblasts (157,158). The amplification of osteoprogenitor cells that occurs after culture expansion of mesenchymal stem cells results in greater bone formation than with the unfractionated bone marrow (153,154). Mesenchymal stem cell therapy may be particularly valuable in older patients and those patients with reduced osteoprogenitor cell stores. This approach, however, carries the risk of *in vitro* contamination.

VivescOs (IsoTis, Bilthoven, The Netherlands) is a tissue-engineered bone developed for application in revision surgery, spinal fusion, and dental implants. The bone marrow cells are harvested from the patient and then expanded in tissue culture. The cells on the scaffold are then made into the desired shape and reimplanted into the patient. This process takes about 4 weeks (57).

## GENE THERAPY

Several studies have shown that gene therapy is a safe and effective way of effecting new bone formation in animals (159,160). Gene therapy entails the transfer of genetic information to cells. When the gene (DNA encoding the protein) is transferred to a target cell, the cell synthesizes the protein encoded by the gene. Unlike gene therapy used for the treatment of genetic diseases, gene therapy used for bone induction is short-term, regional therapy.

The *in vivo* technique involves introduction of the gene directly to a specific anatomic site. This process is relatively simple and convenient, but limited by inefficient gene delivery, nonspecific targeting of cells, and the possibility of a vigorous host inflammatory response. In one study using the *in vivo* technique, the gene encoding for BMP-2 carried on an adenovirus vector was percutaneously injected in the paraspinal muscles of rats (160). Expression of BMP-2 by transfected muscle cells was shown to stimulate significant new bone formation.

The *ex vivo* technique involves harvesting cells from the patient, expanding the cells in tissue culture, and

genetically manipulating these cells which are subsequently reimplanted. Although this technique is more complex and expensive than the *in vivo* technique, it is considered to be safer after thorough screening of the genetically altered cells before their reimplantation. *Ex vivo* approaches are generally associated with high transduction rates and allow for preferential selection of certain target cells.

The vector (vehicle) for gene delivery can be viral (retrovirus, adenovirus, adeno-associated viruses) or nonviral. The gene can be selectively transferred to a targeted cell (osteoblast, fibroblast) at the bone induction site. Nonviral vectors are easier to produce, are more stable, and are less antigenic and theoretically safer than viral vectors. Nonviral vectors include liposomes, which are DNA suspended in lipid vesicles that are able to bind to cell membranes, and gene-activated matrices, which are osteoconductive scaffolds loaded with genetic material. Viral vectors possess superior transduction efficiencies and may be favored over nonviral vectors.

Gene therapy may provide a more potent osteoinductive signal than recombinant growth factors, because these methods result in the sustained local release of osteogenic proteins at levels that are more physiologic than the administration of a single large dose.

Using *ex vivo* gene therapy, Wang et al. implanted rat bone marrow cells, transduced with the BMP-2 gene, combined with a guanidine-extracted DBM in the posterolateral spine of rats (161). The BMP-2-producing cells resulted in solid fusion masses comparable to those produced from the use of recombinant BMP-2 protein. Boden et al. used a posterior spinal fusion model in athymic rats and grafted demineralized bone matrix with bone marrow cells (162). In each rat, one site received marrow cells transfected with the gene encoding the LIM mineralization protein-1 (LMP-1), a signaling intracellular protein (not a secreted factor) that acts by stimulating the synthesis and secretion of other osteoinductive factors and thus initiating bone formation *in vitro* and *in vivo*. At the other site for a control, the marrow cells were transfected with the reverse copy of the complimentary DNA (cDNA) that did not express any protein. Consistent fusions were obtained in all of the animals receiving bone marrow cells containing the LMP-1 DNA sequence, whereas no bone formation was observed in those implanted with cells carrying the inactive copy of the gene.

## SUMMARY AND FUTURE DIRECTIONS

The mere formation of bone does not indicate fusion. For spinal fusion to occur, bone has to be formed and has to bridge vertebrae with incorporation of the graft material into the recipient site. Thus, there has to be an optimal local and systemic milieu for spinal fusion to occur; and that includes decortication of bone, optimal stability,

optimal blood supply, normal bone physiology, and absence of systemic diseases and toxic materials that may suppress osteogenesis.

The newer forms of calcium sulfate and calcium phosphate materials possess a resorption profile that closely matches the rate at which new bone is deposited. They facilitate cellular adhesion, support vascular ingrowth, and promote new bone formation. They are purely osteoconductive materials and can be used as bone graft extenders or carriers for osteoinductive agents.

The advantages of nonbiologic materials such as degradable polymers, bioactive glasses, and various metals include the ability to control all aspects of the matrix, avoidance of immunologic reaction, and excellent biocompatibility. They provide structural support and can be used as spacers. However, these materials by themselves have little osteoconductive potential, and bone ingrowth into them is not optimal. They are mainly used as growth factor delivery vehicles.

Because of the lack of reliable noninvasive techniques to assess the success or failure of an arthrodesis, several investigators have found that an animal model would be a practical solution for studying the efficacy of the different bone graft substitutes. However, one should be cautious when interpreting the results of animal studies. The efficacy of osteoinductive agents largely depends on the amount of protein implanted. The threshold concentration of an osteoinductive agent, below which no significant bone is induced, may be different for different osteoinductive factors, different carrier matrices, different anatomic locations, and even different animal species. In addition, this threshold may need to be raised in the face of systemic healing challenges such as smoking, corticosteroids, chemotherapeutic agents, and diabetes mellitus.

The BMPs are differentiation factors, causing mesenchymal cells to differentiate into bone- and cartilage-forming cells. On the other hand, factors such as platelet-derived growth factor and TGF- $\beta$  are growth factors. These growth factors cause cells to multiply and may cause cells to augment production of cellular products such as extracellular matrix proteins.

Platelets contain several locally active factors, which play specific roles in stimulating bone formation by promoting mesenchymal stem cell chemotaxis, proliferation, and other cellular processes. Several clinical studies to evaluate the use of PDGFs in enhancing spinal fusion are underway. It is still too early to identify the optimal method of obtaining PDGFs and applying the technology in spinal fusions.

Autologous bone marrow contains both osteoprogenitor cells as well as growth factors that may enhance bone formation. The procedure of obtaining bone marrow involves minimal morbidity. Bone marrow aspirates are usually combined to a carrier before application to the arthrodesis site in order to avoid its diffusion away from the area in need for repair.

Gene therapy may provide a more potent osteoinductive signal than recombinant growth factors, because of the sustained local release of osteogenic proteins obtained with gene therapy at levels that are more physiologic than the administration of a single large dose, as is the case with BMPs.

Ceramics, degradable polymers, bioactive glasses and metals, rhBMPs, PDGFs, autologous bone marrow aspirate, and *ex vivo* gene therapy can be used when there is concern about immune reactions and transferred infections, as in immunocompromised patients.

When considering the choice of bone graft substitute in order to attain bone formation, one has to think of the necessary triad for bone formation: osteogenesis, osteoinduction, and osteoconduction. Depending on the anatomic location and the biomechanical loading at the site of arthrodesis, one or more of the three elements has to be supplied. For an anterior cervical interbody fusion, an osteoconductive structural block may suffice in achieving fusion. The compressive loads, along with the contact to a bleeding end plate (provides bone marrow loaded with osteogenic and osteoinductive elements), with the intercession of the vertebral periosteum and surrounding muscle pericytes (osteoprogenitor cells), can provide all three necessary components for bone formation. On the other hand, posterolateral lumbar fusion usually requires at least an osteoconductive nonstructural bone graft substitute in addition to a strong osteoinductive agent provided there is good bridging to viable decoricated bone (primary source of blood supply, bone marrow, and osteoprogenitor cells to the fusion mass) (163).

Although only 10% of bone graft procedures worldwide have relied on synthetic materials (164), including ceramic and polymers, synthetic composite bone substitutes that combine an osteoconductive matrix with osteoinductive growth factors and osteogenic cells, rhBMPs, and gene therapy may ultimately surpass the use of bone grafts. Combined strategies of biologic and mechanical manipulation of spinal arthrodesis should be continuously prudently evaluated with sound scientific methods and well-designed, well-controlled, and rational clinical studies.

## CHAPTER 25

# Principles of Spinal Instrumentation in Degenerative Disorders of the Lumbar Spine

Ashok Biyani and Howard S. An

---

Approximately 72,000 lumbar fusion procedures were performed in 1993 in the United States for degenerative disorders of the lumbar spine (1), and the frequency of lumbar fusion has been on the rise at an annual rate of 8% for last two decades (2). The use of instrumentation to augment fusion in the lumbar spine has become quite popular over the last several years. Although it has been well established that posterior instrumentation enhances fusion rate, it is not clear whether it improves the functional outcome. Although transpedicular fixation has now become widely accepted as the posterior instrumentation system of choice for lumbar degenerative disorders, its indications are not well defined and are not universally accepted. Although several studies have focused on this subject over the last decade, many are retrospective in nature, contain a heterogeneous group of patients with different underlying disorders, and a variety of instrumentation systems have been used. Although there is a relative lack of prospective controlled data in the literature, a better understanding of the indications of transpedicular instrumentation and their outcome seems to be emerging. An increased emphasis is also being placed on the functional outcome and cost-effectiveness analysis of instrumentation.

### **HISTORICAL PERSPECTIVE**

Internal fixation of the spine with wiring techniques has been known for over a century. Screw fixation was attempted by King (3) in the spine in 1940s even before hook-based systems were popularized by Harrington (4) in the 1960s. Harrington rods were used successfully in the surgical management of idiopathic scoliosis, but their applicability in the degenerative conditions of the lumbar spine was limited. Cotrel and Dubousset modified the hook-based systems and introduced the concept of seg-

mental fixation (5). The advent of Luque segmental sublaminar wiring technique brought forth the next major advance in the spinal instrumentation (6). This technique requires an intact lamina for a multilevel fusion construct and provides poor resistance to axial compression or distraction. Although sublaminar wiring is still widely used in the management of neuromuscular scoliosis, its role in management of degenerative spinal disorders is currently limited to correction of degenerative lumbar scoliosis by providing a posteriorly directed force and lateral translation of the apex of the deformity.

Pedicular fixation was first attempted in 1959 by Boucher, who tried inserting the pedicle screws through the facet joints (7). Roy-Camille (8,9) pioneered the technique of pedicle screw placement in the 1960s with further refinement in subsequent years. Transpedicular instrumentation was introduced in the United States by Steffee in 1983 (10). Numerous pedicle screw fixation systems have since been developed. Pedicle screws initially were attached to the plates, but rod-based systems have become more popular in the last decade.

### **INDICATIONS FOR THE USE OF INSTRUMENTATION IN LUMBAR DEGENERATIVE DISORDERS**

The role of instrumentation as an adjunct to lumbar fusion in patients with lumbar degenerative disorders is not well defined. Although the literature is replete with reports on instrumented fusion for a variety of underlying disorders, there is a clear lack of consensus among spine surgeons on the indications for instrumented posterolateral fusion. Some of the more commonly accepted indications, although not without controversy or universal agreement, include degenerative spondylolisthesis and lumbar instability, multilevel fusion, revision surgery for

pseudarthrosis, and spinal deformity including degenerative scoliosis and flat back syndrome. Posterior instrumented fusion for discogenic back pain remains the most controversial of all indications.

### Degenerative Spondylolisthesis

Although untreated degenerative spondylolisthesis may progress over time in 30% of patients (11), the majority of patients respond well to conservative treatment, and only 10% to 15% of patients require operative intervention (12). Posterior decompression and fusion is the surgical treatment of choice for degenerative spondylolisthesis, because laminectomy alone is likely to further destabilize the spine. Herkowitz and Kurz (13) have demonstrated in a randomized, prospective study of patients with degenerative spondylolisthesis that superior results are obtained with decompression and concomitant fusion than with decompression alone. McCulloch (14) recently reported favorable results with microdecompression and uninstrumented single level fusion for degenerative spondylolisthesis in 21 patients. Several authors also have evaluated the role of instrumentation in degenerative spondylolisthesis. Fischgrund et al. (15) performed a prospective randomized study of 76 patients with degenerative spondylolisthesis and spinal stenosis. They reported a higher fusion rate (82%) in the instrumented group versus 45% in the noninstrumented group, but improved fusion rate with instrumentation did not translate into improved clinical outcome in patients undergoing single-level posterolateral fusion with transpedicular instrumentation. At a longer-term follow-up of the same group of patients, these authors reported worse outcome in patients with pseudarthrosis compared with patients who had solid fusion (16).

Yuan et al. (17) performed a large historical cohort study of patients, who underwent posterior spinal fusion with (2,177 patients) or without (456 patients) transpedicular instrumentation for degenerative spondylolisthesis. The fusion rate was 89.1% for the instrumented group and 70.4% for the uninstrumented group. Despite fewer reoperations, less number of spinal levels fused, less use of allograft and lower worker's compensation cases in the uninstrumented group, overall functional results were superior in the instrumented group. Shorter time to fusion, better neurologic recovery, and greater relief of back pain were noted in the instrumented group. The rate of complications, reoperation, and mortality was similar in the two groups.

Booth et al. (18) reviewed 49 consecutive patients with degenerative spondylolisthesis, who were treated with decompression, intertransverse process fusion, and segmental pedicle screw instrumentation. Eighty-three percent patients had satisfactory results with the procedure at a mean follow up of 6.5 years, and 86% reported last-

ing improvement in their back and leg pain. Steffee and Brantigan (19) reported a fusion rate of 91.5% in a prospective study of 250 patients with spondylolisthesis who were treated with variable screw-plate system. Bridwell et al. (20) also reported significant improvement in radiographic fusion rate in patients with instrumented fusion for degenerative spondylolisthesis. Noninstrumented patients had significantly increased progression of spondylolisthesis compared with the instrumented group.

In a retrospective study of 30 patients with degenerative spondylolisthesis treated with decompression and instrumented posterior fusion, Nork et al. (21) reported improved functional outcome using standardized SF-36 questionnaire. Ninety-three percent of patients had successful radiographic fusion. Ninety-three percent of patients were satisfied with their outcome, and their SF-36 scores were superior to a previously published cohort of patients with low back pain. Eighty-three percent of patients had severe back pain preoperatively compared with 3% of patients having severe pain postoperatively. Poor outcome correlated with greater preoperative stenosis or occurrence of complications. The authors acknowledged that preoperative SF-36 scores were not available, and there was no control group of uninstrumented fusion in their study.

However, some studies have failed to find any significant advantages of instrumentation over no instrumentation. In a prospective randomized clinical study of primary or degenerative spondylolisthesis, Thomsen et al. (22) did not observe any significant difference in the fusion rate or functional outcome when decompression and posterolateral lumbar fusion was performed with or without Cotrel-Dubouset instrumentation. A few other authors have reported similar lack of improvement in outcome with instrumentation (23–25). It is obvious from the mixed results of these studies that there is no unanimity among spine surgeons on the role of instrumentation in patients with degenerative spondylolisthesis. Nevertheless, a clear trend seems to be emerging in management of degenerative spondylolisthesis with increasing usage of instrumentation. It is worth noting, however, that solid fusion does not necessarily translate in to a successful functional outcome.

The presence of L4-5 degenerative spondylolisthesis without obvious motion on preoperative flexion-extension lateral radiographs and narrow disc space with end plate-to-end plate contact is a relative indication for an uninstrumented posterolateral fusion following decompression. However, instrumented fusion is recommended in presence of documented instability or relatively preserved disc space height to prevent further postoperative olisthesis secondary to the destabilizing effect of the decompressive laminectomy (Fig. 25-1). The usage of instrumentation is also appropriate when there is a sig-

**FIG. 25-1.** Preoperative sagittal magnetic resonance image (A), and axial image at L3-4 level (B) in a patient with degenerative spondylolisthesis at L4-5 and spinal stenosis at L3-4 and L4-5. Postoperative anteroposterior and lateral radiographs show decompression and instrumented fusion (C,D).

nificant slippage with associated kyphosis. The instrumented posterolateral fusion should be performed either concomitantly with a posterior lumbar interbody fusion or extended to the sacrum for correction of the kyphotic deformity and to gain greater control of L4. Correction of kyphosis associated with spondylolisthesis and restoration of sagittal alignment is made possible by the usage of instrumentation, which not only improves the fusion rate, but may also delay the onset of adjacent segment breakdown (26).

### Degenerative Scoliosis

Degenerative scoliosis may appear *de novo* or degenerative changes may develop in patients with preexisting

idiopathic scoliosis. Degenerative scoliosis is most often accompanied by spinal stenosis. Progression of the deformity may occur because of destabilization if posterior decompression is performed without concomitant fusion, and several factors need to be considered when deciding whether concomitant arthrodesis is indicated. The scoliotic curve is likely to progress with decompression alone, if it is partially correctable on side bending films. Arthrodesis also is indicated when there has been a documented curve progression and in the presence of lateral spondylolisthesis, which is inherently unstable. Other risk factors for curve progression include a Cobb angle of 30 degrees or greater, and grade 3 apical vertebral body rotation. Lateral translation of greater than 6 mm and the presence of L5 seated above the intercrestal line are also

indicative of instability (27). Finally, Loss of sagittal alignment renders the spine more vulnerable to develop progressive kyphosis after laminectomy alone (28).

Patients presenting with radiculopathy that coincides with the concavity of the curve may need wide lateral and foraminal decompression, including partial facetectomy. Fusion is indicated along with central and lateral canal decompression in the presence of degenerative scoliosis, particularly when the laminectomy is performed at the apex of the curve. If the spine is considered unstable intraoperatively after decompression, fusion should be performed. Resection of more than 50% of bilateral facet joints or a whole facet joint is considered to create spinal instability (29).

Fractional curve at the lumbosacral level is most often associated with foraminal stenosis. Adequate foraminotomy may require removal of a substantial part of the facet joints, which may lead to further destabilization. In addition to providing immediate stability, transpedicular instrumentation also facilitates reduction in pedicular kinking and indirect decompression of the foramina by segmental pedicular distraction (30,31). In a cadaveric study, Inufusa et al. (32) were able to increase the foraminal dimensions by 22.6% at L4-5 and by 39.6% at L5-S1 with 6 mm of rod distraction with transpedicular instrumentation.

Simmons and Simmons (34) retrospectively reviewed the results of decompression and instrumented fusion in patients with significant lumbar scoliosis and stenosis. Eighty-three percent of patients had severe pain preoperatively. Ninety-three percent of patients reported mild or no pain at follow-up. Overall fusion rate was 100%, and mean Cobb angle correction was 19 degrees. In another retrospective of 27 patients with adult onset scoliosis, Marchesi and Aebi (35) reported 86% satisfactory results and 4% rate of pseudarthrosis.

The degenerative lumbar curves often extend from the lower thoracic spine to the sacrum. Instrumentation decreases the rate of pseudarthrosis after multilevel arthrodesis, and facilitates correction of deformity and restoration of sagittal alignment. However, the extent of instrumented posterior fusion and concomitant anterior release and fusion are controversial issues in the surgical management of degenerative lumbar curves (33). Long instrumented fusion is associated with significant morbidity, and should be cautiously approached in the elderly population.

### Degenerative Spinal Stenosis

Most patients with degenerative spinal stenosis can be treated with decompression alone in the absence of instability or significant kyphoscoliosis. A laminectomy with lateral recess decompression by undercutting the articular facets and adequate foraminotomy allows neural decompression and often can be performed without causing sig-

nificant iatrogenic instability (36). Mullin et al. (37) reported a 54% incidence of instability after decompressive laminectomy for stenosis, emphasizing the need for careful selection of patients with certain risk factors who may need a spinal fusion in addition to laminectomy. Presence of bridging osteophytes, narrowed disc spaces, calcified annulus, capsule or ligamentum flavum, and a high intercrestal line are considered to be preoperative indicators of spinal stability; such patients should be treated with decompression alone in the absence of other risk factors (38).

Garfin et al. (39) have summarized the predictors of postoperative instability after decompressive laminectomy alone for lumbar stenosis. These risk factors include a large preoperative slip, decompression across normal disc height, greater than 50% facet excision at a single level, increased numbers of levels decompressed, penetration of disc space at the decompressed level, and female sex. Presence of traction spurs and asymmetric narrowed disc space also are indicative of postoperative instability (38). All patients with aforementioned risk factors for postoperative progression of instability should be considered for a concomitant fusion.

Disc herniation is infrequently present in patients with spinal stenosis. A free fragment or a foraminal disc herniation is the most common presentations in this subset of patients. Decompressive discectomy is necessary in these instances to relieve the radicular symptoms. However, vigorous attempts at removing the disc material and radical disruption of the disc may produce iatrogenic instability, particularly in younger individuals with maintained disc height (40). A fusion procedure may be necessary when a radical discectomy is performed in conjunction with a decompressive laminectomy (28).

The criteria for addition of instrumentation to fusion have not been well established in surgical treatment of lumbar stenosis. In general, indications for adding instrumentation to posterolateral arthrodesis include the need for correction of kyphosis or scoliosis, decompression of the foramen, translational motion of more than 4 mm, and angulatory motion of more than 10 degrees in flexion extension lateral radiographs, and in presence of iatrogenic instability (28). By providing immediate stability, instrumentation halts further progression ofolisthesis and increases the fusion rate. The presence of significant facet joint arthritis in patients with lumbar stenosis is a relative indication for concomitant instrumented fusion.

Hansraj et al. (41) noted that decompression and instrumented fusion was efficacious in management of complex spinal stenosis with a 96% patient satisfaction rate. Complex spinal stenosis was defined as the presence of radiographic instability in addition to stenosis, degenerative spondylolisthesis greater than grade 1 with instability, degenerative scoliosis with the curve greater than 20 degrees, and history of prior surgery with radiographic evidence of instability or junctional stenosis.

Recurrent stenosis is frequently seen in patients undergoing laminectomy without fusion, and occurs because of bone regrowth and formation of scar tissue. Postacchini and Cinotti (42,43) reported that recurrent stenosis was significantly less common in patients who underwent decompression and concomitant fusion compared with patients undergoing decompression alone. The reoperation rate for recurrent lumbar stenosis is estimated to be 5% to 23% (44). The management of adjacent segment stenosis usually is straightforward and involves simple decompressive laminectomy. However, management of recurrent stenosis of the previously operated levels is challenging. Significant bone regrowth, hypertrophic facets, and epidural scarring are frequently encountered in patients with recurrent spinal stenosis at the previously operated level, which necessitates more extensive facetectomies that may endanger the stability of the spine. Therefore, an arthrodesis with or without instrumentation may be recommended for patients undergoing decompression for recurrent lumbar stenosis. Because instrumentation improves the fusion rate, adding instrumented fusion to laminectomy is appropriate in these circumstances. However, these patients are often older and therefore are subject to a higher risk of overall complications. Consequently, instrumented arthrodesis should be performed sparingly, and usually is reserved for patients with spondylolisthesis and recurrent stenosis (28).

### **Pseudarthrosis and Flat Back Syndrome**

The overall reported incidence of nonunion is approximately 5% to 7% for single-level uninstrumented fusion and 25% to 35% for uninstrumented degenerative spondylolisthesis (45). There is a significantly higher incidence of pseudarthrosis following multilevel uninstrumented fusion (46). Pseudarthrosis poses complex diagnostic and treatment dilemmas. Established pseudarthrosis can be detected on Ferguson views, AP, and flexion-extension lateral radiographs or reformatted computed tomography (CT) images. However, Kant et al. (47) reported 68% sensitivity of radiographs in correlating with intraoperative confirmation of pseudarthrosis.

The presence of pseudarthrosis does not necessarily correlate with the patient's symptoms. Once a diagnosis of pseudarthrosis has been established, the clinical picture should be carefully reviewed to assure that pseudarthrosis is indeed the underlying cause of persistent pain. The treatment of lumbosacral pseudarthrosis is complicated and challenging at best. Surgical treatment is dictated by a variety of factors, including prior history of instrumentation, associated spinal deformity, and patient factors such as history of smoking. A noninstrumented posterolateral lumbar pseudarthrosis is an indication for revision fusion with rigid transpedicular instrumentation. Rigid segmental fixation also is indicated when a posterolateral fusion is performed for treatment of a failed

posterior or anterior lumbar interbody fusion (48). A combined posterior instrumented revision fusion and anterior interbody fusion may be necessary in selected cases.

The outcome of surgical repair of pseudarthrosis is variable. The rate of successful fusion and improvement in functional outcome is less than primary fusions. Lauerman et al. (49) reported an overall fusion rate of 49% with use of a combination of sublaminar wires, Harrington compression rods, and variable pedicle screw-plate constructs and uninstrumented fusion in patient with pre-existing pseudarthrosis. Eighty-six percent of patients continued to experience low back pain, and 49% patients had poor clinical outcome. West et al. (50) reported 65% fusion rate after lumbar pseudoarthrosis repair with pedicle screw constructs, in contrast with 90% fusion rate in patients who underwent primary instrumented fusion for degenerative disc disease or spondylolisthesis. Horowitch et al. (51) reported a 68% fusion rate after instrumented fusion in a mixed group of patients, two thirds of whom had pseudarthrosis. Zdeblick reported on the results of a large cohort of patients undergoing lumbar fusion, some of who underwent repair of pseudarthrosis with and without instrumentation (52). The group treated with regrafting without instrumentation had a 20% fusion rate, whereas both semirigid and rigid instrumentation yielded 100% union. Despite an acceptable fusion rate, the functional outcome of instrumented repair of pseudarthrosis is more unpredictable.

Carpenter et al. (53) reported a 26% good or excellent outcome after pseudarthrosis repair despite a 94% fusion rate. Kim and Michelsen (54) retrospectively reviewed the results of surgical treatment in 50 failed back surgery patients. They noted an overall significant improvement in pain and function in 66% of the patients. Eighty-one percent of patients with a solid fusion had a satisfactory outcome compared with 23% in patients with failed pseudarthrosis repair. Stewart et al. (55) reported a 72% successful outcome following attempted pseudarthrosis repair, as determined by the ability of patients to return to work, the lack of a need for narcotic analgesics, and overall satisfaction.

Patients with a prior decompressive laminectomy may develop fixed sagittal imbalance owing to loss of posterior stabilizing structures. Fixed sagittal imbalance also may occur owing to breakdown through pseudarthrosis instability at a level above or below previous fusion, or because of multisegmental degenerative disc disease. Many patients with a flat back syndrome suffer from persistent back pain with erect posture owing to loss of lumbar posterior tension band and early fatigue of extensor muscles.

Approximately 15% to 20% of patients who have had a prior lumbar fusion for degenerative disease require revision lumbar surgery over the ensuing 3 to 5 years. Pseudarthrosis, flat back syndrome, and postlaminectomy

tomy instability are some of the common causes of persistent pain that require additional surgery. Correction of flat back syndrome and postlaminectomy kyphosis is best achieved with appropriate osteotomies, restoration of global sagittal alignment, and stabilization with transpedicular instrumentation (56). Although there is a higher risk of complications associated with the technically demanding revision surgery, high rate of osseous union, improved spinal alignment, and functional outcome can be achieved in carefully selected patients.

### Degenerative Disc Disease

The role of posterior spinal fusion and instrumentation in degenerative disc disease without instability is highly controversial. The decision to perform an arthrodesis is based on the assumption that the pain generator can be localized to the degenerative disc space. Improvement in pain presumably occurs because of elimination of motion at a degenerated and painful segment. Posterolateral fusion may be considered for the treatment of intractable discogenic back pain. The fusion rate for single-level noninstrumented posterolateral fusion for degenerative disc disease is approximately 85% to 90% (46).

Several authors have reported improved fusion rate, less back pain, and higher return-to-work rates with instrumented than with noninstrumented fusion for degenerative disc disease (57–60). Lorenz et al. (57) prospectively evaluated 68 patients who underwent one level fusion with or without instrumentation for disabling back pain for 6 months or more, inability to work, and failed conservative care. None of the patients with instrumented fusion had pseudarthrosis and three fourths of patients reported improvement in pain and return to work. In contrast, 58% of patients in the noninstrumented group had nonunion and only one third of patients experienced pain relief and were able to return to work. Louise (58) reported a 97% fusion rate with pedicle screw-plate fixation in patients with intractable low back pain. Eighty-five percent of patients with sedentary work and 56.5% of heavy laborers were able to return to work in that study.

Dawson et al. (61) reported a 92% fusion rate and 70% to 80% clinical success rate in a retrospective study of 58 patients treated with posterolateral fusion for discogenic low back pain. These authors also reported a failure rate of 50% for patients undergoing revision surgery and 45% rate of pseudarthrosis for noninstrumented floating fusion. Hellstadius et al. (62) and Shaw and Taylor (63) also reported a 26% and 27% rate of pseudarthrosis, respectively, for posterolateral fusion without instrumentation. In another study, patients who underwent noninstrumented fusion for lumbar degenerative disc disease were 24 times more likely to have pseudarthrosis than comparable patients treated with transpedicular instrumented fusion (64).

Arthrodesis may be indicated for discogenic low back pain in certain circumstances. These include unremitting back pain and disability for 1 year, failure of conservative management including physical therapy for 6 months, magnetic resonance imaging (MRI) and discographic findings consistent with advanced degenerative disc disease and concordant symptom production at one or two levels. All patients with discogenic back pain who are being considered for spinal fusion also should have a normal psychological evaluation.

Patients with recurrent disc herniation at the same level usually are treated with repeat discectomy without fusion, unless preoperative instability is present or there is significant back pain associated with radicular pain. Routine use of instrumentation is not necessary in the absence of radiographically demonstrable instability. Patients with a second recurrence of disc herniation and those with preoperative or iatrogenically induced instability after their initial recurrence are candidates for arthrodesis (65), preferably with instrumentation. Smokers should have instrumented arthrodesis to enhance fusion rate.

Disc degeneration at a segment adjacent to prior fusion occurs because of increased stress concentration. Whitecloud et al. (66) treated 14 patients with adjacent segment degeneration with decompression and extension of fusion encompassing the degenerated motion segments. Ten of 12 patients treated with instrumented fusion had successful fusion. They recommended instrumented fusion for symptomatic adjacent degenerated segments, because instrumentation provides better control of the high stresses and improves the rate of fusion, compared with noninstrumented fusion.

Discogenic pain may persist despite a solid posterolateral fusion, presumably because of the presence of painful micromotion in the involved segment. Additionally, the disc itself may be a source of pain (67,68) that may benefit from interbody fusion, either with or without instrumentation. The role of interbody fusion is also a controversial subject that is beyond the scope of this chapter. Circumferential arthrodesis may reduce the rate of pseudarthrosis to less than 5%, but the morbidity associated with such an extensive procedure precludes its routine use in the management of lumbar degenerative disc disease. A circumferential fusion should be reserved for patients who are considered to be at high risk for pseudarthrosis, and is best reserved for revision cases and heavy smokers. Gertzbein et al. (69) reported 97% fusion rate and 77% good clinical outcome with circumferential fusion in a difficult group of patients, 62% of whom had previous surgery, 25% with prior pseudarthrosis, 55% with two or more levels fused, and 43% of whom were heavy smokers.

### SPINAL INSTRUMENTATION SYSTEMS

Although a variety of spinal instrumentation systems are available, the role of hooks and sublaminar wires in

the lumbar degenerative disorders is limited. Pedicle screws are available for use with plates or rods as the longitudinal members of the construct. However, rod based pedicle screw systems currently are more commonly used in management of degenerative conditions of the lumbar spine.

### Pedicle Screws versus Hooks and Sublaminar Wires

Mardjetko et al. (70) concluded from their metaanalysis that adjunctive instrumentation leads to higher fusion rate, which, in turn, significantly improves patient satisfaction. However, these authors were not able to find any statistically significant difference in outcome between transpedicular systems and earlier instrumentation techniques such as hooks and rod construct and Luque wiring techniques. This metaanalysis had several design flaws, including a relatively small number of published articles, data from a wide variety of treatments over two decades, and variability in design and quality of many of the studies. Gurr et al. (71) biomechanically evaluated the strength of transpedicular fixation in a corpectomy model using calf spine. They compared posterior hook-based systems and pedicle screw constructs and found that the latter were more rigid, achieved greater fixation, and restored stability better than hook systems.

The use of sublaminar wiring and hook-based systems is outdated in the surgical management of degenerative lumbar spine disorders because of versatility and superior biomechanical characteristics of transpedicular fixation systems. Sublaminar wires are primarily used in the concavity of a degenerative scoliotic curve, whereas the terminal fixation is achieved with pedicle screws distally and either screws, hooks, or both proximally. The sublaminar wires provide a posteriorly directed force with torsional displacement of the vertebral body and lateral translation of the apex of a deformity. Hooks are used in the lumbar spine primarily as infralaminar hooks at the end of the construct or in patients with osteoporosis. Supralaminar or infralaminar hooks adjacent to pedicle screw instrumentation reduce the bending moments at the screw-rod junction (30).

The pedicle has been shown to be the strongest region within the vertebra and has been described as the "force nucleus" where the posterior elements meet the anterior column (10). Transpedicular fixation facilitates application of a rigid shorter length construct, thereby preserving more lumbar motion segment. Pedicle screws facilitate three-column control of the spine from the posterior approach, and permit restoration and maintenance of overall physiologic spinal alignment. An added advantage of a transpedicular system is that greater correction of deformity is feasible because of stronger points of fixation. In addition, concomitant laminectomy may be performed without adversely affecting the quality of fixation. Transpedicular systems avoid insertion of hardware

within the narrowed spinal canal. Solid fixation at the lumbosacral junction is also possible with pedicle screw placement (36,70).

### Screw-Rod versus Screw-Plate Constructs

Several plate screw designs were introduced in the early stages of development of transpedicular instrumentation (8–10,24,72). The plate systems are low profile, and have the ability to resist torsion against large loads. The plates also provide large surface area under which the bone graft can be compressed against the spine. Although plate-based transpedicular fixation has some of the aforementioned advantages, screw-rod constructs are more popular because of several drawbacks of screw-plate constructs. It is difficult to place the plate on multiple screws if multilevel fusion is being performed. Although the plate may be bent in a sagittal plane, correction of a multiplane lumbar deformity is difficult to achieve with a screw-plate assembly. Attachment of sublaminar wires to correct degenerative scoliosis or its use with lamina hooks in patients with osteoporosis is not possible with plate systems. Impingement of adjacent facet joints by the plates is common, and cross connection of plates is difficult. Moreover, there is less space available for bone graft placement, and it is more difficult to visualize the fusion mass in postoperative radiographs in the presence of plates. Finally, the plate screw systems may be associated with a higher incidence of screw breakage because of angulation between the screws and the plate, which may lead to screw-plate malalignment. The reported rate of breakage of the early designs of pedicle screws inserted with plates varied from 4.3% to 23% of patients (73,74).

Screw-rod constructs, on the other hand, are very versatile and overcome many of the disadvantages of the plate systems. Rods also facilitate extension of the instrumentation to the pelvis. Rod systems are assembled either by lateral connectors to the screws or the rods are dropped directly in to the top-loading groove of the pedicle screws. In either case, the construct can be difficult to assemble at times. The overall assembly also tends to be bulkier than plate-based systems.

There are few clinical studies comparing the results of plate-screw and rod-screw constructs. Zdeblick reported on the results of fusion in lumbar degenerative disorders in a prospective clinical series of 124 patients (52). Patients were randomized into three groups; posterolateral fusion without instrumentation, posterolateral fusion with semirigid plate-screw instrumentation, and posterolateral fusion with rigid rod-screw constructs. The overall 1-year fusion rate determined by radiographic analysis showed fusion rates of 65%, 77%, and 95%, respectively. The fusion rate among those procedures augmented with rigid transpedicular fixation was significantly increased as compared with the other groups. In addition, the over-

all good to excellent clinical results were greater in the rigid instrumentation group (95%) as compared with the semirigid (89%) and uninstrumented groups (71%).

### Biomechanical Considerations of Transpedicular Fixation

Transpedicular fixation permits rigid stabilization of the spine, which improves the fusion rate. Goel et al. (75) demonstrated a 70% reduction in flexion-extension and 65% decrease in lateral bending and axial motion with transpedicular fixation in a cadaver model. Kanayama et al. (76) observed significantly higher stiffness, more woven bone, and earlier fusion following instrumentation compared with uninstrumented fusion in a sheep model and concluded that spinal instrumentation creates a stable mechanical environment to enhance the early bone healing of spinal fusion. Kotani et al. (77) demonstrated that transpedicular fixation significantly contributed to anterior and middle column load sharing even after successful posterolateral fusion, when eccentric loading was applied *in vivo* in sheep. McAfee et al. (78) demonstrated an increased rate and cross-sectional area of fusion when posterior instrumentation was performed following anterior and posterior destabilization of the L5-6 motion segment in a beagle model. Although increased fusion rate was observed with a more rigid instrumentation, stiffer constructs also were associated with more severe device-related osteoporosis, although the clinical significance of this was unclear.

Several patient- and implant-related variables may affect the rigidity of transpedicular constructs. Inner diameter of the pedicle is the critical surgical diameter, and is directly related to the height of the patient, but not the gender (79). Several studies also have demonstrated that there are no significant racial differences in the morphology of the pedicle (80–83). Increasing the minor diameter of the pedicle screw decreases the risk of rate of screw fracture, whereas the major diameter, with greater depth of threads, determines the pullout strength of pedicle screws. Pedicle cortical disruption is unlikely if screw diameter is less than the endosteal diameter or is less than 80% of the cortical diameter (84). Consequently, determination of pedicular dimensions is important in preoperative planning.

Pedicle screws are available in conical and cylindrical designs. The potential advantages of conical pedicle screw design include less plastic deformation of the pedicle and improved thread purchase by compacting the cancellous bone at the cancellous–cortical bone interface throughout the pedicle. However, conical screws must be inserted to a correct depth, and loss of pullout strength may occur if the screw is backed out. In a calf model, Lill et al. (85) demonstrated that pullout strength of conical screws that had been backed out half a turn (180 degrees) was diminished by 50% even without cyclic loading. In

contrast, the pullout strength of cylindrical screws was that had been similarly backed out diminished only after cyclic loading.

Pintar et al. (86) performed a biomechanical study with the rods placed medial or lateral to the pedicle screws, and noted up to a 20% decrease in stiffness of transpedicular configuration with medial placement of longitudinal rods without cross connectors, compared with laterally placed rods without cross connectors. However, there was no significant difference in flexibility of the constructs with medially or laterally placed rods when one or more cross connectors were placed. They concluded that transverse connectors are necessary for constructs with medially placed rods to achieve rotational stiffness.

Although a few biomechanical studies have failed to show any biomechanical advantage of cross-linking of left and right longitudinal members (87,88), cross connectors are generally believed to significantly improve the torsional rigidity of the construct (89,90). Dick et al. (89) reported 44% increase in the torsional stiffness of pedicular constructs when one cross connector was used, and an additional 26% increase was noted with two cross-links. Cross sectional area of the cross-link correlated well with increase in torsional stiffness of a cross-linked construct. However, cross-links do not increase stiffness in the lateral flexion mode.

Several authors have recommended convergent placement of the pedicle screws (36,91,92), which decreases the likelihood of injury to the adjacent facet joints and allows insertion of a longer pedicle screw. Angled entry of the pedicle screws also provides an interlocking effect, which, in combination with longer screws, improves the pullout strength of the construct. In a biomechanical study, paired pedicle screws inserted at 30 degrees of convergence provided 28.6% higher resistance to axial pullout than paired pedicle screws placed in parallel (93). The pullout strength is also increased if the screw is placed into the end plate.

Biomechanical studies also have evaluated the optimal depth of insertion of the pedicle screw (91,94). The pedicles offer approximately 60% of fixation strength in the lumbar spine. An increase in the depth of insertion from 50% to 80% of the vertebral body improves the fixation strength by 30% (91). However, pedicle screws inserted to 80% of the anteroposterior depth of the vertebral body on lateral radiographs may penetrate the anterior cortex 10% to 30% of the time (95). The risk of potentially catastrophic vascular complications far outweighs the minor biomechanical advantages of bicortical fixation in lumbar spine (Fig. 25-2). However, bicortical fixation can be achieved safely in the sacrum by directing the screw medially, which increases the fixation strength by as much as 60%.

The bone–screw interface remains the most critical factor in determining the rigidity of transpedicular construct. Several authors (96,97) have shown that a higher

**FIG. 25-2.** Long screws may cause catastrophic vascular complications.

torque of insertion correlates with a higher screw pullout force. Halvorson et al. (98) showed that the pedicle screw pullout strength correlated highly with bone mineral density. Therefore, insertional torque aids the surgeon in determining overall quality of bone mineral density and gauges the rigidity of the pedicular construct intraoperatively. However, intraoperative insertional torque of pedicle screws is a poor predictor of postoperative screw loosening (99).

Poor fixation, intraoperative pedicle fracture, or postoperative screw migration with consequent risk of neurologic injury are major concerns in the presence of osteoporosis (Fig. 25-3). Biomechanical studies have shown that either untapping or undertapping the pedicle hole may improve the pullout force of pedicle screw in the osteoporotic spine (94,98). The bone mineral density of the lamina is affected less severely than that of the pedicles. Coe et al. (100) showed that the mean tensile

**FIG. 25-3.** Hardware migration in a patient with osteoporosis.

strength of lamina hook is 646 N lamina, and lamina hooks provide better fixation than pedicle screws in patients with severe osteoporosis. Other authors have also reported significant improvement in the stiffness of the construct when the pedicle screws are inserted in conjunction with laminar hooks (98,101–103).

Biomechanical and animal studies also have been performed to evaluate the efficacy of cement augmentation in improving the stiffness of pedicle screw based constructs. Pfeifer et al. (104) reported that low-pressure injection of polymethylmethacrylate (PMMA) into the pedicles increased the original pullout strength by 149% compared with 70% increase with milled bone and 56% increase with matchstick graft. Other investigators (105,106) have also reported improvement in pedicle screw pullout strength by PMMA injection into the pedicle. However, injection of PMMA into the pedicles may cause neurologic damage from extrusion of the cement into the spinal canal, and may complicate revision of the pedicle screw.

In one biomechanical study, revision of a 6-mm pedicle screw with a 7-mm screw decreased the pullout strength to 73% of the original pullout strength, but a 325% improvement was noted when a 7-mm screw was augmented with hydroxyapatite (107). In another study on human cadaveric lumbar vertebrae, Lotz et al. (108) demonstrated that augmentation of pedicle screws with injectable carbonated apatite cancellous bone cement improved the pullout strength of pedicle screws by 68%, and improved overall biomechanical performance by 30% to 63% on cyclic loading. Calcium phosphate cement augmentation increases the pullout strength of the pedicle screws by 10% compared with 147% increase by use of PMMA (105). The advantage of these newer bone cement materials is that they are bioabsorbable and are replaced during healing and normal bone remodeling.

### Stainless Steel versus Titanium Implants

Titanium alloy implants have several potential advantages over stainless steel implants. Titanium implants offer superior MRI resolution (109–111), making it easier to interpret postoperative MRI scans. High bioactivity and more flexibility of titanium implants also may improve bone ingrowth and mechanical fixation. In an animal model, Christensen et al. (112) demonstrated 33% more bone growth with higher mechanical binding at the bone–screw interface with use of titanium implant. Generation of particulate debris, however, may occur with the use of titanium implant in the presence of pseudarthrosis. Histopathologic evaluation of periimplant tissue samples obtained during revision surgery in patients with failed lumbar fusion and titanium instrumentation revealed that the wear particles generated by titanium implants are present both in a free state within the fibrous tissue and intracellularly within the macrophages. The latter evokes

a macrophage cellular response in tissues similar to that seen in total joint replacements. Patients with a solid spinal fusion have negligible levels of particulate debris (113,114).

## TRANSPEDICULAR INSTRUMENTATION

The goals of adding instrumentation to a posterior lumbar fusion procedure are enhancement of the fusion rate, maintenance of correction of deformity while the fusion incorporates, preservation of maximum possible segments, and shortening of the time required for rehabilitation of the patient. The immediate rigidity provided by pedicle screw instrumentation permits earlier, more aggressive rehabilitation without the requirement for an external brace. Important principles of transpedicular instrumentation are careful patient selection, safe and reliable method of insertion of pedicle screws, restoration of spinal alignment, meticulous preparation of the fusion bed, and sound fusion technique. The instrumentation also should be easy to use, and surgeon familiarity with instrumentation system is paramount.

### Preoperative Evaluation

Appropriate conservative management should be implemented before surgical treatment. Physical therapy or home exercises and nonsteroidal antiinflammatory drugs (NSAIDs) are recommended. Nonsteroidal antiinflammatory drugs should be used sparingly in the elderly population because of potential complications. If conservative treatment fails, it should be followed by a more detailed evaluation with additional imaging studies such as MRI or CT myelogram. In addition, provocative testing including discography, facet block, or selective nerve root injections may be necessary to determine the pain generator. Overall sagittal alignment should be evaluated on standing lateral radiographs, and the presence or absence of segmental instability should be determined on flexion-extension lateral radiographs. All this information helps the spine surgeon to formulate an appropriate surgical treatment plan that is tailored individually to each patient.

Specific anatomy of the lumbar spine should be carefully reviewed in each patient. Typically, the sagittal diameter of pedicle is greatest at the thoracolumbar level and decreases caudally, whereas transverse diameter of the pedicle is widest at L5 and gradually decreases at more proximal levels. The transverse diameter is the primary factor that determines the size of the pedicle screw. Plain radiographs reveal the relationship of the pedicle to each articular facet and transverse process. Preoperative knowledge of the mediolateral inclination of the pedicle in the presence of rotation is particularly helpful in patients with degenerative scoliosis. Preoperative and intraoperative lateral radiographs provide information on

the cranial-caudal inclination of the pedicles at each level. The presence of identifiable transverse processes on AP radiographs also facilitates intraoperative estimation of the location of the pedicle in revision cases complicated by failed fusion. Computed tomographic or MRI axial images at the level of the pedicle also allow determination of appropriate medial-lateral angulation along with the dimensions of each pedicle.

Determination of bone quality also should be made, and a dual energy X-ray absorptiometry scan may be indicated in certain patients. Instrumentation is best avoided in elderly patients with osteoporosis because of relatively poor fixation afforded by transpedicular instrumentation and higher risk of intraoperative complications, including pedicle fracture, longer operating time, increased blood loss, and potentially higher infection rate. The risk of secondary neurologic complications from hardware migration and loss of fixation is significant as well.

All patients on chronic narcotic medications should be considered for detoxification prior to surgery, and a smoking cessation program should be advised. Smokers have a significantly higher nonunion rate than nonsmokers (115,116). Brown and associates (116) retrospectively reviewed 100 patients who had undergone one or two level laminectomy and fusion. Forty percent of the smokers developed pseudarthrosis compared with only 8% of nonsmokers. History of smoking is a relative indication for the use of instrumentation to improve fusion rate. Finally, preoperative donation of autologous blood should be recommended for all lumbar fusion procedures. Although preoperative administration of Procrit (epoetin alfa) has been advocated by some total joint surgeons to minimize the need for blood transfusion, its role in spine surgery has not been investigated.

### Intraoperative Considerations

Although the choice of an operating table is surgeon dependent, it is critical that attention is paid to restoration of lumbar lordosis during positioning. Proper positioning of the upper extremities and placement of sequential compression stockings are necessary. Intravenous antibiotics are routinely administered and repeated throughout the procedure. Preoperative antibiotics have been demonstrated to diminish the incidence of deep postoperative infection in patients undergoing instrumented fusion (117). Intraoperative blood loss is minimized by use of appropriate hypotensive anesthesia, proper positioning without any pressure on the abdomen, meticulous hemostasis, and use of cell saver, particularly in multilevel fusion cases and revision procedures. Autograft iliac bone is preferred by most spine surgeons and remains the gold standard. Cancellous chip allograft and demineralized bone matrix also are frequently used as graft expanders. Bone morphogenic proteins such as RhBMP-

2 (Infuse), BMP-7 (OP-1), and BMP-14 (MP 52) are currently available for investigational use only. Bone morphogenic proteins may eliminate the need for autograft harvesting in the future if their effectiveness in achieving successful fusion is demonstrated in prospective controlled randomized studies.

The need for safe and accurate placement of pedicle screws cannot be overemphasized. Malpositioning of pedicle screws may cause dural laceration or neural injury (Fig. 25-4). Proper screw placement can be particularly difficult in revision lumbar surgery and in patients with significant degenerative scoliosis. In one of the earliest reported series on transpedicular instrumentation, Roy-Camille (8) reported a 10% incidence of incorrect placement of lumbar pedicle screws. Up to 40% of pedicle screws were placed incorrectly, and medial placement was noted in 29% in a recent study. A medial placement of 6 mm or more was significantly associated a neurologic injury (118). Schulze et al. (119) obtained CT scans in 50 patients after routine removal of 244 pedicle screws to eliminate any artifact from the hardware. Fifty-nine percent of screw tracks were located centrally within the pedicles, and 20% had violated the medial cortex by 2 mm or less. One patient had a neurologic injury because of pedicle screw malposition.

Roy-Camille (8,9) originally described use of a drill to create a pathway for the pedicle screw. However, creation of a burr hole at the screw entry point, followed by free hand development of screw tract with either a stiff probe (gearshift) or a curet, has currently become the most popular method of hole preparation. Boachie-Adjei et al. (120) found the free hand placement of pedicle screws to be safe, reliable, and cost effective in a prospective study of 50 patients with adult spinal deformity. Only 3% of screws were misplaced and 1% violated the medial wall, none with any clinical sequelae, in that study.

**FIG. 25-4.** Medial placement of pedicle screw may cause neurologic deficit and dural laceration.

Meter et al. (121) demonstrated that a true lateral or AP radiographic view of the vertebra provides a high degree of certainty that the screw has not crossed the end plate when a safe zone of 3 mm remains cephalad to the screw tip. Although intraoperative radiography can reduce concern about violation of the superior vertebral end plate, excessive use of intraoperative fluoroscopy should be avoided for fear of cumulative exposure to radiation (122). Biplanar roentgenography is only 73% to 83% accurate in determining position of the screw within the pedicle (123). Odgers et al. (124) prospectively inserted 238 screws from the T11 to L5 vertebral levels with the assistance of lateral plain radiographs. Eighteen screws had penetrated the pedicle wall medially and six laterally. Two screws penetrated the anterior vertebral body cortex. The overall success rate was 89.1%, and only two patients (0.84%) had neurologic complications. They concluded that pedicle screw insertion with the aid of lateral radiographs is safe and effective, and minimizes the operative time and expense arising from biplanar fluoroscopy.

Screw stimulation monitoring is a valuable adjunct to lumbar pedicle screw instrumentation. Several authors have demonstrated the usefulness of intraoperative screw testing by electrical stimulation to determine appropriate placement of pedicle screws (125–127). In general, electromyographic activity at a stimulation threshold of 8 to 10 mA is associated with breach in pedicle cortex, and activity at 4 to 6 mA or less is indicative of screw contact with nerve root or the dura. A stimulation threshold of 15 mA provides a 98% confidence in accuracy of pedicle screw placement.

Tactile sensory skills, anatomic knowledge, judicious usage of intraoperative radiography, and additional modalities such as electromyography monitoring are important in correct placement of pedicle screws. Several authors have reported favorable early experience with computer-assisted frameless stereotactic image guidance (128–131) and robot-assisted insertion techniques (132) in placement of pedicle screws in the lumbar spine. Frank et al. (133) reported the use of a malleable endoscope to visualize the pedicle cortex. However, these techniques are still evolving, and have not been fully evaluated. Moreover, these newer techniques are expensive, and their usefulness remains questionable at this time, given a high degree of accuracy with freehand placement of pedicle screws in all but certain revision cases and in patients with significant spinal deformity.

Percutaneous placement of pedicle screws is being developed also (134), but lack of adequate preparation of the intertransverse fusion bed as well as potentially higher risk of neurologic injury remain major points of concern. Most minimally invasive systems are designed to allow percutaneous screw insertion, and interbody fusion through a small tubular retractor. Some of the purported advantages of these minimally invasive approaches are reduced morbidity, less blood loss, cos-

metically appealing smaller incisions, and reduced scarring. Such procedures, however, are technically highly demanding, have a high learning curve and limited application, and their usefulness has not yet been clearly documented in prospective studies.

### Operative Technique

Important surgical principles of transpedicular instrumentation are strong biomechanical characteristics at the bone–implant interface, safe insertion of screws without neurovascular complications, avoidance of damage to the adjacent facet joints, and restoration of the sagittal balance. Wide surgical exposure of bony landmarks including the transverse processes, pars, and the mamillary processes is the first important step in accurate placement of lumbar pedicle screws. The facet joints at levels not included in the fusion must be preserved. When the sacrum is included in the fusion, lumbosacral facet joints and the ala are exposed, and the location of the first dorsal sacral foramen is determined. When decompression is performed as an integral part of the procedure, palpation of the pedicles from within the canal with the help of a Woodson also helps in determining the location of the pedicle. The accessory process is located in line with the lateral border of the pedicle, whereas the lateral border of pars interarticularis usually coincides with the center of L5 pedicle and medial border of the remaining lumbar pedicles (135).

Several methods of insertion of pedicle screws have been described. Roy-Camille (8,9) described a “straight-ahead” technique where the entrance point is chosen at the intersection of the middle third of the transverse process and a vertical line bisecting the center of the facet joint. A drill is then used to create the pathway for the screw, which is inserted parallel to the end plates in the sagittal plane. The Magerl technique (136) differs from that of Roy-Camille in that the entrance point is chosen at the intersection of the mid portion of the transverse process and the inferolateral aspect of the superior articular process, which allows more medial insertion of the screw parallel with the end plates. This course allows a longer-length screw to be inserted. A superomedially directed pedicle screw at the cranial end of the construct also has been recommended. The entry point for this superiorly directed screw tends to be at the intersection of the inferior one third of the transverse process and the vertical line along the lateral aspect of the superior articular facet (91). The advantage of this technique is that the prominent screw head is less likely to cause impingement at the adjacent intact facet joint at the cranial extent of the fusion. Gaines (137) recommends a direct funnel technique to identify and tap the pedicle isthmus, thereby obtaining a cortical purchase within the pedicle.

The sacral screws may be directed laterally into the ala, or more commonly, medially into the promontory

(138,139). Insertion of sacral pedicle screws requires knowledge of the unique anatomy in this region. The entry point for S1 pedicle screws is located at a point inferolateral to the superior facet, and the screw is inserted caudally parallel with the superior surface of the sacrum. The screw is also angled medially to avoid neurovascular and visceral injury. Mirkovic et al. (139) studied the neurovascular and visceral anatomy anterior to the sacrum and noted that the lumbosacral trunk, internal iliac vein, and sacroiliac joint were most commonly at risk during insertion of the S1 pedicle screw. The sigmoid colon and internal iliac vein were most vulnerable to injury during S2 pedicle screw insertion.

Typically, a pilot hole is created with a burr at the entry point of the pedicle, and the pathway into the pedicle and vertebral body is developed either with a pedicle curette or a gearshift. A blunt probe is used to determine if the cortex has been violated. Radiopaque markers are placed in the pedicle holes and intraoperative lateral radiographs or fluoroscopy are used to determine accuracy and inclination of marker placement. Each screw hole is tapped beyond the pedicle into the vertebral body. Probing after the pedicle hole has been tapped provides an unmistakable tactile feedback of the threads within the pedicle. Tapping is optional in patients with osteoporosis. We prefer to perform decortication and preparation of the fusion bed and bone graft placement prior to screw insertion. Electromyographic stimulation of the pedicle screws may be done to further ensure proper screw placement. As the construct is put together with rods and connectors, care must be taken to avoid impingement on the facet joint at the cranial end of the fusion. The instruments must be handled very carefully while inserting the rod or tightening the set screws because inadvertent slippage of instruments into the spinal canal can cause dural laceration and neurologic damage.

### Postoperative Care

Instrumentation obviates the absolute necessity of postoperative brace wear after lumbar fusion. However, most patients are typically immobilized in a lumbosacral orthosis or a thoracolumbosacral orthosis, depending on the length of the construct. Duration of brace wear varies depending on surgeon preference, length, and rigidity of the construct, and patient’s body habitus and compliance. Transpedicular fixation appears to shorten the duration of postoperative rehabilitation.

Electrical stimulation devices are also sometimes recommended in the postoperative period to enhance fusion. In a controlled prospective study of patients undergoing posterior spinal instrumentation, Kucharzyk (140) reported a slightly improved fusion rate of 95.6% with the use of implantable electrical stimulation compared with 87% in the control group. Fifty-seven percent of patients in the stimulated group had clinical success com-

pared with 46% in the nonstimulated group. Jenis et al. (141) performed a prospective study of 61 patients undergoing instrumented fusion who were randomized to receive no electrical stimulation and implantable device or an external stimulator. They did not find any significant difference in fusion rates in any group. Although there is a scarcity of additional prospective, controlled data on external electrical stimulation in patients with instrumented fusion, the use of external bone stimulation devices may be considered for high-risk patients.

Assessment of bony union is not always straightforward, particularly in the presence of bulky instrumentation. Oblique radiographs may help prevent the hardware from overshadowing the fusion mass and facilitate better assessment of the fusion status. Ferguson view radiographs are necessary for evaluation of lumbosacral fusion. Radiographic demonstration of trabeculation across the intertransverse area is necessary to assess union (142). We routinely also obtain flexion-extension lateral radiographs to document union and detect any instability 6 months postoperatively.

Prolonged stress shielding from retained instrumentation may be of concern. However, Craven et al. (143) reported that initial stress shielding of the bypassed vertebral column that occurs with the use of rigid internal fixation tends to lessen with time in a canine model. They attributed this rebound in the bone mineral density of the fused vertebral segments to several factors, most notably to a shift in load distribution from implant to the spine secondary to screw migration or loosening because of bone remodeling. Additional factors, such as implant-implant interface changes (e.g., loosening and corrosion) also may play a role. However, these authors had used human-sized bicortical pedicle screws in their canine experiment, and the longitudinal loads on the canine spine are typically one tenth of those observed in the human spine.

Retained hardware also may cause irritation from prominent hardware, late hematogenous infection, accelerated degeneration of the adjacent segment, long-term metal toxicity, and increased risk of neurologic injury in the event of future trauma (91). Previous studies (17,144,145) have reported a 12% to 23% incidence of hardware removal owing to local irritation caused by the pedicle screws. However, no data have been reported in the literature to support routine removal of pedicle screws, which in fact, may be dangerous because of significant risk of neurovascular injury. Consequently, routine removal of instrumentation should be avoided.

### Complications

The complication rate with the usage of pedicle screw fixation is low if the surgeon is experienced and attention is paid to principles and details of the operative technique. Several authors have reported an acceptable com-

plication rate and risk of neurologic injury during transpedicular instrumentation (17,145–147). In a historical cohort study, Yuan et al. (17) reported a 5% incidence of intraoperative events associated with the use of screws. Loss of purchase (1.7%) and pedicle fracture and screw breakout occurred in 1%. Neurologic injury, dural tear, and screw breakage were rare complications. In a series of 4,790 pedicle screw insertions, Lonstein (145) noted that 5.1% screws were inserted outside the pedicle, and the incidence of permanent nerve root injury owing to pedicle screw insertion was 0.3%.

When neurologic deficit is noted postoperatively, thin-cut CT scan is the imaging study of choice. Sapakas et al. (148) assessed the position of 220 pedicle screws with CT scan and lateral radiographs postoperatively in a prospective manner in 35 consecutive patients. They concluded that although the accuracy of CT imaging is better than that of plain radiographs, the difference is not statistically significant, and postoperative use of plain radiographs is a reliable method for evaluation of pedicle screw insertion in the absence of neurologic deficit. However, when neurologic deficit is present postoperatively, placement of questionable pedicle screws is best evaluated with thin section CT scan. Farber et al. (149) demonstrated that thin-cut CT scan is 10 times more sensitive than plain radiographs in determining violation of the medial cortex.

Postoperative infection in presence of instrumentation is worrisome. Pedicle screw fixation requires longer operative time with concerns of increased infection rates. Wimmer et al. (150) retrospectively reviewed a large series consisting of 574 posterior instrumented fusions and 274 anterior procedures. They identified an infection rate of 21/574 with posterior procedures and 1/274 with anterior surgery. Increased blood loss and prolonged operative time correlated with postoperative infection. Weinstein et al. (151) reviewed a series of 2,391 spinal operations with an overall infection rate of 1.9%. They observed increased infection rate in the presence of instrumentation and in patients with prior history of surgery. However, no significant difference was noted in the rate of infection between uninstrumented and instrumented spinal fusion in a large historic cohort study (17).

Glassman et al. (152) retrospectively reviewed 858 instrumented spinal fusion procedures and noted an overall infection rate of 4.2% and deep wound infection rate of 2.6%. Cigarette smoking and previous back surgery did not predispose to infection in that study. *Staphylococcus aureus* was the most common offending organism. All patients with deep infection were treated with serial wound irrigation and débridement and antibiotic mixed cement was placed in the lateral gutters. An 80% rate of improvement was noted after an average of 4.7 débridements. These authors concluded that postoperative infection does not adversely affect the rate of fusion. Weinstein et al. (151) also recommend an aggressive surgical

approach consisting of repeated débridement followed by delayed wound closure. Viable bone graft and instrumentation may be left *in situ* to provide stability for achieving fusion.

There is a potential for increased blood loss owing to wider surgical exposure that is necessary for visualization of anatomic landmarks for pedicle screw insertion. Bulky pedicle screw based constructs also create a dead space by elevating the paraspinal musculature off the posterior elements, which may increase the risk of postoperative hematoma and infection secondary to a lack of tamponade effect (36).

Screw loosening at the bone–cement interface is the most common mechanism of failure in most pedicle screw instrumentation systems. However, some radiolucency may be present during the time preceding the union (36). Postoperative fracture of the instrumented pedicle is rare and its reported incidence is 0.2% to 2.7% of patients (143,144,146). Macdessi et al. (153) reported development of bilateral pedicle stress fractures at the uppermost level of the fusion mass in a patient 2 years after pedicle screw removal from an L4-S1 instrumented posterolateral lumbar spine fusion. They concluded that the pedicle is the weakest point in the neural arch after posterolateral fusion. Although movement continues at the level of the disc space anteriorly, the pedicle is susceptible to fracture.

Breakage of pedicle screws is uncommon with newer designs. Breakage of pedicle screws occurred in 0.5% of all screws in 2.2% patients in one study, in which most broken screws were of earlier designs (144). Screw breakage occurred more commonly with greater intervertebral motion, less anterior column loading, and presence of tall discs. Broken screws are not necessarily associated with pseudarthrosis (50), and breakage of hardware does not always require surgical management (Fig. 25-5).

**FIG. 25-5.** Patients with broken hardware may have pseudarthrosis.

However, fusion status must be thoroughly evaluated in symptomatic patients, because up to two thirds of patients with broken screws may have pseudarthrosis (144).

### Adjacent Segment Degeneration

Adjacent segment degeneration has been known to occur in patients with spinal fusion even before the use of instrumentation became widespread. Whether adjacent segment degeneration is a continuing degenerative process or a late complication of fusion is debatable. A solid fusion alters the biomechanics at the adjacent level, resulting in increased mechanical demands. Increased biomechanical forces, mobility, and intradiscal pressure in adjacent segments after fusion have been hypothesized to accelerate the pathologic changes (154–156). Lee (157) suggested that increased adjacent level changes after fusion occur because of stress concentration and posterior displacement of the center of rotation at the adjacent segment.

Whether instrumented fusion leads to acceleration in the degenerative process of the adjacent segments is not clear. Static kinematic testing has shown increased motion at adjacent segments in pedicle screw-based constructs (158). Stress transfer to the adjacent joints increases with increasing number of levels included in the fused segments (159). Wimmer et al. reported that adjacent segment degeneration was more common with multilevel than single-level instrumented circumferential fusion (160). Additionally, part of the facet joint cephalad to the fusion may be resected during insertion of the pedicle screws, or the hardware itself may abut against the facet joint, causing damage to it (91).

Degeneration most commonly occurs in the segment immediately cephalad to the fused segment. However, the next segment adjacent to that segment also has been reported to break down in 58% patients in one study (161). Aota et al. (162) reviewed 65 patients who underwent wide laminectomy, Cotrel-Dubousset instrumentation, and fusion for lumbar degenerative disorders. They used the Roy-Camille technique for insertion of pedicle screw, which involved resection of the tip of the inferior facet. They reported 24.6% incidence of postfusion instability, with a vast majority involving the adjacent segment above the fusion level. Seventy-eight percent instability occurred in sagittal plane and retrolisthesis was the most common instability pattern (nine of 15 patients). Age of the patient appeared to be the most significant factor, with a 36.7% incidence in patients older than 55 years compared with 12% incidence in younger patients.

Etebar and Cahill (163) reported adjacent segment degeneration in 18 of 125 consecutive patients who underwent instrumented posterior lumbar fusion for degenerative instability of the lumbar spine. The mean follow-up was 44.8 months. Twenty percent of all patients with next-segment failure were cigarette smokers. Adja-

cent segment involvement included spondylolisthesis (39%), stenosis (33%), stress fracture of the adjacent vertebral body (28%), and scoliosis (17%) in their study. The risk of adjacent-segment failure was particularly high in postmenopausal women with nearly 50% incidence. In a retrospective review of 49 patients who underwent instrumented lumbar fusion, Rahm and Hall (164) noted 35% incidence of adjacent-segment degeneration, and its occurrence was associated with increasing patient age, the use of interbody fusion, and a worsening of clinical results with time. An average of 2.5 levels were fused in their patient population with a mean age of 53.8 years. Based on their retrospective analysis of 83 patients, Kumar et al. (165) recommended restoration of sagittal alignment and normality of sacral inclination as paramount in minimizing the incidence of adjacent segment breakdown.

In contrast, Wiltse (166) concluded from a comparative study of 52 patients with instrumented fusion and a control group of 31 of uninstrumented fusion that the addition of pedicle screw fixation does not increase the incidence or severity of adjacent segment degeneration in the first 7 years after surgery.

It is clear that adjacent segment degeneration following instrumented lumbar fusion is a topic of major concern among spine surgeons. A thorough understanding of the patient- and surgeon-related factors may aid the surgeon in reducing the incidence of the degenerative process of adjacent unfused segments. Some of the surgeon-related factors include meticulous surgical techniques with preservation of the facet joint capsule, avoidance of facet damage during pedicle screw insertion or abutment of the facet joints against the hardware, and restoration of sagittal balance. Finally, careful consideration should be given to the health of adjacent discs and facet joints for possible inclusion in the proposed levels of fusion and prevention of early breakdown of an adjacent disc.

## COST ANALYSIS

There has been significant increase in the number of instrumented fusion procedures performed in last several years. The economic implications of widening use of instrumentation in lumbar fusion procedures, their cost effectiveness, and potential value to the society are now receiving increased scrutiny. Katz et al. (167) performed a prospective observational study of 272 patients and concluded that uninstrumented fusion provided superior pain relief at 6 and 24 months postoperatively. They also noted that concomitant uninstrumented fusion procedure increased the hospital cost of decompressive laminectomy by 50% and instrumented fusion increased the cost by 100%, compared with patients who underwent uninstrumented fusion. Kuntz et al. (168) calculated the 10-year costs, quality-adjusted life years, and incremental cost effectiveness ratio of fusion lumbar fusion proce-

dures with and without instrumentation, and found instrumented fusion to be significantly more expensive in terms of incremental gain in health outcome. Gibson et al. (169) conducted meta-analysis of instrumented versus uninstrumented fusion and noted improved fusion rate with instrumentation, but no difference in the clinical outcome of the two groups. Whether the added cost of instrumentation is worth the benefit in overall health outcome remains a controversial and unresolved issue.

## CONCLUSIONS

Pedicle screw fixation is a safe and reliable method of achieving rigid internal fixation of the lumbar spine in the hands of experienced surgeons. Instrumentation improves the rate of fusion and clinical outcome in certain degenerative disorders of the lumbar spine. However, more clinical data are needed for establishing the role of transpedicular fixation in patients with discogenic back pain. Although pedicle screw fixation offers several advantages, it should be used judiciously in carefully selected patients to minimize the risk of untoward complications. The risk-benefit ratio of adding instrumentation must be analyzed carefully, particularly in elderly patients. Finally, sound surgical principles of fusion must be practiced.

## CHAPTER 26

# Spinal Instrumentation Overview in Lumbar Degenerative Disorders: Cages

Kenneth M.C. Cheung and John C.Y. Leong

---

### ROLE OF CAGES IN THE LUMBAR SPINE

Cages are interbody spacers used to bridge or reconstruct the interval between two vertebral bodies (1–4). There are many different designs, but in general, they all provide a mechanically strong scaffold inside of which osteoinductive or osteoconductive materials can be placed. Such material maybe autogenous bone graft, allograft, or more recently bone morphogenetic proteins (5–10).

Cages are used in either degenerative conditions of the spine requiring fusion, or as a form of anterior column reconstruction after destruction by tumor, infection, or trauma. This overview concentrates on its application in degenerative spinal conditions, in which cages are either used as an anterior load-sharing device after posterior spinal instrumentation and fusion (1,4,7,11,12); or as a replacement for bone graft after anterior lumbar interbody fusion (ALIF) (13), sometimes referred to as a “stand-alone” cage.

### TYPES OF CAGES

There are no universally accepted classifications for the cages available today. However, they can be broadly divided into different types by their design or material (1).

Three general designs are used, as follows.

#### Horizontal Cylinders

One example is the Bagby and Kuslich lumbar (BAK/L) interbody fusion cage (Sulzer Spine-Tech, Minneapolis, MN) (Fig. 26-1). These devices generally are made from titanium. Usually a pair is inserted together by either the anterior or posterior approach, and by use of either open or minimally invasive techniques (11,13–19).

#### Vertical Rings

An example is the titanium mesh cage manufactured by DePuy AcroMed (Johnson & Johnson, Raynham, MA), sometimes referred to as the Harms cage (Fig. 26-2). They are designed to allow the length to be cut as desired; therefore, they can be used to span either a single disc space or multiple segments of the lumbar spine. Because of the presence of sharp edges, they are usually and more safely inserted via an open technique (20,21).

#### Open Boxes

An example is the Brantigan carbon cage (Fig. 26-3) (22–24). The boxes are designed either with conical superior and inferior surfaces for an anatomic fit into the disc space, or as wedges to recreate lumbar lordosis. Some are designed as a single large cage, which requires an open technique for insertion; whereas others involve two smaller rectangular cages, which can be inserted posteriorly using minimally invasive techniques.

#### Cage Materials

In general, these are usually made from titanium, carbon, or a carbon composite (polyetheretherketone [PEEK]). Titanium is a mechanically strong and bio-inert material that is magnetic resonance imaging (MRI) compatible. Therefore, cages made using this material can have relatively thin struts that allow more room for bone graft in its interior. The presence of a metallic shadow on radiographs makes the assessment of bony fusion within the cage difficult. Some surgeons attempt to overcome this by placing bone graft anterior to the cage as well as within it (5). Carbon and PEEK cages are radiolucent and allow for an easier assessment of bone fusion. Addition-

**FIG. 26-1.** Bagby and Kuslich lumbar interbody fusion cage, an example of a threaded horizontal cylinder.

ally, they have a Young's modulus that nearly matches that of cortical bone. This allows the compressive load on the cage to be shared by the bone graft inside the cage and may facilitate a more consistent and rapid bone fusion. Both carbon and PEEK cages are also MRI compatible.

### INDICATIONS FOR CAGES

Before the advent of cages, bone grafts such as tricortical iliac crest grafts and fibula strut grafts were used very successfully as a form of anterior column support and to promote spinal fusion (25,26). Thus, there are no absolute indications for the use of cages, and the value of cages as an alternative to autogenous bone graft should be judged with the latter as a gold standard. Accordingly, the indication for use of a cage is the same as that for bone graft, namely, anterior column reconstruction and fusion.

Proponents of cages suggest that they may have a number of advantages over conventional bone graft material alone. Such advantages mainly stem from the separation of their mechanical and biological roles and may include:

1. Enhanced mechanical stability
2. Maintenance of intervertebral disc height
3. Avoidance of bone graft donor site morbidity by using alternative osteoconductive and osteoinductive materials inside the cage.

**FIG. 26-2.** Titanium mesh cage (Harms), an example of a vertical cylinder. End-rings (**right side**) can be added to the reduce stress concentration at the ends of the cage, and therefore reduce the chance of sinking into the end plate.

**FIG. 26-3.** Brantigan carbon cage, an example of an open box design.

Cages are designed to have better mechanical stability than bone graft by virtue of their material and design. Cylindrical cages have a threaded design (Fig. 26-1) and use a screw-in technique for insertion (14,27), whereas box cages have a serrated surface (Fig. 26-3) (13,28). Both help to increase motion segment stiffness and resistance to pull-out. It is claimed that this may improve the chance of a successful fusion, although this point remains to be proved scientifically.

Cages may be better at maintaining disc height than bone graft alone. In our long-term follow-up study (mean duration of 14 years) of 67 patients that underwent anterior lumbar interbody fusion at L4-5 with autologous iliac crest graft (29), we demonstrated that there was an initial distraction of the disc space by 34% (4.1 mm) followed by an eventual partial loss of this distraction in 86% of cases despite a successful fusion. The mean preoperative disc space height was 12.1 mm, increased immediately after surgery to 16.2 mm, but settled to 12.6 mm at the latest follow-up. The reduction in distraction occurred within the first 3 months after surgery and was correlated with age, but not with recurrence of symptoms, the amount of initial distraction or sex of the individual. L4-5 segmental angulation followed a similar trend. The early loss of disc space distraction likely resulted from moulding of the bone graft into the created space, and bone graft softening and resorption during remodeling. Studies have shown that restoration of disc space height tightens the posterior ligaments and opens up the intervertebral foramina, thereby indirectly decompressing the neural foramina exiting nerve roots (30). Although this has been used as a justification for using cages, it should be borne in mind that our study showed that the loss of disc space distraction did not correlate with return of the patients' symptoms, and no long-term clinical study is available to demonstrate that disc space height is maintained with cages. Indeed, there is some evidence in both animal and human studies that disc space reduction and loss of lordosis also occur with threaded cylindrical cages (31,32). Special considerations should be given to patients with reduced bone density because there is a risk of end-plate fracture by the implanted cage, which may result in loss of distraction (29,33).

Avoidance of donor site morbidity (34,35) is often cited as another reason for using a cage. However, until recently only osteoconductive materials, such as allograft bone and hydroxyapatite blocks, were available as replacements for autogenous bone. We caution that the use of such materials as the ultimate aim is still to achieve a fusion and autogenous bone graft is still currently the best material for this purpose. There have been several studies examining the use of bone morphogenetic proteins placed inside cages in human patients (8,10). Both studies concluded that recombinant bone morphogenetic protein-2 (rhBMP-2), can effectively achieve a spinal fusion, although the number of patients involved were small, and the follow-up short. Large-scale randomized controlled trials with long-term follow-up are required to prove this definitively.

## CHOICE OF CAGES

The ideal cage should rigidly immobilize the spine in all directions, be strong enough to withstand repeated loading, and have a modulus of elasticity close to that of cortical bone. It should also be easy to insert by either an open or minimally invasive approach, and should be clinically effective by randomized controlled trials and long-term follow-up.

It is difficult to advise readers on the optimal choice of cage because of the wide variety of cages currently available, with more likely to come on the market in the future. However, users should be aware of some biomechanical and clinical considerations with the currently available designs.

### Biomechanical Considerations

In general, studies comparing the stiffness of the spine segment after cage insertion have shown no significant differences among the various designs (13,36–38). All are effective at stabilizing the spine, compared with its intact condition, in flexion, axial rotation, and lateral bending. This effectiveness is dependent on their ability to distract the surrounding soft tissues and their contact with the host bone. Hence, the cage needs to be appropriately sized for height as well as fit (13,39). Differences within a particular category of cage design may have an effect on mechanical stability. For instance, cages with sharp teeth have higher “pull-out” forces (13), whereas Harms cages without the addition of the end-rings impart only marginally better stability in rotation when compared to bone graft (40). All stand-alone cages, however, are less effective in stabilizing the spine in extension, and motion between the cage–bone junction is present unless supplemental fixation is used (41). Addition of fixation, whether anterior or posterior, and by translamina or pedicle screws, will significantly improve the fusion segment stiffness (3,36,38,42).

One area of concern with the use of cages compared to bone graft is that the stiff struts of the cage stress shield the bone graft placed inside the cage. Because bone heals best under compression, this could result in reduced fusion rates. In a study by Kanayama et al. (37), a calf spine model was used to quantify the stress-shielding effects of 11 lumbar interbody fusion cages by measuring pressure within the cages. This was achieved by injecting the cages with a silicon elastomer before insertion, and intracage pressures were measured using pressure needle transducers. The authors concluded that threaded fusion cages demonstrated significantly lower intracage pressures compared with nonthreaded cages and structural allografts. Whether this is clinically relevant is not known, because there are no comparative studies examining fusion rates among the various types of cages.

The possibility of stress shielding and the presence of motion within the spine segment despite the use of cages raise the question of whether they can be used as stand-alone devices, without supplemental fixation. Because of a lack of clinical studies with long-term follow-up, this question cannot be currently answered. There are certainly advocates who recommend supplemental posterior fixation to improve the chance of fusion (38,42–46). It should be borne in mind that iliac crest bone grafting without instrumentation has been used successfully to perform anterior lumbar interbody fusion with fusion rates for a single level fusion of up to 96% (26,29,47,48). This should be the benchmark against which fusions with cages are compared.

### Clinical Considerations

Interbody fusion in degenerative disc disease serves a number of purposes. First, by removing the disc it removes a potential source of pain, and by removing herniated fragments it decompresses the nerve roots. Second, fusion stabilizes the segment and augments the anterior column. Third, restoration of disc space height tightens up the posterior ligaments and opens up the intervertebral foramina, thus indirectly decompressing the nerve roots (30,31). The first two aims can be adequately achieved by anterior interbody fusion with tricortical iliac crest bone graft, whereas a cage may be required for the third aim. However, before a rational choice of fusion devices can be made, surgeons should be aware of the clinical track record of cages.

There are very few reports of long-term results of cages. One of the longest and earliest experiences in the use of interbody spacer was by the senior author in 1994 (49). A titanium mesh interbody spacer was inserted as a stand-alone device without bone grafting in 23 patients with an average follow-up period of 8 years (range, 5 to 12 years). This study demonstrated that bony ingrowth into the titanium mesh occurred in 18 of 23 patients, as shown by lack of a radiolucent line at the bone–implant

junction, and was subsequently confirmed in retrieval studies. However, six of these 18 implants failed by a mid-substance disruption of the mesh, with three implants developing a crack, and three becoming deformed. In all six patients, movement could be demonstrated between the adjacent vertebral bodies, despite the lack of a radiolucent line. The authors postulated that with the solid metal–bone interface, the mesh became subjected to more stress during flexion and extension, such that if solid bone fusion did not occur, the implant failed in its mid-substance. One of the best ways to demonstrate bone fusion is the presence of anterior bridging bone (Fig. 26-4). This occurred in four of the 23 cases, and when this was seen, no further movement between the adjacent vertebral bodies could be demonstrated on flexion and extension, and no mesh failures occurred.

Based on this experience, the authors feel that one should make the distinction between *bone ingrowth* into the periphery of the cage, and *bone fusion*, which extends from one end plate to the other. If the latter does not occur, then the cage may fail in the long term. Thus, in reading the literature on the results of cages, the reader should make this distinction and note the duration of follow-up. Any study with less than 5 years of follow-up is very unlikely to see cage failure because of bone ingrowth only and the lack of a solid bone fusion.

One study examined needle biopsies from tissue within radiographically successful intervertebral body fusion cages filled with autograft (6). Five cages were implanted anteriorly, one with additional fixation, and four cages were implanted as part of a posterior lumbar interbody fusion. Five were carbon cages (Brantigan cage), whereas four were titanium mesh (Harms Cage), with a mean postimplantation biopsy duration of 28 months (range, 8 to 72 months). Biopsies were obtained from within the center of the cages and showed small fragments of

**FIG. 26-4.** Implanted titanium mesh block showing anterior bone bridging and solid fusion.

necrotic bone associated with viable bone and restoration of hematopoietic bone marrow. Numerous cement lines demarcated the edges of previous cycles of remodeling, and the ratio of necrotic to viable bone varied greatly among cases. Small particles of debris were found in four of the five carbon-fiber cages and in one of the four specimens from titanium cages, but there was no visible bone resorption or inflammation. It could be interpreted that, despite stress-shielding by the cage, solid bone fusion eventually may occur, although bone grafts contained within these cages are still undergoing remodeling beyond the 3 to 6 months that autograft is normally expected to fuse and remodel.

In 1997, Ray (50) reported his initial results of using a stand-alone threaded cage packed with autogenous bone graft and inserted via a posterior approach. Fusion, as assessed by plain lateral radiographs and lack of movement on flexion-extension radiographs, was said to occur in 91%. Lack of movement may result only from bony ingrowth into the superior and inferior faces of the cage for a limited distance. The word “fusion” should be used only if there is evidence of continuous bony ingrowth through the entire extent of the cage. To date, this has not been definitively demonstrated in any study.

Kuslich et al. reported on the 4-year follow-up results of the BAK cage in 25.6% of the original study population (18). Their overall “fusion rate” was 91.7% and 95.1% at 2 and 4 years, respectively. This was from a combination of anterior and posterior approaches. Whether or not additional instrumentation was used is unknown. The late-occurring complication rate was 13.8%. Complications necessitating a second operation occurred in 8.7%, and reoperations directly related to the device occurred in 3.1%. This study has been criticized for the small number of patients available for follow-up assessment (51,52).

Studies examining the use of other cages have tended to be combined with posterior fixation, and they all report “fusion rates” in the range of 90% to 100% (7,12,20,23,24,53). However, it should be noted that no movement would be detectable on flexion-extension radiographs with solid posterior fixation, thereby hampering fusion assessment. It requires long-term follow-up to demonstrate nonunion from loosening or implant failure (54).

One additional criterion in the choice of cages is the surgeon’s familiarity with the techniques of insertion. Although the majority of the box cages are used in a similar manner to bone graft, the threaded cylindrical cages require a specialized technique of insertion. Attention to detail is important, because complications arising from inadequate distraction of the annulus fibrosus, under sizing of the cages, and dural tears from a posterior approach all have been described (55). Additionally, some cages are designed for anterior minimally invasive insertion (15–17,56–58), whereas others are designed for

use as a PLIF only. These are all important issues to consider, and any surgeon intending to use such cages should be thoroughly familiar with their indications and design considerations.

## SUMMARY

Lumbar interbody fusion cages may have some advantages over conventional autogenous bone grafting techniques. They have the theoretical potential to maintain vertebral distraction, and separate the structural and biological functions of an interbody spacer. With the development of osteoinductive compounds delivered as a recombinant protein or via gene therapy (59), bone graft harvesting and donor site morbidity theoretically could be avoided altogether. However, techniques of insertion may be demanding and surgeons should be familiar with the design before using a cage of their choice. Finally, one should balance the use of such expensive implants with the low cost and proven effectiveness of autogenous bone graft, which is the gold standard in anterior interbody reconstruction and fusion to date.

# Translaminar Screw Fixation

Dieter Grob

---

One of the surgical concepts to reduce pain originating from the lumbar spine is to immobilize the involved vertebrae. The most natural way to achieve this is to take advantage of the process of bone healing. By preparing the parts to be fixed with decortication and additional placement of bone graft, fusion may be enhanced. The mechanical situation of the spine, with considerable lever arms and multiple segmental centers of motion, implies a relatively low success rate of solid bony bridging.

To improve the fusion rate and reduce the need for rigid and cumbersome external fixation postoperatively, internal fixation has been introduced to temporarily immobilize the spine and thus enhance bony calcification. For this purpose Hadra (1) introduced first metallic wires in 1891. Before the era of pedicular screw fixation was introduced in Europe in the early 1960s (2), attempts to stabilize vertebrae posteriorly with screws only were attempted. The use of facet screws was first reported by King (3), whose technique was to immobilize the lumbosacral joints with short screws traversing the facets. With this technique he achieved a fusion rate of 91% without prolonged postoperative external fixation. Boucher (4) adopted this idea and improved the technique. He achieved a 100% fusion rate in single level fusions by penetrating the ipsilateral pedicle with the tip of the screw, thus improving the bony purchase. This method of screw insertion implied that the tip of the screw had to be placed near the foramen and the nerve root and carried the risk of nerve injury. In addition, there was a risk of decreased stability of this construct if the screw broke through the cortex of the posterior aspect of the facet. These complications of screw fixation in the lumbar spine made them unpopular despite the simplicity of the technique. It was Magerl 1984 (5) who modified and improved the technique of screw fixation and popularized revival of this type of immobilization. By inserting the screws from the contralateral side through the lamina, through the facet and ending in the base of the transverse process, most of the disadvantages of the former techniques were eliminated without losing their advantages.

Bony purchase was increased by the passage of the screw through the lamina, and the procedure was less risky because: (a) the insertion of the screw was clearly posterior to the neural elements; (b) the technique could be performed under direct visualization; and (c) the direction of screw insertion was parallel to the exiting nerve root, thereby minimizing the risk of injury to the nerve.

### BIOMECHANICAL CONSIDERATIONS

A simplified but practical biomechanical concept of the lumbar spine with a three-column model was conceived by Louis (6). The anterior column is represented by the disc, the vertebral body, and the two posterior columns by the facets. In the course of evolution, anatomy adapted to the physiologic requirements of the spine; therefore, it seems reasonable to assume that the facets developed in response to mechanical necessity.

The importance of the facets has been demonstrated by several *in vitro* experiments in which partial or total resection of the facets led to dysfunction of the functional spinal motion unit (7,8). Together with the intervertebral disc, the facets share and support the axial load of the spine. Although the disc appears to be the primary load-bearing structure (8), the facets function as an indispensable part of the three-column concept to transmit part of the axial load, which varies according the position of the individual (9,10). Structural and morphologic changes that occur with destruction of cartilage and osteophyte formation underscore the important mechanical properties of the facets. Because the load passes partially through the facets, the lever arm acting on an internal fixation device through the facets remains small. A low-profile fixation device is sufficient to block segmental motion efficiently enough to enhance solid bony fusion (11,12).

Despite the fact that translaminar screw fixation represents the lowest profile implant for the lumbar spine, the stability in flexion achieved with this technique *in vitro* is similar to that provided by pedicle screw fixation (13,14).

**FIG. 27-1.** Ten years postoperative: In addition to the solid fusion posteriorly, spontaneous calcification of the immobilized disc occurred. Axial loads are shared equally in the anterior and posterior columns.

The mechanical stiffness of a segment instrumented with translaminar screws is 2.4 times that of an uninstrumented segment; the stiffness was maintained for 5,000 cycles in static and cyclic loading tests (13,14).

The fact that the transfacet screw fixation *in vivo* might be less rigid than pedicle fixation may be an advantage rather than a disadvantage by promoting bone formation because rigid fixation results in stress shielding of the fusion and impedes bone remodeling (Fig. 27-1).

## INDICATIONS

Translaminar screw fixation might be indicated in cases where segmental motion in the lumbar spine must be eliminated. It can be used as a primary fixation or as a supplemental procedure to protect and augment an existing fixation.

### Translaminar Screws as Primary Procedure

#### *Segmental Dysfunction*

Motion between two or more anatomic structures causes wear and tear and a gradual change in their microstructure and macrostructure that may or may not lead to altered function and possibly pain (15). Given the complexity of the spine, diagnosis and localization of the pain source remains a challenging problem. In addition to clinical and radiologic examination (16), facet blocks and discography may be helpful to determine the painful segment. Temporary fixation with an external fixator also may be used as an invasive diagnostic method to identify a painful segment (17).

Once the diagnosis and localization of the painful segmental motion is established, posterior immobilization

with translaminar screw fixation provides a simple and effective means of selective fusion of the involved segment (18). Dysfunction of a segment before the development of significant macroscopic structural changes represents an ideal indication for translaminar screw fixation.

### *Lumbar Spinal Stenosis*

Degenerative lumbar spinal stenosis can be effectively treated with surgical decompression. If the compressive structures are removed, reduced leg pain and increased walking distance may be expected (19). It is reasonable to assume that the decompression may adversely affect the stability of the involved segment (7). Complete laminectomy with removal of a major portion of the facets, as may be required for lateral spinal stenosis, may jeopardize the segmental stability (8,20,21,22). Fusion also should be considered in these circumstances. Once the posterior elements have been removed, only transpedicular fixation systems are feasible. By using the more anatomic, atraumatic, and physiologic technique of “undercutting laminectomy,” an effective decompression of the spinal canal can be performed leaving the posterior elements essentially intact (23–28). If fusion is considered necessary under these circumstances, the translaminar screws can provide fixation without considerable risk or lengthening of the operative time.

### *Revision Surgery*

Persistent or recurrent pain after decompressive procedures might be associated with mechanical problems. Scar formation or persistent bony stenosis might irritate neurologic structures during motion. Therefore, immobi-

lization of a previously operated segment may be indicated. If there is foraminal narrowing as a result of disc space narrowing following prior discectomy, additional distraction will open the foramen (29). Resection of one facet joint or bilateral resection of more than 50% of both facets may produce segmental instability (30). Because translaminar screws rely on the integrity of the posterior elements, this technique is only possible where the lamina and facet joint are sufficiently intact to receive a 4.5-mm cortical screw. Because the posterior bone stock is reduced, careful posterolateral intertransverse dissection must be done.

### ***Disc-Related Syndromes***

#### ***Lumbar Disc Herniation***

Excision of a protruding disc fragment through a limited exposure is the accepted surgical treatment for herniated lumbar discs (31). A 5% to 10% incidence of recurrent disc herniation and a 10% to 15% incidence of postoperative low back pain is to be expected with this technique (32). Routine concomitant fusion after disc excision is not justified. However, in the presence of long-standing back pain and degenerative changes in the involved segment, fusion may help to improve outcome.

#### ***Disc Resorption and Internal Disc Disruption***

When the underlying pathology is the degenerated disc itself (23,33), posterior fusion may help to relieve pain by immobilizing the segment. Posterior translaminar screw fixation is indicated if anterior surgery is not advised or indicated for other medical reasons or when posterior bony decompression is to be performed simultaneously.

### **Translaminar Screws as a Supplemental Procedure**

#### ***Augmentation of Anterior Fusion***

Translaminar screws efficiently immobilize the posterior columns in the presence of an intact anterior column. If there is a structural deficiency anteriorly, anterior reconstruction with a compression-resistant device must be performed. Biomechanically, anterior struts are ideal in resisting compressive forces but inadequate in neutralizing axial rotational forces. Therefore, supplemental translaminar screws are ideal in augmenting anterior procedures by immobilizing the facets and thereby eliminating axial rotation.

#### ***Augmentation of Pedicle Systems***

The weak point in long lumbosacral pedicle constructs is sacral fixation. Different from the anatomy of the lumbar pedicles, the sacral pedicles are wider and provide less solid bone for screw fixation. The additional stability

**FIG. 27-2.** Transarticular screw fixation as a supplement to increase stability at the lumbosacral junction.

achieved by supplementary transarticular screws fixation in the lumbosacral joint may help to overcome this anatomic disadvantage (Fig. 27-2).

#### ***Repair of Anterior Pseudarthrosis***

In cases of anterior pseudarthrosis, posterior supplemental fusion is preferred to a repeat anterior procedure. Scar formation around the aorta, iliac vein, and vena cava may increase the operative risk of revision anterior surgery considerably. Translaminar screw fixation with additional posterior bone grafting offers a simple and effective method to stabilize the back.

### **CONTRAINDICATIONS AND LIMITATIONS**

Translaminar screws rely on bony purchase to the posterior elements of the vertebrae (lamina, facets, and transverse process). Therefore, the posterior elements must be substantial enough to hold a screw. Severe osteopenia might jeopardize the screw purchase. Screw loosening and pseudarthrosis are more likely to occur in these cases. Because transfixed facets eliminate rotation in the y and z axis, but are less effective in the x axis, an intact anterior column is mandatory for this technique. The translaminar screws provide segmental fixation at each level fused, but avoids intersegmental connections between each fused segment. In our series, there were no statistical differences in solid bony union between monosegmental and bisegmental fixations; the number of three segmental fixations was too few to allow valid statistical analysis. However, for mechanical reasons, we do not advocate translaminar fixation of more than two adjacent segments.

For the same reason, translaminar screws should not be used to extend an existing fusion.

### OPERATIVE TECHNIQUE

The surgical exposure is performed through a standard midline incision. The spinous processes, lamina, facet joints, and transverse processes are visualized and decorticated to receive the bone graft. The facet joints are opened by excision of the capsule, and osteophytes are removed. The cartilage of the dorsal aspect of the joint is removed, taking care not to injure the underlying subchondral bone in order to avoid loss of screw fixation.

The insertion of the screws by the Magerl technique is performed from the contralateral side of the spinous process of the segment to be fused, using a 50- to 54-mm long 4.5-mm screw. Fixation in slight flexion can be achieved if desired by applying interspinal distraction. Using a 3.2-mm drill bit, a hole is bored from the contralateral side of the spinous process into the opposite lamina. From there, the drill crosses the facet joint through its center and ends at the base of the transverse process (Fig. 27-3). This technique allows a nearly perpendicular screw direction in relation to the plane of the joint to be fused. In obese patients, percutaneous insertion of the drill through a separate stab incision may be necessary to obtain the proper direction of the screw. A dissector may be introduced between the attachment of the ligamentum flavum and the lamina, to minimize the risk of penetrating the spinal canal during the drilling procedure. An iliac bone graft must be placed posteriorly along the bony structures previously decorticated.

**FIG. 27-3.** Correct position of the screws in axial computed tomography scan: through the lamina and the facet joint into the base of the transverse process. Permanent stability is achieved with a proper grafting technique.

The postoperative management is straightforward and simple. Mobilization is begun on the first or second postoperative day. A soft corset brace is worn while out of bed for 3 months to restrict gross motions. Patients are encouraged to walk, and no physical therapy is performed during the first 2 months.

### PATIENTS AND RESULTS

One hundred seventy-three consecutive patients underwent translaminar screw fixation of the lumbar spine, of which 145 (83%) were reassessed after an average follow-up of 58 months (34). Fifty-seven percent had a single-level fusion, 40% a two-level fusion, and 3% a three-level fusion. As a simultaneous procedure, 30% had a nucleotomy and 52% had a decompression of the spinal canal for clinically relevant symptoms of spinal stenosis.

A solid bony fusion, with a radiologically solid fusion mass and no apparent motion on the digitized flexion-extension radiographs in the fused segments, was documented in 163 patients (94%) and 241 segments (96%). Radiolucency around the screws was detected in five patients (3%). Two screws were broken; however, no motion could be detected on the flexion-extension radiographs.

Preoperatively the subjective pain rating was 7.6, which decreased to a pain rating of 2.9 at follow-up. Thirty-three patients (19%) were taking analgesics because of lumbar back pain. One hundred sixty (92%) of the patients stated that they would undergo the same treatment again if in the same situation as prior to surgery.

## CHAPTER 28

# Lumbar Disc Disorders

Mats Grönblad

---

Medicine, to produce health,  
has to examine disease,  
and music, to create harmony,  
must investigate discord.  
—Plutarch, c.e. 46–120

Low back pain, including that resulting from lumbar disc disorders, is multifactorial, as is the disability caused by it (1,2). Perhaps the most common causes of low back pain are musculoligamentous injuries and age-related degenerative processes of spinal structures (1). Degenerative processes are partly age-related and partly genetically determined (3–5). Spine problems and spinal degeneration are not problems of modern society, they have been reported in ancient times as well (6).

### SOFT TISSUE

#### Definitions

Any muscle in the body may be strained or sprained, including low back muscles. Verifying such sprains as the cause of low back pain is, however, difficult. Often, however, either the term *low back strain* (7,8) or *sprain* (9) is used for any acute low back pain symptoms that commence suddenly (e.g., at the workplace). Of note, however, it has been suggested that sudden increases in physical activity will mainly affect the intervertebral disc, which is the most vulnerable spinal structure, due to its avascular nature and low metabolic rate. Thus, adaptive remodeling changes in the disc could lag behind those in other spinal tissues (10).

#### History and Physical Examination

Whenever a patient visits for low back pain, the most important thing is to first exclude any serious underlying disease or disorder that may warrant specific treatment. The so-called *red flags* (Table 28-1) are of great help when trying to exclude serious underlying disorder. When one or more of the red flags has been determined to be present, there is up to a 10% probability that the

patient has a serious underlying disease causing the low back pain symptoms (13). A report of nighttime pain may also suggest underlying systemic disease (1) (e.g., malignant disease or inflammatory spondyloarthropathy). This is particularly the case if the pain shows progressive worsening with time. The combined history and erythrocyte sedimentation rate have been reported to have relatively high diagnostic accuracy in vertebral cancer (14). Moderately accurate items for diagnosing ankylosing spondylitis are a need to get out of bed at night and to move around a bit as well as reduced lateral mobility of the spine (14).

Pain radiating below the level of the knee may be suggestive of sciatica, and should warrant a thorough neurologic examination. While in the waiting room the patient may complete a pain drawing, depicting areas of pain and pain radiation, possibly with separate markings or colors for pain, numbness, and “pins and needles”. Viewing such a precompleted chart will give the examining physician a quick notion of the presence or absence of sciatic pain radiation. Pain drawings may be an important adjunct in the assessment of chronic low back pain (15–18) and have been shown to have acceptable repeatability (18).

One should be alert to signs of systemic disease (e.g., fever). Following low back strain or sprains, possibly suggesting a muscular source for the pain, palpating vertebral muscles for tenderness can be done, but unfortunately, such palpation of tenderness is not reproducible between examiners (1). Interpreting limited spinal motion is also problematic, because the correlation with disability assessments or visual analog scale pain intensity is reportedly quite low (19). As well, in a normal busy clinical environment the reliability of such measurement of spinal motion is apparently quite low (20). With thoroughly trained examiners, however, the inter-tester reliability for physical examination findings may be somewhat better (21,22). Measures of spinal flexibility have been reported to be poor predictors of future back pain in an industrial setting (23). Borge et al. (24) recently con-

cluded, based on a systematic literature review, that there is presently no satisfactory answer whether or not physical examination tests have any prognostic value in the nonoperative treatment of patients with low back pain. An exclusively medical approach for the measurement of physical disability following low back strain or sprains should probably be abandoned in favor of a multifactorial biopsychosocial approach to low back disability assessment (19,20).

### Treatment

Following lumbar strain or sprains, the mainstay of any treatment should be to try to keep the patient active, not use bed rest as a treatment modality, and to support the patient in attempts to return to work as quickly as possible (25–27). The choice of treatments should be based upon published guidelines for treating patients with low back pain (11,28–32). It may also be helpful, when attempting to predict further chronicity of the low back problem, to consider so-called *yellow flags*, which are suggested psychological risk factors for delayed recovery (Table 28-2).

**TABLE 28-2.** Yellow flags (*psychological risk factors*) that may help predict prolonged recovery

---

Attitudes and beliefs: The experienced pain is harmful to the spine
Inadequate illness behavior (e.g., extended rest)
Compensation
Diagnosis and treatment: Causes confusion or fear about outcome
Emotions: fear, irritation, low mood
Work issues: Belief that work is harmful; absence of interest of employer; no possibilities for gradual return to work; high biomechanical demands

## DISC DEGENERATION

### Definition

A study by computed tomography (CT) discography on 300 patients with various prediscography diagnoses indicated a major role for intradiscal pathology in non-specific low back pain syndromes (33). Also by CT discography, Schwarzer et al. (34) determined internal disc disruption to be present in 39% of 92 subjects studied. Such internal disc disruption was most commonly present at the L5-S1 and L4-L5 levels (34). Distinguishing pathologic disc degeneration from disc alterations due to normal aging is, however, problematic. In a clinical setting, it has only recently been possible to radiologically evaluate the extent and distribution of disc degeneration. Radiologic findings that have been interpreted as suggestive of disc degeneration are, however, also commonly observed in asymptomatic subjects (35,36). In a large-scale magnetic resonance imaging (MRI) study on asymptomatic women between the ages of 16 to 80 years, Powell et al. (35) noted a linearly increased prevalence of one or more degenerate disc with age. Disc degeneration on MRI was, however, already present in more than one-third of the women between the ages of 21 to 40 years (35). A more recent study by Goupille et al. (37) compared spinal cadavers of subjects who had suffered from chronic low back pain, in the absence of radicular pain, with subjects who had been free of back complaints. No individual type of degenerative abnormality was found to relate specifically to low back pain, but the extent of pathologic change did show such a relationship with prior chronic low back pain (37).

### Natural History

There is now moderate evidence indicating that physical demands of work play only a minor role in the development of disc degeneration (3,38,39). In a recent large-scale longitudinal study on 1,165 nurses, low back pain at baseline was highly predictive of future low back pain, and the longer back pain was consistently reported (in a total of 8 follow-up questionnaires completed 3 months apart), the greater the likelihood that it would also be present at the next follow-up. Furthermore, the investigators showed that disabling low back pain carried a worse prognosis, as did back pain associated with sciatica (40). Thus, low back pain should not be regarded as an acute event that can be cured but as a persistent problem with intermittent exacerbations (1). As the observations by Smedley et al. (40) suggest, determining a presence or absence of disability, already at an early stage, is of paramount importance.

Follow-up by MRI of asymptomatic individuals with lumbar disc abnormalities, for an average of 5 years, showed progression of disc degeneration findings in 41.5% of the subjects (41). Medical consultation at fol-

low-up was, however, not predicted by MRI findings at baseline, but by job-related variables (41). Another similar 7-year follow-up study on asymptomatic subjects showed that MRI findings were not predictive of either the development or the duration of low back pain (42). The individuals with the longest duration of low back pain did not have the greatest degree of abnormality on the baseline MRI scans (42). Interestingly, in schoolchildren degenerative abnormalities on MRI have been shown to predict future recurrent bouts of low back pain (43). It was suggested that disc degeneration present soon after the phase of rapid physical growth predicted recurrent pain up to early adulthood (43). At the other end of the age scale, a study by CT discography on 291 subjects with an age range of 17 to 79 years noted that the proportion of severely degenerated but painless discs increased with age, as did discs producing dissimilar pain (44). According to the investigators, such degenerated but asymptomatic discs, particularly in older subjects, may at least in part explain the well-recognized poor correlation between low back pain symptoms and radiographic images (44).

### History and Physical Examination

In a study on male cadavers, examined radiographically and osteologically, history of back injury showed a relationship with the presence of symmetric disc degeneration, annular ruptures, and vertebral osteophytosis (45). In another study, lumbar disc degeneration, as observed by plain radiography, showed an age-independent association with both a history of lumbago and a history of sciatica (46).

The same basic principles presented previously for muscular strain and sprain also apply to patients with disc degeneration. Thus, it is of paramount importance to first exclude serious underlying disorder (Table 28-1). Unfortunately, there are no clinical tests that are specific for internal disc disruption that can be diagnosed by CT discography (34). Recent studies suggest that for measurements of spinal range of motion, there is both poor intra- and inter-rater reliability (47). Furthermore, range of motion measurements show poor validity with respect to relationships with physical and functional impairment (19,48). There is currently also strong evidence that back function testing machines producing isometric, isokinetic, or isoinertial measurements have no predictive value for either future low back pain or disability (39). Waddell et al. (49) have presented a validated battery of measures of physical impairment that can be recommended. Whichever symptom characteristics or clinical signs are used, they should show acceptable intra- and interexaminer repeatability and predictive validity with respect to major outcome measures of interest (50). Clinical observation of overt pain behavior may also be helpful, even if there may be a problem of standardization (51).

## Imaging

### Plain Radiography

The main indication of imaging is to exclude serious underlying disorder, when red flags are present (Table 28-1) or otherwise. In older patients the possibility of osteoporotic fracture should also be kept in mind (1). For the evaluation of disc degeneration, plain radiography produces far too many nonspecific findings, with doubtful clinical relevance (Figs. 28-1, 28-2). It is almost impossible to reliably relate such findings to clinical symptoms of low back pain. Overinterpretation is much too common, and may have an adverse effect on the outcome by labeling the patient and increasing the sick role. This will have an effect opposite to the mainstay of the treatment protocol, namely to keep the patient active, functional, and to decrease perceived disability (52). Reliability of measurement may pose a problem (53).

### CT and MRI

As is the case with plain radiography, these imaging modalities should be used mainly to exclude serious underlying disorder (Table 28-1) or when the patient has progressive or persistent neurologic deficit. Of note, there is now strong evidence that plain radiography and MRI findings have no predictive value for future low back pain or disability (39). They also do not correlate well with clinical symptoms in patients with nonspecific low back pain, or with work capacity (39).

**FIG. 28-1.** Plain radiograph anteroposterior and sagittal views of the lumbar spine of an asymptomatic 61-year-old woman. Note general disc narrowing and minor osteophytes both anteriorly and laterally. There is also slight scoliosis. (Courtesy of Dr. Kaj Tallroth, Orton Hospital, Helsinki, Finland.)

**FIG. 28-2.** Plain radiograph anteroposterior and sagittal views of a 46-year-old woman with low back pain. Disc narrowing, osteophytes, and end-plate changes appear only at the L4-L5 level. (Courtesy of Dr. Kaj Tallroth, Orton Hospital, Helsinki, Finland.)

CT should be combined with discography for imaging disc degeneration. With respect to MRI, it should be kept in mind that particularly disc bulges and protrusions are commonly observed in asymptomatic subjects, whereas disc extrusions are not (Table 28-3). But even when extrusions are observed, they should be interpreted within the entire clinical context to determine whether neural compromise is present or not. Bulges and protrusions are particularly prevalent at the two lowest lumbar levels and the prevalence of disc bulges increases with age (36). There are now several studies that show MRI abnormalities in asymptomatic adults (1).

In a study on cadavers that used in parallel MRI, biochemical, and histologic analysis, decreased total proteoglycan content and chondroitin-keratan sulfate ratio in subjects with low signal intensity on T2-weighted MRI could be observed, supporting the validity of MRI for diagnosing disc degeneration (54). Signal intensity on T2-weighted MRI has been considered the most sensitive available measure of disc degeneration (Fig. 28-3),

(Courtesy of Dr. Kaj Tallroth, Orton Hospital, Helsinki, Finland.)

whereas the assessment of disc height has less validity (55). In a large scale study, significant dehydration and degeneration on MRI was present in less than 5% at the two uppermost lumbar levels, whereas marked changes were observed at the two lowest lumbar levels in more than 20% of the patients (56).

### Discography

When MRI and discography have been used in parallel for the assessment of disc degeneration, a high correlation has usually been observed (57-59). It is considered that MRI can be used for detecting early disc degeneration (58). Also quantitative disc manometry has been suggested to show good correlation with MRI for assessing disc degeneration (60). Disc manometry may be suitable for evaluating early stages of disc degeneration and may detect tears of annular fibers that go undetected on MRI (60). Results are not entirely consistent, however (61).

Of all imaging modalities currently available, discography is the only one that can locate a degenerated and symptomatic disc and which visualizes internal disc disruption (Figs. 28-4, 28-5) (33,34,62-65) (Table 28-4).

**FIG. 28-4.** Sagittal view discography in a 46-year-old man with low back pain. Note normal cotton ball-type images at L3-L4 and L4-L5, whereas there is abnormal spread of contrast in the L5-S1 disc. (Courtesy of Dr. Kaj Tallroth, Orton Hospital, Helsinki, Finland.)

**FIG. 28-5.** Sagittal and anteroposterior discography views in a 36-year-old woman with low back pain. There is slight abnormal spread of contrast at the L3-L4 level, with more severe degeneration in the two lowermost discs, as seen by the widespread distribution of contrast. (Courtesy of Dr. Kaj Tallroth, Orton Hospital, Helsinki, Finland.)

**TABLE 28-4.** Summary of position statement of North American Spine Society Diagnostic and Therapeutic Committee on lumbar discography

Lumbar discography can be used in select cases such as:

- When there is persistent pain with suspicion of disc abnormality, and noninvasive tests have not provided sufficient diagnostic information.
- To determine whether discs within a proposed fusion segment are symptomatic, and whether adjacent discs are asymptomatic.
- In patients who have undergone previous spine surgery, but with nonremitting significant pain, to differentiate between postoperative scar and recurrent disc herniation.
- To investigate the condition of a disc within, or adjacent to, a fused spinal segment, to better delineate the source of symptoms.
- To confirm a contained disc herniation, possibly requiring minimally invasive discectomy.

Modified from Guyer RD, Ohnmeiss DD. Lumbar discography position statement from the North American Spine Society Diagnostic and Therapeutic Committee. *Spine* 1995;20:2048–2059, with permission.

Internal disc disruption has been postulated to be an important cause of low back pain, and a taxonomy has been established by the International Association for the Study of Pain (Table 28-5) (34). The clinical usefulness and interpretation of discography is, however, controversial (33,62–69). In particular, it has been observed that discographic pain reports are not only related to anatomic abnormalities within the disc, but also to scores on the Minnesota Multiphasic Personality Inventory (MMPI) (70), somatization disorder, compensation issues, and abnormal results on psychological testing (69). Thus, it would seem mandatory to perform psychological testing on any patient undergoing discography with interpretation of pain provocation, particularly if the discography procedure is used for preoperative evaluation. Even though discography may be problematic for clinical decision making, studies performed with discography have considerably widened the horizons for understanding mechanisms of low back pain and the locations of pain generators within the spine (62,64), including intricate mechanisms of pain radiation (65).

**TABLE 28-5.** International Association for the Study of Pain (IASP) taxonomy for internal disc disruption

The pain should be reproduced on provocation discography  
Computed tomography/discography should reveal internal disc disruption

As a control, stimulation of at least one other disc should fail to reproduce the pain

From Schwarzer AC, Aprill CN, Derby R, et al. The prevalence and clinical features of internal disc disruption in patients with chronic low back pain. *Spine* 1995;20:1878–1883, with permission.

**NONOPERATIVE TREATMENT****Types and Results**

For treating lumbar disc disorders, a profusion of alternative therapies are available to the clinician, as is often the case when there is a lack of more precise knowledge regarding etiology and pathophysiology. The clinician may, however, obtain support in the choice of therapies from several recently published guidelines, and the mainstay of any treatment protocol should be to try to adhere to such guidelines whenever possible (11,28–32,39).

With an increasing shift to self-management strategies that empower patients to participate in decisions in their care (27,71,72), all patients should be provided with basic information regarding course and prognosis (Table 28-6). However, the mainstay of any treatment protocol should be to try to keep the patient active and to try to influence an often wide array of perceived functional limitations in daily activities and at work. The principal goal is to continue normal daily activities (27). Table 28-7 presents some main principles that will guide the clinician in the treatment of patients with lumbar disc disorders and non-specific low back pain. Prolonged low back pain and disability will usually require a well-organized multidisciplinary rehabilitation program (82), even if there is presently a lack of knowledge regarding the optimal content of such programs (83) (e.g., whether any specific type of exercise has any specific physical effect or not) (84). In one study on multidisciplinary rehabilitation of patients with chronic low back pain, the most important variable for determining a successful treatment outcome was the reduction of subjective feelings of disability, whereas treatment outcome was not predicted by variables such as medical background, medical diagnosis, physical impairment, or physical variables such as mobil-

**TABLE 28-6.** *Some clinically relevant facts regarding the course and prognosis of nonspecific low back pain*

---

It is very common, in fact, it may be considered abnormal to live a single year <i>without</i> a backache (73).
Recovery from an acute spell of low back pain is generally rapid (74).
It is not an acute disease that can be cured, but once established, a chronic problem with intermittent exacerbations (1).
After 1 year 10%–45% still suffer from low back pain (75,76). In about one third the pain may still be disabling at 1 year (77).
Only about 2% remain on sick leave after 1 year (76).
Recurrences are common and have been reported in about 40% within 6 months (78) and about 75% within 1 year (75).
Even though recurrences are common, both pain and disability are usually less severe during such recurrences (75).
Once low back pain has become chronic, pain intensity and physical functioning improve only little after 1 year (79).

---

**TABLE 28-7.** *Main principles for managing lumbar disc disorders*

---

Neither sick leave nor inactivity will benefit recovery from low back pain (27).
To prevent adverse effects of fear avoidance beliefs, a principal goal should be the continuation of normal daily activities (27,80,81). Advice to stay active often leads to shorter periods of work loss and fewer recurrences, in comparison with traditional medical treatment (39).
Chronic cases will benefit from multidisciplinary rehabilitation programs (27).
Traditional biomedical education, based on an injury model, will not reduce future low back pain, nor work loss (39).
Lumbar belts or supports do not reduce work-related low back pain, nor work loss (39).
With respect to persistent symptoms and disability, and the response to treatment and rehabilitation, individual and work-related psychosocial factors play a key role (39).
Workers' own beliefs that their low back pain was caused by work, and their own expectations about inability to return to work, should be monitored, because they are important prognostic factors (39).
Most workers will be able to continue working, or can return to their ordinary work, within a few days or weeks, and do not need to wait until they are completely pain free (39).
The longer a worker is away from work, the lesser the chance of returning to work. For example, it has been shown that if a worker is off work for 4–12 weeks, the estimated risk of still being off work at 1 year is 10%–40%. With work absence of 1–2 years chances to return to any type of work are near nil (39).
With protracted work absence, treatments become ineffective for returning people to work, even though the treatments may still produce some clinical improvement (39).

---

ity, strength, endurance, or physical performance (82). There are several available validated condition-specific (19,85–93) and generic (94–97) functional disability scales that may be used for assessing outcome. It is important to remember, however, that disability is multifactorial (52,98).

With respect to the choice of treatment program, there is presently insufficient evidence to justify intensive and expensive programs, which are likely to be less cost-effective (39). In the treatment protocol, the role of the workplace and work-related factors should not be overlooked, since recent studies suggest that a close association between clinical care and occupational intervention may produce superior results to other treatment protocols, particularly in patients with subacute work-related low back pain (99). However, there is a need for more detailed information on the role of various risk factors for the various phases of work-related disability (100).

## CHAPTER 29

# Facet Joint Denervation: A Minimally Invasive Treatment for Low Back Pain in Selected Patients

David J. Hall

---

It is accepted that the lumbar zygapophyseal joints (facet joints) are a potential source of low back and referred leg pain. However, as a clinical entity, facet syndrome remains ill-defined and hence the extent and significance of its contribution in disabling low back pain is a subject of ongoing debate. Nevertheless, it is possible to identify, through diagnostic testing, a very select group of patients that can be successfully treated by percutaneous radiofrequency facet joint denervation.

### BACKGROUND

Although Goldthwait (1), in 1911, is credited as the first to recognize the lumbar facet joint as a potential source of back and leg pain, it was Ghormley (2), in 1933, who first coined the term “facet syndrome.” However, their theories focused more on the facet joint exerting mechanical pressure on nerves as the origin of symptoms.

Later, in 1971, Rees (3,4) published his work on multiple bilateral subcutaneous rhizolysis, where he reported a technique of denervation of the posterior spinal structures, including the facet joints, merely by the sweep of a Beaver blade and claimed apparently successful treatment in 998 out of 1,000 consecutively treated patients.

Following up on Rees’ work, Shealy (5) initially experimented with Rees’ technique but encountered problems with hematoma in several patients that led him to the use of a radiofrequency lesioning device under fluoroscopy guidance. Mooney (6) was impressed by his observations of Shealy’s technique and was stimulated, along with Robertson (7), to undertake their important work in an attempt to provide more scientific evidence of the facet joint as a source of back pain. In their study, injection of the zygapophyseal joints in normal volun-

teers induced both back and referred leg pain and, moreover, they found that the pain could be obliterated by injection of local anesthetic into the same joints.

Accordingly, the concept of the facet joint block as a diagnostic test was born. Since then there have been numerous studies exploring the utility of facet joint injections as both a diagnostic and therapeutic tool in the treatment of low back pain; it is fair to say that there have been widely varying results (8–16). Nevertheless, injection of local anesthetic into lumbar facet joints or at their nerve supply is accepted as a diagnostic test of facet joint pain and it was a natural progression to explore facet joint denervation procedures in the hope of providing longer-lasting and perhaps permanent relief of facet joint pain (6,17–26). In order to refine techniques of facet joint denervation there was a renewed interest in anatomic studies to improve the understanding of innervation of lumbar spine structures and, in particular, to precisely map the afferent nerve supply of the facet joint (18, 26–30).

### ANATOMY

The major afferent nerve supply to the facet joint is provided by the medial branch of the posterior primary ramus. The medial branch descends from the posterior primary ramus over the base of the transverse process in a groove at the root of the superior articular process, which is bridged by the mamillo-accessory ligament (Fig. 29-1). The mamillo-accessory ligament is formed by a condensation of the intertransverse ligament fibers passing from the mamillary body to the transverse process and occasionally it is ossified. After passing under the bridge of the mamillo-accessory ligament, the medial branch courses across the lamina deep to multifidus and

**FIG. 29-1.** A sketch of a dorsal view of the branches of the left lumbar dorsal rami. Mamillo-accessory ligaments (mal) have been left *in situ* covering the L1 and L2 medial branches. A, articular branches; *ib*, intermediate branch; *ibp*, intermediate branch plexus; *lb*, lateral branch; *m*, medial branch; *is*, interspinous branch, *zj*, zygapophyseal joint. (From Bogduk N. The innervation of the lumbar spine. *Spine* 1983;8(3):289.)

finally enters the muscle. Deep to the muscle it sends fibers innervating the caudal portion of the facet joint immediately above before sending fibers to the facet joint below.

Paris (29) proposed a greater multiplicity in afferent supply to the facet joint. In particular, he described an ascending facet branch that passed to the posterior aspect of the facet joint one level above, and throughout its course was entirely intramuscular and did not lie on any bony structures. He also suggested a more proximal origin of branches to multifidus and theorized that they would contain accessory afferent supply to the facet joints. However, this description of the anatomy, and in particular the ascending facet branch, could not be verified by Bogduk in his anatomical dissections (18,26–30). The existence of an intramuscular ascending facet joint branch infers a “triple innervation” of the facet joints

where a single medial branch supplies the adjacent facet joint and the joints above and below. However, there is broader acceptance of the “dual innervation” as proposed by Bogduk where the medial branch supplies its adjacent facet joint and the joint immediately below. There is agreement throughout the literature that the medial branch of the posterior primary ramus is constant and is fixed adjacent to the bone in the region of the mamillo-accessory ligament. There is no evidence of nerve fibers crossing the midline so that facet joints on each side have a unilateral innervation.

## PATHOLOGY

In the majority of cases the cause of lumbar facet joint pain is not known. Although facet joint osteoarthritis is a relatively common occurrence, it is rare to find other definite recognizable pathology affecting the zygapophyseal joint such as systemic inflammatory arthropathy, facet joint fracture, or infection (6,7,15,31–34). Exclusion of such disorders is important, leaving osteoarthritis, which has been proposed as a cause of facet joint pain. Interestingly, it has been demonstrated that facet joint degeneration almost invariably follows disc degeneration at the same level and, accordingly, degenerative changes within the facet joint rarely, if ever, exist in isolation (32–34). In spite of this, a study by Schwarzer (12), evaluating patients by provocative discography and facet joint blocks, concluded that it was rare to suffer symptomatic disc degeneration in combination with symptomatic facet joints.

## DIAGNOSIS

Although most clinicians recognize a clinical presentation, which is presumed attributable to facet joint pain, there is no literature to support any pathognomonic historical, physical examination or imaging findings associated with lumbar facet joint syndrome (6,9,11,14,15,16,19,31). Typically, it is thought that facet joint pain is aggravated by rest in any posture and is relieved by movement. The pain may be unilateral or bilateral in the lower back, with or without radiation to the lower limbs. Radiculopathy is absent and the pain should not radiate below the knee. Morning stiffness may be associated with a stooped posture on rising; lumbar extension is the movement most likely to aggravate symptoms. Despite the consistency of this description throughout the literature, clinical features have not proved to be predictive of the response to diagnostic facet joint blockade (13–16).

Facet joint injections form part of the investigative armamentarium when evaluating patients with nonradicular low back pain who have failed to respond to appropriate nonoperative management, including an exercise program, and in whom there are no sinister features of alternative underlying pathology. Lumbar facet joint

injections, combined with the use of intra-articular corticosteroids, have been used as both a diagnostic and therapeutic modality. However, their use remains controversial (7,8,10,11,15). As a therapeutic option, some authors have found facet joint injections to be of no use, whereas at best the injections may provide temporary relief of sufficient duration to allow resolution of symptoms by natural processes or through an appropriate rehabilitation program.

A series of studies undertaken by Bogduk and associates have shown that targeted medial branch blockade is a valid diagnostic test in the evaluation of facet joint pain (12,13,16). Indeed, from a technical viewpoint, medial branch block is more easily performed than facet joint injections and there is less prospect of diffusion of the local anesthetic to involve surrounding structures, which may confound the response.

In addition, differential blocks undertaken on separate occasions using local anesthetic agents with different pharmacologic properties and durations of action have been able to exclude false-positive results (13). Based on these studies and others where the placebo response is controlled, facet joint pain is thought to have a prevalence of up to 40% in chronic nonradicular low back pain (14,15).

If facet joint pain is accepted as a significant contributor in disabling low back pain, then it follows that facet joint denervation may provide long-term or even permanent relief of symptoms attributable to the facet joints. Facet joint denervation is appealing given the accessibility of the facet joint and, more particularly, the medial branch of the posterior primary ramus, which has a constant course adjacent to an easily identifiable bony landmark.

Bearing this in mind, when investigating a patient for consideration of radiofrequency denervation, it is logical that a medial branch block is a more appropriate diagnostic tool than facet joint block because it directly evaluates the structure scheduled for ablation.

## TECHNIQUE

The original technique described by Shealy (5) targeted the electrode lateral to the midpoint of the facet joint and then swept the electrode in a cephalad and caudad direction so that there were three electrode positions for each joint covering the lateral aspect of the facet joint. The following modified technique is recommended in view of improved anatomic knowledge.

Under sterile conditions with the patient lying prone over a pillow to reduce the lumbar lordosis, on a radiolucent operating table, the levels to be denervated are located by antero-posterior (AP) fluoroscopy. The target point (i.e., the base of the transverse process where it meets the root of the superior articular process) is marked on the skin (Fig. 29-2). A puncture site is marked a cen-

**FIG. 29-2.** Antero-posterior radiograph of lumbar spine illustrating target points for medial branch neurotomy. The target points lie exactly at the tip of either the arrows at L1, L2, and L5, or the guide needles at L3 and L4. Note, at the L3 and L4 levels, how the silhouette of the superior articular process overlaps the target point, demonstrating why electrodes should be introduced obliquely. The overhanging superior articular process protects the target point in a dorsoventral approach. The guide needles are indicating the target points; however, a more caudal entry point is now recommended in order to allow introduction of the electrode more or less parallel to the respective medial branches at L4 and above. On the right side of the figure the courses of the medial branches of the dorsal rami have been superimposed. (From Bogduk N, Long DM. Percutaneous lumbar medial branch neurotomy: a modification of facet denervation. *Spine* 1980; 5:196.)

timeter or two lateral and caudal to the target point for the L1 to L4 levels. (The L5 level is treated differently owing to the different anatomy, and is described in the following.) The lateral and caudal entry point is chosen to prevent deflection of the probe from the target at the base of the transverse process by the overhanging superior articular process and the bulging mamillary process. Because it has been shown that the uninsulated portion of the probe produces a radial spread of the lesion that does not extend beyond the tip of the electrode, a more caudal approach is chosen to allow the introduced probe to lie nearly parallel to the target nerve so that the nerve is more likely to be encompassed by the radial spread of the lesion (35). The L5 dorsal ramus courses in the groove between the ala and the superior articular facet of S1 and can be approached in a more sagittal direction with the probe laying parallel to the dorsal primary ramus proper as it hooks over the sacrum. The intended puncture sites

are anesthetized using Lignocaine 1% down to the level of the deep fascia, being careful not to anesthetize deep around the facet joint, which may interfere with nerve conduction and patient response.

An 11 blade is used to puncture the skin before insertion of 3½-inch, 14-gauge Shiley needles with trocars under AP fluoroscopy. The Shiley needle is advanced until it is blocked by the base of the transverse process, which obviates the need for lateral fluoroscopy to check the depth of placement. The trocar is removed and the blunt-tipped electrode is introduced via the Shiley needle, which can be used to steer the electrode. The transverse process is palpated easily and the electrode is then directed in a cephalad and medial direction so that it slips off the transverse process into the intertransverse space. The probe is then gradually withdrawn so that the uninsulated portion lies at the root of the superior articular process, more or less parallel to the course of the medial branch. At L5, as mentioned, the probe comes to lie in a more sagittal direction in the groove on the superior aspect of the ala, adjacent to the superior articular facet and is parallel to the posterior primary ramus proper. Antero-posterior fluoroscopy is used to confirm the position of the tip of the electrode.

A stimulation mode can be used to confirm that the electrode tip is properly positioned adjacent to the medial branch of the posterior primary ramus and away from the anterior primary ramus. At 2 Hz, motor stimulation may occur and if twitching of the lower limb muscles is observed, the probe should be withdrawn to a more posterior position. At 100 Hz, a sensory response is elicited in the posterior primary ramus, which may produce pain or tingling similar to the presenting symptoms. However, the sensory response is not diagnostic and this step should not be necessary because the symptomatic levels should have been identified by prior medial branch blockade.

After satisfactory placement of the electrodes, lesions are made with a radiofrequency generator; the electrode tip temperature is raised to 80°C for 90 seconds. During the production of the lesion, the patient should be awake and cooperative in order to alert the surgeon as to the development of any radicular symptoms that would necessitate repositioning the lesioning electrode. Usually the patient experiences an exacerbation of back pain that reaches a crescendo and then settles as the lesion is completed. The neurologic status is checked immediately post-operatively. The procedure is undertaken on an outpatient basis with minimal or no sedation and the patient is allowed to return to normal activity as symptoms permit.

## RESULTS

Since the introduction of radiofrequency denervation of the facet joint by Shealy (5), the technique has been modified and used with varying results (6,17,18–26).

To date only three randomized controlled trials (20,22,24) have been published evaluating the effect of radiofrequency lumbar facet joint denervation in chronic low back pain. However, the studies are not directly comparable because they each used either different diagnostic criteria or different surgical technique.

In 1994, Gallagher (20) included 60 patients who were judged on clinical grounds to have symptoms of low back pain suggestive of facet joint origin. Forty-one patients reported improvement or were equivocal in their response following injection of local anesthetic into and around the facet joints that were thought to be appropriate. Those patients were randomized to undergo either radiofrequency facet joint denervation or a sham procedure using the invalidated technique of Shealy. Nevertheless, relief of symptoms was noted in patients who had a clear improvement following facet joint injections compared to patients who were equivocal in their response to the injections. The results were evaluated at 1 and 6 months and were statistically significant.

Van Kleef (22), in 1999, reported results in 31 patients with chronic low back pain selected on the basis of pain relief following diagnostic blockade of the medial branch of the posterior primary rami. The technique of lesion production was similar to the modified technique as described in the preceding text, although the approach was more from a posterolateral oblique direction than the more caudal oblique approach, as promoted by Bogduk (35). At least 50% pain relief following medial branch blockade was required to be eligible to enter the study and then patients were randomized to undergo radiofrequency lesioning or a sham procedure. Interestingly, in the final analysis, the results were superior in patients who reported complete relief of pain with diagnostic nerve blocks compared to those with only partial relief of pain. Statistical analysis at 3, 6, and 12 months following treatment showed significant improvement in pain and functional disability in the treatment group.

In 2001, Leclair (24) published results examining a larger sample size of 70 patients but a shorter follow-up of only 3 months and reported no significant improvement in the treatment group compared to the sham group. However, it is noteworthy that patients were included in the study based on their response to intra-articular facet joint injections rather than diagnostic medial branch blockade.

## COMPLICATIONS

There have been no serious complications associated with the procedure apart from transient radiculopathy and the report of a skin burn through poor earthing (5,19–25).

## CONCLUSION

It is apparent that there exists a very select group of patients with disabling low back pain that can be attrib-

uted to the facet joints and may be successfully treated by facet joint denervation.

The careful use of diagnostic medial branch blockade is the critical factor in patient selection for facet joint denervation. Meticulous attention to detail through the use of differential medial branch blockade is required to accurately identify a highly selected group of patients who may respond to radiofrequency denervation. Following recommended protocols is a tedious process that may test the patience of the clinician (not to mention the patient) and may explain the paucity of high-quality studies and the widely varying results published in the literature. Despite a plethora of literature dealing with anatomy and experimental studies, evaluating the facet joints as a potential source of pain, there is an extremely narrow evidence base of high-quality clinical studies examining the utility of radiofrequency denervation of the facet joints. In particular, there is a single study (22) that employed the theoretical best practice methods of patient selection, accurate lesioning technique, and rigorous scientific methodology that showed significant alleviation of pain and functional disability in a select group of patients both on a short- and long-term basis following radiofrequency denervation.

There are many factors that may lead to failure of the technique, including the technical adequacy of diagnosis by medial branch block and the adequacy of subsequent radiofrequency medial branch neurotomy. Additionally, there is always the question of alternate symptomatic pathology and, in particular, symptomatic disc degeneration because disc degeneration has been shown to always coexist with facet joint degeneration. It has been postulated that late resurgence of symptoms may be associated with nerve regeneration, in which case repeat procedures may be indicated after re-evaluation. Nevertheless, the minimally invasive technique of radiofrequency facet joint denervation is appealing given the accessibility of the medial branch of the posterior primary ramus and the reassurance that the reporting of complications from the procedure is virtually nonexistent.

# Intradiscal Electrothermal Therapy

Jeffrey A. Saal and Joel S. Saal

---

The treatment of chronic discogenic low back pain presents one of the most difficult challenges to the spine specialist. Nonoperative measures are frequently unable to reduce pain and improve function in this patient subgroup (1, 2). Interbody fusion for these patients has yielded mixed and often poor results (3–5). An alternative therapy to address this problem is therefore desirable. The SpineCATH system (Smith & Nephew, Inc., Largo, FL) to perform intradiscal electrothermal therapy (IDET) was developed to address this difficult clinical dilemma.

Patients with chronic lumbar pain fall into two clinical categories: chronic recurrent and chronic persistent. Chronic recurrent patients have multiple pain flares with varying durations of 2 weeks to 3 months. Many patients within this group will begin to have more frequent recurrences with fewer pain-free intervals as time passes. Chronic persistent patients have persisting symptoms that do not abate and last longer than 3 months. The disc has been shown to be the pain source in the majority of patients with chronic symptoms (6). Carey et al. recently reported that patients who do not experience a resolution of their back pain within 3 months of onset had a poor prognosis for further recovery. When the patients were assessed at 22 months they continued to have persisting complaints of low back pain and were dissatisfied with their outcomes (1). Von Korff reported that although 80% of patients had resolution of their acute low back pain in 12 weeks, 60% of the patients experienced recurrent symptoms (2). These recent studies underline the fact that chronic low back pain does not necessarily have a favorable prognosis and that the long held truth that 90% of patients will experience resolution of their back pain within 6 to 12 weeks is incorrect and misleading.

### **PATHOPHYSIOLOGY OF INTERNAL DISC DERANGEMENT**

The natural history of the degenerating disc includes loss of nuclear hydrostatic pressure, which leads to buck-

ling of the annular lamellae. This phenomenon leads to increased focal segment mobility and increased shear stress to the annular wall. The process progresses to delamination and fissuring of the annular wall. Annular delamination has been shown to occur as a separate and distinct event from annular fissures (7). Fissures can be radial or concentric. In addition, electron microscopy has demonstrated micro “fractures” of collagen fibrils with disc degeneration. The progressive degeneration of the disc, manifested by any of these morphologic changes, has been shown to alter disc mechanics (8).

Tearing and delamination of the annulus can cause chronic pain. Mechanoreceptors in the disc have been shown to discharge with disc mobilization (9). Nociceptive tissue has been shown to be sensitized resulting in a decrease in their firing threshold after treatment with inflammatory enzymes and mediators (10–12).

A scenario for chronic discogenic pain is created when any combination of annular fissures, delamination, or microfractures of collagen fibrils leads to mechanical distortion of annular lamellae and subsequent sensitization of nociceptors that may have also been presensitized by PLA2 (13), nitrous oxide (14, 15), interleukin 1 (15), and metalloproteinase enzyme activity (15), or other chemical mediators. Afferent stimuli produce substance P release and nociception. Repetitive stimulation of the dorsal root ganglion (DRG) has been shown to create prolonged neural activity from the dorsal horn receptor fields (10,16,17). As the patient continues to load the disc, the neuronal activity continues. Clinically, the disrupted disc will often cause referral pain into the buttocks and leg due to DRG stimulation or from direct chemical irritation of the nerve roots.

A combination of mechanical and neural properties creates an interplay that leads to chronic discogenic pain. A high-intensity zone (HIZ) on the T2 of the magnetic resonance (MR) image has been shown to correlate with a pain-producing fissured disc 65% to 95% of the time (18–20). However, MRI predicts the presence of annular

fissures less than 50% of the time and asymptomatic patients may have an HIZ (19–22). Therefore, a patient may have a painful annular tear without concomitant MRI findings. Disc bulging is due to, and directly associated with, annular degeneration and fissures; however, this phenomenon does not always create clinically significant low back pain (21).

Certainly not all chronic lumbar pain is discogenic. It is estimated that more than 50% of patients with chronic low back pain may have the disc as the primary source of pain (6), however, an accurate diagnosis can be elusive. Screening for patients with facet problems, sacroiliac joint dysfunction, psychosocial problems, systemic disease, neoplasm, and infection should be undertaken when appropriate. A chronic pain syndrome with primarily soft tissue pain and somatization often occurs in the low back pain population. Practitioners must be aware of the potential existence of these phenomena.

### THERMAL IMPACT ON TISSUE

Innervation of the intervertebral disc has been well documented by researchers since the 1930s. More recently, Bogduk's work illustrated the sources of lumbar disc innervation (23). Coppes et al. found nociceptive properties in nerves of the outer annular wall. In fact, they observed nerve fibers "deeper than the outer third of the annulus fibrosus" (24). Freemont et al. also discovered significant neovascularization with neural expression of substance P, and linked that growth to disc degeneration and back pain. They identified nerve fibers as deep as the inner third of the annulus fibrosus and into the nucleus pulposus in several disc samples (25).

Letcher et al. established that irreversible nerve blocks due to neural thermocoagulation occur at 45°C in the brain (26), and Cosman et al. (27) used radiofrequency lesioning to produce 45°C isotherms for neural tissue lesioning. The intradiscal temperatures generated by the SpineCATH (48° to 75°C) are in the range necessary to create thermocoagulation of neural tissue in the target zone accessed (28, 29).

Collagen contraction, or shrinkage, has been well documented in the use of nonablative laser energy on joint capsular tissue and more recently in radiofrequency application in the glenohumeral joint capsule (30,31). Research has shown that there is a direct correlation between the amount of heat and duration of the heating applied to tissue and the resulting collagen contraction (32–36).

The breaking apart of the heat-sensitive bonds of the collagen fibrils causes tissue shrinkage. The framework of the intervertebral disc is composed primarily of types I and II collagen, which have a similar molecular structure. The tensile strength of these collagen fibers is derived from the extended conformation of the triple helix molecule, which is cross-linked with hydrogen

bonds. A portion of these bonds is heat sensitive, breaking apart when exposed to a range of temperatures over time. The disruption of these stabilizing hydrogen bonds releases the molecular strands, which collapse. This collapse, like the release of a spring-held taut, results in a new contracted state called the denatured or random coil conformation of the collagen fiber.

The optimal temperature for collagen contraction is reported to be 65°C. The lowest practical temperature at which heat-sensitive hydrogen bonds will start to break is 60° C. As the temperature increases, more bonds break. It is unclear whether there is an additional shrinkage effect over 75°C.

Kleinstueck et al. attempted to study intradiscal temperature dispersion from the SpineCATH (37). They placed the device in the nucleus rather than in the annulus and were able to measure temperatures of great than 42°C (temperature sufficient to thermocoagulate unmyelinated nerve fibers) at distances greater than 10 mm from the probe. However, their use of previously frozen cadaveric discs, and the placement of the heating element in the nuclear cavity rather than in the annulus as is done in clinical practice may have limited the peak temperatures. Freeman et al. presented temperature maps *in vivo* on sheep demonstrating higher peak temperatures (38). They found temperatures of greater than 65°C adjacent to the catheter. In a recent report Shah et al. found microscopic evidence of acute collagen modulation in cadaveric discs heated with a SpineCATH (29).

Recently Barendse et al. reported on a randomized controlled trial evaluating the efficacy of a radiofrequency probe placed into the center of the nucleus and then heated (39). The treated group fared no better than placebo. Houpt et al. (40) has previously demonstrated the inability of temperature dispersion for a radiofrequency device to raise intradiscal and annular temperatures. For these reasons the IDET technology (i.e., SpineCATH) does not use radiofrequency as a heating element but rather uses a thermal resistive coil, which produces conductive heat. Additionally, contrary to the radiofrequency device studied by Barendse (39), the IDET device is deployed into the annulus and is not deployed in the center of the nucleus (28,41).

### CLINICAL RESEARCH REVIEW

The first published series of patients treated with IDET reported the 6-month (range 6 to 9 months, mean 7 months) outcome results for 25 patients with chronic low back pain of documented discogenic origin with mean duration of preoperative symptoms of 58.5 months. These were patients who failed to adequately improve with a comprehensively applied nonoperative care program and who elected IDET instead of chronic pain management or spinal fusion (41). The results demonstrated a statistically

significant improvement in functional outcome as measured by Visual Analogue Scale (VAS) scores, Social Functioning (SF)-36 scores, sitting tolerance times, and narcotic analgesic medication. Sixty-two patients treated with IDET and followed for a minimum of 1-year (mean 16 months, range 12 to 23 months) postprocedure demonstrated outcome evaluation scores that did not statistically vary from the 6-month group. The mean group change for the SF-36 bodily pain was 17 and physical function was 20. These scores are consistent with significant clinical improvement (42).

A 2-year follow-up study noted continued improvement of SF-36 scores and sitting tolerance times (43).

Karasek and Bogduk (44) reported on the 1-year outcome of patients treated with IDET (35) and compared them to a control group of patients (17) similarly diagnosed but denied insurance authorization for IDET. The researchers used a 50% reduction of VAS scores as an indicator of success. On this basis, 60% were considered successes. Additionally, they noted that 23% of the patients had total relief of symptoms. They reported that only one patient in the control group improved and the remainder continued to have similar pain intensity.

Derby et al. (45) reported that 62.5% of patients treated with IDET had a favorable outcome based upon the Roland Morris Scale, VAS, North American

Spine Society (NASS) outcome instrument, and a general activity scale. If patients had preserved disc height and had not undergone previous surgery at the index level, the success rate was 76%.

Wetzel et al. presented the 2-year results of a multicenter prospective cohort study and found statistically significant improvement in pain reduction and physical function in their study group (46). To date, there are no published randomized controlled trials of IDET. Clearly, such trials will be extremely valuable in determining the validated efficacy of IDET and other spine therapies. Until those data are available, physicians and surgeons should proceed with caution prior to determining the path of care for their patients with chronic discogenic pain.

## MECHANISMS OF ACTION

The precise mechanism of action of the observed positive clinical effect is currently under investigation. Moore et al. attempted to create annular in-growth of nerve fibers after surgically induced injury. They followed this with IDET in an attempt to determine if IDET reduced the population of nerve fibers in treated versus untreated control specimens. Unfortunately, neither the control nor the treated specimens had enough neural in-growth to determine a differential effect (47). Pollintine et al. presented a cadaveric disc study demonstrating an equalization of stress across the IDET treated disc (48). This may lend useful insight into the mechanism of

action of IDET. Clearly, further work on the mechanism of action is required.

## DIAGNOSTIC WORKUP AND PATIENT SELECTION FOR IDET

The following 12 criteria represent our present criteria for IDET candidacy. To date, these criteria have not been validated by controlled studies. They represent our experience, and are a work in progress.

1. Severe, function-limiting, chronic low back pain for more than 3 months.
2. Failure to adequately improve with a comprehensively applied aggressive nonoperative treatment program consisting of stabilization exercise training, back education, activity modification, and when appropriate, fluoroscopically guided selective epidural cortisone injections and, in some circumstances, facet injections.
3. A duration of 3 months for the nonoperative care program is recommended (this would bring the total duration of symptoms to an approximate minimum of 6 months prior to IDET).
4. Normal neurologic examination.
5. Negative straight leg raise (SLR)—no reproduction of “true sciatica”.
6. MRI that does not demonstrate neural compressive disease.
7. Preservation of disc height at the symptomatic level (less than 30% disc space collapse).
8. No measurable segmental instability.
9. No lytic or degenerative spondylolisthesis.
10. Discogram that demonstrates an annular fissure and reproduces concordant pain at one or more levels at an injection volume of less than 2 cc, with a documented negative control level.
11. No irreversible psychosocial barriers to recovery.
12. Motivation to improve with realistic expectations of outcome.

In summary, IDET is intended for psychologically stable and motivated patients with chronic function limiting low back pain with a documented discogenic source of pain who have failed to improve with an aggressive exercise-based rehabilitation program. Discography criteria for low-volume concordant pain provocation attempts to separate appropriate patients with focal annular lesions who will experience pain reproduction at low volumes from patients who are questionable candidates with global annular degeneration who will often experience pain reproduction only at larger volumes of injectate (i.e., greater than or equal to 2 cc volumes). We have noted that patients with severe disc space collapse (greater than 50%) may have a lower likelihood of success than

patients with preserved disc height. This theorem however has not been vigorously tested. In addition, the effectiveness of IDET on the previously operated segment remains an open question.

## PROCEDURAL TECHNIQUE

### Overview

Local anesthesia and conscious, monitored sedation is applied to the patient in an outpatient surgical or radiologic setting. A 17-gauge procedure needle is introduced into the symptomatic disc under multiplane fluoroscopic guidance. The SpineCATH is introduced through the procedure needle and navigated to the offending portion of the annulus. The SpineCATH position is documented in at least the anteroposterior and lateral radiologic view. Care must be undertaken to avoid catheter kinking, which may lead to catheter breakage. Treatment may be achieved with unilateral catheter deployment, but roughly 40% of the time, due to multiple annular fissures, bilateral deployment is necessary to cover the entire posterior annular wall. The ORA-50 (Smith & Nephew, Andover, MA) autotemperature heat generator controls the catheter heat delivery system. Typically a maximum catheter temperature of 90°C is attained (corresponding to tissue temperature adjacent to the catheter of approximately 72°C). There are occasions when the temperature profile must be modified to a maximum catheter temperature of 85° to 89°C to achieve patient comfort. The patient must be alert enough to be observed for the development of radicular pain during the procedure. If this occurs, the catheter is repositioned or removed. Most patients will experience their typical back pain and referral leg pain during the procedure. However, this must be differentiated from radicular pain, especially if the patient experiences it early in the heating cycle (i.e., catheter temperature 65° to 90°C). If this occurs, it is usually indicative of an extremely attenuated posterolateral annulus or a catheter that is extradiscal. It is our preference to inject 2 to 5 mg of cefazolin into the disc after treatment and removal of the SpineCATH.

A survey of complications was presented noting a 6 per 1,750 incidence of reversible nerve injury due to needle puncture and a 1 per 1,750 incidence of discitis. There is one published report of cauda equina injury due to IDET (49). IDET when performed by a skilled practitioner is relatively safe, but certainly not entirely without risk.

### Course of Recovery and Postoperative Rehabilitation

Most patients will experience an increase in their typical pain (back, back and leg) in the early postoperative period. The postoperative pain gradually subsides over the first 1 to 7 days. Typically most patients will return to

at least their preprocedure pain level between the 7th and 14th postoperative day. We have noted that patients often have resolution of their preoperative leg pain symptoms in the first 4 weeks, whereas the improvement in back pain requires 6 to 12 weeks to occur. Initial study patients have been noted to progressively improve between 2 and 9 months. The 2-year data documented that the patient group demonstrated substantial improvement between 1- and 2-year follow-up points (43). The clinical course in the first 4 to 6 months is often variable. However, many of these patients will stabilize, and at 1-year follow-up demonstrate significant improvement. Patients who have not improved above their preoperative baseline by 6 months should be considered unsuccessful.

The most important postoperative principle appears to be allowing time for a healing reaction. This requires delaying aggressive exercise training for at least 3 months postprocedure. It is our practice to place patients in a semirigid lumbar corset for 8 weeks postprocedure. During this period, patients are encouraged to walk. At 8 weeks a progressive stabilization exercise program is begun and the corset is discontinued. Patients should be able to return to office work or light duty assignment by 2 weeks and light lifting duties at 6 weeks postprocedure, although return to heavy work may require 4 to 6 months. Optimization of return to work timing and postoperative management deserves further study.

## CONCLUSION

IDET may offer a group of carefully selected patients with chronic discogenic low back pain an option other than chronic pain management or spinal fusion. Randomized control trials are necessary to validate the efficacy of IDET as well as spinal fusion for the treatment of patients with chronic discogenic low back pain.

# Operative Management of the Degenerative Disc: Posterior and Posterolateral Procedures

Gunnar B.J. Andersson and Francis H. Shen

---

In medicine, a successful outcome from a specific intervention is intimately associated with making an accurate diagnosis. In the case of degenerative disc disease making an accurate diagnosis can be challenging (1–3). Patients with degenerative disc disease may present with a variety of symptoms ranging from predominantly low back pain at one end of the spectrum, to leg pain at the other end (3–5). As a result, the management of degenerative disc disease has been controversial (4–8).

In patients with predominantly leg pain the source of the pain may be a degenerative herniated disc or associated lateral recess or foraminal stenosis resulting in lumbar radiculopathy. However, there is a subset of patients with axial back pain (low back pain without radiculopathy) where the history, physical findings, and confirmatory tests attempting to identify the source of pain have not been as clear. Pain generators in these patients may arise directly from the annulus of the degenerative disc (9,10), from arthritic facets (11,12), or from pathologic segmental instability and micromotion (13). It is this subset of patients that may benefit the most from a lumbar fusion.

In this section we review the operative indications, surgical options, techniques for posterolateral lumbar fusion, and role of instrumentation for axial back pain from disc degeneration. Management of the patient with radiculopathy from a herniated disc or stenosis is addressed in later chapters.

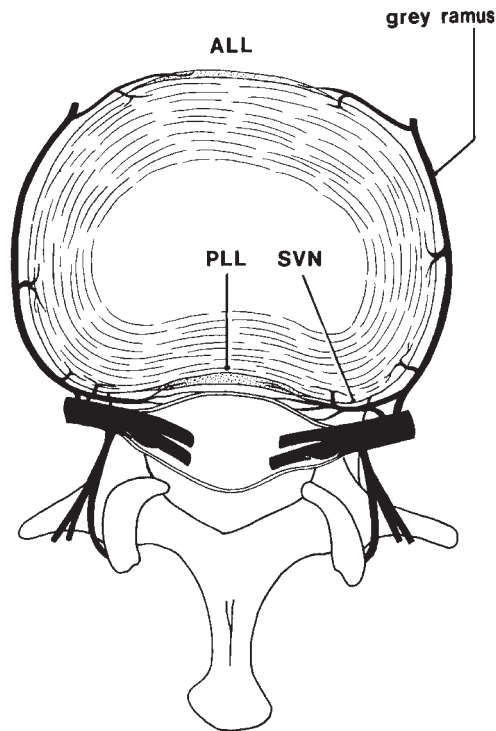

### ETIOLOGY

Studies have focused on the annulus as a source of pain in the degenerative disc (9,10). Innervation of the annulus has been well characterized, with the outer third being innervated by pain transmitting free nerve endings (Figs. 31-1,31-2) (14). The sinuvertebral nerve, arising from the ventral root and gray rami communicants, provides inner-

vation to structures within the spinal canal, the posterior longitudinal ligament, ventral dural sac, and posterior portion of the annulus (15). The ventral primary rami and the sympathetic nervous system innervate the lateral and anterior aspects of the annulus fibrosus, whereas branches of the gray rami communicants or the sympathetic trunk innervate the anterior longitudinal ligament (Figs. 31-1,31-2) (14,16). Furthermore, in a degenerative disc, the annulus fibrosus, as well as the cartilage end plates and underlying cancellous bone of the adjacent vertebra have been shown to be more extensively innervated than normal healthy discs and vertebra (17). In a study of 193 patients by Kuslich and colleagues, direct mechanical stimulation of the central and lateral portions of the annulus and vertebral end plates produced typical back pain symptoms in approximately two thirds of the patients (10).

Many of these same nerve endings are also involved with the production of pain-related neuropeptides (18). The number of neuropeptides known to be present in primary afferent neurons has been steadily increasing (19). These neuropeptides are produced within the dorsal root ganglion cell body and are delivered by axonal transport to the central and peripheral processes of the neurons. Their release has been demonstrated in response to intense electric stimulation of peripheral nerves; however, their exact role in pain modulation from degenerative disc disease has not yet been fully elucidated.

Because of the three-joint concept of the lumbar spine (20), axial back pain is likely the result of several factors (13). It is possible that with increasing ligamentous and capsular laxity there is progressive mechanical overload of the degenerative disc and facets resulting in segmental instability and pathologic motion potentially causing additional pain (13,21,22). The associated loss of disc height can increase stress across facet joints resulting in facet arthrosis. Although controversial, facet arthrosis has

**FIG. 31-1.** The nerve supply of a lumbar intervertebral disc is depicted in a transverse view of the lumbar spine. Branches of the gray rami communicantes and the sinuvertebral nerves (SVN) are shown entering the disc and the anterior and posterior longitudinal ligaments (ALL and FLU). Branches from the sinuvertebral nerves also supply the anterior aspect of the dural sac and dural sleeve. (From Bogduk N, Twomey LT. *Clinical anatomy of the lumbar spine*, 2nd ed. Edinburgh: Churchill Livingstone, 1991:117.)

also been implicated as a possible source of back pain (11,12,23). However, the clinical picture is variable. Although nociceptive nerve fibers have been clearly identified in facet joint capsules and pericapsular tissue, facet joint injections as a diagnostic and therapeutic modality are not always effective (23). Randomized studies have not demonstrated a difference between the efficacy of placebo and that of steroids and local anesthetics during facet injections (24,25).

### OPERATIVE INDICATIONS

Before the diagnosis of degenerative disc disease can be made, a careful history, physical examination, and appropriate confirmatory studies should be performed. Once the diagnosis has been made, nonsurgical options should be exhausted before operative treatment is considered. The authors agree and stress that most individuals with chronic disc degeneration and axial back pain can be managed effectively with nonoperative treatment (2,4, 8,26). The natural history of axial back pain is continued improvement with resolution over time. In cases where

**FIG. 31-2.** Neuroanatomic definition of the lumbar motion segment. 1, Ascending branch of sinuvertebral nerve; 2, ascending facet branch; 3, sinuvertebral to facet; 4, direct branch to facet; 5, branches to multifidus; 6, medial branch of posterior primary ramus; 7, local facet branch; 8, descending facet branch; 9, branch to sacroiliac; 10, sympathetic chain; 11, branch under anterior longitudinal ligament; 12, branches from gray ramus to disc; 13, sinuvertebral to disc; 14, gray ramus communicans; 15, branches from anterior primary ramus to disc; 16, lateral branch of posterior primary ramus. (From Oudenhoven RC. *The role of laminectomy, facet rhizotomy and epidural steroids*. Spine 1979;4:145-147.)

pain persists, it often becomes a diffuse process throughout the entire lumbar spine, and it becomes difficult to determine with certainty which of the several levels are the source of the pain.

Although the majority of patients improve with nonoperative measures, surgical intervention has a valuable role in selected cases. In a recent multicenter study, the Swedish Lumbar Spine Study Group randomized 294 patients with severe chronic low back pain into either surgical or nonsurgical treatment groups. The investigators concluded that in carefully selected patients with severe chronic low back pain without symptoms of leg pain or signs of nerve root compression, the improvement in pain and disability after surgical fusion was significantly superior to that of nonsurgical treatment (7). Current indications for fusion include the patient with (a) unremitting pain and disability for greater than 1 year; (b) failure of aggressive physical conditioning and conservative treatment for at least 3 to 4 months; (c) magnetic resonance imaging consistent with advanced disc degeneration limited to one or two disc levels; and (d) a negative psychiatric evaluation and lack of secondary gain (27,28).

**TABLE 31-1.** Fusion techniques for degenerative disc disease

Lumbar fusion techniques
Posterolateral intertransverse fusion
Posterior lumbar interbody fusion
Transforaminal lumbar interbody fusion
Anterior lumbar interbody fusion
Combined antero-posterior lumbar interbody fusion

Although some agreement has been reached concerning operative indications, the ideal surgical procedure for the management of the symptomatic degenerative disc has not yet been answered. Because the pain is believed to originate from either mechanical degeneration of the intervertebral disc or pathologic motion between vertebrae segments, the majority of surgical interventions focus on lumbar arthrodesis (Table 31-1). Fusion of the pathologic and painful lumbar segments would theoretically stabilize the progression of mechanical disc degeneration and eliminate pathologic motion and pain (2,4).

## SURGICAL OPTIONS

Once the decision for operative intervention is decided on, then the options for arthrodesis include posterior-posterolateral fusions, posterior lumbar interbody fusions, anterior lumbar interbody fusions, and combined anterior-posterior fusions (4,5,27). There are few comparative studies that analyze the various techniques (29); the decision of whether or not to fuse the intervertebral disc is still under debate.

Some authors believe that a posterolateral fusion alone may be insufficient to address anterior pathology at the level of the intervertebral disc (30–32). They argue that if the annulus fibrosus has been identified as a potential pain generator, then treatment should address the pathology directly by complete elimination of the disc. Some studies have demonstrated anterior motion and concordant pain on discography of levels that lie beneath a solid posterior fusion (33). Proponents of posterolateral fusion argue that the posterior fusion alone is sufficient to provide relief of axial back pain symptoms in the majority of patients and that the associated morbidity from an interbody fusion cannot be justified (2,5,34).

Reported fusion rates vary among surgical techniques. Because of decreased vascularity of the vertebral endplates, pseudoarthrosis rates have been reported to be higher with interbody techniques (3,29). MacNab and Dall compared anterior interbody, posterior, and intertransverse fusions and found that the incidence of pseudoarthrosis after intertransverse fusions was significantly lower than with the other two methods. The investigators felt that the larger bone surface available from the transverse processes, lateral articular processes, and intervening isthmus region, combined with local vascu-

larity, enhanced the rate of neovascularization of the bone graft (29). Furthermore, interbody fusions often partially collapse and may potentially extrude during graft incorporation. Newer instrumentation and surgical techniques may improve fusion rates and decrease graft settling; however, long-term follow-up is still unavailable.

Biomechanically, the closer the fusion is to the center of the motion segment, the greater the stiffness achieved (3). Theoretically, interbody fusion techniques should have the highest rigidity, and the posterior and posterolateral fusions should have the least. However, the relatively larger fusion masses created posterolaterally during intertransverse process arthrodeses increase considerably the area moment of inertia, thus improving stability, particularly in axial rotation and lateral bending.

Historically, techniques that extend the fusion mass posteriorly to include the laminae, facet joints, and spinous processes have increased the rigidity of posterior fusions proportionally. However, this technique can lead to iatrogenic spinal and foraminal stenosis from bony overgrowth (4) and has been associated with a high rate of pseudoarthrosis (35). In McBride's original description of the posterior fusion, he stressed the importance of the facet joint and used a morselized transfacet bone block for lumbosacral arthrodesis (36). Cadaveric studies performed by Boden et al. analyzed the axial and torsional stiffness of various techniques and questioned that method (37). Those authors concluded that disruption of the facet joint capsule required for placement of the transfacet bone blocks resulted in loss of spinal stability as compared with posterior intertransverse process arthrodesis alone. One significant advantage of the posterolateral technique over posterior fusions is that it can be performed in the absence of posterior elements. Posterior fusions are rarely performed today, and posterior and posterolateral techniques most commonly refer to intertransverse process arthrodeses (38).

## POSTEROLATERAL INTERTRANSVERSE LUMBAR ARTHRODESIS

### Historical Perspective

Spinal fusions were first reported in 1911 for the treatment of Pott disease by providing mechanical stability to inhibit progressive deformity and the spread of the tuberculous infections (39). Also in 1911, Hibbs described his experience with spinal fusion for tuberculosis and suggested that this technique could be used in the treatment of scoliosis (40). He performed his first fusion for scoliosis in 1914, and reported on his first 59 cases in 1924 (40). Eventually this led to the use of spinal fusions for the treatment of a variety of spinal deformities and diseases, including fractures, spondylolisthesis, scoliosis, kyphosis, and intervertebral disc disease.

Since that time, the techniques and surgical approaches for posterior-posterolateral lumbar fusions have changed

significantly. There has been a significant increase in the basic science behind lumbar fusions and the understanding of the role of instrumentation. All fusion techniques involve surgical preparation of the site of intended fusion and an attempt to stimulate the formation of bone (41). Traditionally, graft materials were either autologous or allograft bone. However, an increasing number of synthetic and bioactive substances are currently in use or under investigation. Three basic requirements are necessary for a successful fusion: (a) graft material with adequate osteogenic, osteoinductive, and osteoconductive properties; (b) adequate local vascularity to produce and support the bone healing; and (c) an acceptable local environment for bone formation (41). A fusion is considered fused when the newly synthesized bone is mechanically contiguous with the local host bone and can sufficiently bear physiologic loads without failure of the fusion mass. A pseudarthrosis is said to take place if this does not occur.

### Technique

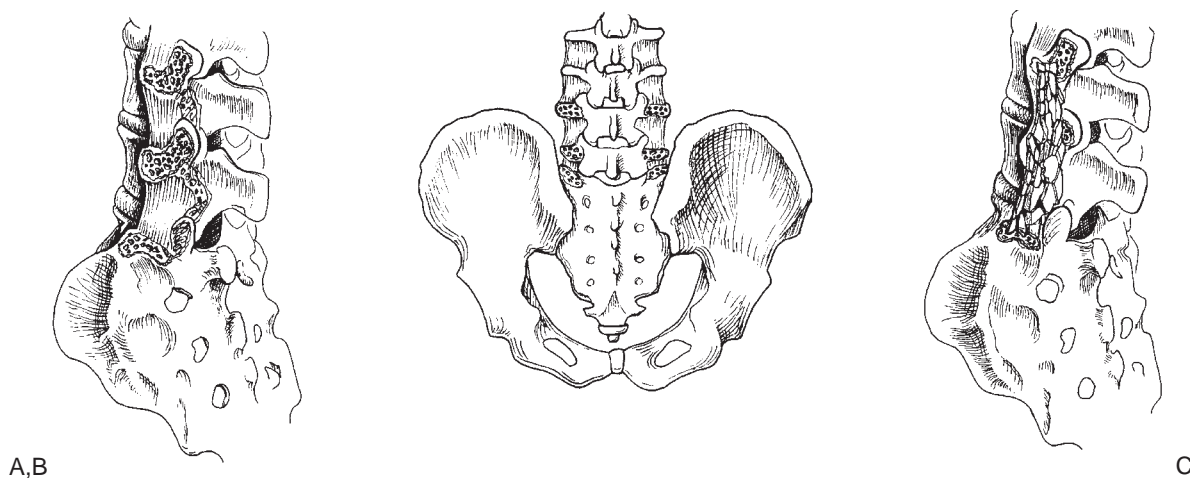

This operation usually is performed under general anesthesia with the patient in the prone position. Chest and iliac crest rolls are placed with the chest and abdomen hanging free to allow pulmonary excursion, minimize abdominal compression, and minimize distention of the epidural veins. The use of prophylactic antibiotics is recommended.

A midline incision is centered slightly superior to the spinous processes of the involved levels, and the incision is extended proximally and distally to include the levels above and below to ensure adequate exposure. Electrocautery is used to divide the subcutaneous tissue down to the fascia in line with the skin incision. The fascia is

incised in the midline and the paraspinal muscles are stripped subperiosteally from the spine with electrocautery and a Cobb periosteal elevator. Radiographs should be scrutinized for evidence of previous surgical or congenital bony defects to minimize inadvertent entry into the spinal canal. As the dissection progresses, sponges are packed tightly within the wound to help control bleeding. The facet joints are preserved until the appropriate levels have been identified. An intraoperative radiograph should be obtained if any question exists.

Once the level is confirmed, the dissection should progress laterally out to the transverse processes. This is performed by incising the fascia directly lateral to the facet joints and following the superior articular facet of the inferior vertebra out inferolaterally onto the transverse process. Deep retractors are repositioned as needed throughout the dissection. The muscle and soft tissue are carefully cleared off the transverse process, making sure not to fracture it. The dissection is carried superiorly and inferiorly as needed to include the appropriate levels. The spinous processes at the involved levels are connected by dissecting the muscle off the intertransverse ligament, thus creating space for the graft.

If the fusion is to extend to the sacrum, the ala should be prepared in a similar manner. The ala is exposed by dissecting lateral to the superior articular facet of the sacrum. It is important to note that in this area there are dense ligaments that must be dissected from the sacrum in order to obtain a clear exposure of the ala. At the end of the dissection, a continuous trough should exist laterally between the transverse processes and the ala. Bilateral decortication of the transverse processes, lateral portion of the pedicle, lateral portion of the articular facets, and ala is performed with a burr or sharp curettes (Fig. 31-3).

**FIG. 31-3.** Preparation of the fusion bed. **A:** Oblique view of meticulous decortication of the outer face of the facet joint, transverse process, pars, and alar cortical surfaces. **B:** Posterior view of decorticated bilateral lateral graft bed. **C:** Oblique view of fusion bed packed with cancellous and corticocancellous bone graft. (Zindrick MR, Selby D. Lumbar spine fusion: different types and indications. In: Wiesel SW, Weinstein JN, Herkowitz H, et al., eds. *The lumbar spine*, 2nd ed. New York: Lippincott Williams & Wilkins, 2004:600.)

At this point a preliminary sponge count should be performed and the wound checked both visually and with manual palpation to look for retained sponges. The wound is then irrigated and the posterolateral trough is packed ideally with autologous bone graft (see the following). The graft should not be harvested until the transverse processes, ala, and lateral structures have been exposed and decorticated to minimize the period when the bone is not in contact with tissue. At the end of the case hemostasis is obtained, any devitalized tissue is débrided, and a suction drain inserted into the wound if necessary. The fascia and subcutaneous tissue are closed in the standard manner.

### **Bone Graft Harvesting: Posterior Iliac Crest**

Despite rapid advances in bone graft substitutes, the use of autologous iliac crest bone remains the gold standard at this time. Iliac crest is still the most common source of autologous bone harvest for posterolateral lumbar fusions because of its superior osteogenic, osteoconductive, and osteoinductive properties combined with easy accessibility.

If amenable, the same midline incision used during the exposure of the posterior spinal elements can be used to obtain access to the posterior ilium. Maintaining a full thickness flap, dissect just superficial to the fascia out laterally to the posterior superior iliac spine. If using the same incision results in excessive dissection or inadequate exposure, a second separate incision can be used. The second incision can be oriented either vertically or obliquely, with the posterior superior iliac spine at approximately the inferior or medial margin of the incision. Regardless of the approach, care should be taken, if possible, not to expose beyond 8 cm lateral to the posterior superior iliac spine, because this may result in injury to the superior cluneal nerves and cause numbness in the skin overlying the gluteal region (42).

Dissect down to the posterior superior iliac spine and expose the iliac crest. Incise the iliac crest periosteum and subperiosteally dissect the muscle and periosteum off the outer table of the posterior ilium. This is performed with a combination of electrocautery and a Cobb elevator. After the muscles and periosteum are stripped, a Taylor or similar retractor is placed deeply into the wound, taking care not to inadvertently enter into the greater sciatic notch distally.

Once the graft donor site is exposed, begin harvesting corticocancellous strips using a half-inch osteotome. Make sure to score the outer table only by creating several vertical strips approximately 7 mm in width. The distal extend of the vertical cuts are then connected horizontally with a curved osteotome to prevent distal propagation of the strips during harvest. Start at the top of the iliac crest, and use a curved osteotome wedged between the inner and outer tables of the ilium to remove

the precut corticocancellous strips. Once they are removed, the intramedullary cavity is available for cancellous bone removal with gouges or curettes. When an appropriate amount of bone graft has been obtained hemostasis is achieved, the wound irrigated, and a drain inserted if necessary. The incision is closed in the standard fashion.

### **Postoperative Management**

Antibiotics are continued until the drains are removed, usually on the first or second postoperative day. Typically the diet is advanced as tolerated unless an ileus develops. The patient is encouraged to be out of bed and is allowed to ambulate the day of or day after surgery. An external orthosis or brace is recommended for support and comfort, particularly if multiple level fusions were performed. Early mobilization has not been shown to lower the rate of successful fusion and may actually improve muscle tone, decrease edema, promote hematoma resolution, and improve patient function and psychologic outlook.

After discharge from the hospital, the initial visit is often scheduled at 2 to 3 weeks postoperatively. The patient is then reevaluated at 6-week intervals for the first 3 months, and then every 3 months for the first year. The patient can usually return to light duty or part-time work by 4 to 6 weeks, although heavy lifting and vigorous athletics should be avoided for 6 months. As the patient's recovery improves, a more vigorous exercise program is gradually instituted with focus on proper back care and mechanics.

### **INSTRUMENTED VERSUS NONINSTRUMENTED POSTEROLATERAL FUSIONS**

Significant interest and debate exists over the use of instrumentation in posterolateral lumbar fusions. Various constructs have been investigated and include wires, hooks, and pedicle-screw based segmental fixation techniques. Currently, segmental instrumentation with pedicle-screw fixation is the construct of choice because of the ability to control all three columns of the spine from a posterior approach, the ability to limit the fusion to involved motion segments, the ability to obtain spinal fixation in the absence of posterior elements, and the capability to avoid placement of instrumentation within the spinal canal (27,43,44).

From a theoretical standpoint, spinal instrumentation provides immediate stability to the spinal segments being fused and therefore increases fusion rates. Multiple studies support this hypothesis (4,44–47). For a single level posterolateral fusion without instrumentation pseudoarthrosis rates are reported to be between 10% and 15%. The addition of pedicle instrumentation may lower this to

5%. In a prospective, randomized trial of 49 patients, Zdeblick demonstrated a statistically significant difference in fusion rates between instrumented and noninstrumented posterior fusions for degenerative disc disease. The fusion rate for the group with pedicle instrumentation was 93% compared to 45% without instrumentation (47).

The use of instrumentation has been shown to reduce the pseudoarthrosis rate in patients undergoing multiple level fusions. In a prospective study by Grubb and Lipscomb (45) that looked at one- and two-level fusions, the authors found higher fusion rates in patients having instrumentation. Similar results from a prospective, multicenter trial were reported by Wood and colleagues (44), who examined the use of instrumentation in one- to four-level fusions, with the majority of them being two levels or greater. Compared to historic controls, the authors found that patients who underwent fusion without instrumentation were over 24 times more likely to develop a pseudoarthrosis when compared to patients with instrumented fusions.

Other reported advantages of instrumentation include decreased rehabilitation time, reduced need for postoperative bracing (47), and possible reduced requirement for postoperative use of pain medication (43,47,48). However, these findings should not mandate the routine use of instrumentation during lumbar arthrodesis. Compared to fusion *in situ*, the use of instrumentation has been associated with higher morbidity and mortality (Table 31-2). A cohort study sponsored by the North American Spine Society for the use of pedicle instrumentation reported an overall instrument related complication rate of 5% (48). The risks and benefits of instrumentation should be considered in each individual case, particularly in the elderly patient, where the advantages must be balanced carefully with the potential risks associated from the use of instrumentation. Furthermore, the use of instrumentation should be performed only by experienced surgeons, who are knowledgeable and comfortable with the specific techniques. The occasional use of instrumentation by the inexperienced surgeon is associated with an unacceptably high complication rate and should be avoided.

We believe that in cases where an increased risk of pseudoarthrosis is present, the use of adjuvant instrumen-

tation is beneficial for posterolateral intertransverse lumbar fusions. In particular, this includes patients with risk factors such as diabetes and smoking, in multilevel fusions and in revision cases for failed back or surgical treatment of established pseudoarthrosis.

## CONCLUSION

Significant debate exists over the role of surgery in the management of degenerative disc disease. The lack of randomized, prospective studies makes the comparison and evaluation of outcomes difficult to assess. Furthermore, studies on the role of posterolateral arthrodesis for the treatment of disc degeneration often includes patients with multiple pathologies, including herniated discs, spondylolisthesis, and spinal stenosis, some of whom may have undergone prior decompressive procedures or arthrodesis. Despite these shortcomings, posterolateral arthrodesis in properly selected patients is a viable option for the treatment of axial back pain from degenerative disc disease. Currently autologous iliac crest remains the gold standard for bone graft material during posterolateral lumbar fusions. The adjuvant judicious use of instrumentation improves fusion rates by providing immediate stability; however, its routine use should be avoided and decisions about its use should be made on an individual basis.

# Posterior Lumbar Interbody Fusion

Casey K. Lee and Kenneth J. Kopacz

---

Degenerative disc disorders are probably the most common cause of acute or chronic low back pain, but the natural history and the mechanism of pain production of degenerative disc disorders are poorly understood. Many different phases of degenerative disc disease (i.e., “degenerative cascade”) are described well by Kirkaldy-Willis et al. (1). The acute onset of low back pain, the first time or very occasional recurrences, usually becomes symptom-free after a short duration. Some pathologic conditions of degenerative disc disease (DDD) are, however, responsible for recurrent or chronic persistent low back pain that significantly affects a patient’s lifestyle. These include *internal disc derangement* which is defined as a derangement of the internal disc structure (nucleus and annulus) or biochemical alterations without having any external disc pathology such as disc bulge, herniation, disc height narrowing, or abnormal displacement. Another subtype of DDD is classified as stable DDD. This is described as degenerative disc changes without having gross abnormal displacement such as degenerative spondylolisthesis.

Spinal fusion for DDD has been a most controversial subject for many decades. The effectiveness of spinal fusion for DDD was difficult to prove without knowledge of the natural history of various degenerative conditions. Yet, DDD has been the most common pathologic condition for which spinal fusion is indicated. Davis reported that 51% of spinal fusions performed in the United States during a 10-year period (1980 to 1990) were for DDD (2). In a review of English-language literature by Bono and Lee (3) for spinal fusion for DDD between 1980 and 2000, spinal fusion was indicated for various conditions of DDD. The most common indication was for stable DDD (67%) which included internal disc derangement, DDD without instability, and postdisc excision for disc herniation. The second most common indication was for DDD with spondylolisthesis (25%).

Indication for spinal fusion for certain conditions of DDD such as degenerative spondylolisthesis, progressive

degenerative scoliosis, or hypolordosis (“flat back syndrome”) is well accepted while indication for others such as stable DDD and internal disc derangement (IDD) is still controversial. Spinal fusion for chronic low back pain caused by DDD has been proven more effective than nonoperative treatments in a recent controlled clinical study (4). For IDD, there is no controlled clinical study that conclusively proves the effectiveness of spinal fusion over the natural history or nonoperative treatments, and it remains a most controversial subject. There is, however, some indirect clinical information suggesting that spinal fusion for IDD may be a more effective treatment than the natural history or nonoperative treatments. In a 5-year follow-up study of patients with chronic low back pain caused by IDD (discography-positive) who were treated with nonoperative treatments, none of the patients became symptom-free and approximately 50% were experiencing the same or worse pain (5). In another study, patients who were candidates for spinal fusion with the diagnosis of IDD but were denied fusion by insurance payors were followed for one-and-a-half years. Two-thirds of patients were experiencing the same or worse symptoms at follow-up (6). The published results of spinal fusion for IDD indicate a high rate of symptom relief and return to work. In a report on a properly selected group of patients with IDD, spinal fusion provided better clinical success rates of pain relief (89%) and return to work (82%) (7).

## CHOICE OF SPINAL FUSION TECHNIQUES

### Posterolateral Fusion versus Interbody Fusion

Lumbar interbody fusion is preferred to posterior or posterolateral fusion in patients with discogenic pain (stable DDD and IDD) and in patients with anterior column weight-bearing deficiency, especially with angular instability in the sagittal or coronal plane. It is also preferred in patients with failed previous posterior or posterolateral fusion.

**FIG. 32-1.** Disc degeneration with anterior column weight-bearing function (“flat-tire syndrome”). Magnetic resonance imaging of the lumbosacral spine of a patient with chronic disabling low back pain shows the L4-5 disc with diffuse circumferential bulge (*arrows*) and with minimally decreased disc height. The disc has deficient anterior column weight-bearing function.

Various types of spinal fusion produce different biomechanical effects on the fused segment and on adjacent segments (8,9). In a biochemical study, Rolander reported that posterior fusion did not eliminate motion across the disc within the fused segment and suggested that this retained motion across the disc may be the source of chronic persistent pain after successful posterior fusion. Clinical studies by others further support this concept (10,11). In these clinical studies, some patients with discogenic pain had persistent pain after successful posterior or posterolateral fusion, and their pain symptom was successfully relieved after subsequent lumbar interbody fusion.

Effects of different types of lumbar fusion on adjacent segments are primarily caused by changes in stiffness and changes in the center of rotation of segmental motion of adjacent levels to fusion (9). Degeneration of the disc results in changes in biomechanics of the motion segment. In certain cases, the motion segment may become unstable in sagittal, coronal, axial or combination motions due to mechanical incompetence of the disc (anterior column weight-bearing deficiency) (Fig. 32-1). Interbody fusion is more effective in correcting the anterior column deficiency than is posterior or posterolateral fusion. Posterior or posterolateral fusion for DDD with anterior column deficiency, especially for angular instability (segmental hypolordosis or disc space wedging), may produce significant adverse effects on the adjacent segments (12,13).

### Posterior Lumbar Interbody Fusion versus Anterior Lumbar Interbody Fusion

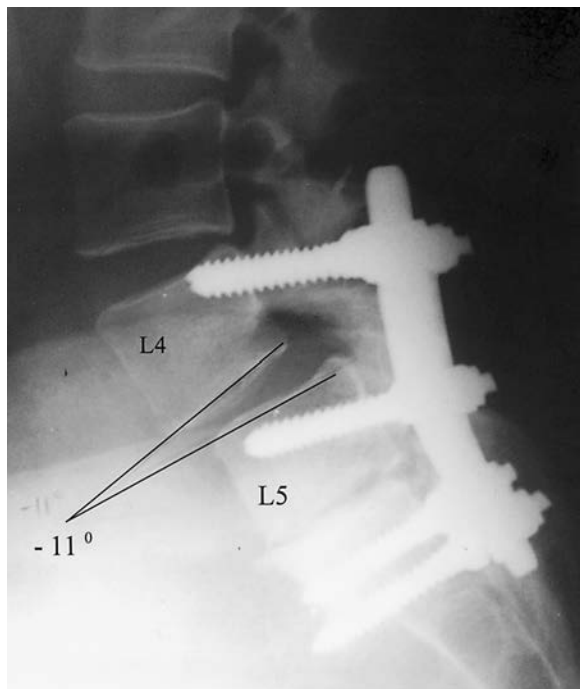

Indications for, and the fusion rate of posterior lumbar interbody fusion (PLIF) are very similar to those of ante-

rior lumbar interbody fusion (ALIF). The clinical success rate is comparable for the two, but the “surgeon factor” (skills and experience) is an important factor (14). Each procedure has advantages and disadvantages. ALIF has a wider and easier surgical exposure, but often requires a second surgeon (vascular or general). It is associated with inherently more significant and serious complications than PLIF, such as vascular or visceral injuries, impotence, or retrograde ejaculation. When rigid fixation is required for ALIF, an additional posterior approach is required for pedicle screw fixation. PLIF is primarily indicated for the lower lumbar and lumbosacral spine (L3-5 and S1). In the upper lumbar spine above the L2 level, the surgical exposure for PLIF is limited by the presence of conus medullaris and by the short interpedicular distance. The surgical exposure of PLIF is more limited and more difficult to master than ALIF. However, PLIF has definite advantages over ALIF in other aspects: all three columns of the motion segment can be addressed through one exposure—posterior decompression, restoration of anterior column weight-bearing function, correction of degenerative deformities and instability, and rigid posterior fixation. It has different complications from ALIF: excessive epidural bleeding, dural tear, or neural injury. PLIF is preferred to ALIF for patients who require addressing all three columns at the same time: posterior decompression, restoration of anterior column weight-bearing function, and rigid posterior fixation.

### PLIF Indications

Indications for PLIF are as follows:

1. The *preferred* indication for PLIF is DDD with anterior column weight-bearing deficiency (Fig. 32-2).

**FIG. 32-2.** Disc degeneration with disc space wedging and loss of lordosis. A lateral view of the lumbosacral spine of a female patient shows persistent segmental kyphosis at L4-5 after posterolateral fusion. She has severe persistent low back pain and was unable to stand up straight. Posterolateral spinal fusion failed to correct segmental kyphosis and failed to relieve her symptoms.

- a. DDD with diffuse circumferential disc bulge with or without disc space collapse (“flat-tire syndrome”) (12) (Fig. 32-1)
- b. DDD with segmental instability such as degenerative spondylolisthesis
- c. DDD with segmental deformity—hypolordosis or disc space wedging (Fig. 32-2)
2. PLIF is a good choice for chronic disabling low back caused by:
  - a. IDD
  - b. Stable DDD
  - c. Post-disc excision DDD
3. Other indications for PLIF are:
  - a. Failed posterolateral fusion
  - b. The rare indication of a disc space infection with epidural abscess resistant to nonoperative treatment that requires surgical intervention for débridement and stabilization
  - c. Degenerative scoliosis where posterior decompression, correction of deformity, and rigid internal fixation are combined with fusion

#### **PLIF Contraindications**

PLIF is contraindicated where the neural elements cannot be retracted in such conditions as conjoined nerve

roots or severe epidural scarring following previous surgery. PLIF is not recommended above L2 because of the very narrow interpedicular distance, narrow spinal canal, and proximity of the conus medullaris.

#### **PLIF Surgical Techniques**

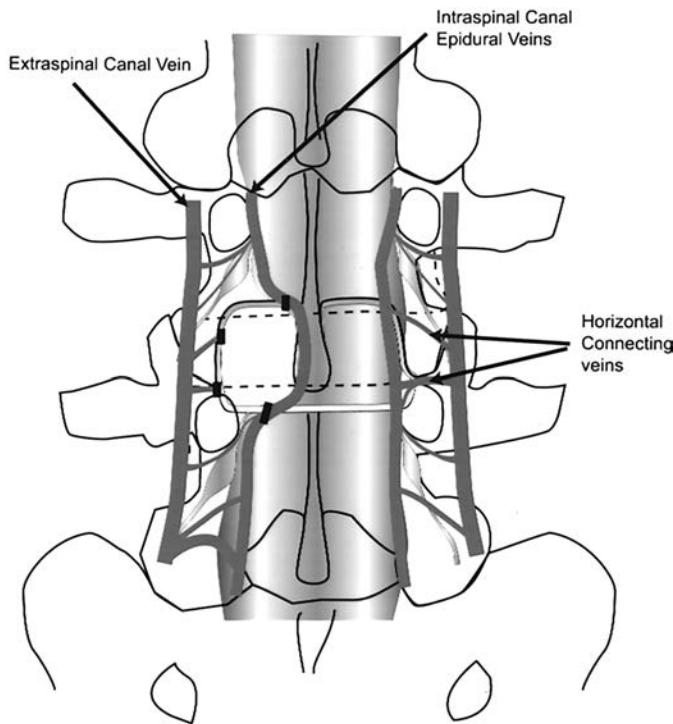

Successful results of PLIF depend on proper patient selection, indications, and good surgical techniques. The PLIF procedure requires: (a) adequate exposure; (b) adequate mobilization, retraction, and protection of neural elements; (c) proper preparation of the vertebral end plates (graft bed); and (d) placement of an adequate amount of appropriate bone graft. Basic surgical techniques are described well by others (15–19). Some selected important points are described here.

#### **Exposure**

Bilateral large laminotomies and medial one-half facetectomies provide a sufficiently large enough exposure for the basic PLIF technique (Fig. 32-3). Proper control of epidural bleeding is essential for mobilization and retraction of the dura and nerve roots. Bipolar coagula-

**FIG. 32-3.** The surgical exposure for the basic posterior lumbar interbody fusion (PLIF). Bilateral laminotomies and medial one-half facetectomies (dotted line) will provide sufficient exposure for the basic PLIF. Most of the lamina, spinous processes, interspinous and supraspinous ligaments, and lateral one-half of facet joints are saved for stability of the fusion construct.

**FIG. 32-4.** Control of epidural bleeding and retraction of neural elements. Epidural vessels have regular anatomic arrangements, vertically running intraspinal canal vessels and horizontally running connecting vessels between intraspinal and extraspinal canal systems. Horizontally running vessels are coagulated with a bipolar cautery and divided immediately above the pedicles and near the lower vertebral end plate. The traversing nerve root, dura, and intraspinal vertical epidural vessels are retracted to the midline.

tion and division of cross-linking epidural veins between the extraspinal canal and intraspinal canal venous system superior to the pedicles provides a dry surgical field and allows easier mobilization of the dura and nerve roots medially to the midline (Fig. 32-4).

#### *Mobilization, Retraction, and Protection of Neural Elements*

The dura and the traversing nerve root may be retracted to the midline (Figs. 32-4, 32-5). A prolonged continuous retraction of the nerve root should be avoided, especially for patients who had previous posterior surgery. The exiting nerve root above the disc may occasionally be in the way at the superior lateral corner of the surgical field under the facet joint. All of these neural elements should be retracted and protected all the time during the procedure, especially during insertion of bone graft or any fusion device into the disc space.

#### *Preparation of the Vertebral End Plates (Graft Bed)*

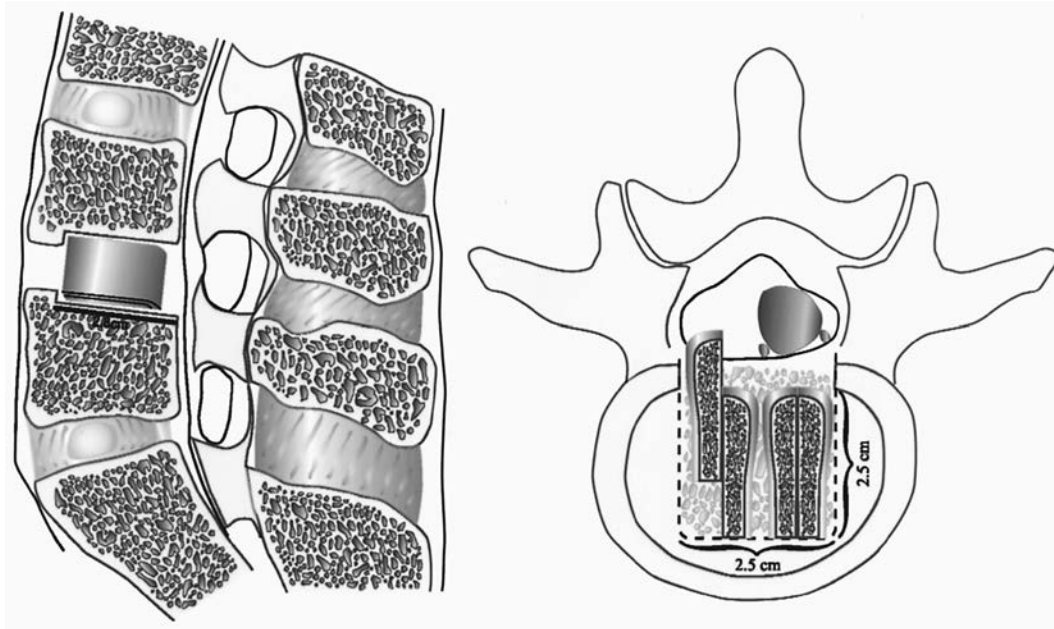

Contact surface area between graft bed and bone graft is the most important factor for bone healing and subsi-

dence. Exposure of sub-end-plate cancellous bone promotes bone healing. Biomechanical tests indicate that decortication of the vertebral end plates does not have any significant effect on the compressive strength at the interface between bone grafts and vertebral bone (20). The three most important factors for subsidence of bone grafts or interbody fusion devices are bone mineral density of the vertebral bone, applied compressive load, and contact surface area at the interface. To prevent subsidence, a PLIF construct requires a minimum contact surface area of  $6.25 \text{ cm}^2$  for stability at the interface for a patient with normal bone mineral density under normal postoperative physiologic conditions (21). This amount of contact surface area can be obtained by preparing the end plates for  $2.5 \text{ cm} \times 2.5 \text{ cm}$  for bone grafts. For the average-size adult Caucasian, laminotomies and medial one-half facetectomies with retraction of neural elements medially to the midline provide adequate exposure (1.3 to 1.5 cm on each side) for decortication of vertebral end plates between pedicles (1.25 cm from each side) and to the depth of 2.8 cm anteriorly. This contact surface area of  $6.25 \text{ cm}^2$  is approximately equal to the total contact surface area of two tricortical iliac crest bone grafts.

#### *Bone Graft Insertion*

Stand-alone PLIF construct (PLIF construct without internal fixation systems such as pedicle screw fixation or facet screw fixation) requires bone grafts that provide sufficient compressive strength to prevent graft collapse, that provide a sufficiently large contact surface area to prevent subsidence, and that have good bone healing potential. Two autologous tricortical iliac crest bone grafts meet all of the requirements. Each tricortical iliac crest bone graft may be harvested and split in half and inserted in four blocks of split grafts (Fig. 32-5). An alternative graft is to remove the outer wall of the iliac crest, obtaining four corticocancellous blocks. These modifications allow easy placement of graft into the disc space without excessive retraction of neural elements, and save the inner cortical table of the iliac crest. Patients treated with stand-alone PLIF with four blocks of autologous one-half iliac crest bone grafts show no significant graft subsidence or graft collapse. Furthermore, there is no significant difference in graft subsidence or fusion rate between stand-alone PLIF and PLIF with pedicle screw fixation. This strongly suggests that stand-alone PLIF provides a high rate of fusion without subsidence or graft collapse when the basic principles of PLIF techniques are diligently followed. These include: (a) saving posterior structures of interspinous and supraspinous ligaments and lateral one-half facet joints; (b) adequate size of vertebral end-plate preparation for contact surface area with bone graft; and (c) proper choice of bone graft in quantity and quality.

**FIG. 32-5.** Preparation of the vertebral end plates and insertion of bone grafts. The vertebral end plates are decorticated between the pedicles (about 2.5 cm) and to the depth of approximately 2.8 cm toward the anterior aspect of the spinal column. Four blocks of bicortical corticocancellous graft (each with 0.7 cm width, 2.5 cm depth, and with an appropriate height) are impacted into the disc space. The space available for bone graft insertion is limited to approximately 1.25 to 1.3 cm when the neural elements are retracted to the midline. A bone graft wider than 1.3 cm is very difficult and requires further retraction of neural elements or total facetectomy.

### *Modifications of the Basic PLIF Technique*

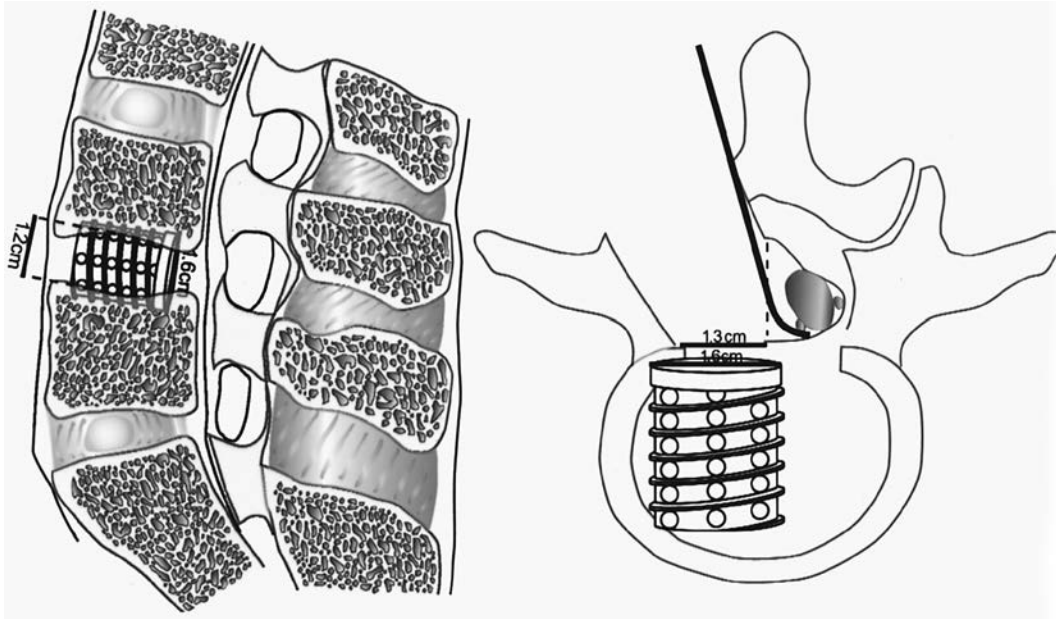

Many different types of modification of PLIF surgical techniques have been described in the literature (22–31). Some advocate bilateral total facetectomies and laminotomies for a larger surgical exposure and for easier insertion of bone grafts or interbody fusion devices. This surgical exposure, however, produces an unstable PLIF construct and requires additional rigid internal fixation systems such as pedicle screw fixation or facet screw fixation. One other similar variation is unilateral approach: laminotomy and facetectomy, insertion of bone graft or interbody fusion devices and pedicle screw fixation are performed on one side only. Little information is available in the literature about the success rate of the unilateral PLIF.

Facet screw fixation or other posterior tension band devices have been used with PLIF for additional stability of the fusion construct. PLIF with pedicle screw fixation provides a marginally better fusion rate than stand-alone PLIF. A good stand-alone PLIF construct provides sufficient enough stability for prevention of subsidence or bone graft collapse. A clinical comparison study of stand-alone PLIF versus PLIF with pedicle screw fixation demonstrated no significant difference in subsidence and graft failure (32). Patients with stand-alone PLIF do not require any external brace postoperatively. Patients with

PLIF and pedicle screw fixation appear to have easier and faster mobilization during the immediate postoperative period.

Although autologous iliac crest corticocancellous bone graft has been the standard for basic PLIF procedure, many other alternatives have been used. These include local bone graft from spinous process or lamina removed during the operation, cortical or corticocancellous allograft, graft substitutes, or various types of interbody fusion devices. In recent years, the use of ready made cortical or corticocancellous interbody fusion grafts or interbody fusion cages have become popular. Most of these products require facetectomies to provide a large exposure for insertion, and therefore require supplemental pedicle screw fixation. Some of these devices are poorly designed and do not satisfy the basic principles of interbody fusion techniques (Fig. 32-6).

The average interpedicular (right to left) distance of the lower lumbar spine of an adult Caucasian is about 2.5 cm, and the average disc height in the lower lumbar spine is 1.2 to 1.3 cm. In order to have a cylindrical cage sufficiently contact the vertebral end plates, the diameter of the cage has to be greater than 1.6 cm. A smaller cage will result in gradual subsidence or failure of bony union. A cage with a 1.5 cm diameter or greater will be very difficult to insert posteriorly because of the anatomic limitations described herein. It requires total facetectomy or

**FIG. 32-6.** Interbody fusion devices. For a lower lumbar disc with disc space height of 1.2 cm, the diameter of a cylindric cage should be more than 1.6 cm for adequate contact surface area. To insert this through the posterior approach, the surgical exposure requires total laminectomies and facetectomies and requires retraction of the neural elements far beyond the midline.

excessive retraction of the dura and the nerve root beyond the midline for insertion of such a large cage. The interpedicular distance in the Asian population is smaller than that of Caucasians, and the procedure becomes even more difficult and riskier for excessive bleeding and neural injury (33). Any interbody device or prepared bone graft in excess of 1 cm wide is difficult to insert posteriorly into the disc space, and it requires an excessive amount of retraction even with total facetectomies. The design of interbody fusion devices for PLIF should be different from that for ALIF because of these anatomic limitations. Surgeons must be familiar with these limitations and choose a proper device to avoid serious complications.

### **Complications of PLIF**

PLIF has a steep learning curve and it carries the risk of various complications (34–41). Most complications during PLIF are related to inadequate exposure, excessive epidural bleeding, and poor understanding of anatomic and biomechanical principles of the procedure.

Excessive epidural bleeding can be a problem during the PLIF procedure. This may cause not only an excessive amount of blood loss but also poor visualization of the surgical field leading to dural tear or neural injury. Adequate bleeding control with a dry surgical field must be obtained before mobilization of neural elements and work within the disc space.

The incidence of neuropraxia is reported in the range of 1.5% to 4% (34,41). Okuyama et al. reported a high

rate (8%) of neuropraxia, but all had transient neuropraxia with no permanent neural palsy (40). This is primarily due to excessive and prolonged retraction of the nerve root. To avoid this complication, one must have constant visualization and adequate mobilization of the dura and nerve roots, and must avoid prolonged retraction of neural elements. When PLIF procedure is performed on a patient who had previous posterior disc surgery with perineural scar, one must pay extra attention to mobilize the neural elements and release them more frequently from retraction. The incidence of dural laceration is reported in 1.5% (34). This is primarily due to poor visualization of the dura either by an inadequate size of exposure or by excessive bleeding. Over-sized bone graft or interbody fusion device is another cause for dural laceration during insertion.

The incidence of bone graft migration into the spinal canal is reported in the range of 0.3% to 2.4% (34,35, 41). The common causes for this complication are misfit of bone graft or interbody fusion device in the disc space or an unstable fusion construct. Proper preparation of the vertebral end plates and adequate size of bone graft are essential for a stable fusion construct. When posterior spinal structures are removed during the PLIF procedure, especially the facet joints, the fusion construct must be adequately stabilized with a rigid internal fixation system.

Excessive epidural fibrosis has been blamed to be a cause of failed PLIF procedure, although it has not been proven by any credible study. Excessive epidural bleeding

and rough handling of the neural elements during the procedure may result in excessive scarring that may adversely affect the outcome. Adequate control of epidural bleeding, as described earlier, will minimize any significant epidural fibrosis.

# Operative Treatment of Anterior Procedures

Kambiz Hannani and Rick Delamarter

---

Low back pain has been a significant cause of disability. Disc pathology, such as degenerative disc disease and instability, is believed to contribute to chronic low back pain. Anterior lumbar interbody fusion (ALIF) addresses this issue by removal of the disc and stabilization of the vertebrae via bone graft or substitutes, including autograft or allograft bone or bone morphogenetic protein. In the past 5 years, cages have been introduced in addition to bone grafting to improve anatomic alignment and provide stability. More recently, artificial disc replacement has been investigated for the anterior treatment of degenerative disc disease.

Axial pain caused by degenerative disc disease continues to be the main indication for stand alone ALIF. Multiple studies have demonstrated the presence of nociceptors in the annulus of the disc. The innervation of the disc is found to increase in discogenic disease (1). Therefore, the removal of the pain generator (disc) is a logical approach to improve patients' symptoms.

Determining which patients with low back discomfort have discogenic pain is challenging. Multiple factors, including the patient's signs and symptoms, radiographic findings, and provocative tests need to be combined to make an accurate diagnosis and treatment plan. Patients with discogenic disease tend to complain mainly of low back pain with minimal leg radicular symptoms. The pain usually worsens with flexion and on the return to the erect posture.

Radiographic findings may be subtle on X-ray films. Degenerative disc disease (DDD) can be identified radiographically by a decrease in disc space height and the presence of osteophytes. Magnetic resonance imaging (MRI) is helpful in identifying DDD. Magnetic resonance imaging findings of DDD include decreased signal of the disc on the T2-weighted images. A high-intensity zone (HIZ) may be identified, which is thought by some to be associated with positive discography and annular tears. Discography, although controversial, is helpful in identifying symptomatic DDD. Concordant pain during discography may respond to surgical fusion (2).

Multiple surgical options are available for the surgical treatment of symptomatic DDD. Anterior lumbar interbody fusion alone, combined ALIF and posterior fusion with instrumentation, posterior fusion alone or combined with posterior lumbar interbody fusion (PLIF) are all potential options available to the surgeon. Although many patients having fusion do well, the removal of the disc appears to improve the surgical outcome for DDD (3–6). The two approaches that allow for removal of the disc are ALIF and PLIF.

Cloward first reported on posterior interbody fusion in 1943 (7). In 1956, he described an anterior cervical interbody fusion (8). However, anterior lumbar interbody fusion was first reported by Paul Harmon in 1963, and Crock described a bilateral Dowel technique in 1982 (9,10). Although multiple options are available for the surgical treatment of DDD, ALIF has many advantages compared to other procedures. In contrast to posterolateral intertransverse fusions (PLIF), ALIF restores the disk height thereby allowing decompression of neuroforaminal stenosis. Anterior column support favors load transmission and places the bone graft volume under compression. Finally, ALIF removes the disc, which may be the painful structure (11). Compared to PLIF, ALIF affords a more complete discectomy and avoids dissection of the posterior paraspinal muscles. The operative time is significantly less with ALIF compared to PLIF, and it can be performed using minimally invasive procedures (11).

Allograft or autograft can be used for ALIF procedures. Historically, autograft has been the gold standard with excellent incorporation and high fusion rates. Good clinical outcomes with ALIF autograft have been reported. Penta reviewed 125 patients who underwent ALIF with iliac crest bone graft (ICBG) over a 10-year period (12). Sixty-eight percent of the patients were satisfied. The overall fusion rate was 72.4%, and varied from 91% for single level fusions to 51% for multilevel fusions. However, one drawback of ICBG is the risk of

graft subsidence and collapse, which is less common with allograft struts (13,14). Furthermore, the iliac crest donor site is a significant source of morbidity.

Allograft bone has also been used as a stand-alone device with ALIF. Kozak reported excellent results with a combination of cortical and cancellous allograft with 97% fusion rate at 1-year follow-up. Recently, however, unfavorable results with this procedure were reported by Dawson et al. (15). Seven of 16 patients in that study

developed a pseudarthrosis that required posterior fusion. Additionally, all patients showed subsidence of their grafts within the first year, with the pseudarthrosis group having a threefold increase in subsidence compared to the fused group (Fig. 33-1).

The fusion rate increases when ALIF using autograft is combined with posterior instrumentation (16,17). Sarwat reviewed 43 patients undergoing combined antero-posterior fusions using femoral allograft rings packed with

**FIG. 33-1.** **A:** Lateral X-ray of a lumbar spine illustrating instability and grade I spondylolisthesis at L4-5 with moderate disc space loss and degenerative disc disease at L5-S1 interspace. **B:** T2 sagittal magnetic resonance image confirming the degenerative disc disease at the lower two levels with decrease T2 signal and end plate changes at L4-5. **C:** Lateral X-ray of the lumbar spine following anterior lumbar interbody fusion using femoral ring allografts at the L4-5 and L5-S1 interspaces; the disc spaces have been restored with anatomic reduction of the spondylolisthesis at L4-5. **D:** Antero-posterior X-ray following anterior lumbar interbody fusion.

cancellous allograft with supplemental posterior stabilization (17). One hundred percent of the one level and 93% of the two level fusion were solid radiographically on follow-up. Allograft bone provided improved compressive strength but required more time for incorporation compared to autograft bone (18). At our institution, stand alone allograft ALIFs are not performed without supplemental posterior instrumentation.

Within the past decade, cages have been popularized for performing ALIF. Cages were initially introduced by Bagby for the treatment of wobblers disease in horses in 1977. Multiple modifications of the original cage design have been made since 1988. The BAK cage, Ray Cage, and Interfix Device are all cylindrical cages that are packed with bone graft. Two cylindrical cages are inserted in the interspace and give excellent overall stability (Fig. 33-2).

**FIG. 33-2.** **A:** Lateral X-ray of the lumbar spine illustrating a disc space narrowing at L4-5. **B:** Sagittal T2-weighted magnetic resonance image of the same patient showing decreased height and disc hydration consistent with degenerative disc disease. **C:** Lateral X-ray findings after an anterior interbody fusion using two cylindrical cages. **D:** Antero-posterior view of the cage construct seen in **C**.

Tapered threaded devices are also available and have the theoretical advantage of improved lordosis and anatomic alignment.

Cages have been shown to increase the stability of ALIF. In reviewing five types of cages, Tsantrizos concluded that cages decreased the range of motion at the interspace by an average of 63% in flexion and extension, 69% in lateral bending, and 23% in axial rotation (11). Cages have other advantages compared to other fusion methods. In a sheep study by Sandhu et al., a lower subsidence rate was shown with cages compared to autograft alone (19). Compared to PLF, ALIF using cages increases the axial stiffness of the interspace by 80% (compared to 40% seen in PLF). Moreover, higher nonunion rates have been reported with the PLF compared with ALIF (11). The increased stability is likely a function of increased disc space distraction seen with cage placement versus bone grafting alone.

The design of the cage also contributes to its stability. Cages with sharp teeth were found to exhibit higher pullout forces (20,21). Flexible cages constructed with carbon fiber reduce stress shielding of the bone graft. Stiffer cage constructs transmit less stress to the bone graft and the stress shielding effect of stiff cages may have a deleterious effect on bone graft incorporation (Fig. 33-3) (22).

The results of interbody fusion with cages have been reported in two Food and Drug Administration studies. Anterior lumbar interbody fusion was evaluated by Kuslich using the bar cage in 1998. Nine hundred forty-seven patients underwent ALIF using the BAK cage in that multicenter study. Bony fusion was noted in 86% of patients

at 12 months, 91% at 24 months, and 98% at 3 years after surgery. More than 85% of the patients reported pain reduction and 91% had improved function by 24 months postsurgery. Seventy-eight percent of the employable patients were working at 24 months and 91% at 3 years after surgery (5). In 1997, Ray reported on 236 undergoing PLIF using the Ray cage. In this prospective study, functional improvement was excellent in 40%, good in 21%, fair in 21%, and poor in 14% of the subjects. The complication rate was less than 1%.

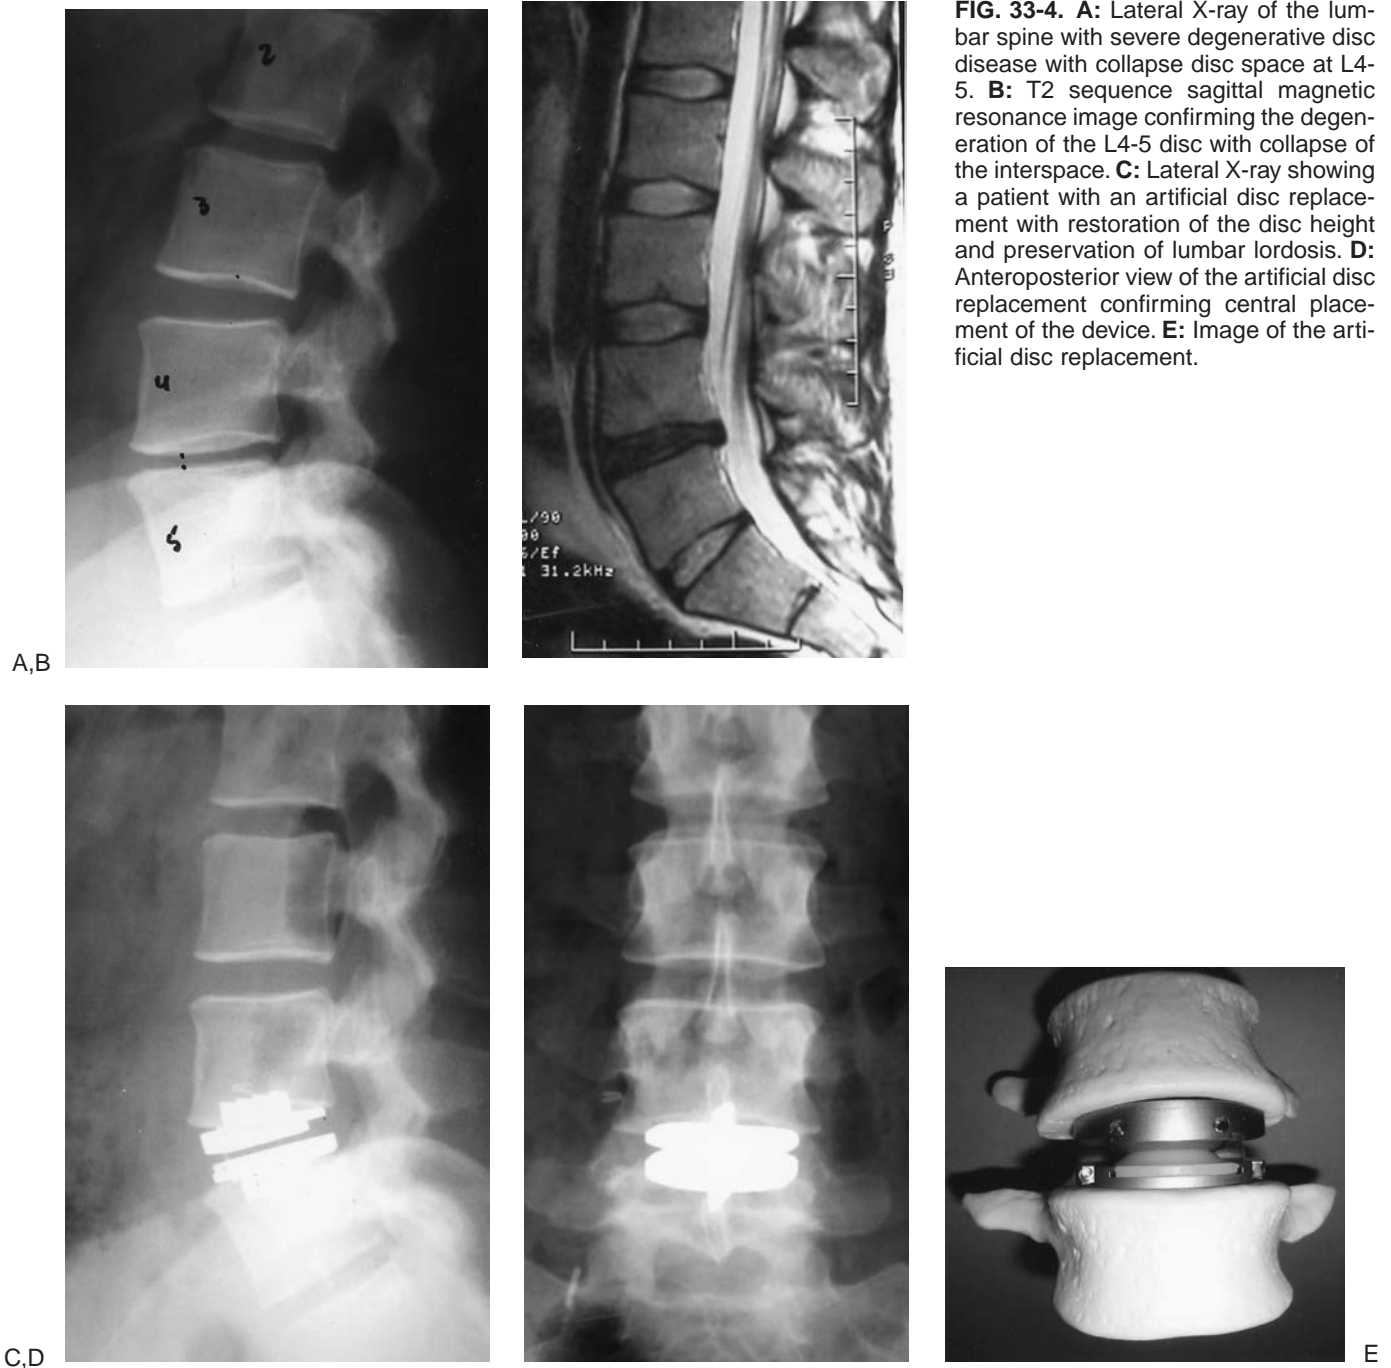

Kleeman reported on the use of bone morphogenetic protein (BMP) in laparoscopic ALIF. Using computed tomography and X-ray evaluation at 6 and 12 months postoperatively, he found that 100% of 22 patients were fused (23). Furthermore, all of the subjects were satisfied with the treatment at 12 months with relief of back pain and improved leg symptoms.

Currently, artificial disc replacement (ADR) is being evaluated for the treatment of lumbar DDD. Preliminary results in the United States and long-term results from Europe are encouraging. The advantage of ADR is that it allows motion at the involved level compared to fusion surgery and decreases stress on adjacent level with a hypothetical decrease in future adjacent level disease. One artificial disc is composed of cobalt-chrome alloy end plate elements, and an ultra-high molecular weight polyethylene inlay element. The disc functions based on the ball-and-socket joint principle (Fig. 33-4).

Multiple variations of the anterior approach are available for ALIF, including mini-open, endoscopic assisted,

**FIG. 33-3. A:** The growth of bone through a cage confirming fusion. **B:** Histologic confirmation of bone growth across the cage.

**FIG. 33-4.** **A:** Lateral X-ray of the lumbar spine with severe degenerative disc disease with collapse disc space at L4-5. **B:** T2 sequence sagittal magnetic resonance image confirming the degeneration of the L4-5 disc with collapse of the interspace. **C:** Lateral X-ray showing a patient with an artificial disc replacement with restoration of the disc height and preservation of lumbar lordosis. **D:** Anteroposterior view of the artificial disc replacement confirming central placement of the device. **E:** Image of the artificial disc replacement.

or microsurgically assisted (24–26). The most common surgical method is the retroperitoneal lumbar approach for anterior discectomy with interbody fusion. The retroperitoneal or transperitoneal approach can be used with minimal morbidity from extensive dissection of muscle, as seen with posterior procedures.

Multiple investigators have reported good results with laparoscopic ALIF (23,27). Regan compared laparoscopic with open ALIF with the BAK cage in a multicenter study (28). The laparoscopy group had a shorter hospital stay and reduced blood loss but increase operative time. Ten percent of the cases needed

to be converted to an open procedure. However, complication rates were comparable between open and laparoscopic procedure.

The laparoscopic approach at L4-5 interval is more challenging than at the L5-S1 level. Zdeblick compared the mini-open and laparoscopic approach in 50 consecutive patients undergoing ALIF at L4-5. He found that the rate of complications was significantly higher with the laparoscopic procedure (20% versus 4%). The operative time was 25 minutes longer for the laparoscopic group; furthermore, 16% of the laparoscopic group had inadequate exposure for the placement of two cages.

The anterior retroperitoneal approach can be complicated by venous injury requiring repair as well as development of subsequent thrombosis. Arterial occlusion of the internal iliac artery has also been reported (29). Patients that present with ongoing leg pain and weakness in a nondermatomal distribution following ALIF should be evaluated for iliac vessel thrombosis (30).

Complications are associated with the ALIF procedures. Bone graft collapse or extrusion and cage malposition or migration can result in poor alignment and pseudoarthrosis. Iliac crest bone graft donor site morbidity has been reported in up to 30% of patients that may last for years (11,16). Moreover, allograft bone has the potential for disease transmission and immunologic reaction. The risk of HIV infection, for example, has been estimated at less than 1/1,000,000 in properly screened donors (31).

Retrograde ejaculation results from injury to the superior hypogastric plexus. This plexus is responsible for bladder neck closure during ejaculation. Retrograde ejaculation has been reported in as many as 8% of patients with ALIF (32). In a review of 4,500 patients, 0.42% of patients experienced retrograde ejaculation (33). Regan found an incidence of retrograde ejaculation in 2.3% of his open versus 5.1% of his laparoscopic ALIF cases. Fifty percent of the patients had resolution of their symptoms at follow-up. Other rare complications reported in ALIF include pituitary apoplexy, urethral injury, and pancreatitis (29,34,35).

In summary, the disc may be a significant cause of chronic low back pain in degenerative disc disease. One surgical option for DDD is anterior lumbar interbody fusion using bone graft or substitutes with or without cage instrumentation. The anterior approach has multiple advantages over posterior procedures, including the avoidance of muscle dissection, excellent restoration of the disc space height and neuroforaminal decompression, and improved biomechanics. New technologies, such as BMP and ADR, have decreased the risk of iliac crest graft site morbidity and adjacent level disease.

## CHAPTER 34

# Operative Treatment of Anterior and Posterior Fusion

Björn Strömqvist

---

### PROS AND CONS

Although everybody dealing with lumbar spine fusion is aware that selection of the right patient is more important than selection of the surgical technique, this should not keep us from optimizing the technical aspects of the procedures and identifying the most appropriate procedure in each case. In spite of the fact that many patients with degenerative disc disease (DDD) experience the so-called “instability catch” (1), the lumbar spine with disc degenerative changes is inherently stable. Hypermobility has not been demonstrated except in isthmic spondylolisthesis (2) and radiostereometric analysis (RSA) has recently shown that patients with DDD have decreased segmental mobility (Axelsson et al., personal communication). Thus, the basic attitude toward fusion of DDD should be to select the least possible invasive procedure with the least morbidity that will address the underlying pathology. Recent randomized controlled trials have not been able to demonstrate instrumentation to improve the outcome of lumbar spine fusion (3,4). In the Swedish National Lumbar Spine Study, posterolateral uninstrumented fusion seemed to fare equivalently to posterior instrumented or 360° (anterior and posterior) fusion (5). The fact that his and other prospective randomized studies show posterolateral uninstrumented fusion to give results equal to combined techniques, however, does not mean that posterolateral fusion is the preferred operation in every case. Patients undergoing lumbar spine fusion are very heterogeneous in regard to indications, demographics, personality traits, and anatomic aspects (6); individual considerations may have to be made.

### INDICATIONS

Combined anterior and posterior fusion may be considered under the following circumstances:

1. Facetectomy. If concomitant facetectomy is performed bilaterally or unilaterally, an unstable situation is present and the ability to obtain a facet fusion is lost (7,8).
2. Inability to cope with postoperative regimen. In patients who cannot tolerate postoperative orthotic treatment and spine immobilization, a combined procedure may be indicated to resist the loading forces on the stabilized segment and therefore reduce the risk for nonunion or implant failure. This also may apply to patients with high performance demands.
3. Revision surgery. Patients with unsuccessful prior surgery for degenerative lumbar spine disorders are given the diagnostic label failed back surgery syndrome. Some studies report good results with combined anterior and posterior fusion in such cases (9,10), although no randomized studies exist.
4. Other metabolic or anatomic variants (e.g., osteopenia, insufficient bone surfaces for bony fusion, and deficiency disorders) may indicate the need for a combined antero-posterior fusion.

### SPINAL STABILIZATION

Comparing anterior, posterolateral, and posterior fusion, Lee and Langrana (11) in a biomechanical study concluded that the posterolateral fusion technique was the best method of providing stabilization to the fused segment and having the least effect on the adjacent unfused segment. The combined anterior and posterior fusion provides better stabilization from a biomechanical point of view, but whether or not this has any relationship to future adjacent segment problems is not known (12,13). Using the RSA technique to study *in vivo* kinematics (14), it has been possible to demonstrate a slow healing rate of uninstrumented posterolateral fusion,

which becomes stable between 6 and 12 months after surgery. With the addition of posterior transpedicular instrumentation, immediate stability is obtained (15). Stand-alone interbody cages demonstrate an intermediate time required for segmental stabilization (16). This fact may be interpreted as obviating the need for routine use of combined procedures in the inherently stable degenerative lumbar spine. Although increased surgery time and more blood loss occur (5,17), many nonrandomized studies, however, report very good outcomes with combined fusions. When combined fusions are considered, one prerequisite is that they should be performed by spine surgeons very familiar with the technique in order to minimize the complication rate. The risk of retrograde ejaculation and for sympathetic trunk disturbance, for example, is solely associated with anterior surgery and may be minimized by limiting the procedure to surgeons experienced with anterior procedures.

A major issue in surgery for axial pain is determining the location of the pain generator. The spine, being a three-joint complex, can have pain from the disc as well as facet joint–related pain. This has been one argument for including vertebral body fusion because some micromotion may remain over the disc even in the presence of a solid posterolateral fusion (18,19). In some instances, this micromotion produces pain.

## SURGICAL OPTIONS

### Posterior Fusion plus Anterior Lumbar Interbody Fusion

This procedure requires posterior fusion and instrumentation, either from the midline approach or via the Wiltse approach between the longissimus and multifidus muscles (Fig. 34-1). Anterior disc replacement is performed via the transperitoneal or retroperitoneal approach (20). These approaches have been described previously. If

compression of the interbody implant is desired, anterior disc resection and implant insertion must be done before posterior compression is applied to the anterior implant. This is a complex procedure, but provides the most pronounced stability to the segment immobilized. Posterior transpedicular fixation techniques with rods or plates are used, and are usually combined with bone harvesting from the iliac crest. Anterior cortical bone grafts in the form of either autografts or allografts may be used or metal cages or other types of metal implants (usually titanium) (Fig. 34-2). These implants are presented elsewhere in this and other chapters. Immediate mobilization and early rehabilitation without orthosis usually is permitted.

### Posterior Lumbar Interbody Fusion

This procedure is described elsewhere in this text (Chapter 32), and is essentially a combined anterior and posterior procedure performed via a posterior approach (21). Typically, transpedicular instrumentation is used, and the cages are inserted in the axilla between the common dural sac and the exiting nerve root. This may necessitate some traction on the nerve root and also may be associated with troublesome venous plexus bleeding; therefore, this procedure requires experience with the technique. Compression of the interbody graft is achieved by the posterior construct.

### Transforaminal Lumbar Interbody Fusion

Transforaminal lumbar interbody fusion (TLIF), or monoportal posterolateral intertransverse fusions (PLIF), has been described by Harms and Tabasso (22). This is an operation performed posteriorly. One of the facet joints is resected, the disc is removed, and intercorporeal implants are filled with cancellous bone and are inserted. Posteriorly transpedicular instrumentation is used and compres-

**FIG. 34-1.** Axial image of the lumbar spine showing (arrows) the Wiltse approach giving good access to pedicles and transverse processes when performing posterolateral fusion with and without instrumentation. The cleavage plane is between the longissimus and multifidus muscles.

**FIG. 34-2.** Lateral radiograph after combined fusion using rods, pedicle screws, and autograft posteriorly and cages anteriorly.

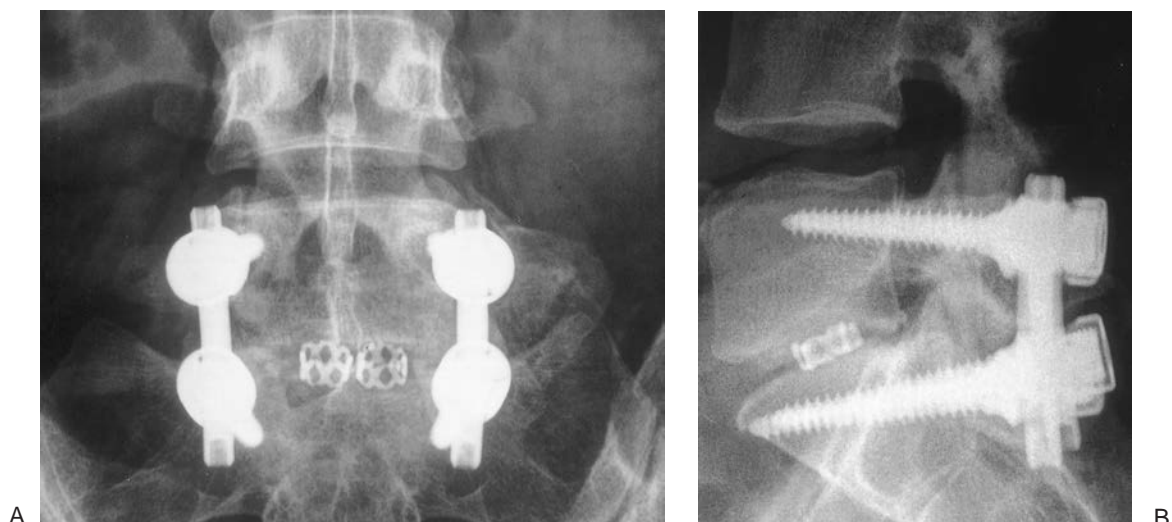

sion is applied as with a PLIF. This approach provides access to the disc lateral to the nerve root, gives a wider access to the disc, and can reduce traction to the nerve root at the disc level.

A possible disadvantage of TLIF compared with PLIF is that one entire facet joint must be resected, although significant parts of both facet joints usually are resected

with PLIF. Threaded cages are less suitable for the TLIF procedure and smaller cages are used instead, for example, two Harms cages, which are inserted from the facet joint resection side; the first cage is moved to the contralateral side and the second is retained on the ipsilateral side (Fig. 34-3). Posterior compression is performed by the transpedicular system as in the other two procedures. To date this technique is not so well documented in the literature but seems like an attractive alternative when combined procedures are considered.

## CONCLUSION

This chapter briefly described techniques for performing combined anterior and posterior (360°) fusions of the lumbar spine and discussed the advantages and disadvantages of combined fusion procedures in DDD. Combined procedures require surgical skill in the technical aspects of the procedure in order to minimize complications. Their indication is limited in the inherently stable degenerative spine; for example, in patients where concomitant facetectomy must be performed or in patients unable to tolerate the postoperative immobilization. Some studies have shown very good results from combined anterior and posterior procedures, especially in the failed back surgery syndrome, but in randomized controlled trials superiority of the technique has not been proved. Although an increased complication rate has been reported, this technique may be indicated in selected cases when performed by spine surgeons familiar with the technique. Future prospective studies may help to determine the optimal fusion procedure, taking into account biomechanical, biological, and psychosocial

**FIG. 34-3.** Postoperative radiograph in patient operated on with a transforaminal lumbar interbody fusion technique. Posterior fixation is demonstrated with Diapason rod, screws, and autografting, interbody fusion with Harms cages, and autograft, both harvested from the posterior iliac crest. **A:** Anterior and posterior image. **B:** Lateral image.

aspects of an individual patient. With our current knowledge, however, it may be appropriate to conclude by re-emphasizing that patient selection is more crucial than technique selection in deciding whether or not to perform a lumbar spine fusion for degenerative disc disorders.

## CHAPTER 35

# Degenerative Disc Disease: Fusion Cages and Dowels

Richard D. Guyer and Donna D. Ohnmeiss

---

The treatment of symptomatic degenerative disc disease (DDD) is a controversial topic. Some regard disc degeneration as merely a natural process that generally does not merit operative intervention. However, some of the acute annular tears that may trigger the degenerative process can be extremely painful and remain painful for a long period, significantly decreasing the patient's quality of life. If one accepts the concept of surgical treatment for symptomatic disc degeneration that is unresponsive to nonoperative treatment, then the question remains as to which procedure is the best treatment for this condition. The primary purpose of interbody fusion for the treatment of disc-related pain is to remove the pain generator—the pain-producing disc tissue—and maintain or increase disc height, which indirectly decompresses the neuroforamen while allowing the fusion to take place. Generally good results have been reported from interbody fusion for the treatment of disc-related pain (1–7). On the other hand, the results of posterior fusion alone for the treatment of disc-related pain typically have been poor (2,8,9). These poor results may be related to the inability to directly address the disc with a posterior fusion alone. The pain-producing disc tissue remains in the segment, and posterior fusion alone may not be adequate to sufficiently reduce the load on the disc, producing mechanical pain. Biomechanical studies have reported that the disc pressure is the same in a disc spanned by posterior fixation as in an uninstrumented disc (10). Clinical studies report that anterior interbody fusion has provided pain relief when performed at the level of a solid posterior fusion for the treatment of ongoing discogenic pain (11,12). The interbody fusion allows removal of the disc tissue and stabilizes the segment.

Traditionally, autogenous iliac crest graft was used for lumbar interbody fusion. Because of the complications

associated with harvesting iliac crest grafts, including pain and infection, other alternatives were sought. Use of allograft addresses this issue and decreases the operative time by eliminating the time needed to harvest the graft. Allograft for interbody fusion encompasses a variety of forms, including dowels, chips, strips, and femoral rings. Allograft bone can be taken from a variety of donor sites, including iliac crest, femur, and patella. Although these materials eliminated donor site complications, there was some concern as to whether they produced results as good as autogenous graft. The optimal size, shape, and composition (cortical versus cancellous bone) have been debated. There is also a concern with potential transmission of diseases. There was consensus that the most desirable interbody graft would be one that produced a high fusion rate, reduced or eliminated donor site morbidity, maintained the height of the disc space and ideal spinal alignment, and provided rapid stabilization of the spine. However, identifying a graft material with all these properties was and remains a challenge. Many designs and concepts of fusion cages have emerged in the course of seeking a solution to the problem of identifying the ideal interbody graft. The role for fusion cages in the treatment of symptomatic degenerative disc conditions includes distraction of the disc space and provision of early stabilization to the operated segment while bony incorporation of the fusion mass takes place. In this chapter, we discuss various designs of cages that have been used for lumbar interbody fusion.

### INDICATIONS

The indications for the use of cages in the treatment of DDD are similar to those for traditional lumbar interbody fusion. The patient should have failed a trial of nonoper-

ative management including activity modification, medication, and active rehabilitation before considering surgical intervention. If the patient fails nonoperative management and has a history and physical examination that correlates with imaging studies for disc-related pain, then surgery may be considered. Discography is a provocative and confirmatory test that generally is helpful in determining the source of pain and helps determine which level(s) should be included in the fusion. The anatomy of the patient's disc space needs to be evaluated with respect to the placement of a pair of fusion cages. In some cases it is difficult or impossible to properly place a pair of cages. Sometimes this is the case in patients with a relatively tall disc space, requiring large-diameter cages.

Patients with a significant behavioral component to their pain are generally poor surgical candidates for cage fusions. In patients with a presentation that is not clear or suggests a significant behavioral component, preoperative psychological screening can be very helpful. Block has reported on the use of such an instrument that we use in our clinic (13). This instrument was found to predict success or failure in a high percentage of spine surgery patients.

### BIOMECHANICS OF FUSION CAGES

There have been many reports on the biomechanical testing of various lumbar fusion cages. However, the results can be difficult to compare because of differences in the type of cage used, the specifics of the test parameters used, the manner in which the data are presented and analyzed, and the fact that most studies suffer from a small number of specimens tested. The testing can determine the stiffness of a cage, but the ideal stiffness is unknown; that is, the stiffness that provides optimal stability for fusion to occur, but has the least adverse effect on the adjacent segment. In other words, the ideal cage must provide strength, yet still allow load sharing with the vertebral bodies. As with any laboratory testing, there is great difficulty in trying to extrapolate the results to the clinical situation since the role of the musculature has been eliminated. In addition, testing provides information only about the immediate effect of the implants. The device performance once scarring, and bony changes have occurred cannot be evaluated. Also, testing provides comparative data on segmental motion, but cannot determine the optimal amount of permissible motion.

One important parameter is the compressive strength of the devices. Laboratory testing of fusion cages shows that they are unlikely to fail from compressive loading. Jost et al. compared the compressive strength of a carbon cage, a porous titanium implant, and a metallic threaded fusion cage with and without posterior fixation (14). They found that in some specimens, the carbon fiber cage failed at levels within the range of physiologic load, but the other two cages did not. Posterior fixation did not sig-

nificantly increase the compressive strength of any of the devices. Low bone mineral density was associated with construct failure by device displacement into the vertebral bodies.

Oxland and Lund performed a comprehensive review of the biomechanics of interbody fusion cages in human cadaveric specimens (15). They found that, as stand-alone devices, cages provided stability in flexion but did not perform as well in extension. Interestingly, there was no difference in the stability achieved by anterior versus posterior approach to implanting the devices. This finding showed that the destruction of the anterior longitudinal ligament by an anterior approach did not result in reduced stability in extension. Anterior implantation was associated with more stability in axial rotation than with posterior surgery. This most likely results from the loss of the lamina and part of the facet joints required to allow access to the disc space with posterior implantation of the devices. The anterior approach also was associated with greater stability in lateral bending. The authors found that the addition of posterior fixation increased the stability of the operated segments.

### EARLY FUSION CAGES

One of the earliest cages commonly used was a femoral ring allograft packed with cancellous bone. Although this graft was used in the 1980s before the term "fusion cages" was in vogue, this graft configuration was similar to that of later cylindrical cages. That is, the dense bone of the femoral ring provided early support to the operated segment. There was concern whether the density of the femoral ring would allow bony ingrowth. The rings were later packed with a plug of cancellous bone to provide scaffolding for bone growth. In our own experience, using this graft type in the late 1980s, an 80% fusion rate was reported for the entire group, including both single and multiple level fusions (16). In the series of 112 patients, there were no cases of graft collapse. There were seven cases of graft migration, three of which were significant and required reoperation. The migration problems occurred in patients before cutting grooves in the inferior and superior surfaces of the femoral ring. Subsequently, a cancellous screw was sometimes placed anteriorly as a "doorstop" to prevent anterior graft migration. Holte also reported on the use of femoral ring allograft packed with autogenous graft (17). Supplemental posterior fixation was used in the majority of these cases, and a fusion rate as high as 96%, depending on the number of levels fused, was reported. In another series with the same graft construct without posterior fixation, and with the addition of an anterior screw to prevent graft migration, the fusion rate was 84% to 97% depending on the definition of fusion used (18). In recent years, there has been renewed interest in the use of these cages made from allograft femoral rings packed with cancellous bone.

### THREADED CYLINDRICAL CAGES

Perhaps the best-known fusion cages are threaded cylindrical fusion cages. The introduction of these devices in the 1990s sparked widespread interest in interbody fusion devices. Two cages are typically placed at each operated disc level. The cages have fenestrations, with the largest ones being on the inferior and superior surfaces to allow bone to grow from the vertebral bodies, into the bone graft packed inside the cage. These cages can be placed into the disc space using either an anterior or posterior surgical approach. With the anterior approach, either an open or a laparoscopic technique may be used. One such cervical threaded metal cage, the Bagby and Kuslich (BAK) device (Sulzer-SpineTech, Minneapolis, MN) evolved from cervical fusion cages used to treat wobbler's syndrome in horses (19). The cage designed for that application was a rectangular cage filled with bone graft. A veterinarian (Bagby) teamed with an orthopedic surgeon (Kuslich) to design a device for human implantation. The result was the BAK cage.

#### Fusion Rates

Determining the presence or absence of fusion is difficult. The only reliable way to determine if a patient has a solid union is by reoperation and direct exploration of the fusion mass. Trying to determine fusion from radiographic images is unreliable. One study investigated radiographic imaging and computed tomography (CT) scanning of four different interbody devices that had been implanted into cadaveric specimens (20). Eight of each cage type were implanted, and radiographs and CT failed to identify lucency around some of the devices. The authors also reported that chips packed into the cages could look identical to bridging bone through the center of the cage, thereby making the determination of fusion difficult. The ability of CT to detect fusion in patients with metal fusion cages has been questioned by other authors (21).

In addition to the difficulty in detecting fusion, the actual definition of fusion itself is not uniform across studies. In some studies of metal cylindrical fusion cages, up to 5° of motion on flexion-extension radiographs was considered acceptable for fusion (22). In one study involving mesh cages combined with anterior buttress plates and posterior fixation, 3.5° of motion was permitted for solid fusion (23). Our own experience is similar to that of McAfee, who noted that a good indication of fusion with open-ended cages is bridging of bone anterior to the disc space (Fig. 35-1), the so-called "sentinel fusion" (24).

Another difficulty encountered in many studies is the lack of data concerning the repeatability of measurements. This factor could greatly influence the reliability of the reported fusion rates.

**FIG. 35-1.** Radiograph showing abundant bone growth anterior to the threaded fusion cages, frequently termed a "sentinel fusion."

Bone biopsies have been performed on a small number of patients who received carbon fiber or mesh cages and who appeared to have a solid fusion on radiographic imaging (25). The authors reported that there was much variability in the results of the biopsy; however, all showed histologic evidence of bone graft incorporation. In most of the biopsies, there was fibrous and necrotic tissue, suggesting that incorporation was not complete. They also noted particles of carbon fiber or metal within the biopsies, although these did not cause bone resorption or inflammatory reactions.

Thalgott et al. reported a 95% fusion rate in patients whom instrumentation was not removed for continued symptoms (23). The criteria for a solid fusion in this study were rather liberal for a combined anterior posterior fusion procedure, allowing up to 3.5° of motion on flexion extension films. The authors provided no data on the reproducibility of their measurement method.

The reported fusion rates for threaded metal cylindrical cages have been as high as 95% or greater for single-level fusions (22,26). The fusion rates for two-level procedures are lower, in the range of 71% to 80%. High rates of fusion of 86% to 100% also have been reported for carbon cages supplemented with pedicle screws (27–29).

Methods for improving the fusion rate of threaded fusion cages are being investigated. There have been no

clinical studies investigating the possible role of bone growth stimulators to enhance fusion with cages. However, in a study involving sheep implanted with titanium threaded fusion cages packed with autograft, bone growth stimulation was associated with a greater fusion rate (30). Other possible methods to enhance the fusion rate achieved with cages is the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) (31–33), local gene therapy (34), and recombinant human osteogenic protein-1 (rhOP-1) (35). These materials have yielded high fusion rates in studies using animal models (31,35). In a small patient series, a 100% fusion rate was seen in a group of patients receiving BMP packed in tapered cylindrical cages (36). This material appear to be capable of achieving a high fusion rate and has the additional benefit of eliminating risk of complications and pain associated with harvesting iliac crest autograft. Larger series of patients are needed to determine if these promising early results can be maintained.

## CLINICAL RESULTS

The clinical outcome achieved with fusion cages are difficult to evaluate due to inconsistency of the outcome measures used, use of nonstandardized and nonvalidated measurement tools, mix of diagnoses in the various studies, and different techniques and devices used within individual studies.

It should be noted that several of the large studies discussed in the following were performed as part of the approval process for sale of the devices in the United States. These studies have the benefits of enrolling a large number of patients, being closely monitored, and having a minimum of 2-year follow-up. However, such studies also tend to have some shortcomings that make it difficult to extrapolate the results to broader future applications. These include rigorous inclusion-exclusion criteria and their use by highly specialized and experienced surgeons recruited to participate in such studies.

### Threaded Cylindrical Titanium Cages

In a large study of patients undergoing BAK cage fusion, Kuslich et al. reported a significant decrease in postoperative pain scores (22). However, only 32% of the group from which the preoperative scores were derived was included in the 24-month follow-up data. Four-year follow-up data on a subgroup of 185 patients has been reported (37). Pain and function were significantly improved at the 3-month follow-up compared to the preoperative values and did not deteriorate at 4-year follow-up. Work status improved from 44.1% preoperatively to 71.2% postoperatively. The results of this study have been criticized because some of the 17 patients who required additional surgery after the cage procedure were counted as having a good clinical outcome, and only 185 of the

original 947 patients enrolled in the original study were included in the analysis.

Results also have been reported on the 2-year follow-up of 226 of 236 patients who received the Ray threaded fusion cages (TFC) (26). Sixty-five percent of patients had good to excellent results and 65% had good to excellent function. Unfortunately, this study provided no data comparing the preoperative to postoperative function, so that conclusions concerning clinical improvement were not possible. Poor results were reported with the use of this cage in a series of only 13 patients, all operated at the L5-S1 level (38). Seven of the 13 patients went on to reoperation for symptomatic pseudarthrosis. The authors felt that the use of oversized cages, destruction of the anterior longitudinal ligament, and removal of part of the annulus contributed to the poor outcome.

### Threaded Bone Dowels

Threaded bone dowels are similar in design to metal threaded fusion cages. Their potential benefit is that radiographic assessment is easier because of the lack of artifact created by cages. However, there are concerns about the consistency of the strength of these cages, which are made from allograft bone. Barnes et al reported 1-year follow-up on a series of 28 patients undergoing interbody fusion using threaded cortical bone dowels packed with autogenous iliac crest bone graft (39). Patients with disc-related pain alone underwent anterior interbody fusion, using the cages as stand-alone devices. In patients with concomitant spinal stenosis, decompression and posterior interbody fusion with supplemental posterior pedicle screws without bone graft was used. There was a relatively low rate of follow-up in the anterior interbody fusion group (67%). The rate of fusion was less in the anterior group than in the posterior group (13% versus 95%). Similarly, patient satisfaction was greater in the posterior group than in the anterior group (38% versus 70%). Based on their results, the authors strongly advocated the use of posterior fixation in addition with the threaded bone dowels.

There have been a few studies comparing the use of bone dowels to other fusion procedures. In one such study, laparoscopic anterior interbody fusion using threaded cortical bone dowels was compared to posterior fusion using pedicle screws (40). The laparoscopic group had shorter hospital stay, less blood loss, and less operative time than the posterior fusion group. However, it should be noted that the study was not randomized; therefore, there may have been differences in the patients treated with the two procedures. In a prospective randomized study, Schofferman et al. compared threaded titanium cylindrical cages packed with autograft to threaded bone dowel cages packed with demineralized bone matrix (41). At the 12-month follow-up, both groups improved significantly based on Oswestry and

pain scores, and there were no significant differences in outcome between the two groups.

### Carbon Fiber Cages

Carbon fiber cages are designed to be used in pairs and with posterior fixation. The carbon fiber allows for easier assessment of fusion status because this material is not visible on radiographic images and does not create artifact on CT scans. One disadvantage of carbon fiber cages is that they may fracture or collapse, which may result in release of some of the carbon fibers. Brantigan reported 2-year follow-up data for 221 patients receiving carbon fiber cages and pedicle screw fixation as part of a multicenter study (28). In the subgroup of 92 patients with a diagnosis of DDD, the fusion rate was 100% and 86% had a good clinical outcome; however, there were numerous complications in the series.

There have been other reports on the use of carbon fiber cages. One series included 71 patients with carbon fiber cages and posterior fixation (27). It reported a 90% fusion rate, but at the median follow-up of 28 months, only 66% of patients were satisfied with the results of the surgery and would have the procedure again for the same result. Two studies on the use of carbon fiber cages have reported fusion rates of 82% and 86%, but provided no clinical outcome data (29,42).

### Mesh Cages

Mesh cages, also sometimes referred to as a type of vertical cage, can be cut to the height desired to fit into the disc space. The cages are packed with bone graft and inserted into the disc space. Reinforcement rings may be placed around the superior and inferior ends of the cage to provide axial support. There have been only a few reports on the clinical results of mesh cages, none of which deal specifically with disc-related pain. The patient population in these studies was typically a mixed group of patients with pseudoarthrosis, deformity, post-laminectomy syndrome, or disc-related pain. One study described the results of 50 patients undergoing combined antero-posterior lumbar fusion using mesh cages packed with coralline hydroxyapatite mixed with demineralized bone matrix (23). A buttress plate was placed anteriorly over the operated segment to prevent potential displacement of the cages. Pedicle screws or facet screws were used with the posterior fusion. The mean follow-up was 50 months, ranging from 36 to 64 months. The authors reported good results with the procedure, although there were several cases requiring posterior fixation removal.

One study evaluated the outcome following non-threaded cages (either Brantigan or Harms) for the treatment of single-level, disc-related pain was performed in a group of 15 active-duty servicemen (43). The cages were inserted posteriorly and packed with autogenous iliac

FIG. 35-2. Modular rectangular fusion cage.

crest graft and were supplemented with pedicle screw fusion. The authors reported that 12 of the 15 servicemen, 80%, returned to full duty. This compared favorably to the 36% who returned to active duty in a selected group who elected not to have surgery for their single-level symptomatic disc degeneration.

### Modular Rectangular Cages

There is a rectangular, modular cage (InFix; Spinal Concepts, Austin, TX) (Fig. 35-2) designed to be used as a stand-alone device and to be implanted using an anterior approach to the spine. It consists of two plates with struts that are placed on the periphery of the plates to control the height and angulation between the plates, thereby allowing anatomic restoration of the disc height and lordosis. The plates have holes to allow bony ingrowth from the vertebral bodies to unite with the bone packed inside the cage. This device is being evaluated in a large, multicenter study, but currently no results from this study have been reported.

## LAPAROSCOPIC LUMBAR INTERBODY FUSION

The introduction of fusion cages came at a time when laparoscopic spinal fusion was being developed. The cages complemented this evolving surgical technique. They were small enough to be passed through the cannulas used in the laparoscopic procedures. The role of laparoscopic spinal fusion has gained some acceptance but some still question if it reduces morbidity, reduces hospital stay, and reduces recovery time. The endoscopic technique has been criticized as having an increased complication rate, being too expensive, being too difficult to perform at the L4-5 level, and offering no benefit over open surgery.

Laparoscopic spine surgery requires developing new skills not typically learned by spine surgeons. They must

manipulate the instruments based on what is viewed on a video monitor. Several authors have reported on the learning curve associated with laparoscopic spine surgery (44–46). In several reports, laparoscopic fusion is reported to have longer operating time but less blood loss than open anterior fusion (47,48). In both of these studies, laparoscopic surgery was also associated with reduced hospitalization time. There is debate concerning the effectiveness and safety of using endoscopic techniques to fuse the L4-5 level. Vraney reviewed radiographic vascular examinations performed for vascular conditions, and recorded the feasibility of accessing the L4-5 disc using laparoscopic techniques (49). He suggested that in only one-third of patients could the disc space be accessed safely because of the vascular anatomy. Zdeblick also expressed concern about the safety of accessing the L4-5 disc due to a greater incidence of complications (50). He advocated that laparoscopic fusion was feasible at L4-5 if the bifurcation of the vessels was above the L4-5 space and that an open approach should be used if the bifurcation was at or below the disc. Kathkouda et al. reported the feasibility of laparoscopic surgery at the L5-1 level (51), but discouraged its use for multilevel procedures because of difficulty accessing the L4-5 disc. However, it should be noted that they performed only 24 cases in the 3 years of their study. This small a number of cases may suggest that they had not overcome the learning curve associated with the technique. The laparoscopic approach to the L4-5 space was analyzed by Regan et al. (52), who found that by varying the approach to the L4-5 disc space, based on the location of the bifurcation of the great vessels, the disc space could be accessed safely laparoscopically. They noted that no patients were denied laparoscopic fusion because of vascular anatomy at the L4-5 level. The ability to safely assess the L4-5 disc laparoscopically has been reported by other authors as well (47,53).

Results from an animal study using mesh cages showed that laparoscopic fusion resulted in a less stiff spinal segment than that achieved by an open procedure (54). They attributed this difference primarily to the fact that less of a discectomy and less decortication of the end plates were performed laparoscopically than with an open procedure. The authors felt that these factors contributed to less bone growth into the cages, thereby reducing the stiffness of the fused segment. These laboratory findings were supported in a clinical study by McAfee et al. comparing the fusion rate achieved with partial versus complete discectomy (55). They found that the fusion rate was significantly greater in the group in whom a complete discectomy was performed than in patients having a partial discectomy. These results suggest that it is desirable to perform a complete discectomy when using fusion cages. This has been confirmed in another study (47).

There has been one published report of a large number of laparoscopic spine fusion cases performed using cages

(48). The authors of this study reported on a multicenter series of 240 consecutive patients. The series was compared to a historical cohort of 591 consecutive patients undergoing open anterior lumbar interbody fusion using the same design of fusion cages. They found that the laparoscopic technique was associated with reduced hospital stay, less blood loss, but had greater operative time. Complications in the two groups were comparable.

There has been one prospective, randomized study directly comparing the results of laparoscopic to open anterior lumbar interbody fusion using the same design of interbody fusion cages (47). The authors reported that the laparoscopic procedure was associated with a longer operating time but reduced hospital stay. The hospital costs for the two techniques were similar. The laparoscopic group had a greater percentage of patients who returned to work and they did so more quickly than patients undergoing open fusion.

Surgeons considering performing laparoscopic fusions must have appropriate training in the technique and should do enough of the procedures to overcome the learning curve in order to attain and maintain a high skill level with this procedure.

#### **ANTERIOR VERSUS POSTERIOR APPROACH FOR DEVICE IMPLANTATION**

Several interbody fusion cages can be implanted from either an anterior or posterior approach to the disc space. There appears to be no recommended preference of approach based on clinical results from the procedure. Therefore, the decision regarding the approach generally is based on several other factors. One important factor is the training and experience of the surgeon. If there is neural compression, a posterior approach is preferable in order to address these problems. A posterior approach reduces the risk of injury to the major anterior vascular structures and also avoids damage to neural structures that can result in retrograde ejaculation. If the patient has significant calcification of the vessels or prior abdominal surgery in the vicinity of the disc level to be operated, anterior surgery may be risky. However, there are several advantages to the anterior approach. It provides a wider access to the disc space allowing more room to work. Posterior interbody fusion has a potential risk of injury to the nerve roots owing to overretraction and requires removal of some of the facet joints, which may contribute to instability if too much bone is removed. Finally, the posterior approach damages the posterior musculature, which may be a source of pain and disability.

#### **DISTRACTION AND SUBSIDENCE**

Interbody fusion should restore normal disc space height and prevent future collapse. Most fusion cages are strong enough to prevent failure and collapse. Disc space

height may be lost if the cages subside into the adjacent vertebral bodies. In a study using a sheep model, it was found that fusion cages significantly distracted the disc space (56). Although there was subsidence for 2 months after surgery, by 4 months the operated levels were solidly fused and the disc space height was greater than it was preoperatively. Distraction and maintenance of the disc space height have been investigated in two recent clinical studies (57,58). Both studies reported reduction of initial disc space height following surgery, but the height remained greater than the preoperative height. Distraction of the disc space height also results in indirect decompression of the neural foramen. Results of a laboratory study showed that the implantation of interbody cages resulted in opening of the foramen (59). This finding was supported in a clinical study investigating changes in foraminal height when cages were inserted into collapsed disc spaces (60). These findings paralleled those of the studies on distraction of the disc space. That is, although the foraminal height decreased over the 2-year study period, it remained greater than the preoperative value.

## LUMBAR LORDOSIS

It is desirable to create or maintain normal lumbar lordosis when fusing the spine. However, the impact of minor variation in alignment on clinical results has not been established. Klemme et al. compared the amount of lordosis produced by threaded devices alone to vertical cages with posterior fixation (61). They found that cylindrical fusion cages placed parallel to the end plates did not maintain lumbar lordosis as well as vertical mesh cages combined with pedicle screws. Another study investigated sagittal alignment with threaded fusion cages (62). The authors found that there was a significant decrease in lumbar lordosis at 2-year follow-up in patients with a posterior interbody fusion, although the values were within a normal range. They also found that lumbar lordosis was not related to ultimate clinical outcome. Another study compared the degree of lordosis achieved with wedged-shaped cages compared to rectangular cages (63). All cages were made of polyetheretherketone. The authors found that both cage designs improved the sagittal alignment and that there was no particular benefit with the wedge-shaped cages.

## CAGES AS STAND-ALONE DEVICES

There is great debate concerning the use of fusion cages without supplemental posterior fixation. Biomechanical studies show that greater stability is achieved when posterior fixation is included. However, the question of how much immediate stability is needed to achieve good long-term outcome remains unanswered. The potential disadvantages of supplemental posterior

fixation include increased operating time, increased blood loss, increased cost, damage to the posterior musculature, and risk of mechanical failure and reoperations associated with the posterior instrumentation. In addition, the additional stiffness provided by supplemental posterior fixation may be associated with long-term accelerated breakdown of the adjacent segment. Several methods have been proposed to address some of these potential problems. There include use of pedicle screw fixation without bone graft, facet screw fusion, and use of trans-laminar screws without bone graft.

Although there is concern about the use of cages as stand-alone devices, there is little clinical evidence that there is a significant problem when using them in this manner. The clinical outcome reported from the large series of patients enrolled in the Food and Drug Administration Investigational Device Exemption (IDE) studies for the BAK and Ray TFC cages indicate that the devices perform well without supplemental posterior fixation. Hacker et al. compared the results of stand-alone posterior interbody fusion with titanium threaded fusion cages with combined antero-posterior fusion using allograft dowels (64). There was no significant difference in the percentages of patients reporting excellent or good results in the two groups. The total costs in the stand-alone cage group were less than in the combined group, although the follow-up time for the former was less than that of the combined antero-posterior fusion group.

O'Dowd et al. reported a revision rate of 31% at a mean of 17.8 months (range, 2 to 25 months) when using cages alone in anterior interbody procedures (65). In a review with 3- to 7-year follow-up of patients in whom cages were used as stand-alone devices, Tran et al. reported that 8.1% of patients underwent reoperation at the same level (66). However, 2.1% of this group underwent reoperation soon after the initial surgery to address problems with cage placement. Therefore, only 5.2% of the group underwent reoperation at the same level as the index surgery for unresolved or new onset pain. Their results support the concept that cages can be used effectively as stand-alone devices. In the large-scale studies reported by Kuslich et al. and Ray, in which cages were used as stand-alone devices, there was not a high reoperation rate to add supplemental posterior fixation (26,37).

In one small study of interbody fusion using cages only, cages supplemented with *in situ* posterolateral bone graft were compared to cages supplemented with posterolateral pedicle screw fixation (67). Cage subsidence was more common in the group without pedicle screw fixation, and device loosening was more common at the L3-4 and L4-5 levels. They suggested that pedicle screw fixation should be used when operating at levels above L5-1. However, this study did not compare clinical results to determine if there were any differences in outcome.

Carbon fiber cages were designed to be used with pedicle screw fixation (28). In Brantigan's study, the

fusion rate was reported to be 100% in a subgroup of their patients, although their incidence of reoperation and complications was much greater than in the other studies using cylindrical titanium cages as stand-alone devices (26,37,66). There is a trend now among many clinicians to do combined antero-posterior fusions. Fusion cages in the proper clinical setting have proven useful as stand-alone devices. The best candidates are those who have relatively narrow disc height compared to those with normal heights.

### COMPLETE VERSUS PARTIAL DISCECTOMY

There has been some discussion concerning the optimal preparation of a disc space prior to the implantation of threaded fusion cages. Some of these devices have been implanted after the removal of cylindrical plugs of disc tissue to make a space for the cages to be inserted. The primary theoretical benefit of this method is less damage to the anterior longitudinal ligament. The practicality of the situation is that once the surgeon finishes putting both cages of a dual cage construct, there is negligible anterior longitudinal ligament left. The potential benefits of complete removal of the disc are elimination of the pain generator and removal of disc tissue that might promote growth of fibrous tissue into the cage. The influence of complete versus partial discectomy in achieving solid fusion when using threaded titanium cages has been investigated in a randomized study (55). At the 2-year follow-up, all patients in whom a total discectomy was performed had a solid fusion compared to 86% fusion rate in group in whom a reamed channel discectomy was done. The importance of total discectomy was also discussed by Sachs et al., who reported a high fusion rate using the cages as stand alone devices (47). In general it makes intuitive sense to carry out a complete discectomy if a fusion is a desired end point.

### COMPLICATIONS

Complications encountered in the treatment of symptomatic disc degeneration are discussed in detail in another chapter of this book (Blumenthal and Ohnmeiss). In general, the complications associated with the use of fusion cages are similar to those reported for other interbody fusion methods. We could not find any reports of frank device failure related to the use of threaded metal cylindrical cages. As expected, the anterior approach to the disc space is associated with problems related to injury of vascular and sympathetic structures as are encountered with fusion not involving cages. Posteriorly, complications have been related to retraction of the nerve roots to allow access to the disc space. There have been reports of a few cases of device migration or malpositioned cages requiring reoperation for revision. In a review of 20 patients with cage-related complications,

McAfee concluded that the problems were owing to technical error in all cases (68).

### DISCUSSION

In recent years, a variety of fusion cages have been used as devices for interbody fusion procedures. They can provide initial stability to the operated segment and can increase the fusion rate. As with other spine surgery procedures, many questions remain concerning the use of the cages. There has been much discussion concerning optimal cage design. Items that have been discussed include the shape and modulus of elasticity of the cages, the optimal bone-implant interface area, the degree of penetration of the cage into the end plates of the vertebral bodies, and the use of posterior fixation. There have been attempts to address some of the issues in laboratory testing, but they have not been adequately addressed in clinical studies. The use of cages as stand-alone devices remains controversial. There are reports of good results with this method. However, although there has been much discussion concerning the potential problems with this procedure, there have been little or no data published on a large series of patients in whom the use of cages as stand-alone devices was related to poor results. Although routine use of posterior fixation may possibly minimize problems related to using cages as stand-alone devices, this increases costs, operative morbidity, and the potential for complications related to the additional instrumentation. As with other spine surgery procedures, there is a need for well-defined clinical outcome studies on cages investigating the impact of multiple factors such as approach and technique, posterior fixation, discectomy technique, graft material, device shape, size, and placement.

Although fusion cages have been reported to yield good results in many patients, surgeons must pay careful attention to patient selection and surgical technique. There needs to be a thorough diagnostic evaluation with correlative imaging studies. Patients should have failed an adequate course of nonoperative management prior to being considered a candidate for surgery. Patients with a poor psychological profile will likely do poorly with fusion using cages or any other operative intervention.

There is little doubt that the number of future interbody fusions will decrease as the use of disc prostheses increases. The indications for some of these devices will be similar to the indications for fusion cages in the treatment of disc-related pain. However, spinal fusion will continue to be performed for specific conditions and in patients who are not good disc replacement candidates. As discussed, the details of spinal fusion cage procedures needs further investigation, although based on the data currently available, these devices appear to have a significant role in the treatment of patients with back pain and remain an important part of the spine surgeon's arma-

mentarium. We believe that in the properly selected patient, cages offer the surgeon a satisfactory option as a stand-alone device.

## CHAPTER 36

# Minimally Invasive Procedures for Anterior Column Fusion and Reconstruction

H. Michael Mayer

---

The term “minimally invasive” has been used in the surgical scientific literature since the introduction of microsurgical and endoscopic surgical approaches. It has been applied in various fields, mainly abdominal, gynecologic, and thoracic surgery (1–3). Although arthroscopic techniques in the peripheral joints or microsurgical techniques for discectomy or decompression have been used for many years in orthopedic surgery, the term “minimally invasive” was very rarely used or associated with these procedures. In fact, it has only come to our perception in recent years, when it was increasingly used to describe or characterize procedures or surgical approaches for the treatment of degenerative lumbar disc disorders.

It is important to distinguish between “true” minimally invasive procedures for diagnostic and therapeutic purposes and minimally invasive approaches for curative surgical procedures. Typical examples for minimally invasive diagnostic and therapeutic procedures include different kinds of infiltrations including epidural catheters, root blocks, facet joint block, discography, intradiscal electrothermal therapy, and others. These procedures, however, are either “diagnostic instruments” that are used to supplement information from noninvasive imaging techniques such as magnetic resonance imaging (MRI), or represent noncurative modalities with temporary therapeutic effects. They should thus be classified as semi-invasive conservative measures.

For the definitive surgical treatment of degenerative disorders of the lumbar spine, a variety of minimally invasive techniques have been developed over the last 15 years. All these techniques represent surgical *approaches* that are less invasive than the usual standard approaches (Table 36-1).

This leads to a very fundamental but important concept which should be appreciated to avoid misunderstandings and misinterpretations: minimally invasive surgery for the definitive curative treatment of segmental lumbar disc

degeneration is a minimally invasive approach to perform “target surgery” such as disc excision, fusion, or disc replacement—procedures that are (maximally) invasive.

Wrong indications for surgery, undesired side effects, complications, and poor results are strongly influenced by the surgical approach to the target area (4,5). Less invasive techniques, in general, decrease the degree of “iatrogenic” surgical trauma. They ameliorate early postoperative morbidity and enable early and aggressive rehabilitation of the patient without an increase in complications. This chapter describes the rationale for surgery for degenerative lumbar spine disorders, the goals of surgical procedures, and the implementation of minimally invasive techniques into the surgical standard strategies.

### RATIONALES FOR SURGERY

There is a long-standing controversy about the surgical treatment of degenerative lumbar disc “disease.” Although there are no evidence-based data to support spinal fusion or reconstruction of the “functional spinal unit,” surgery is performed worldwide with varying frequency depending on national or continental philosophies. The “gold standard” procedure has always been segmental spinal fusion. This can be performed by different techniques and has become one of the classic “experience-based” procedures with poorly predictable success rates due to the lack of an international consensus for patient selection, surgical approach, fusion technique, and postoperative management (6–9).

In the last 2 years, there has been a tremendous acceleration in the development and application of a new philosophy that is termed “spine arthroplasty.” This term encompasses all surgical techniques that aim for a dynamic reconstruction and preservation of motion without performing a fusion (Table 36-2). Principles of some of these procedures are described in Chapters 38–40.

**TABLE 36-1.** *Minimally invasive access surgery for lumbar fusion and disc reconstruction*

Laparoscopic anterior lumbar interbody fusion (22,23)
Percutaneous posterolateral interbody fusion (12)
Mini-open microsurgical posterolateral fusion (13)
Mini-anterior lumbar interbody fusion (24)
Mini-open total disc replacement (26)

## GENERAL PRINCIPLES

Disc degeneration may lead to clinical symptoms of pain (“discogenic” low back pain). However, low back pain due to disc degeneration is usually “multifactorial”. Whereas young patients may present with pure discogenic back pain, the majority of patients present with a mixture of discogenic, arthrogenic, and musculoligamentous symptoms. Surgical procedures to deal with these symptoms have common goals: the excision or elimination of pain source(s), the elimination of biomechanical pain generating mechanisms, the restoration and retention of the physiologic segmental curvature, as well as the restoration of disc and foraminal height, especially in cases with lateral recess or foraminal stenosis. There is no doubt that these goals can be most reliably achieved by 360° or 270° fusion of one or several lumbar segments. Using this technique, all potential pain sources (disc, end plates, facet joints, facet joint capsules) are excised. Pathologic load patterns due to loss in disc height (“vertical instability”) as well as macroinstabilities (e.g., degenerative spondylolisthesis) are eliminated by the fusion (Fig. 36-1). Disturbances of lumbar curvature in the sagittal (kyphosis, hyperlordosis) as well as frontal (degenerative lumbar scoliosis, segmental tilt) plane can be reduced and maintained by posterior instrumentation. Disc height and foraminal height can be restored in cases with root symptoms associated with low back pain. Thus spinal fusion is the only “curative” salvage procedure to treat degenerative low back pain.

## LUMBAR FUSION

The controversial discussion on the role of lumbar fusion is the result of an obvious discrepancy between the technical achievement of the surgical goals (discussed previously) and the clinical outcome. The majority of undesired side effects, complications, and poor outcome is determined or influenced by the surgical approach to the target area (4,5).

The main prognostic factors for outcome of lumbar fusion surgery are patient selection and surgical technique (7,10,11).

### Patient Selection

The reader is referred elsewhere in the text (Chapters 28–35, 39, 45) to information on the current “state-of-the-art” treatment of degenerative low back pain. There is consensus that spinal fusion in degenerative conditions of the lumbar spine should be the last therapeutic step when noninvasive or semi-invasive conservative measures have failed. However, there is neither consensus on the identification of lumbar levels to be fused nor on the type of fusion (7,8,11,12). The most frequently used techniques are listed in Table 36-3.

### Less Invasive Techniques for Lumbar Fusion

#### *Microsurgical Posterolateral Fusion (13)*

Posterolateral fusion has been the most widespread fusion technique for the past 25 years. It has been performed without instrumentation (11,14) or with instrumentation (15), with varying clinical success and fusion rates. Decortication of laminae, facet joints, and transverse processes is followed by the application of autograft or allograft bone “posterolaterally” in order to achieve a solid bone bridge between adjacent segments. It is the easiest technique in fusion surgery, however, it also is the most traumatizing technique because of damage to the paravertebral muscles during the approach (16–18) (Fig. 36-2).

Unacceptably high pseudoarthrosis rates have limited the popularity of this fusion among spine surgeons in Europe (6,11,19).

In 1998 McCulloch described a microsurgical modification of the “classic” posterolateral/intertransverse lumbar fusion (13). Based on his experience with microsurgical discectomy, McCulloch described a minimally invasive paramedian approach to the intertransverse area. Soft-tissue dissection is reduced to a minimum. Preservation of a “soft tissue envelope” (paraspinal muscles, intertransverse ligament and muscle) is presumed to provide a vascularized bed for autologous bone graft. Decortication of the facet joints and the transverse processes is performed with high-speed drills. The use of autologous bone graft is recommended.

The clinical results described by McCulloch revealed the advantages of this minimal invasive technique: In a series of 22 patients with single-level degenerative disc disease, microsurgical posterolateral fusion was per-

**FIG. 36-2.** X-ray lumbar spine, frontal view. Shaded area is necessary for muscle retraction for posterolateral L4-5 fusion.

formed. Follow-up after 2 years showed good and excellent results in 86.4% of the patients. The average hospital stay was less than 3 days, the average intraoperative blood loss less than 300 cc. There was only one pseudoarthrosis (13). In a similar series of 22 patients with degenerative spondylolisthesis and acquired spinal stenosis, the rate of satisfactory results was 91%. The pseudoarthrosis rate however was 14% (13).

Although this technique has not become very popular, it seems to be a reasonable alternative to the “classic” posterolateral type of fusion performed through the Wiltse approach.

#### *Minimal Invasive Anterior Approaches for Interbody Fusion*

In 1990 Obenchain first described a laparoscopic approach to the L5/S1 disc (20). This “key” publication triggered the development of a variety of less invasive anterior accesses to the lumbar spine that dominated the last decade. Laparoscopic surgery was associated with a variety of technical pitfalls and hazards and has never reached the status of a “routine-procedure” (21–23). However, the need for less invasive anterior approaches was obvious, since 360° or 270° fusion achieves the highest fusion rates of all techniques (5,10,24). In 1997, I described two “mini-open” access techniques to the lum-

**TABLE 36-3.** Spinal fusion techniques

bar levels for anterior interbody fusion (24). They were based on the application of microsurgical philosophy to the well-known standard anterior approaches.

#### *Lateral Retroperitoneal Access to L2-L5*

Monosegmental as well as multisegmental anterior fusion can be performed through a standard anterior approach to the lumbar levels L2-L5. With this technique, the abdominal muscle layers are cut, irrespective of their orientation, and the lumbar segment(s) are approached anterior to the psoas muscle (25).

#### *Microsurgical (Mini-Open) Access*

The mini-open anterior lumbar interbody fusion (ALIF) technique (mini-ALIF) has been described extensively (9,24), so only the basic principles are repeated here:

The patient is placed in a right lateral position (Fig. 36-3). The approach is from the left side. The operating table is tilted slightly posteriorly ( $20^{\circ}$  to  $40^{\circ}$ ) which facilitates the access to the lumbar spine through a small skin incision, even in very obese patients, since all abdominal contents and fat tissue “fall-away” anterior from the surgical field. The retroperitoneal cavity is entered through a 4 cm skin incision that is directed obliquely parallel to the direction of the external oblique abdominal muscle. The use of a bright head lamp (Xenon light source) and optical aids (surgical microscope, loupes) is recommended in special situations (e.g., obese patients, reoperation). The muscle layers (external oblique, internal oblique, transversus abdominus) are exposed by a blunt, muscle-splitting technique. The peritoneal sac is bluntly dissected from the psoas muscle and the disc space is exposed anterior and medial to the psoas muscle. The anterior circumference of the disc space is exposed from

the midline to approximately 2 cm lateral to the insertion of the anterior longitudinal ligament. This requires a small splitting (1 to 1.5 cm) of the medial insertions of the psoas. The anterolateral circumference of the disc space is exposed bluntly and kept free from surrounding tissue by insertion of frame-type retractors that are anchored in the adjacent vertebral bodies or by an external frame holder.

#### *Fusion Technique*

The type of anterior fusion performed is optional once the target area is exposed. All types of fusion techniques are possible (autologous bone graft, vertical cages with bank bone or autologous bone, femoral ring grafts, stand-alone ALIF cages, etc.) (Fig. 36-4A, B).

**FIG. 36-3.** Positioning of an obese patient for mini-open retroperitoneal approach to L2-L5.

A

B

**FIG. 36-4.** **A:** A 360° instrumental fusion at L5-S1 with autologous bone graft. **B:** Both anterior approaches were done through a 6 cm skin incision at L4-5 with vertical titanium cage.

*Midline Retroperitoneal or Transperitoneal Access to the Lumbosacral Junction*

The conventional approach to the lumbosacral junction is either through a midline longitudinal or transverse skin incision using a transperitoneal route or through a para-rectal retroperitoneal approach. The patient is placed in a supine neutral position with the surgeon standing either on the left or right side of the patient

*Mini-Open Access to L5-S1*

Mini-open access to L5-S1 is performed through a 4 cm transverse or longitudinal skin incision in the midline and a mini-laparotomy. Patient positioning has been modified with the patient in a supine position with the legs abducted so that the surgeon can stand between the patient's legs.

Thus, the visual axis of the surgeon is parallel to the L5-S1 intervertebral space. The level of the skin incision can be marked in two different ways: in slim patients, the abdominal wall is slightly indented with a blunt metal marker and a lateral fluoroscopy is used to show the position of the marker over the L5-S1 disc space. In obese patients, the orientation and anterior border of the lumbosacral junction is identified by lateral fluoroscopy and a "corridor line" is drawn from there onto the abdomen. The transverse skin incision is placed 2 cm caudad to the corridor line (8).

The rectus sheath is exposed and split in the midline. L5-S1 can be approached through a retroperitoneal route either from the left or from the right side. To mobilize and shift the peritoneal sac, it is necessary to incise the posterior rectus sheath. In obese patients and in patients with previous abdominal surgery, a transperitoneal route is recommended. Dissection of the prevertebral part of the peritoneum should generally be from the right to the left. Electrocautery should be avoided to minimize the risk of injury to the superior hypogastric plexus and retrograde ejaculation in men. The anterior circumference of L5-S1 is exposed between the common iliac veins. The median sacral vessels need to be either ligated or coagulated with bipolar electrocautery and dissected. L5-S1 is exposed with the help of special retractors. The options for fusion are the same as in the levels L2-L5.

**Results**

Results of mini-open anterior fusion have already been described (5,8,9). The combination of mini-open anterior fusion with pedicle instrumentation produces excellent and good results in 75% to 85% of the patients (5,8). The pseudoarthrosis rate is 3% and the rate of complications due to the anterior approach is 5.2%. Perioperative morbidity is extremely low with clinical results that seem to be comparable to conventional fusion techniques.

*Minimal Invasive Midline Accesses for Total Disc Replacement*

Total disc replacement for the treatment of painful degenerated lumbar disc is an alternative to lumbar fusion (26,27). The principles of minimal invasive access surgery can be applied to this new technology (26,28). However, total disc replacement requires a midline approach to all lumbar segments. This mandates a modification of the approach to the L4-5 and more proximal levels. The surgical approach technique for L4-5, L3-4, and L2-3 is described subsequently.

Positioning of the patient and localization of the level are performed as previously described. Care must be taken to place the patient in a neutral supine position without hyperextension to prevent hyperlordosis that complicates implantation of the artificial disc.

*L4-5 Level*

A small transverse skin incision is centered over L4-5 or placed slightly left of the midline (28). The rectus sheath is exposed and can be split either longitudinally in the midline or transversely on the left side. In slim patients, midline splitting of the sheath can provide sufficient exposure to begin the retroperitoneal dissection from left to right (discussed previously). In obese patients, it is advisable to mobilize the rectus muscle circumferentially and begin the retroperitoneal dissection lateral to the muscle belly after incision of the posterior rectus sheath. It is important to first mobilize the common iliac artery and to identify the iliolumbar vein beneath the psoas muscle. Mobilization of the common iliac artery is performed with finger dissection and small peanut swabs. The iliolumbar vein must be identified, ligated, and cut before the common iliac vein is mobilized toward the midline (9,28). Once the vessels are mobilized toward the midline, the disc space can be palpated with the tip of the index finger. The segmental vessels of L4 on the left side then need to be identified and ligated if necessary (Fig. 36-5).

Thus, the anterior portion of L4-5 can be exposed and the retractor system can be inserted. Sharp retractor blades or pins should not be used since they could cause vascular injury (28,29).

*L3-4 Level*

The approach to L3-4 is performed the same way as for L4-5 except that a curved longitudinal incision is recommended if the L3-4 disc is at the level of the umbilicus. Usually the iliolumbar vein does not need to be identified, but the segmental vessels at L3 and L4 on the left must be ligated before the aorta and the vena cava are mobilized from left to right. Rarely, the L3-4 disc can be approached between the aorta and the vena cava. In this

**FIG. 36-5.** Vessels to be identified for the midline approach at L4-5 as seen on three-dimensional computed tomography-angiography (*l.il.v.*, left iliolumbar vein; *l.c.i.v.*, left common iliac vein; *xx*, left segmental vessels L4).

case, the segmental vein(s) on the left and the segmental artery(s) on the right side must be ligated (26).

*L2-3 Level*

The approach to L2-3 for total disc replacement is rarely necessary since symptomatic disc degeneration at this segment is unusual. The skin incision is located at the level of or cranial to the umbilicus. A transperitoneal approach is recommended since retroperitoneal dissection is difficult. Care must be taken to avoid dissection through the mesentery. The mesentery and small intestine are pushed cranially to the right and the prevertebral peritoneum is split in the midline. Care must be taken to avoid the renal artery.

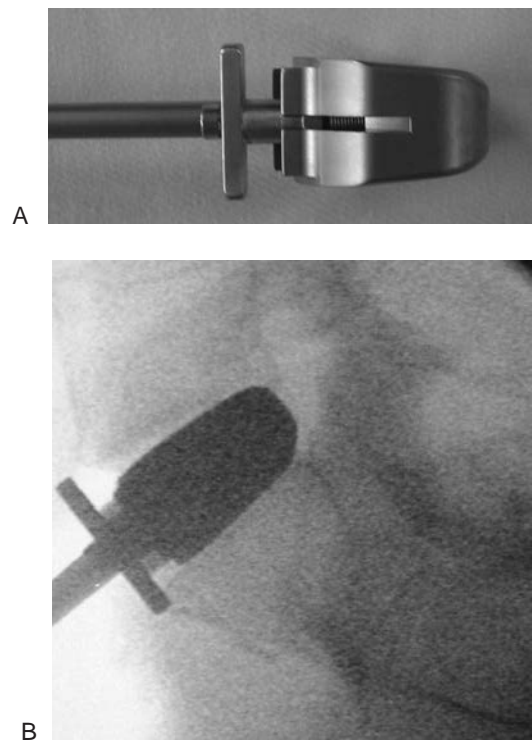

**Minimal Invasive Implantation of the Prodisc Implant**

The Prodisc Total Disc (Spine Solutions, Inc., New York, NY) is the only implant that can be inserted through the minimal invasive approaches described in this chapter (Fig. 36-6). Once the anterior circumference of the disc space is exposed, the midline is marked and verified through anteroposterior fluoroscopy. A rectangular window is made in the disc space and the anterior annulus fibrosus is removed. The nucleus and the cartilaginous end plates are carefully removed with curettes. Preservation of the subchondral bone is of paramount importance. The trial implant can then be inserted (Fig.

**FIG. 36-6.** The Prodisc implant (Spine Solutions, Inc., New York, NY), modular design: two metal end plates, ultra-high-molecular-weight polyethylene inlay.

36-7A, B). This trial implant determines the size, height, and degree of lordosis of the final implant. Once it is placed in the correct position, a groove is chiseled in the adjacent vertebral bodies for the two keels of the implant. After removal of the trial implant, the end plates of the modular total disc are implanted, the disc space is distracted, and a polyethylene insert is implanted (Fig. 36-8A,B).

## CONCLUSION

Minimally invasive surgical approaches for spinal fusion or reconstruction in degenerative diseases have been popularized within the last 10 years. Preoperative planning and modification of surgical strategies with innovative instruments and implants are key factors for performing safe and successful surgery. A vascular or general surgeon is extremely helpful in providing access to the surgical target area. The main advantages of minimal access surgery are the reduction in perioperative morbidity and the possibility of early and aggressive mobilization and rehabilitation of the patient. Although experience is still limited, disc replacement is a new and exciting application of less invasive surgical approaches.

## CHAPTER 37

# Degenerative Disc Disease: Complications of Surgery

Scott L. Blumenthal and Donna D. Ohnmeiss

---

Many strategies for the surgical management of symptomatic disc degeneration have been developed. Potential advantages and disadvantages are associated with each of them. The development of fusion cages and artificial discs has brought renewed interest in surgery for symptomatic degenerative disc disease. The effectiveness of some of these techniques and devices is still in question. Another important issue is the safety of these devices and of the operative techniques required for them. In this chapter we will focus on the complications associated with lumbar fusion, particularly interbody fusion, artificial disc replacement, and intradiscal electrothermal therapy (IDET) used in the treatment of symptomatic disc degeneration. In order to focus this review on current techniques and instrumentation, the majority of the literature reviewed will cover the period from approximately 1990 to 2002. We tried to include information dealing specifically with the treatment of symptomatic degenerative disc disease; however, many articles involved a mixed group of diagnoses.

### OVERVIEW OF POTENTIAL COMPLICATIONS

With most of the procedures discussed in this chapter, complications directly related to the surgery may arise from several sources. The greatest potential for complications is related to technical problems executing the surgery, poor implant selection, device failure, and poor patient selection. Technical problems can be grouped based on the operative approach used. With anterior lumbar interbody fusion, the most readily recognized risk is injury to the great vessels. This may occur by tearing or puncturing one of the structures with an instrument or during retraction. Other complications associated with anterior spine surgery include damage to the sympathetic chain resulting in temporary or permanent sexual dysfunction, urologic problems, or altered sensation in the lower extremities. When placing devices from the anterior approach, one must be

aware of the depth of the implant to avoid impingement of neural elements either directly by the device or by pushing disc tissue into the canal.

Posterior interbody fusion is also associated with potential significant complications. Injury to neural structures can result from making direct contact with an instrument or from retraction. Typically, bone must be removed from the posterior elements in order to gain access to the disc space, which has the potential to create or contribute to instability of the operated spinal segment. As with the anterior approach, the surgeon must be acutely aware of the depth of implants or bone graft since aggressive insertion of implants or graft can result in significant vascular injury. Other complications associated with posterior spine surgery include damage to the posterior musculature from dissection and retraction of these tissues. Also, screws placed posteriorly can penetrate the cortical bone of the pedicle injuring neural structures.

In surgeries using autogenous iliac crest bone graft, there are complications related to the donor site. These include injury to neural or vascular structures, fracture, infections, and persistent pain.

### ANTERIOR APPROACHES TO THE LUMBAR SPINE

Interest in the anterior approach to the lumbar spine has increased dramatically in recent years due to the introduction of fusion cages, laparoscopic fusion techniques, and disc replacement. In this section we will review general complications as well as complications associated with specific devices implanted using an anterior approach.

#### Vascular Injuries

The risk of significant vascular complications during anterior lumbar interbody fusion is related to the proxim-

ity of the vena cava and aorta to the disc spaces. These structures are at greatest risk during the exposure of the disc space, but can also be injured by blunt contact or retraction during the placement of devices or bone graft. There is a great deal of individual variation with regard to the level of the vessel bifurcation that determines the approach. Surgery can either be above the bifurcation, below it, or in some cases between the vessels. Weiner et al. investigated variation in vascular anatomy with respect to anterior lumbar interbody fusion (1). They reported that in about 60% of cases, the vascular anatomy was predictable and the lumbosacral disc could be accessed below the bifurcation. In 30% of cases, there were minor variations in vascular anatomy, which did not significantly alter the approach to the spine. In the remaining 10% of cases, a significantly different approach to the disc was required due to variation in vascular anatomy. The altered surgical approach involved working above the bifurcation. In all of these cases, the operated level was a functional lumbosacral level above a fixed transitional vertebra.

One study reported the results of a retrospective review of 105 consecutive cases in which the retroperitoneal approach was used to gain access to the lumbar spine (2). These authors reported that the overall incidence of vascular complications was 15.6% (16/105). This included tears of the common iliac vein (10.5%), the inferior vena cava (3.8%), and the iliolumbar vein (0.9%). The authors found that the complication rate was almost twice as great with the hypogastric paramedian approach as with the anterolateral approach. The majority of complications occurred during the surgical exposure. Fortunately, these complications resulted in only one case of deep vein thrombosis, and there were no cases of pulmonary embolism or catastrophic blood loss.

In a detailed review of general surgery complication in anterior spinal fusion, the rate of vascular injury was found to be 6.6% (3). In two cases, venous injury occurred during the exposure of the disc space, and in one case, the injury occurred during graft placement. In all three cases, the problem was addressed intraoperatively with no serious sequelae. The other vascular injury occurred during the exposure in a case to revise or remove a malpositioned cage. That injury was attributed to dense adhesions that had formed after the initial surgery. There was significant blood loss and the surgery was abandoned.

The risk of vascular injury was of particular concern as laparoscopic fusion was being developed. With this procedure, injury to a major vessel has the potential for more severe consequence since it cannot be repaired directly. There was concern about whether or not the endoscopic procedure could be rapidly converted to an open procedure to repair a damaged vessel before the situation became critical. Tears of vessels have been reported during laparoscopic fusion (4). In the cases requiring con-

version to an open surgery, the vascular injury was addressed without serious sequelae. It was reported that among six cases converted to an open procedure due to iliac vein laceration or excessive bleeding, only one patient received a blood transfusion. When performing laparoscopic fusion, one must be acutely aware of the risk of vascular injury and have a plan to convert to an open procedure if needed. The equipment necessary for quick and safe conversion to an open procedure must be readily available.

Based on a review of abdominal vascular studies, Vraney et al. suggested that the L4-5 disc could be accessed laparoscopically in only approximately one-third of patients (5). The limiting factor was the location of the bifurcation of the great vessels with respect to the L4-5 disc space. The risk of vascular complications was thought to be too great in the remaining cases. However, Regan et al. reported that by varying the approach to the disc, to either above the bifurcation, below the bifurcation, or between the vessels, the disc space could be assessed in all cases and no patient had been denied a laparoscopic fusion based on the location of the vessel bifurcation (6).

A rare vascular complication of anterior lumbar interbody fusion is occlusion of the common iliac artery. This has been discussed in a few case reports (7–10). One case of aortic thrombosis following anterior-posterior fusion has been reported (11). The patient's condition continued to deteriorate after intensive treatment and she died 8 days after the spine surgery. In such cases, the vascular occlusion is usually caused by direct pressure of the vascular structures by the retractors. Vascular complications may be more likely or more severe in patients with risk factors such as smoking and vascular calcification.

### Sexual Dysfunction

Retrograde ejaculation can occur with anterior spine surgery as a result of injury to the superior hypogastric plexus which is responsible for closing the bladder neck during ejaculation. This complication can be permanent; however, it typically resolves in 3 to 6 months after surgery, although it has been reported to take longer in some cases. The incidence and outcome of sexual dysfunction were studied in detail in a series of 41 men who underwent anterior lumbar interbody fusion using a retroperitoneal approach (12). The authors reported that 8% of the patients experienced retrograde ejaculation, but none had any alteration in attaining erection or achieving orgasm. Among the four patients in that study with retrograde ejaculation, two were permanent, one could not ejaculate for six months and had reduced ability to ejaculate thereafter, and the status of the other patient was unknown. In another study of complications related to anterior spine surgery, 9.6% of 31 male patients reported sexual dysfunction

(two with retrograde ejaculation and one with reported impotence) following anterior spine surgery (3). Although impotence has been reported as a direct complication of anterior spine surgery, it is not very likely (3) since the parasympathetic plexus, which is responsible for erection, is located deep within the pelvis and should not be at risk during anterior spine surgery.

### Ureteral Injury

Ureteral injury from blunt trauma can occur during anterior approaches to the lumbar spine. If not identified and addressed intraoperatively, the patient can experience severe abdominal pain from a large collection of urine in the abdomen. A few cases of ureteral injury related to anterior spine surgery have been reported (13–15). Bladder dysfunction from injury to the parasympathetic presacral nerve during the anterior portion of a combined anterior-posterior fusion has been reported (16). The patient was treated with self-catheterization and she ultimately regained bladder control in 3 months.

### Neural Injury

Injury to the cauda equina or nerve roots may occur during anterior spinal surgery. This can be the result of passing instruments too deeply into the disc space, placing devices or bone graft too far posteriorly, by pushing disc tissue into the canal space, or by stretching the roots by over-distraction of the disc space.

In a cadaveric study, Taylor et al. investigated the occurrence of foraminal violation and nerve root impingement related to the use of anteriorly placed interbody fusion cages (17). Although the number of samples was small, the authors concluded that the occurrence of foraminal violation or neural impingement was reduced if a device was placed directly in the midline. The incidence of impingement was increased when the devices were placed 10% off midline, and increased further when the devices were placed 20% off midline.

Several studies have reported that the lateral placement of cages can cause disc tissue to be displaced posteriorly, resulting in nerve root compression (18,19). Patients with this complication generally complain of severe radicular pain immediately following surgery. Imaging can sometimes be difficult to interpret due to artifact from the metal cages. In a nonrandomized study comparing open to laparoscopic fusion using BAK cages, disc herniation was the only complication that was more common in the laparoscopic fusion group, occurring in 2.8% of cases (4).

Sympathetic sensory changes can occur and may result in a “warm leg”, temperature variation, dysesthesia, discoloration, or swelling of the leg or foot (3,20). These patients should be evaluated carefully to rule out possible arterial complications. If the problem is not vascular, the

altered sensations generally resolve over the course of several months.

Papastefanou et al. reported two cases of femoral nerve palsy due to patient positioning during anterior lumbar interbody fusion (21). The patients’ symptoms resolved in 3 to 6 months. The authors attributed the injury to the patients being positioned intraoperatively with the spine and hip immobilized in a position of maximum stretch of the psoas muscle, compressing the femoral nerve.

## COMPLICATIONS REPORTED IN VARIOUS ANTERIOR FUSION STUDIES

The reported incidence and types of complications related to anterior spine surgery vary greatly. This may be due to the different types of procedure performed, the type of graft or device used, the skill and experience level of the spine and access surgeons, the associated patient comorbidities present, and other factors. Presented herein is a review of complications reported in some studies of anterior lumbar spine surgery. The review deals primarily with publications since 1990 and those involving patients with symptomatic disc degeneration.

Newman and Grinstead reported a series of 36 patients undergoing anterior interbody fusion with autogenous graft specifically for discogenic pain (22). Complications in their series included one each of pulmonary embolism, retrograde ejaculation, donor-site wound hematoma, and graft extrusion. There were no vascular complications, although 16.7% of patients received a blood transfusion. Reoperation occurred in 8.3% of patients from extruded graft, symptomatic pseudoarthrosis, or for disc herniation above the fusion.

In one of the largest series of anterior lumbar interbody fusions, Kuslich et al. reported on 591 patients in whom BAK cages packed with autogenous iliac crest graft were used as a stand-alone device (23). The data were collected from the multicenter United States Food and Drug Administration Investigational Device Exemption (FDA IDE) trial. The incidence of complications reported in that series included neurologic injury (2.0%), superficial infection (3.1%), ileus (3.1%), new radicular pain (1.3%), retrograde ejaculation (4% of males), hematoma/seroma (1.5%), vessel damage/bleeding (1.7%), atelectasis/pneumonia (1.9%), urologic complications (1.4%), wound problems (1.2%), phlebitis/pulmonary embolism (0.7%), fatigue fracture of the S1 vertebral body (1.3%), and other complications (0.3%). In 0.8% of the study group, implant migration required reoperation. In an additional 1.5% there was implant migration not requiring reoperation. The authors did not provide data for the total reoperation rate in the patients undergoing anterior fusion with the cages. There were no cases of device failure, death, major paralysis, or deep infections. The low complication rate in this series was very impressive, since it represented the initial experience using this implant.

The BAK-Proximity cage was designed to be paired with an original BAK cage. It is similar to the original BAK cage design but is flat on two sides, making it easier to fit within the disc space. Two reports involving small groups of patients having two Proximity cages implanted at the same level, recommended against this technique (24,25). In one of the studies, the reoperation rate was 29%, significantly greater than with paired BAK cages (24). The other study (25) reported similar results with a pseudoarthrosis rate requiring reoperation that was significantly greater in the group with two Proximity cages than in the group receiving two of the original devices (23% versus 0%). There was no information available on the use of a BAK paired with a Proximity cage at an operated level.

Pavlov et al. reported on a small series of only 13 patients undergoing anterior interbody fusion with the Ray Threaded Fusion Cage (Ray TFC) cage packed with autogenous bone graft (26). They reported one case of transient retrograde ejaculation, and 7 of the 13 patients underwent reoperation consisting of a translaminar facet screw fusion for symptomatic pseudoarthrosis. The reasons for the high pseudoarthrosis rate in this series could not be determined and was different from the experience described in another larger series of patients (27).

### Laparoscopic Anterior Lumbar Interbody Fusion

The advent of threaded fusion cages coincided with the development of laparoscopic spinal fusion that introduced the possibility of smaller incisions, reduced hospitalization time and possibly related costs, and shorter postoperative recovery. These benefits have since been debated. There has also been concern about the potential complications of and difficulties associated with this procedure. The surgeon must adapt to operating using indirect visualization. There was also concern about the ability to address complications such as injury to a major vascular structure. In all reported cases of vessel damage during laparoscopic fusion, the case was successfully converted to an open procedure without significant sequelae.

In a nonrandomized study, Regan et al. compared 215 laparoscopic fusions to 305 open fusions (4). All procedures were single-level and performed using BAK cages. In the open group there was a 0.7% incidence of vessel damage and a 0.3% incidence of pulmonary embolism. There was a 1.0% incidence of implant migration requiring reoperation. Other complications in the open group included ileus (3.3%), leg pain (0.7%), hematoma (1.0%), retrograde ejaculation (2.3%), atelectasis/pneumonia (0.7%), urologic complications (1.0%), wound problems (1.0%), infection (2.0%), and other (1.0%). In the laparoscopic group, 10% of cases were converted to open procedures due to bleeding, difficulties with accessing the disc space, poor visualization, or technical diffi-

culty with cage placement. Reoperation was undertaken in 4.7% of the laparoscopic cases, primarily to relieve nerve root compression caused by displaced disc tissue. Other complication in the laparoscopic series included infection (1.4%), ileus (4.7%), device migration (0.5%), leg pain (0.5%), retrograde ejaculation (5.1%), atelectasis/pneumonia (0.9%), thrombosis (0.5%), fractures (1.4%), and other (1.4%). As discussed earlier, the only complication that occurred significantly more often in the laparoscopic group than in the open group was disc herniation. There was no significant difference in the complication rate for the open and laparoscopic groups.

The occurrence of complication in one surgeon's experience of 127 consecutive laparoscopic fusion cases has been analyzed (18). Half of the complications occurred during the first 40 cases, suggesting a learning curve and the development of the technique and specialized instruments.

The results of a nonrandomized comparison of open retroperitoneal to laparoscopic transperitoneal anterior spinal fusion have been reported (15). Complications in the laparoscopic group included one of each of the following: intraoperative disc herniation, ureter injury, iliac vein laceration, transient retrograde ejaculation, and deep vein thrombosis. In the open group the only complication was a single case of ileus. However, it should be noted that in the laparoscopic group 68% of the surgeries involved two levels compared to 40% in the open group. Multilevel surgery is often associated with more complications.

A prospective, randomized study comparing laparoscopic lumbar fusion to open fusion using threaded fusion cages as stand-alone devices was recently reported (28). All cases were performed using Ray TFC cages packed with iliac crest graft and inserted through a transperitoneal approach. Among laparoscopic cases, the complication rate was 20%; there was one bladder perforation, one vena cava perforation that required conversion to open surgery, one case of urinary retention, and two cases of retrograde ejaculation. In the open group, complications occurred in 12% of patients consisting of one case of prolonged ileus and one case of pneumonia.

Lieberman et al. reported their experience with 44 patients undergoing transperitoneal laparoscopic exposure for lumbar interbody fusion (20). One case was converted to an open procedure due to bleeding, and surgery was abandoned in two other patients, who subsequently underwent posterior fusion. One of these patients developed intraoperative hypotension, hypoxemia, and hypercarbia following insufflation. In the other patient the location of the bifurcation of the vessels over the L4-5 disc made the exposure risky. In another patient with dense bowel adhesions, there was a suspicion that the bowel serosa may have been breached. The area was oversewn, the surgery aborted, and the cages were inserted two weeks later. In two other patients, the cages were

repositioned laparoscopically soon after the initial surgery because of radiculopathy from neural impingement from cage malposition. No patient required blood transfusion and there were no cases of deep vein thrombosis or pulmonary embolism. Transient retrograde ejaculation occurred in 7% of male patients that resolved within 8 weeks. Three patients developed peripheral sympathetic symptoms of a “warm leg” that resolved within 3 months. There was one case of small bowel obstruction that required laparotomy 8 days after fusion. There was one superficial wound infection at the donor site. The authors stressed the importance of proper training in order to perform the procedure safely.

The role of laparoscopic fusion, particularly in multi-level procedures has been questioned (29). One study reported that 17% of cases were converted to open surgery due to vascular injury or mesenteric tear, and retrograde ejaculation occurred in 27% of male patients. The authors of that study were discouraged with the procedure, although it should be noted that the authors performed the 24 cases during a 3- to 4-year period, which suggests that they may not have fully overcome the learning curve for the technique. Based on other authors' experiences, it appears that the surgeons who perform the procedure frequently have a lower complication rate.

## POSTERIOR LUMBAR INTERBODY FUSION

The complication of greatest concern in relation to posterior lumbar interbody fusion (PLIF) is neurologic injury. In order to gain access to the disc space, the neural structures must be retracted. Injury may be a result of neural over-distraction or blunt trauma to the nerves from an instrument. This may cause either neural injury or dural tear. These tears are generally identified immediately and repaired intraoperatively. This often requires additional posterior decompression that may contribute to instability. When inserting devices posteriorly, the instruments or devices must not be placed too deeply into the disc space because of the risk of penetrating the disc space anteriorly and injuring a vascular structure. As with all open posterior procedures, there is inevitable injury to the posterior musculature. As with anterior interbody fusion, the complications from posterior cage insertion are generally related to the approach and are greater if the cages are forced through too small an annulotomy.

Lee et al. reported on PLIF using autogenous iliac crest block grafts for the treatment of disc-related pain (30). In a group of 62 patients, donor-site pain occurred in 4.8%, wound hematoma in 1.6%, superficial wound infections in 3.2%, and peroneal nerve palsy which resolved in 3.2%. The peroneal problems were related to rolls and bandages being applied to the legs as antiembolic measures. The problem ceased after this practice was abandoned.

Kuslich et al. reported the results of a multicenter FDA IDE trial of 286 patients undergoing PLIF using BAK

cages packed with autogenous iliac crest graft as stand-alone devices (23). The most common complication was a 10.1% incidence of dural tears. Other complications included neurologic injury (3.9%), superficial infection (1.4%), new radicular pain (1.4%), hematoma/seroma (0.8%), vessel damage/bleeding (0.3%), urologic problems (0.3%), phlebitis/pulmonary embolism (0.3%), and other complications (0.8%). There was a 1.7% incidence of cage migration requiring reoperation and a 1.4% incidence of cage migration that did not require reoperation. There were no cases of device failure.

Complications in another FDA IDE study were reported by Ray in 236 patients undergoing posterior interbody fusion using Ray TFC cages packed with autogenous iliac crest graft (31). Complications in the study included dural tears (5.5%), foot weakness or numbness (10%, which resolved in all but 2 cases), deep infection (0.8%), and superficial infection (2.1%). There were no cases of device failure, cage dislodgement, or cage migration. In three cases (1.3%), the cages were placed too far anteriorly and reoperation was undertaken within two weeks after surgery to adjust the depth of the cages.

Another study reported the results of Ray TFC cages used for posterior interbody fusion in a series of 67 patients (32). Initially a high rate of dural tears involving the exiting nerve root were noted. Alternation of the operative technique by removing the superior spinous process and performing a total bilateral inferior facetectomy reduced this complication. Complications in that series included dural tears (15%), the need for blood transfusion (25%), “wrong level fusion” (1.5%), retained cottonoid (1.5%), retained sponge (1.5%), death (1.5%), posterior cerebral infarction resulting in visual defect (1.5%), superficial wound infection (3.0%), seroma (1.5%), new motor deficit (1.5%), sexual dysfunction (3.2% of males), and sacroiliac arthritis (1.5%). When combining the figures for intraoperative and perioperative cases of inadequate device placement, the incidence was 10%. The overall rate of reoperation was 28% and included 21% of the group undergoing posterior fusion with pedicle screws and plates to treat persistent pain and instability at the operated segment. In one patient, a piece of bone graft had extruded from the cage (the cage end cap had not been used), in two patients the cage migrated into the spinal canal requiring device removal, and in one patient reoperation was required to retrieve a sponge. The rate of complications and reoperations in this study was much greater than that in other studies using the same device. The need to reoperate to add supplemental posterior fixation for instability may be related to the operative technique used to access the disc space, namely, bilateral inferior facetectomy and partial removal of the spinous process.

Uzi et al. reported on two cases of retropulsed titanium cages in posterior interbody fusion (33). Both cases involved the use of Stryker threaded cages. The patients

experienced the sudden onset of radiating leg pain, one at 2 months postoperatively and the other at 10 days postoperatively. X-rays showed that in both cases, both of the cages had migrated posteriorly. Reoperation was undertaken using pedicle screws to distract the disc space open. The retropulsed cages were then visualized and pushed anteriorly, and compression was then applied to the pedicle screws to lock the cages in place. The authors did not report the total number of cases in which the devices had been used and therefore the overall incidence of cage retropulsion could not be calculated.

Whitecloud et al. described their experience in a retrospective, nonrandomized study comparing a transforaminal posterior interbody fusion with combined anterior-posterior fusion (34). All procedures were performed using Harms cages packed with autogenous graft and pedicle screw fixation. Among the patients in the combined anterior interbody group, there was one iliac vein tear and six cases of ileus, only one of which prolonged the hospital stay. Twenty-three of the 40 patients received a blood transfusion, averaging 2.2 units. In the transforaminal group, there was one dural laceration, and six of the 40 patients received packed red blood cells, averaging 1.2 units. The transfusion rates in this study were much greater than reported in other studies and no reason for the high rate of transfusion could be determined.

### Cages as Stand-Alone Devices

The use of titanium-threaded cylindrical cages as stand-alone devices without supplemental posterior fixation has been very controversial. However, there is little information suggesting significant problems using cages as stand-alone devices. One study reported a 31% reoperation rate among patients in whom the cages were used as stand-alone devices (35). The revision surgery was to add posterior fixation. This experience did not mirror that reported in some of the large series in which less than 8% of patients underwent reoperation at the same level to add supplemental posterior fixation (4,23,27). The reason for the discrepancies cannot be determined.

## POSTERIOR FUSION

There is little literature available on the treatment of symptomatic disc degeneration using posterior fusion alone. Most surgeons think this is a suboptimal method for treating disc-related pain because the disc is not addressed directly. However, there have been a few reports on using this treatment method. Wood et al. reported on a series of 28 patients undergoing posterior fusion with pedicle screw and plate fixation and autogenous iliac crest bone graft (36). Reoperation for the removal of the internal fixation was performed in 14% of patients. There was a 32% complication rate including 6 wound infections (9.7%) (3 of which required reopera-

tion), phlebitis (3.2%), ileus (1.6%), pulmonary embolism (1.6%), urinary retention (1.6%), and wound necrosis (1.6%). Screw loosening occurred in 3 patients, but there were no cases of neurologic complications, pedicle breaches, or broken screws. However, it should be noted that this was a small series of patients, which makes it difficult to determine the true incidence of complications.

## COMBINED ANTERIOR-POSTERIOR SPINE SURGERY

The term *combined anterior-posterior fusion* is synonymous with a 360° (circumferential) fusion, that is, an anterior interbody fusion combined with posterior fusion, with or without pedicle screw fixation. One benefit of 360° fusion is that it directly addresses the interbody space anteriorly, thereby avoiding the potential difficulties of posterior interbody fusion. The posterior fusion allows direct access to any posterior pathology, such as nerve root compression, and permits stabilization of the posterior column of the spine. The disadvantages of the combined procedure include the prolonged operative time, increased blood loss, greater risk of complications, and higher cost. The 360° fusions have typically been associated with a high fusion rate, but it has a greater risk of complications since two approaches to the spine are involved. There is also a risk of accelerated deterioration of the adjacent segment(s) due to the rigidity of the construct. The role of combined anterior interbody fusion with a posterior fusion is controversial. In recent years, however, it has gained popularity partially because of newer technologies, such as carbon fiber and other forms of cages, because of renewed interest in femoral ring allografts, and because of the use of minimally invasive posterior instrumented fusion, translaminar facet screw fusion, and other modifications.

### Traditional 360° Fusion

Complications of traditional 360° fusions were reported by Gertzbein et al. in a series of 82 patients who underwent fusion with anterior allograft and posterior pedicle screw fusion (37). Complications included one death due to pulmonary embolism, two cases of deep vein thrombosis, two cases of paralytic ileus, and one case each of the following: iliac vein injury requiring repair, deep infection, superficial infection, dural tear, pneumonia, pulmonary edema, reflex sympathetic dystrophy, graft fracture, retroperitoneal hematoma, S1 nerve root injury, and wound dehiscence. Instrument-related complications included three broken screws and one broken rod. The posterior fixation was removed in two patients due to presumed symptoms.

Liljenqvist et al. reported their experience with 360° fusion using anterior femoral ring allograft and posterior

translaminar screws in 41 patients (38). Complications included one of each of the following: peritoneal tear, common iliac vein tear, intraoperative fracture of the femoral graft, postoperative fracture of the femoral graft, deep vein thrombosis, dural tear, and retrograde ejaculation. One case of nerve root irritation required reoperation, as did one case of incisional abdominal hernia. Chronic graft donor-site pain was reported by 23.5% of patients.

Thalgott et al. reported on what was termed a “minimally invasive 360°” fusion (39). The technique combined endoscopic anterior interbody fusion with minimally invasive posterior screw fixation and fusion. Of the original 64 patients, 18 (28%) were converted to an open anterior fusion. Complications in the remaining 46 patients included one vessel laceration and six dural tears, all of which were repaired without event. There were four cases of interbody cage migration, none of which were of consequence. The authors noted that this series represented their initial experience with this new technique. The high rate of conversions to open surgery likely represents the authors’ learning curve and a cautious approach to avoid significant complications.

Schofferman et al. reported on combined anterior-posterior fusion with pedicle screws, randomizing patients to receive either bone graft or no bone graft with the posterior instrumentation (40). Among the 26 patients in the group receiving bone graft, the complications included 1 case of deep vein thrombosis (3.8%) and 3 dural tears (11.5%). In the group of 22 patients who received instrumentation but no bone graft, the complications included 2 dural tears (9.1%). The reoperation rate to remove instrumentation was high in both groups at 62% and 64%, respectively, for residual low back pain associated with tenderness over the instrumentation.

### POSTERIOR INTERBODY WITH POSTERIOR FUSION OR FIXATION

Some surgeons advocate combining PLIF with posterior fusion or fixation. This approach has the potential benefit of avoiding additional anterior spine surgery. There are several methods for accessing the disc space posteriorly as well as various types of posterior fixation, used either with or without bone graft.

Freeman et al. reported a 5-year follow-up of 60 patients undergoing combined posterior interbody and instrumented posterolateral fusion (41). In the majority of the interbody fusions, autogenous iliac crest graft was used. Complications in the series included four neurologic complications (6.7%), two of which resolved spontaneously, one of which required reoperation to reposition a pedicle screw, and one of which had bilateral foot drop, which resolved unilaterally. Three patients developed deep vein thrombosis, and there was one superficial wound infection.

There have been several studies reporting the use of carbon fiber cages and posterior fixation. Carbon fiber cages are typically rectangular and are used in pairs at each operated level with bone graft packed into the cages. They are designed to be used with posterior fixation, rather than as stand-alone devices. The potential benefit of carbon fiber cages compared to metal cages is that radiographic assessment is facilitated. The largest series of patients undergoing fusion with carbon fiber cages was published by Brantigan et al. (42) and involved 221 patients undergoing PLIF with supplemented pedicle screw fixation. There was a 13.5% rate of cage-related complications, including two cages that were cracked during implantation and 16 broken pedicle screws in 13 patients. Other complications in the series included two intraoperative deaths (one due to intraoperative bleeding and the other due to myocardial infarction), deep infections requiring reoperation (8 patients), deep vein thrombosis (2 patients), reflex sympathetic dystrophy (3 patients), increased motor deficit (3 patients), and myocardial infarction (1 patient). Two other patients in the study died of unrelated medical problems and two committed suicide. Additionally, the authors reported a 13.2% rate of what they described as “minor nondevice-related” complications and a 26.2% rate of what was termed “insignificant events” including 41 dural tears. The reoperation rate was 46.1%, including removal of the posterior instrumentation in 78 patients (35.2%). Other reoperations included repair of dural tears (6 patients), removal of retained drains (3 patients), the need to address pain coming from a different disc level (6 patients), and revision of pedicle screws or cages (5 patients). The complication rate in this series is greater than that reported in other studies. It cannot be determined if this is attributable to the devices themselves, the technique use to implant them, patient selection, or the skill level and training of the physicians involved. However, the data were from the FDA IDE study, which typically involves surgeons with a high level of expertise.

In a smaller series of 51 patients undergoing posterior interbody fusion using paired carbon fiber cages augmented with pedicle screw fixation, Tullberg et al. reported no cases of device failure (43). They reported three dural tears, one infection, and one case of screw loosening. Several years later, Tullberg published a case report involving a failed carbon fiber cage (44). During reoperation to remove the posterior fixation, a black discoloration of the dura and nerves was noted. The broken cages were later removed, and histologic analysis showed many carbon fiber particles but little inflammation around them. This case exemplifies one of the concerns of using carbon fiber implants, that is, fracture of the device with pieces of the cage infiltrating the area near neural structures.

In a series of 71 patients undergoing fusion using Ostaped carbon cages supplemented with posterior pedi-

cle screw fixation (45) complications included seven neurologic complications (9.8%), two of which required reoperation for removal of the pedicle screw and plate fixation. Four additional patients underwent removal of the posterior fixation due to continued pain. The authors also reported two dural tears that were repaired intraoperatively.

In a study dealing primarily with psychological factors and surgical outcome, Tandon et al. reported on 58 patients who underwent interbody fusion using carbon fiber cages supplemented with posterior pedicle screw and plate fixation (46). Complications in this series included transient altered sensation in the foot (4), foot drop (1), malpositioned cages resulting in reoperation requiring piecemeal removal of the devices and fusion anteriorly (1), and one asymptomatic broken pedicle screw.

Some authors have advocated a transforaminal approach for posterior interbody fusion. Purported advantages of this technique include excellent access to the disc space and reduced risk of neurologic injury. Humphreys et al. compared the posterior and transforaminal approach for lumbar interbody fusion (47). Pedicle screw fixation was used in all cases. In the transforaminal cases, bone graft was packed anteriorly and a single Harms cage was placed in the middle and posterior portion of the interspace. In the posterior interbody group, a single cage was also used. The authors reported no complications in the group of 40 patients with transforaminal interbody fusion. Complications in the 34 patients with posterior interbody fusion included radiculitis (four cases), broken hardware (one case), screw loosening (one case), screw removal (two cases), superficial infection (one case), and pseudoarthrosis requiring reoperation (one case).

Jun et al. reported a small study of 36 patients undergoing posterior interbody fusion using a facetolaminotomy approach to the disc space (48). After placing carbon fiber cages and a block of autogenous iliac crest bone in the disc space, a facet fusion was performed using translaminar facet screws. The authors reported no neurologic complications or any screw breakage or loosening with this technique.

### ADDRESSING FUSION CAGE PLACEMENT DIFFICULTIES

The large number of threaded cages has created the need to understand the genesis of complications and how to treat them. McAfee et al. reviewed a group of 20 patients who underwent reoperation for cage-related problems (19) and concluded that in all cases, the problems were due to technical error. In anterior procedures, the main problem was that the cage placement was too lateral, which pushed disc tissue from the space and resulted in compression of the nerve roots. When we encounter malpositioned cages placed too far anteriorly

and pushing disc tissue onto the nerve roots, we perform a posterior decompression and remove the compressing tissue (49). If the cage is positioned too far posteriorly, an anterior procedure can be performed to remove the cage and to replace it with bone graft, or to rotate the cage and move it more anteriorly. Typically, malpositioning problems are recognized early in the postoperative period, and anterior revision surgery is performed soon after the initial surgery. This allows the problem to be addressed as soon as possible before significant scar had formed. Repeat anterior surgery can be difficult as well as hazardous due to scarring and adhesions to vascular structures. In a review of complications related to anterior spine surgery, Rajaraman et al. reported significant difficulties when trying to retrieve a malpositioned cage (3). This resulted in a major vascular injury due to dense adhesions between the posterior vessel wall and the instrumentation. There was significant blood loss and the surgery had to be abandoned.

Reoperation to remove a migrated cage more than 14 months after posterior interbody fusion and pedicle screw and plate fixation has been reported (50). To avoid potential complications related to revising the cage through a posterior approach, an anterior approach was used. An osteotomy of the superior vertebral body was required because of bony ingrowth into one cage. The migrated cage was noted to have a fibrous union and was removed. During subsequent revision of the posterior fixation, it was noted that two of the four pedicle screws had breached the canal or foramen. The patient had a good result after the revision.

In some cases, two cages cannot be placed safely due to the degree of vessel retraction required to gain adequate access to the disc space (49). In such instances, a femoral ring allograft can instead be used without injury to the vessels. In some patients, the disc width cannot safely accept two cages of the diameter required to produce adequate purchase. Under such circumstances, one cage can be placed in the center of the disc space and bone graft placed on each side.

In a series of 35 patients, Hodges et al. reported intraoperative cage loosening in three patients (51). In these cases, the initially placed cage appeared to be well positioned and firmly seated. However, after the implantation of the second cage, the first cage was noted to be loose. In all three cases, the loose cage was replaced with a larger cage without subsequent problems. The loosening was only identified during a final check before closing. We have also noted cases where a loose cage fit was noted intraoperatively (49). Under such circumstances, the cage can be removed and replaced with bone graft.

In a review by McAfee et al. of malpositioned cages, posterior interbody procedures were associated with cage migration into the epidural space (19). This was attributed to the selection of too small of a cage to achieve adequate purchase into the vertebral bodies or the cages not

being seated deeply enough into the disc space. The selection of small cages may have been related to the difficulty of trying to adequately access the disc space for fear of over-distracting the neural structures.

### DONOR SITE COMPLICATIONS

One of the potential complications of lumbar spinal fusion is related to harvest of autogenous iliac crest graft. The reported incidence of donor-site pain varies in the literature that is likely related to variation in surgical technique, and the methodology for recording and defining pain. There are also other potential complications from the harvesting of autogenous iliac crest graft. Vascular injury, particularly to the superior gluteal artery, can occur. Neurologic injury can also occur at the donor site. The anterior nerve primarily at risk is the lateral femoral cutaneous nerve, although the ilioinguinal nerve may also be injured. The superior cluneal nerves are at risk with posterior iliac crest harvesting. Painful neuromas may occur with nerve injury. Fracture of the ilium may also occur, although this is not common. Fractures are typically seen in patients with osteoporosis, or in patients with previous injury to the ilium. There is a risk of deep or superficial infection, or hematoma formation.

One study compared the donor-site pain associated with two different harvest methods in two groups of 30 patients each (52). In one group of patients, harvesting included the outer cortex and cancellous bone beneath it. In the other group, a small opening was made in the cortex and only cancellous bone from between the cortices was taken. The authors found no statistically significant difference in donor-site pain with either method used. Two years after surgery, donor-site pain was reported in 17% in the first group and 20% in the second group.

In a prospective study of donor-site pain, Robertson and Wray reported relatively minor levels of donor-site pain (53). On a scale of 0 to 10, at 3 months after surgery, the mean score was 1.6, and at 12 months postoperatively it was only 1.2. A score of greater than 3 was reported by 12% of patients, while 55% of patients reported a score of 0. Although the mean pain values were low, the authors reported that 13% of patients had numbness at the scar, 10% had local sensory loss in the distribution of the cluneal nerves, and 35% had a palpable soft-tissue defect, many with related tenderness.

In another study involving 290 patients, 25% of patients had significant donor-site pain, 24% had an acceptable level of pain, and 51% had no pain (54). In a subgroup of 81 patients who returned for an assessment, significant numbness at the donor site was noted by 31% of patients, and an additional 17% had lesser degrees of numbness. Radiographs taken in another subgroup of 58 patients showed that none of the donor sites filled in with

new bone to any significant degree, and in some patients, bony spikes had formed in the harvest area.

In a review of 414 patients, major donor-site complications occurred in 5.8% of patients (55). These included two donor-site hernias, three vascular injuries, six nerve injuries, seven deep infections, four deep hematomas, and two iliac fractures. Minor donor-site complications were reported in 10% of patients and consisted of superficial infections, seromas, and hematomas. The authors did not report on donor-site pain.

In a series of 147 patients, Fernyhough et al. found that 29% of patients had chronic donor-site pain at 1-year follow-up (56). They found no difference in the incidence of pain related to harvest technique when comparing a midline incision (harvesting through the same incision as the posterior fusion) versus a separate lateral incision to access the posterior iliac crest. Although an aching sensation was common in the entire study group, it was more common in the midline group, possibly because of the close proximity of the lateral incision to the cluneal nerves. The authors also reported that patients who underwent reconstructive surgery were twice as likely to have donor-site pain as patients who underwent surgery for traumatic injuries. This finding suggests that patients with chronic pain may be predisposed to more postoperative pain complaints that may be related to psychological or other factors.

In another study, two approaches to the posterior iliac crest for graft harvest were compared (57). In one group, an oblique incision was made parallel to the iliac crest (standard incision). In the other group, a more vertical incision was made parallel to the superior cluneal nerves and perpendicular to the posterior iliac crest (modified incision). At 1 month after surgery, 44% of the modified incision group and 74% of the standard incision group reported numbness at the donor site. At 6-month follow-up, these figures improved slightly in both groups to 42% and 68%, respectively. The percentages of patients reporting deep pain at 6 months was similar in the 2 groups (60% and 54%), although the modified incision group had less activity-related tenderness.

Another review of 225 patients reported no injuries to the superior gluteal artery or sciatic nerve. There were also no deep wound infections, herniation, meralgia paresthetica, instability, or fracture (58). Ten percent of patients had major complications, including two patients with wound drainage, one with a scar requiring revision surgery, twelve with unsightly scars, and three with chronic pain, limiting activities. Most of these patients also had local dysesthesia at the donor site. Minor complications were noted in 39% of patients. These included dysesthesia that resolved in 6 months, prolonged wound drainage, one superficial infection, and one retained drain. Of note is that many of the minor complications were identified by patient questionnaire but were not recorded during follow-up visits. This may suggest an

under-reporting of problems unless the physician specifically addresses donor-site pain or scar problems during all follow-up visits. Several authors noted that scar problems emerged more than 6 months after surgery.

One potential method to avoid donor-site complications is the use of allograft. However, there may be concerns about the quality of allograft and risk of disease transmission. The use of allograft with fusion cages has not been investigated. For posterior fusion, the use of local autogenous graft has been reported to yield fusion rates similar to that using iliac crest graft (59). If enough local bone graft is not available, a graft extender or supplement can be used. Bone morphogenetic protein (BMP) and local gene therapy hold great promise for enhancing fusion rates and avoiding donor-site complications (60,61). BMP has yielded promising results in a small clinical series (62).

### ARTIFICIAL DISCS

In recent years there has been a great deal of interest in artificial discs. The approach used to implant disc replacements is the same as is used for anterior interbody fusion using other devices. Disc replacement is most commonly used to treat symptoms related to internal disc disruption or disc degeneration that has failed to respond to nonoperative care. Currently, there are two total disc replacements and one disc nucleus replacement that have been used in large numbers of patients. One of the artificial discs, the Charité, has been used in Europe for more than 15 years. The third modification design of this device has been used for more than 10 years. This device is a polyethylene core placed between two metal plates. With the initial two designs of this disc, there were problems with subsidence. The third design addressed problems encountered with the earlier models. The other total disc replacement, the ProDisc, has been used in Europe for more than 10 years. There are several reports in the literature on complications related to these devices. In addition to complications related to any anterior spine surgery, the primary potential complications related to disc replacement devices are displacement, device failure, and wear debris.

With the early designs of the Charité disc, failure of the metallic endplates in occurred 31% of cases (63). In addition, anterior displacement of the device occurred in 22% of patients. In 31% of patients, the device subsided into the vertebral bodies. Redesign of the device (the Charité III) and subsequent experience have resulted in a much lower rate of complications. There have been no reported cases of device failure associated with the SB Charité III.

Evaluating the rate of complications from the Charité artificial disc is difficult due to overlap between authors of some of the series, which may have resulted in some

patients and complications being recorded more than once. In a series of 105 patients, Lemaire et al. noted a 10% complication rate (64). This included five vascular problems, two cases of neurologic deficits (one resolved spontaneously, the other required to revision surgery and fixation), and four cases of bone-related complications (one posttraumatic vertebral body endplate fracture, one case of subsidence into osteoporotic bone, and two cases of periprosthetic ossification). Cinotti et al. reported on a separate group of 46 patients (65). Implant subsidence occurred in four patients in whom too small of an implant was used, although this did not affect clinical outcome. Periprosthetic ossification was related to immobilization from a corset for 3 months postoperatively, and to malposition of the implant. David reported a 5-year follow-up of 96 patients, in which complications included one device removal and fusion for severe sciatica, one case of bone migration requiring reoperation and fusion, and eight cases requiring subsequent instrumented posterior fusion for device malpositioning and facet pain (66).

A multicenter review of the Charité III involving 93 patients and 139 disc levels revealed only one device-related problem, that being one case of deformation of the metal ring around the polyethylene core (67). This remained in place and posed no clinical risk to the patient. There was a 6.5% incidence of implant migration or subsidence due to using the wrong size implant. Other complications identified included phlebitis/leg thrombosis (2 cases), vein injury (6 cases), wound bleeding or dehiscence (2 cases), superficial infection (1 case), muscle atrophy (1 case), urinary tract infection (4 cases), incontinence (3 cases), constipation (4 cases), nausea (1 case), skin paresthesia (1 case), hematoma (11 cases), hypotension due to blood loss (1 case), retrograde ejaculation (1 case), reflex sympathetic dystrophy (1 case), paresthesia (1 case), unspecified neurologic problems (2 case), and pain (10 case). There were three reoperations in the group of 93 patients that included one case of percutaneous nucleotomy, one foraminotomy, and one combined anterior-posterior fusion. The authors did not describe if the fusion was at the same level as the prosthesis or at another segment.

Zeegers et al. reported a series of 50 patients in which there were 52 problems in 30 patients (68). Unresolved complications included dysesthesia into the legs (3 cases), sympathetic effect (4 cases), and malpositioned prosthesis (1 cases). Complications that did resolve included neurologic problems (7 cases), hematoma (12 cases), painful or numb scars (5 cases), abdominal problems (3 cases), new or progressive pain (5 cases), vascular problem (1 case), urinary tract infection (4 cases), retrograde ejaculation (1 case), and deep vein thrombosis (1 case). In one patient, repositioning of a malpositioned prosthesis was attempted and abandoned with subsequent fusion performed. There were instances of significant

vascular injury during the procedure. In total, there was a 24% reoperation rate, primarily for pain control. The authors noted that this series consisted of their first 50 consecutive patients, and many of the problems encountered were likely attributable to a learning curve.

Sott and Harrison reported a series of 14 patients undergoing the Charité disc replacement (69). They found five patients (36%) with a “warm” left foot related to injury of the paravertebral sympathetic nerves, and one case of implant subsidence.

The other artificial disc that has been used for more than 10 years in Europe is the ProDisc. This design includes two metal plates with a polyethylene core between them. The core is flat on the inferior surface and slides into the inferior metal plate. There have been no reports of device failure related to this artificial disc, but there are only a few articles reporting on this device. In one study reporting 8- to 10-year follow-up, complications included one iliac vein tear that was uneventfully repaired intraoperatively, one case of appendicitis with peritonitis, and one disc herniation at the level above an ankylosed prosthetic disc (70).

One disc nucleus replacement, the Ray PDN (Prosthetic Disc Nucleus), has been used in large series of patients, although no reports on clinical experience with it have been published at this time. The device consists of a hydrogel material placed inside a woven restraining jacket. The hydrogel absorbs water and expands after being placed into the evacuated disc space. Two devices are placed at each operated level. The primary complication related to this device is migration, which has been reported in 10% of patients (71).

## INFECTION

There has been little published on infection associated with surgery for the treatment of symptomatic disc degeneration. Several series report on the occurrence of superficial wound infections at the surgical site or the donor site. Of greater concern are deep infections. Fortunately these are rare. Glassman et al. investigated the treatment and outcome of 19 patients with deep infection related to spine surgery (72). The patients were treated with multiple irrigation and débridement procedures as well as antibiotic treatment. Outcome was assessed 12 to 42 months after the fusion surgery. Compared to their preoperative condition, 57.9% of patients were significantly improved, 21.0% were improved, and the remaining 21.1% were unchanged or worse than their preoperative condition (one of whom had a permanent neurologic injury during the surgery). Solid fusion was achieved in 73.6% of patients and in 21.0% fusion was probable. These results indicate that although deep infection related to spinal fusion is a significant problem, acceptable long-term results can be achieved with aggressive treatment.

## INTRADISCAL ELECTROTHERMAL THERAPY

One relatively new method available for the treatment of disc-related pain is intradiscal electrothermal therapy (IDET). During this procedure, a catheter with a thermal coil is percutaneously placed into the disc. As the device heats up, it is thought to cause thermocoagulation of nociceptors in the disc annulus. It is also thought to modify the collagen in the disc as it heals. This is a new treatment with few reports on its outcome and complications. The most likely potential complication is injury to the nerve root during placement of the guide needle for the catheter. Other possible complications include thermal damage to the cord or nerve roots, and infection. Two reports on IDET published by the originators of the procedure noted no complications (73,74). A third paper by other authors did not comment on complications (75). One case of cauda equina injury during IDET has been reported (76). The presence or absence of complications associated with IDET has been addressed in less than 100 reported patients. This number is too small to adequately address the risk of occurrence of complications, particularly since these are the earliest reports using this device, many of which were performed and reported by the physicians who devised the procedure and were best acquainted with the device.

## DISCUSSION

Many treatment options are available for symptomatic disc degeneration unresponsive to nonoperative treatment. The surgical treatment armamentarium for this condition continues to grow. In addition to traditional fusion, there are now a variety of different surgical approaches and devices to use. Avoiding complications is a primary goal in any operative procedure. In order to do so, one must consider the options available, the advantages and disadvantages of each—with particular application to the individual patient, and the surgeon's own level of training, experience, and comfort level associated with each option. As seen in this review, the type of complications and their incidence vary greatly. The reasons for this are not clear. It probably has to do with patient selection, patient comorbidities, skill and experience of the surgical team, the type of surgery used, and other factors. As discussed by Kain et al. in a review of complications of anterior lumbar interbody fusion, the complication rates appeared to be lower among surgeons with the largest group of patients (77). It may be that not only must one be properly trained in performing a technique, one must practice frequently enough to build and maintain an optimal skill level.

As described earlier, some potential complications can be avoided by altering the operative plan when difficulty is encountered. This is seen in laparoscopic cases where

conversion to open surgery is done when there is difficulty with exposure, visualization, or other problems. When using cages, for example, difficulty placing a pair of cages or one of the devices may mandate altering the procedure to use allograft rather than a cage. One must plan to have proper equipment and graft materials readily available for unexpected changes in preoperative plans.

There are now many options available for the treatment of disc-related pain. There are various forms of fusion cages, some of which can be used as stand-alone devices, and others that are designed for use with posterior fixation. Other surgical options include disc replacement and IDET. It is likely that in the future, even more treatment options will be available. There are no definitive answers concerning which option is the best for any individual patient. IDET, for example, has the benefit of being a minimally invasive procedure. However, it is applicable to a relatively narrow spectrum of conditions and still needs further investigation. Artificial discs have been used with great success in Europe. The complications associated with these devices seem similar to those traditionally encountered with anterior interbody fusion. Artificial disc replacement is currently available in the United States only on a limited basis as investigational devices. Therefore, interbody fusion is currently the primary treatment option for symptomatic disc degeneration unresponsive to nonoperative care. The decisions concerning which fusion cage or allograft to use, which surgical approach to use, and whether or not to combine it with supplemental posterior fixation, are left to the discretion of the surgeon. The choice of treatment will vary based on the surgeon's training and experience, the patient's anatomy and history, and the details of the problem being treated. Surgeons must take every reasonable measure to reduce the risk including being aware of patient comorbidities and previous surgical history. One of the most important factors in reducing complications and the severity of their course is the surgeon's training and experience. New procedures should be undertaken only after the surgeon has undergone appropriate training. Important considerations include appropriate patient selection, the presence of anatomic variations and contraindications to the procedure, and hands-on training in the use of the instruments and surgical techniques. Despite enthusiasm over new techniques and devices, caution and appropriate training is mandatory to avoid complications.

# Dynamic Stabilization in the Treatment of Low Back Pain Due to Degenerative Disorders

Dilip K. Sengupta

---

Several reports in the literature indicate that successful fusion may fail to improve chronic low back pain in a significant number of patients (1,2). This has renewed the interest in dynamic stabilization in the lumbosacral spine. Essentially, dynamic stabilization means instrumentation to control movement and load transmission through the motion segment. The terms *semirigid fixation*, *flexible stabilization*, and *soft stabilization* are apparently synonymous with dynamic stabilization. However, there is an essential difference between these terms. When the goal of stabilization is to improve the rate and quality of fusion without stress-shielding, the technique is called semirigid fixation. In contrast, when the goal is to preserve a controlled motion it is usually described as soft stabilization or flexible stabilization.

The following discussion elaborates the rationale, techniques, and evolution of the various dynamic stabilization systems in the treatment of chronic low back pain.

### ROLE OF FUSION

The role of fusion in the treatment of degenerative low back pain is a matter of debate. In a review of the Cochrane databases for randomized controlled trials, Gibson et al. (1) concluded that for degenerative lumbar spondylosis there is no scientific evidence in favor of the effectiveness of any form of surgical decompression or fusion when compared with natural history, placebo, or conservative treatment. In contrast, in a multicenter randomized controlled trial, the Swedish Lumbar Spine Study Group reported that the outcome of fusion is significantly better than that of nonsurgical treatment. However, most authors agree that in a significant number of patients successful fusion may not produce adequate pain relief.

### ETIOLOGY OF PERSISTENT BACK PAIN AFTER SUCCESSFUL FUSION

Chronic low back pain due to disc degeneration is believed to be generated by abnormal movement, abnormal load transmission, or both in the motion segment. When conservative treatment fails, the traditional surgical treatment is fusion. Theoretically, fusion should address both these mechanisms; load transmission is direct from bone to bone and there should be no movement after fusion. Instrumentation may be added to increase the fusion rate. Evolution of instrumentation techniques during the last decade has improved fusion rates to close to 95%. Unfortunately, this has not resulted in an equivalent success in the functional outcome (2).

It is unclear why pain persists in some patients following a successful fusion. The possible explanations that have been suggested by various authors may be summarized as follows:

1. Misinterpretation of pseudarthrosis as solid fusion
2. Adjacent segment disease
3. Abnormal load transmission despite fusion
4. Abnormal sagittal balance.

It has been well recognized that radiologic assessment of fusion is often unreliable (3–5). McAfee (6) reported that many cases of failed back syndrome following successful fusion were in fact a misinterpretation of pseudarthrosis. He emphasized that presence of the “sentinel sign”, bridging bone in front of the cages, is the only definitive evidence of fusion. In a study involving 100 cases of failed back syndrome following apparent fusion, three-dimensional computed tomography (CT) uncovered incomplete fusion in 17%, transitional syndrome in 13%, and pseudarthrosis in 6% of cases (3). A solid fusion alters the biomechanics at the adjacent level, resulting in increased mechanical demands (7). There

have been reports of increased rates of adjacent-level pathologic lesions after fusion, but these have not been taken into account for the natural history of degenerative changes (8,9). After solid fusion using metallic interbody cages, the mechanical stress at the contact surface of the end plate to the cages may be much higher than normal and may generate pain (10). Studies of finite element models have demonstrated that vertebral loads corresponding to certain activities may generate end-plate stresses at the control surface with cages that approach and exceed the failure stress for cortical bone (10,11). Loss of sagittal balance and “flat-back syndrome” following lumbar fusion may increase the stress at the adjacent segment leading to persistent back pain (12). In a review of 83 consecutive cases of spinal fusion, patients with abnormal C7 plumb line or abnormal sacral inclination in the immediate postoperative radiographs were found to have a much higher incidence of adjacent level degeneration compared with patients with normal sagittal balance (13). This has also been established in an *in vivo* study in a sheep fusion model (14).

### ALTERNATIVE TO THE CONVENTIONAL FUSION PROCEDURES

Because of failure of fusion to relieve back pain, alternative surgical approaches have been developed. These may be broadly divided into three categories:

1. Semirigid stabilization—to achieve fusion without stress shielding
2. Artificial disc or nuclear prosthesis—to preserve motion and to stabilize the segment, while replacing a component of the motion segment
3. Dynamic stabilization—to preserve motion while stabilizing the segment, without replacement of any anatomic structure.

#### Semirigid Stabilization

As opposed to rigid stabilization, semirigid stabilization uses a somewhat flexible construct for fixation. The goal is to achieve fusion of the motion segment. The objective of semirigid implants is to avoid “stress shielding” which may discourage formation of the fusion mass, lead to osteoporosis, and cause loosening of implants. *In vitro* biomechanical studies showed semirigid devices share load with the anterior bone graft or cage to promote fusion (15,16).

Most authors describe semirigid rods between the pedicle screws. Musha et al. (17) reported over 97% successful fusion rate using a semirigid system consisting of rod and pedicle screws. Gertzbein et al. (18) reported 97% fusion rate using 4 mm threaded rod and polyaxial pedicle screw. They suggested that the system should only be used in conjunction with an anterior structural

support. Without this anterior support, the construct is expected to fail. Mochida et al. (19,20) described an ingenious method of using a Dacron ligament (Leeds Kieo Ligament, Neoligaments, Ltd., Leeds, UK) for spinal fusion, which was originally introduced for reconstruction of the anterior cruciate ligament. They described the technique as syndesmoplasty in which each end of the ligament is fed into a hole in the pedicle, crossed in a tunnel in the vertebral body, pulled out of the contralateral pedicle, and tied around the spinous process of the inferior segment. Their results were comparable to that with rigid fixation when the instability was small.

#### Artificial Disc or Nucleus Prosthesis

The goal of prosthetic replacement of the disc or the nucleus is to preserve motion. The pain is controlled by removing the pain generator, the diseased disc, and also by uniform load transmission through the end plate and the facet joints. The stabilization provided is indirect and is dependent on tensioning the remaining annulus and the ligamentous structure after insertion of the prosthesis. The artificial disc or nucleus differ from dynamic stabilization by prosthetic replacement of a section from the motion segment.

Artificial disc and nucleus have been discussed in Chapters 39 and 40.

#### Dynamic Stabilization

Due to the unpredictable outcomes of fusion procedures, spinal surgeons are showing an increasing interest in dynamic stabilization procedures. The goal of dynamic stabilization is to preserve motion while stabilizing the motion segment. It may be used alone or in conjunction with rigid stabilization, to “top off” the proximal segment adjacent to fusion to prevent its accelerated degeneration.

The ideal mechanism of dynamic stabilization has not been clearly defined in the literature. The issues of the degrees of restriction of motion and how much disc unloading is necessary have not been resolved. A clear understanding of the cause of low back pain in disc degeneration is needed before we may consider the ideal mechanism of dynamic stabilization.

### ETIOLOGY OF CHRONIC LOW BACK PAIN DUE TO DISC DEGENERATION

#### Segmental Spinal Instability

The role of instability as a cause of chronic low back pain is not well understood. Panjabi (21) suggested that instability is a mechanical entity and is defined as a loss of stiffness to a given load. Frymore and Krag (22) echoed the same definition, as a loss of motion segment

stiffness, such that application of force would produce greater than normal displacement. This may result in pain, progressive deformity, and neurologic deficit. However, biomechanical and radiological studies using open magnetic resonance imaging (MRI) in flexion and extension has shown that segmental motion either does not change significantly with the disc degeneration (23–25), or may in fact decrease, except during early stages of disc degeneration (26). Mulholland and Sengupta suggested that the era of back pain due to a disorder called “instability” was based on interpretation of spinal instability in a purely biomechanical sense, validated to some extent in other joints like the knee and shoulder, and fusion was seen as the appropriate solution (27).

In the clinical scenario of mechanical back pain, the instability concept fails to explain two commonly observed facts. First, patients with disc degeneration often experience episodes of acute exacerbations superimposed on a mild to moderate degree of baseline symptoms. If there were any abnormal translation or instability in the diseased segment, symptoms would be continuous. It is difficult to understand that if instability or abnormal movement is the cause of pain, why then is the acute pain only periodic rather than continuous. Secondly, manipulation by chiropractors, at least in some patients, results in dramatic relief of symptoms in an acute episode of low back pain. If instability is the etiology of the pain, it would not be reduced by manipulation. This also contradicts the notion that instability is the causative factor in low back pain secondary to disc degeneration.

### **Back Pain: Movement or Load-Related?**

The intervertebral disc has two important biomechanical functions; it must transmit load and it must allow a controlled range of motion. This movement must not compromise the adjacent neural elements. Following disc degeneration, either the load transmission or the movement or both may become abnormal. The contribution of each of these to back pain in disc degeneration is unclear.

### ***Load Transmission through Normal and Degenerated Discs***

In the normal disc, the hygroscopic nature of the proteoglycan in the nucleus with intact annulus acts like an inflated car tire and helps in uniform distribution of load across the end plate. In a degenerated disc, the structure of the nucleus changes to a nonhomogeneous mixture of fragmented and condensed collagen, areas of fluid, and on occasion, areas of gas. Isolated fragments of annulus or end plate may add to the loose fragments inside the disc (28). The nucleus becomes depressurized and an increasingly larger load is transmitted through the annulus, which leads to splitting and inward folding of the

annulus (29). The central area of the end plate overlying the depressurized nucleus now transmits lesser load, and corresponding end-plate changes, such as destruction and thinning of the trabeculae and thinning of the cartilaginous end plate (30,31), are noted in this area.

### ***Mechanical Back Pain Related to Posture and Activity***

The abnormal distribution of load across the disc space following disc degeneration as explained previously may cause baseline mild to moderate pain or discomfort. In the degenerated disc the principal area of load transmission becomes dependent on posture. In flexion, the anterior annulus bears major component of the load, while in extension the posterior annulus bears the major component. The abnormal high load transmission through the various areas of the annulus with changes in posture may explain the activity- and posture-related mechanical back pain.

### ***Acute Episodes of Pain and “Stone in the Shoe” Hypothesis***

It seems most likely that the acute episodes of back pain must be related to a movement of tissues within the disc. In a degenerated disc, the fragments of nucleus, end-plate cartilage, or annulus may move under the end plate, and become areas of high spot loading depending on their position within the disc. The best analogy for this theory is the “stone in the shoe,” a concept proposed by Mulholland (27). When a stone moves under the heel, it causes high spot loading and pain, similar to an acute exacerbation of back pain. When the fragment shifts, the pain may subside. Manipulation of the lumbar spine by a chiropractor may, on occasion, dislodge the fragment from its weight-bearing position, bringing an immediate relief of acute pain (27).

McNally and Adams (32) demonstrated the nature of load distribution across the normal and degenerated disc. Disc pressure profilometry studies in cadaver spine shows that in the normal disc the load is evenly distributed, but in degenerated disc the nucleus is depressurized, higher load is transmitted near the peripheral annulus, and there are irregular areas of high spot loading. A subsequent *in vivo* study established that abnormal pressure profiles correlate with abnormal discograms with positive pain provocation (33).

## **THE RATIONALE AND PRINCIPLES OF DYNAMIC STABILIZATION**

If the primary cause of back pain is abnormal load transmission, the aim for treatment should be unloading the disc. In particular, the abnormal high spot loading and abnormal high load transmission through the annulus should be prevented. Movement should be preserved since the transport of nutrients and metabolites in the disc is dependent on movement (34). However, any abnormal

**FIG. 38-1.** The pressure tracing from the center of the disc in cadaver lumbar spine during flexion and extension movement. Normally (*N*) the pressure is lowest during the early phase of extension and rises both during flexion and extension. Following Graf ligament application (*G*), the pressure was raised at neutral position. Following application of FASS system (described later) with moderate degree of compression by the ligament (*F-1*), the disc was unloaded during flexion but not during extension. When the FASS system was applied with larger compression force by the ligament (*F-2*), the system became rigid in flexion and unloaded the disc further, indicating a possibility that such a system would eventually fail. It should also be noted that with the FASS system there was very little effect on disc unloading in extension.

range or direction of motion may secondarily cause areas of spot loading, and therefore should be prevented.

The pertinent questions in the dynamic stabilization therefore are (a) how much disc unloading; (b) how much control of motion would be desirable; and (c) in the long-term, how can fatigue failure be prevented, in view of constant movement of the stabilized segment. Pseudarthrosis may lead to failure of rigid implant, but a flexible implant should be able to accommodate the movement without failure.

The fatigue life of a dynamic stabilization system will depend on two factors: (a) load-sharing property, and (b) instant axis of rotation (IAR). The system should share the load with the disc and facet joints uniformly throughout the range of movement. Let us consider arbitrarily that the system should bear around 30% of the load and allow the

remaining 70% of the load to be transmitted through the disc and facet joints. If at any time during the range of motion the implant system has to bear near 100% of the load, and unload the disc fully, the system would eventually fail (Fig. 38-1). Secondly, each spinal motion segment has an optimum IAR, depending on the anatomy of the disc and the facet joints. Similarly, every dynamic stabilization device has an optimum IAR, which can be determined in laboratory, when the system is implanted in two polyethylene blocks representing vertebral bodies, not connected by the disc or facet joints. If there is a mismatch in the location of the IAR of the motion segment and the device after implantation, they will tend to fight against each other during motion. This will lead to abnormal high stress to the device and the implant-bone junction, leading to the failure of the instrumentation in the long run. The ideal dynamic stabilization device should be a load-sharing device throughout the range of motion, and have an IAR close to that of the motion segment.

The various dynamic stabilization systems described in the literature are all posterior implants (35–43). Most of these devices aim at restriction of some motion but do not describe the mechanism of action or extent of disc unloading. Table 38-1 provides a classification of the currently described dynamic stabilization devices.

### The Interspinous Distraction Devices

These are floating devices (i.e., not rigidly connected to the vertebrae). This avoids the possibility of loosening, a major concern for any implant that would have to survive against motion. The primary indication for interspinous distraction devices is degenerative spinal stenosis with neurogenic claudication in an older adult patient. By causing distraction between the spinous processes at the stenotic

segment, an interspinous distraction device unfolds the buckled ligamentum flavum and posterior annulus, thereby relieving the stenosis. The device holds the segment in relative flexion, a posture adopted by these patients to relieve their symptoms. The posterior distraction may unload the facet joint joints and the posterior part of the disc. However, kyphosis of the segment may increase the load in the anterior part of the disc and these devices may not be suitable for primarily discogenic back pain.

**FIG. 38-3.** The Wallis implant consists of polyetheretherketone interspinous spacer, anchored in its place by wrapping two woven Dacron ligaments around the spinous processes of the adjacent vertebrae under tension. (From Sengupta DK. Dynamic stabilization devices in the treatment of low back pain. *Orthop Clin North Am* 2003; 35(1):43–56, with permission.)

Minns and Walsh (35) described silicone interspinous spacers, which on biomechanical testing in the cadaver spine showed unloading the disc and correcting sagittal plane imbalance of the spine. No clinical application of this system has since been described by the authors. A titanium interspinous distraction device, X-Stop (Fig. 38-2) has been described by Lindsey et al. (SFMT, Concord, CA) (37). These are typically indicated for older adult patients with spinal stenosis presenting with neurogenic claudication. Senegas et al. (36) described an interspinous spacer made of polyetheretherketone (PEEK), “the Wallis implant” (Fig. 38-3), which is held between the spinous processes with Dacron tape. The addition of the Dacron tape provides further restriction of motion. The authors have advocated this system for treatment of early disc degeneration.

### The Interspinous Ligaments

These devices are applied directly to the vertebrae, without using any metal anchorage. There is no rigid component to share the load. These devices do not unload the disc or the facet joint. Their primary mechanism of action is by limitation of the range of motion.

Caserta et al. (38) reported their experience of using elastic ligament using alone or to supplement the segment adjacent to fusion (Fig. 38-4). The authors have used the

**FIG. 38-4.** The elastic interspinous ligament as described by Caserta et al. Peroperative picture of L4-5 elastic stabilization following rigid fixation of the L5-S1 segment. (From Caserta S, La Maida GA, Misaggi B, et al. system in 82 cases since 1994 and described encouraging results. Unfortunately, their report does not describe any detail of the implant material or the clinical results. Garner et al. (39) described a tension-band device, the Loop System (Spinology, Inc., Stillwater, MN), which consists of a braided polyethylene cable for stabilization of the spine across the spinous processes. The polymer cable provides high fatigue strength, in addition to tensile strength similar to that of metallic cables (Fig. 38-5).

#### Ligaments across Pedicle Screws

These devices are designed to be anchored to the vertebral bodies through the interface of pedicle screws. A fabric ligament connects the screw heads to restrict the motion of the spinal segment. In addition to the ligament, some of these devices may have a semirigid component.

The Graf ligament (Neoligaments, Leeds, UK), described by Henry Graf in 1989 (40), is the most commonly used device in this group (Fig. 38-6). This system consists of a pair of Dacron ligaments applied to the pedicle screws with a predetermined compression force. It immobilizes the spine in lordosis and locks the facet joints into full extension. No biomechanical study on the effect of this system has been published by the inventor. The system restricts motion but does not unload the disc. An independent biomechanical study shows that, in fact, it increases the load in the posterior part of the disc and

**FIG. 38-6.** The Graf ligament system (Neoligaments, Leeds, UK), applied between pedicle screws at L4-5 and L5-S1 segment in saw-bone. (From Mulholland RC, Sengupta DK. Rationale, principles and experimental evaluation of the concept of soft stabilization. *Eur Spine J* 2002;11[Suppl 2]:S198–205, with permission.)

the annulus (45). The Graf ligament has been used by several independent surgeons in Europe and Asia, who reported with clinical success comparable to that of fusion (45–51). The proposed clinical indications include back pain due to segmental instability, to supplement a direct repair of low-grade spondylolisthesis, and in combination with fusion to stabilize an adjacent segment. In the author's experience the Graf ligament was found to be most useful for stabilizing multisegment disc disease in younger patients, where fusion has obvious disadvantages. One common complication with the Graf ligament is postoperative leg pain due to narrowing of the foramen or buckling of the posterior annulus secondary to hyperlordosis; a prophylactic decompression of the nerve roots has been recommended in these situations. The initial encouraging clinical results tend to deteriorate during next 2 years of follow-up (45) and the long-term results have been reported to be disappointing compared to fusion (52). This is probably because the Graf ligament increases the load in the posterior part of the disc and the facet joints causing accelerated degeneration and also that the ligament stretches over time and becomes ineffective (52).

The Dynesys (the dynamic neutralization system [Centerpulse Spine-Tech, Minneapolis, MN]) was described by Gilles Dubois (41) in 1994. The system consists of titanium alloy (Protasul 100) pedicle screws, polyester (Sulene-PET) cords, and polycarbonateurethane (Sulene-

**FIG. 38-7.** The Dynesys system consists of pedicle screws, connected with a fabric cord, passed through the cylindrical spacers between the heads of the pedicle screws. (From Mulholland RC, Sengupta DK. Rationale, principles and experimental evaluation of the concept of soft stabilization. *Eur Spine J* 2002;11[Suppl 2]:S198–205, with permission.)

PCU) cylindric spacers (Fig. 38-7). The pedicle screw heads are connected by a cord under a given tension similar to the Graf ligament. The cord is threaded through the hollow cylindric spacers between the pedicle screws, which prevents excessive compression between the screw heads by the cord. The stabilizing cord carries tensile forces and the spacers resist compressive forces. The purpose of the system is to establish a mobile load transfer and control motion of the segment in all planes.

The biomechanical testing of the Dynesys system is mostly limited to fatigue testing of the whole construct and determining biocompatibility of the nonmetallic components. In a recent biomechanical study on cadaver spine, the Dynesys system was found to provide greater flexibility in extension and rotation but similar stiffness in flexion and lateral bending as compared to rigid fixation (53). There is no data available for the load-sharing characteristics of the spinal motion segments with the Dynesys system.

The initial clinical results in a multicenter trial have been encouraging and the device was found to be safe (41). However, unlike the Graf ligament, screw loosening was observed in seven cases. Early surgical intervention was needed in four cases, and late surgery was needed in

five cases in the same segment and in seven cases for adjacent segment disease.

The distraction between the pedicle screw heads by the Dynesys system may force the segment into kyphosis and increase the load in the anterior part of the disc. The spinal extensor muscles may be able to restore the lordosis of the segment by distracting the disc space and unloading the disc. This will force the spacers to act as a load-bearing fulcrum. Therefore, the lordosis and load sharing by the plastic cylinder depends very critically on distraction produced by the implant, and on the ability of the patient to achieve lordosis with the extensor muscles (27).

The Fulcrum-Assisted Soft Stabilization (FASS) system (Fig. 38-8A, B) was introduced (42) to address what was perceived as disadvantage by the author of the Graf system. These include posterior compression leading to narrowing of the foramen and increased load over the posterior annulus.

In the FASS system a flexible fulcrum is placed between the pedicle screws, in front of the ligament to distract the posterior annulus. A fabric ligament, preferably of elastic material, placed posterior to the fulcrum, applies a compressive force across the pedicle screws and maintains lordosis. The fulcrum transforms this posterior compression force into an anterior distraction force, which distracts and unloads the disc, independent of muscle action. The degree of disc unloading depends on the relative tension and compression produced by the fulcrum and the ligament. For a given distraction by the fulcrum, the higher the compressive force applied by the ligament the greater would be the disc unloading. Laboratory experiments on spine models and cadaver spines demonstrated that, as greater unloading of the disc was achieved by adjustment of the tension in the ligament and the fulcrum, the system shared higher load, and the motion segment lost flexibility (42). An undue stiffness of the system may be unphysiologic and may cause early loosening of the screws or implant failure. The other disadvantage of the FASS system was that the polytetrafluoroethylene (PTFE) fulcrum was solid and although flexible from side to side, was not compressible along its long axis. The fabric ligament was also not elastic. The combination of such a fulcrum and ligament leads to a gross limitation of flexion, but almost no limitation in extension. Consequently, disc unloading was greater in flexion but very little in extension (Fig. 38-1). A second generation of the FASS system was tested, where the fulcrum was made up of a compressible titanium spring, but the ligament was the same. This spring-based FASS system unloaded the disc and resisted flexion and extension more uniformly throughout the range of motion (54). An ideal FASS system should consist of a flexible as well as compressible fulcrum, and an elastic ligament that would not creep significantly. Currently such a system is under development.

**Semirigid Metallic Devices across the Pedicle Screws**

Currently there is no semirigid metallic device for soft stabilization without fusion available for clinical use. There are a few such devices under development.

The Dynamic Stabilization System (DSS) system (43) (Spinal Concepts, Inc., Austin, TX) is presently

being tested in the laboratory. This system consists of a titanium spring connected to the vertebra with the pedicle screws. Two designs of the springs have been tested. The DSS-I system (Fig. 38-9A) consists of a “C”-shaped spring, 3 mm in cross-sectional diameter. The DSS-II system (Fig. 38-9B) consists of an elliptical coil spring of 3 to 4 mm in cross-sectional diameter. These

A

B

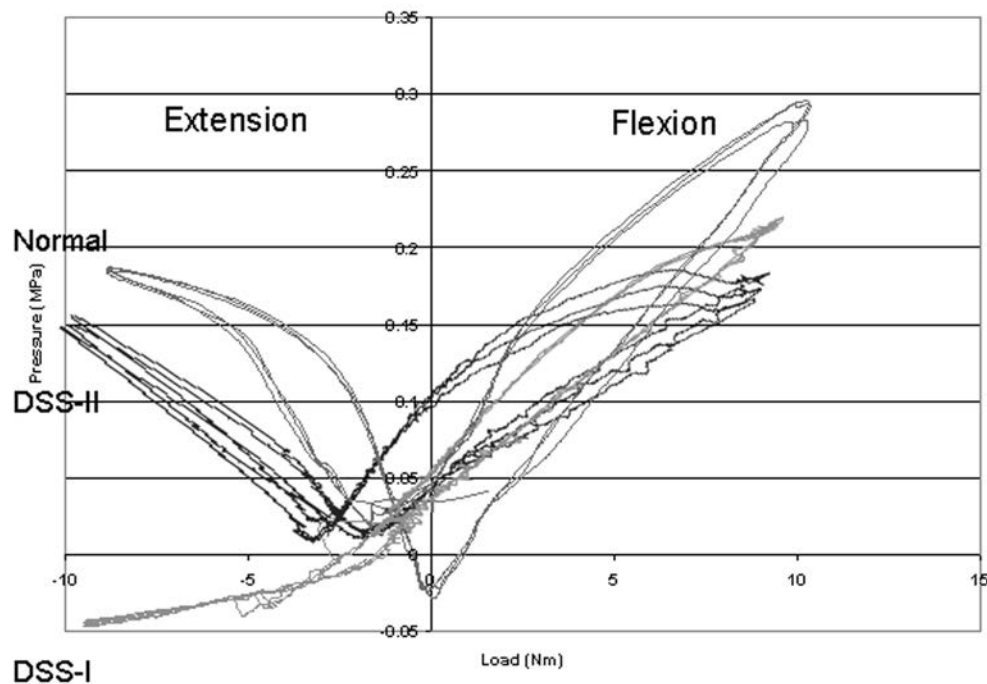

**FIG. 38-9. The Dynamic Stabilization System (DSS)** (Spinal Concepts, Inc., Austin, TX). **A:** DSS-I system consists of titanium spring in the shape of a “C”, the straight ends of which are attached to the vertebral body with the pedicle screws. The axis of rotation of this spring is located at the center of the curvature of the spring at C both during flexion and extension. **B:** DSS-II system consists of a titanium coil spring. The axis of rotation of this spring lies in front of the coil spring, at C0 location in resting position, moves forward in flexion to CF, and backward in extension to CE locations.

systems may be applied to the motion segment, with an appropriate degree of distraction and lordosis, to produce a mild disc unloading at resting position. The stiffness of the spring limits the range of motion and unloads the disc further during motion.

As explained earlier, the uniform disc unloading throughout the range of motion will require the IAR of the spring to lie close to that of the motion segment. The axis of rotation of the DSS-I system is located close to the center of the "C" (Fig. 38-9A). In the DSS-II system, the axis of rotation is located in front of the coil, and moves forward and backward during flexion and extension, respectively, resembling the translation of IAR of a spinal motion segment (Fig. 38-9B). Therefore, the DSS-II system unloads the disc more uniformly during flexion-extension motion. This has been established in a continuous record of disc pressure from the center of the disc in cadaver lumbar spine, following application of the two spring systems (Fig. 38-10). Normally, the disc pressure at the center of the disc is lowest at the early phase of extension, and rises both in flexion and in extension because the anterior part of the disc is compressed in flexion and the posterior part in extension. Biomechanical testing on cadaver spine

shows that the DSS-I system unloads the disc and restricts motion favorably during flexion. However, in extension the system forces the entire disc into distraction, resulting in greater restriction of motion and also lowest disc pressure at full extension. This is because the IAR of the DSS-I lies far behind that of the motion segment, and it becomes a full load-bearing structure toward the end of extension. This indicates that DSS-I is more likely to experience fatigue failure or loosening. The IAR of the DSS-II system translates like that of a normal spinal motion segment. Therefore, application of DSS-II system causes a more uniform disc unloading and restriction of motion in flexion and extension (Fig. 38-10).

Semirigid metallic devices across the pedicle screws have a unique advantage over the other dynamic stabilization devices. They may be applied with the initial pre-tension, to distract the disc, when disc unloading is intended. Conversely, it may be applied with an elastic compression force on the disc, when a fusion is intended. Therefore DSS-I may be used in conjunction with an interbody graft to keep the graft under compression, and to resist the instability in extension caused by excision of the annulus in anterior lumbar interbody fusion.

**FIG. 38-10.** The disc pressure tracing at the center of the disc in cadaver lumbar spine during flexion-extension movement, with 10 Nm pure moment, in a 6° freedom spine tester. Normally the pressure rises both in flexion and extension and is lowest during the early phase of extension. Following stabilization with DSS-II system the disc was partly unloaded both in flexion and extension, because of uniform load sharing with the disc. Following DSS-I stabilization the disc was partly unloaded in flexion, but fully unloaded in extension, which indicates that the implant becomes a fully load-bearing structure in extension, and therefore is more likely to experience fatigue failure or loosening.

## SOFT STABILIZATION AS AN ADJUNCT TO DISC PROSTHESIS

Prosthetic disc replacement is an equivalent of a partial joint replacement. In the presence of significant facet joint arthritis, disc replacement may not relieve pain. When radicular pain warrants decompression involving partial facetectomy, prosthetic disc replacement may destabilize the motion segment. A posterior dynamic stabilization system may add the necessary stability for disc prosthesis to work in this situation. In effect, addition of a posterior dynamic stabilization system may convert disc replacement into a total joint replacement.

## SOFT STABILIZATION AND DISC REPAIR

If a favorable environment may be created in the motion segment by unloading the disc and permitting near normal motion, the disc may be able to repair itself. Gene therapy in degenerative disc diseases, either by promoting enzymes to produce proteoglycans, or by preventing enzymes like proteases that damage the disc, is an emerging technology with much promise. Soft stabilization may further enhance the reparative process activated by the gene therapy.

## SUMMARY

In summary, dynamic stabilization appears to have an important role in the treatment of the degenerative lumbar spine. Fusion of one or two motion segments does not make a significant difference in the total range of motion of the lumbar spine. However, preserving flexibility of a motion segment may prevent adjacent segment disease. Dynamic stabilization is more physiologic and may deliver a better clinical outcome in chronic low back pain than fusion. Additionally, it may permit disc replacement, even when facet joints need to be excised. If a favorable environment is created in the motion segment by unloading the disc and permitting motion by dynamic stabilization, the disc may be able to repair itself or may supplement reparative potential of gene therapy.

Despite all these bright prospects, a cautious approach is recommended before accepting any new implant system. The implant for fusion only has to serve a temporary stabilization until fusion takes place. Implant loosening is not uncommon in the presence of pseudarthrosis. After soft stabilization, the implant has to provide stability for an indefinite period, and also stay anchored to the bone despite allowing movement. This sounds like a daunting task. This may only be possible if the dynamic stabilization device functions only as a load-sharing device throughout the range of motion and does not become a load-bearing structure at a certain range. To achieve uniform load sharing and disc unloading, the instant axis of rotation of the implant has to lie close to that of the

motion segment. Any mismatch between the kinematics of the implant system and the motion segment would result in an early implant failure or loosening. Therefore, the need for a strict bench test in the laboratory cannot be overemphasized. The few dynamic stabilization systems that have been used clinically have been reported to produce clinical outcomes comparable to that of fusion. No prospective randomized controlled trial has been reported yet, which is essential for the practice of evidence-based medicine.

## CHAPTER 39

# Lumbar Artificial Disc Replacement: Rationale and Biomechanics

Geoffrey M. McCullen and Hansen A. Yuan

---

Stability of the vertebral motion segment is dependent upon the structural integrity of the disc, facet joints, and the musculoligamentous complex. Intervertebral discs transmit 85% of the axial load and provide rotational/translational support and shock absorption (1,2). In a standing position, the intradiscal pressure at L3-4 is 1,000 N, increasing to 3,000 N when sitting, leaning forward, or carrying 20 kg (3,4). The estimated number of walking cycles a person performs is approximately 2 million per year (5). Each walking cycle loads the disc 150 to 1,250 N in compression and -40 N to +450 N in shear (5). The estimated number of lifting cycles is 125,000 per year, each producing an estimated compressive load between 200 and 2,250 N (5).

The magnitude and frequency of such imposed loads on the spinal motion segment will inevitably lead to wear and degenerative changes over time. Three sequential clinical and biomechanical stages of spinal degeneration have been proposed: dysfunction, instability, and stabilization (6,7). Segmental motion increases with the severity of disc degeneration (8) and facet degeneration most typically follows (9,10). Segmental axial rotation motion increases with the degree of cartilage degeneration within the facet joints (8). Stabilization occurs with advanced disc collapse associated with marked end-plate sclerosis and osteophytosis.

### **RATIONALE FOR THE ARTIFICIAL DISC**

Spinal arthrodesis significantly alters the biomechanics of the spine and results in an increased compensatory motion and mechanical loading in the adjacent free segments, particularly within the facet joints (11-15). Changes in the adjacent segments become more pronounced as the fixation range extends and as the rigidity of the construct increases (13,16,17). A 45% increase in intradiscal pressure occurs adjacent to a fusion (17,18).

Elevated intradiscal pressure acts to alter the diffusion characteristics of nutrients into the disc (19,20) and leads to biochemical changes including an elevation of type 1 collagen and a decrease in proteoglycan chondroitin sulfate, type 2 collagen content, and water content (2,21). Single photon emission computed tomography imaging 4 years after lumbar fusion demonstrates 62% with increased uptake within the vertebral bodies and facet joints in the free motion segment adjacent to the fused segment (22). Symptomatic juxtafusion degeneration is estimated to occur in 35% of postfusion patients (23).

Discectomy adversely affects the mechanical properties of the segment and alters coupled motions within adjacent segments (24,25). The level above a discectomy experiences an increased anterior-posterior translation in flexion and increased lateral translation with lateral bending irrespective of the amount of disc removed (24). Removal of the nucleus from the disc causes the inner margins of the annulus to bulge inward rather than outward during loading causing delamination of the fibers and further degeneration (26-28). Subtotal discectomy induces significantly less abnormal motion than total discectomy in all loading modes (24,25).

The aim of an artificial disc is to decrease pain, provide stability while maintaining near-physiologic motion, and diminish the likelihood of adjacent-level degenerative cascade. Two artificial disc interventions have evolved: (a) a total disc replacement (nucleus and annulus) and (b) a nucleus substitute. Many designs have been suggested. Few devices have been analyzed in biomechanical or clinical studies.

### **TOTAL DISC REPLACEMENTS**

Total disc replacements are used to treat degenerative disc disease when removal of all possible sources of discogenic pain, including the annulus, is desired. The

elective indications for a total disc replacement are single- or double-level degenerative disc disease, juxtafascia degeneration, and postdiscectomy axial pain that have failed a significant trial of nonoperative care. Absolute contraindications include: local or systemic presence of tumor or infection; osteoporosis (dual energy X-ray absorptiometry T-score less than  $-2.5$ ); obesity (body mass index: weight (kg)/height (m) greater than 40); overlying thoracolumbar kyphosis; spondylolisthesis (greater than grade 1); disabled posterior elements unable to contribute in load-sharing with the prosthesis; and facet osteoarthritis and facet-mediated pain patterns (Table 39-1).

The natural spine triple joint complex provides six degrees of freedom: (a) compression, (b) distraction, (c) flexion, (d) extension, (e) lateral bending, and (f) rotation. For the total disc replacement, the degree of “constraint” refers to the relative range of motion of the prosthetic joint compared with the healthy intact joint within each of these degrees of freedom (5,29). An “unconstrained” device provides no mechanical restraint or limit. An “under-constrained” device imposes limits to motion outside of the naturally occurring constraint of motion. With a “critically” constrained implant, motion is allowed within the physiologic range but blocked beyond. The “over-constrained” prosthesis prohibits natural motion by imposing limits within the normal range of motion.

Many current total disc devices are rotationally unconstrained and require intact posterior elements (facets and musculoligamentous complex) for load sharing and biomechanical stability. Over time, such a device risks overloading, injury and degeneration of the posterior elements, particularly the facets. Alternatively, designs with rotational over-constraint would off-load the facets at the expense of increasing stress at the implant-host interface. In addition, the majority of current devices have high compressive stiffness (over-constraint in axial compression) resulting in decreased shock-absorbing capacity and increased risk of vertebral body fracture with significant loading.

All total disc replacements are implanted through anterior open approach (transperitoneal or retroperitoneal). During implantation, the anterior longitudinal ligament

and the anterior annulus are excised. These two anterior ligamentous structures provide a balanced tensile resistance to rotation on the opposite side of the center of rotation from the facets (30). Methods of retaining or reconstructing the anterior longitudinal ligament may lead to restoration of normal load sharing and segmental stiffness (30). Ligament tensioning is the key to restoring segmental sagittal balance. Restoring the “normal” disc height can cause over-stretching of the spinal ligaments that would limit ultimate segmental motion. To avoid over-distraction, it is advisable not to increase the height of a degenerated disc by more than 3 mm (31).

The total disc implant requires support from the peripheral cortical shell of the vertebral body. The end-plate periphery is stronger while the center is weaker (32,33). The device end-plate “foot print” should cover the largest possible area of the vertebral end plate for optimal load distribution and to decrease the formation of heterotopic ossification occurring at the end-plate margins.

Improvements in material and design specifications are leading slowly toward the ideal artificial disc (Table 39-2). Material properties to be considered are cytotoxicity, fatigue strength, and the modulus of elasticity. The design must attempt to approximate the natural disc dynamics, plan for compatibility between materials, use safe insertion technique, and have a reliable fixation between host and implant.

## Metal Devices

The primary advantage for using an all-metal total disc replacement is the optimal fatigue strength. Biocompatibility has been shown in other orthopedic applications including joint arthroplasty. Designs include the springs with hinge and the ball-in-socket.

Kostuik has developed a device that uses two springs coiled between plates with a posterior hinge allowing flexion and extension (34) (Fig. 39-1). This device allows  $15^{\circ}$  to  $20^{\circ}$  of axial rotation in the sagittal plane,  $3^{\circ}$  of lateral bending, and less than  $1^{\circ}$  of axial rotation (5). The hinge pin has a decreasing diameter as the ends of the pin are approached. This feature, combined with elongated holes in which the pin rotates, is intended to allow a small amount of rolling lateral rotation ( $3^{\circ}$  to  $6^{\circ}$ ) (5). The springs sit in pockets that are designed to minimize off-axis loading and provide for a mechanical stop to prevent the springs from being loaded to the point that the coils touch (5). The springs are made of titanium alloy and are designed to provide adequate stiffness in both flexion and extension with a combined resistive torque in sagittal plane rotations of 2.24 N per degree (5). The springs have been successfully tested to more than 100 million full deflection cycles without failure (5). Hot isostatically pressed cobalt chrome alloy, with high carbon content to improve wear characteristics, is employed in the remain-

der of the device. Vertically projecting tabs are placed at the front and side of the plate members through which screws are placed for fixation. Using different metals, galvanic corrosion is a concern but minimal corrosive issues have been seen in short duration animal models (5). In a sheep model, with histologic analysis at 6 months, fibrous tissue does not grow between hinges or around coils (35). If such an in-growth were to occur, it would be expected to significantly interfere with the disc mechanics.

Reminiscent of hip arthroplasty, a prosthetic device shaped as a ball and socket has been proposed (36) (Fig. 39-2) and has subsequently been redesigned. The Maverick (Medtronic, Sofamor Danek, Memphis, TN) is made entirely of cobalt chrome and is axially rigid. There is no inherent rotational stiffness (unconstrained). Finite element analysis (FEA) has predicted that surgical variables will modulate the loads transmitted through the posterior elements after implantation (30). When the Maverick is placed anteriorly, the FEA predicts that facet loads will increase 2.5 times. A Maverick implanted posteriorly within the intervertebral space will successfully unload the facets in axial compression.

FIG. 39-1. Kostuik's all-metal device with two springs coiled between plates with a posterior hinge allowing flexion and extension (34).

### Nonmetal Devices

Whereas the principal advantage of metals is fatigue strength, the primary benefit of using nonmetals such as rubber and the elastomers (silicone, polyurethane, polyethylene) is the biomechanical similarity to the natural disc (37). By using a material with a lower modulus of elasticity, it is easier to replicate disc dynamics, attenuate shocks, and distribute loads evenly across the end plates. Difficulties, however, arise when attempting to develop a long-lasting nonmetal component that has a stable host-device interface. In addition, a polymer disc prosthesis that has optimal rigidity in axial compression may possess insufficient torsional rigidity. Alternatively, a polymer disc that is suitably rigid in torsion frequently becomes too rigid axially (38). Polymers do not allow the defining of a stable center of rotation for a disc implant. Lastly, delamination commonly occurs between polymer materials.

In 1975, Stubstab and Urbaniak introduced a total disc constructed entirely of synthetic nonmetal materials (39). Silicone or other elastomers such as polyurethane were formed into the general kidney shape with a fluid-filled

FIG. 39-2. All-metal ball-and-socket design by Salib (36).

core between flat superior and inferior elastomeric plates. Simulating the annulus, the device was covered by a weave of Dacron fibers creating pores for tissue ingrowth. This device has been implanted into eight chimpanzees followed for one year (40). Erosion and reactive end-plate bone formation have been attributed to an unstable host-implant interface.

Lee and Parsons (41,42) have designed what has been referred to as the “New Jersey disc” (Fig. 39-3). Two material designs have been described. In the first, a soft elastomer central core is surrounded by a fiber-reinforced polyurethane (12 layers of Dacron with alternating multidirectional pattern:  $-45, 0, -45$ ). In the second, the core is surrounded by a nonfiber reinforced polymer, C-flex (polysiloxane-styrene-ethylene-styrene-butylene) (Concept Polymer Technologies, Clearwater, FL) (38,43). Two stiff end plates using elastomer or hydroxyapatite frame the disc. This disc has been studied both *in vitro* and in finite element models (43,44). Questions remaining for the New Jersey disc include: material biocompatibility, fatigue, and wear resistance; and the adequacy of short- and long-term implant fixation.

The “3-DF” disc is a three-dimensional fabric woven with an ultra-high-molecular-weight polyethylene (UHMWPE) fiber and a surface spray-coated with bioactive ceramics (45,46). Made of one material, the device avoids a composite interface. No changes in biomechanical parameters have occurred after 2 million loading cycles with compressive loading of 200 N (45). Creep-relaxation testing has demonstrated a viscoelastic strain-time curve almost identical to the normal intervertebral disc (45). The “3-DF” device has been studied using an *in vivo* sheep model (46). Highlighting the problems inher-

**FIG. 39-3.** The New Jersey disc designed by Lee et al (41). A soft, central elastomer core is surrounded by either a fiber-reinforced polyurethane or a nonfiber-reinforced polymer. Two stiff end plates using elastomer or hydroxyapatite frame the disc.

ent in animal models, complete removal of the end plates was required in order to fit the 10 mm artificial disc. This created a different implant-host interface than is clinically intended. The segmental biomechanics and interface histology were evaluated at 4 and 6 months. Implant displacement without complete dislodgement was noted. Those devices implanted with temporary internal fixation (Kanada one-rod Smooth Rod system) were firmly in place and demonstrated a successful bony bonding to the host. Work is now being directed toward the creation of a supplemental bioabsorbable spinal fixation device.

### Combination Metal and Nonmetal Devices

To overcome the shortcomings found when using metals or nonmetals alone, designs have combined the materials. Most commonly, this has taken the form of a metal-polymer-metal sandwich disc. The metal tray is employed to improve fixation with spikes, tabs with screws, or porous coating for bony ingrowth. With the component thus stable and fixed, the central polymer provides the needed flexibility.

In 1991, Steffee developed the Acroflex disc (DePuy, Acromed Corporation, Cleveland, OH) (47). This disc replacement consists of a hexane-based, carbon black-filled, polyolefin rubber core vulcanized to the two titanium plates. Fixation is accomplished with a porous coating promoting ingrowth and four 7-mm cone-shaped posts that extend into the vertebral body. A significant subsurface shear is experienced at the rubber-metal junction producing failures with fracture of the rubber core (48).

The ProDisc (Spine Solutions, Inc., New York, NY) is a cap-cup matching articulation designed by Marnay (49) (Fig. 39-4). The end plates are made of a cobalt chrome molybdenum alloy with a central fixation keel projecting through the vertebral end plates. The convex bearing surface is made of UHMWPE that snaps into the inferior end plate. The device has a fixed center of rotation and is critically constrained in flexion-extension, unconstrained in rotation, and over-constrained in translation.

Buettner-Janz and Schellnack developed the Link SB Charité disc (Waldemar LINK GmbH and Co., Hamburg, Germany) (Fig. 39-5) (50). Since the first design in 1984, three revisions have been made. The current device (Link SB Charité III) includes two symmetric end plates made of cobalt chromium alloy. Immediate fixation is by anchoring teeth projecting from the outer end plate. For bony ingrowth, the end plates are porous coated with two layers of thin sintered titanium beads (pore size ranging from 75 to 300 microns) covered by electrochemically bonded hydroxyapatite. A primate model has demonstrated ingrowth over 48% of the end-plate surface (51).

The inner end-plate surface contour is an oval-shaped concave surface that articulates with a central high-density polyethylene core [modulus of elasticity 420 to 1,200

**FIG. 39-4.** The Marnay device (49). **A:** The polyethylene cups snaps into the inferior end plate. The device is unconstrained in axial rotation. **B, C:** The device in flexion and extension with movement occurring around a fixed center of rotation.

mega Pascals (MPa)] (52). The device allows 20° of motion in flexion-extension and lateral bending (underconstrained). There is no limit to motion in axial rotation (unconstrained) (53). Hysteresis (the conversion of strain energy into heat formation during cyclic loading) of the polyethylene occurs at loads less than 4.2 kN with incipient irreversible polyethylene deformation occurring with loads between 6 and 8 kN (53).

With movement in flexion and extension, the polyethylene core moves: in flexion the polyethylene moves posteriorly and in extension it moves anteriorly. This changing of the instant axis of rotation (IAR) is meant to replicate the natural disc (52). Because of the changing IAR, the Link SB Charité disc needs to be placed poste-

**FIG. 39-5.** The SB Charité disc (50). **A:** Both top and bottom inner end-plate surfaces articulate with the central polyethylene. With flexion, the polyethylene moves posteriorly. **B:** In extension, the polyethylene moves anteriorly, changing the instantaneous axis of rotation. **C:** The device allows 20° of motion in flexion-extension and lateral rotation and is unconstrained in axial rotation.

riorly within the intervertebral disc space. Anterior positioning of the device will significantly decrease the available motion (52,54).

In a human cadaveric biomechanical study, the Link SB Charité prosthesis showed an average percentage increase in segmental axial rotational range of motion of 44% when compared to the intact control (55). The increase in axial rotation reflects the excision of the anterior longitudinal ligament required during insertion and the unconstrained nature of the disc in axial rotation. Flexion and extension range-of-motion between the in-

tact specimen and a segment implanted with the Link SB Charité disc were not significantly different. The disc preserved the normal mapping of segmental motion at the operative level and at the adjacent levels.

Clinically, postoperative segmental motion is equal to preoperative motion (54,56). The motion permitted by the implanted prosthesis appears to be determined by the extent of the degenerative changes in the adjacent structures such as the facet joints and neighboring spinal ligaments. The average postoperative range-of-motion for the SB Charité III is 9° of flexion and extension (52,54,56). At the L4-5 level 9.6° flexion, 3.4° extension, and 4° lateral bending motion has been reported (52). At L5-S1 these values are decreased with 6° flexion, 3.5° extension, and 3.2° of lateral bending (52). Clinical studies confirm that anterior device positioning decreases postoperative motion (54). Over-distraction causes excessive tightening of the posterior ligaments and decreases segmental motion. To obtain and maintain available motion, early postoperative motion is encouraged (54) (Table 39-3).

In published series, further surgery has been required in up to 24%, the majority for "pain control" as a result of ongoing or developing facet-mediated pain (56). Device dislocation/migration occurs in 2% to 6.5%, usually secondary to poor size selection (54,57). Eight percent of the devices have subsided most commonly because of an undersized device "footprint" (54).

## NUCLEUS REPLACEMENTS

There are two potential indications for nucleus replacement: (a) as an adjunct to discectomy (open and percutaneous nucleotomy), addressing the biomechanical alterations of discectomy; and (b) to relieve back pain resulting from early stage degenerative disc disease that has failed to improve with nonoperative means.

Nucleus substitutes should be made of biocompatible materials; restore intervertebral height and tension the annulus with normal end-plate load distribution; recreate the intradiscal hydraulic pumping mechanism for pressure modulation and nutrient delivery to the remaining

nucleus and the inner annulus; and demonstrate safe, possibly minimally invasive implantation with a revision strategy in cases of failure.

Nucleus replacement requires the satisfactory condition of the annulus and the vertebral end plates. Sufficient annular containment is essential to stabilize the device in the disc space and to avoid excessive motion that could lead to migration and an elevated rate of wear on end-plate or implant surface. When end plates are weakened by osteoporosis or Schmorl nodes or challenged by obesity (weight greater than 90 kg or body mass index greater than 30) subsidence of the implant into the vertebral body can occur.

Successful tensioning of the annulus will depend upon the implant modulus of elasticity and the implant/cavity conformity. The inward bulging of the annulus after nucleotomy is reversed by a nuclear implant with Young's modulus of elasticity of 3 MPa (range 0.2 to 40 MPa) (27). Restoration of intervertebral disc height with a nucleus replacement can best be accomplished if the starting disc height is greater than or equal to 5 mm. In late stage disc disruption, with failure of the annulus, end plate and facets, a nucleus replacement would certainly be ineffective. Annulus repair and methods to achieve annulotomy healing remain elusive.

Fernstrom developed the first nucleus replacement in 1966 (58). These devices were spheric, solid, stainless steel balls, up to 16 mm in diameter that were meant to serve as intervertebral spacers while allowing movement. Contact area with the vertebral bodies was small. No pressure modulation was possible with position change. The device did not restore the normal load distribution across the end plate and was ultimately abandoned because of implant migration or subsidence.

In the 1960s, work began with the injection of self-curing silicone and polyurethane into the disc space (3). The potential advantages of this technique were the minimally invasive, percutaneous route of insertion resulting in reduced annular injury and the *in situ* polymer curing that offered the possibility of obtaining good end plate-implant conformity. The problems encountered included: long polymerization reaction times; incomplete polymerization; exothermic reaction temperatures; high injection pressures; polymer containment; and the production of particulate wear debris (59). Subsequent efforts in nucleus replacement have been directed toward developing contained systems that allow a more reproducible fabrication and accurate prosthetic placement.

In 1988, Ray introduced the Prosthetic Disc Nucleus, or "PDN", (Raymedica, Minneapolis, MN) with dual disc cylinders resting side-by-side (60). In the original procedure, a trephine was used, from the posterior approach, to bore a passage into the center of the disc. After nucleotomy, the cylinders were slid into position and filled with a water-absorbing gel held within a semipermeable membrane. Prefilled devices have subsequently

replaced *in situ* fill of the cylinders. The outer device layer of the PDN is constructed with a flexible but inelastic polyethylene fiber jacket that constrains the ultimate swelling of the hydrogel.

The PDN implants have passed U.S. Food and Drug Administration guidelines for biologic safety, cytotoxicity, carcinogenicity and long-term animal implantation. Fatigue studies to greater than 50 million cycles under simulated physiologic loads (200 to 800 N) have been successful (61). After nucleotomy *in vitro* insertion of the PDN has restored the segmental mobility in all movement/directions (62).

The first PDN clinical trials began in 1996. Initially, the PDN used a hydrogel polymer, HYPAN 68 (polyacrylonitrile-polyacrylamide), which absorbs 68% of its weight in water. Early analysis indicated that this device was too rigid, promoting pressure concentrations on the cartilaginous end plate (61). In 1998, a change was made to HYPAN 80, which absorbs more water and thus is softer. A higher rate of implant migration with a 38% revision rate was recognized (61). Further changes in design and surgical protocol followed. PDN devices are now two differently shaped units: a tapered anterior unit and a rectangular posterior unit placed transversely and connected by tethering sutures (Fig. 39-6). To accommodate the two units the end-plate anteroposterior diameter must be 37 mm or greater (61).

For device containment, the annulotomy must be kept as small as possible with a sequential annular dilating technique rather than a cut entry. Using lateral decubitus positioning and a lateral retroperitoneal exposure,

**FIG. 39-6.** The PDN devices (62). **A:** Sagittal view. **B:** Axial view demonstrating a tapered anterior unit and a rectangular posterior unit placed transversely and connected by tethering sutures. The annulus and end plates must be in satisfactory condition.

Bertagnoli has developed the anterolateral transposoas approach (ALPA). The annulus is cut to create a hinged flap. The overlying psoas muscle covers the lateral annulotomy site, diminishing the risk of implant extrusion (63). A restricted postoperative protocol with the use of a brace for 6 weeks is recommended (63).

Moderate to severe end-plate remodeling, likely due to changes in load distribution, has been noted in some patients implanted with the PDN (63). Sixty patients with PDN have been followed with postoperative MRI (64). Six weeks postoperatively there is an increase in degenerative end-plate changes in 27% of the implanted levels (64,65). At one year, the incidence of such changes increases further to 70%. Advanced degenerative changes within the end plate at 1 year are seen in 7%. The clinical implications of these radiographic changes have yet to be determined.

Other nucleus replacements are emerging in various stages of early development. Bao has designed a polyvinyl alcohol (PVA) hydrogel nucleus replacement in the form of beads held within a retaining membrane (66) (Aquarelle Hydrogel Nucleus, Stryker/Howmedica, Mahwah, NJ). It is inserted in the dehydrated form, through a 5 mm cannula. Water, drawn from the surrounding tissues, fills the membrane to a 70% water content and the prosthesis nearly doubles in size. This *in situ* expansion creates an interference fit. Like the natural nucleus, the hydrogel replacement is able to absorb and relinquish water with changes in applied load. Biomechanical studies have confirmed restoration of disc function after hydrogel implantation (67,68). Preventing implant migration and extrusion remains a problem. The Newcucleus (Sulzer SpineTech, Edina, MN) is an elongated, elastic memory-coiling, spiral-shaped polycarbonate urethane (69,70). It is inserted into the disc through a cannula device to create a spiral coil of the material. The Prosthetic Intervertebral Nucleus, or "PIN" (Disc Dynamics, Minnetonka, MN) is a polyurethane balloon inserted in deflated form into the disc and then inflated with an incompressible liquid (71). The size and shape of the nucleus prosthesis can be significantly altered during implantation and regained or restored after implantation.

#### DEVICE LONGEVITY

The generation of particulate debris can occur as a result of wear and corrosion and should be expected any time an artificial disc implant is used. The accumulated magnitude of the debris over time and the resultant clinical sequelae after disc replacement has yet to be determined. In long-term patient outcomes for total knee and hip replacements, microscopic wear fragments have disseminated to the liver, spleen, and paraaortic lymph nodes (72). Local wear debris can incite a local cytokine-mediated [tumor necrosis factor- $\alpha$ , prostaglandin-E<sub>2</sub>, interleukin (IL)-1, IL-2 or IL-6] immunologic reaction

that causes destruction of bone at the prosthetic-bone interface (73). The optimal particle size to disseminate and to incite macrophages to release cytokines is 1 to 5 microns (72,73).

Among the metals implanted in the spine, titanium debris fragments appear to be the most reactive in eliciting a cytokine-mediated response (73,74). Polyolefin rubber compound particles have been generated *in vitro* and placed in subcutaneous pouches in rats and adjacent to the lumbosacral dura in sheep (75). A local foreign body reaction was created but no particle migration from the site of implantation was identified and no apparent local or systemic toxic effects resulted.

In a nonhuman primate study with the Link SB Charité III, histochemical assays showed no accumulation of particulate debris (no titanium, UHMWPE, or cobalt chrome) and no cytokines 6 months after implantation (51). The lack of long-term evaluation or anatomic differences including the absence of synovial fluid in the disc may be the reason why particulates have not been generated.

The SB Charité disc has more than 10 years of clinical use but no long-term clinical outcome studies. Neither osteolysis nor late loosening has been reported in clinical studies. It is a possibility that some cases will be identified with longer duration follow-up. Repeat anterior retroperitoneal approaches are fraught with potential hazard because of the development of a thick scar enveloping the spine and vascular structures. Therefore, when total disc devices fail, the safest revision strategy is a posterior spinal instrumented fusion.

## CONCLUSIONS

With innovations in materials and design, the artificial disc is becoming a reality. Optimal short-term clinical results will depend upon patient selection.

Poor clinical results are expected when disc replacement is applied to advanced degeneration (76). Long-term outcome will depend upon the ability of the device to replicate natural kinematics and to withstand the repetitive loads over time. Long-term clinical evaluations after disc replacement will be essential to identify the rate and extent of progressive degenerative change within the facet joints and the adjacent segments.

For accurate comparability between developing devices, biomechanical terminology and methodology for the artificial disc must become standardized. The optimal device constraint for particular clinical situations must be determined.

## CHAPTER 40

# Lumbar Disc Replacement: Current Model, Results, and the Future

Robert D. Fraser

---

---

More than 100 different designs for a disc prosthesis have been patented or described in publications (1) since Fernstrom first replaced the nucleus with a metal bearing ball in the late 1950s (2). Very few of these devices have been used clinically, however, reflecting the difficulty of translating the success of hip and knee arthroplasty to the spine. The prostheses that have been implanted in humans can be classified as (a) nucleus devices or spacers, (b) mechanical devices with moving parts, and (c) elastomeric implants that aim to reconstruct the normal elastic properties of the disc.

### NUCLEUS PROSTHESES

The nucleus replacement device used most extensively in humans is the Prosthetic Disc Nucleus, or PDN (Raymedica, Minneapolis, MN). This consists of a hydrogel pellet contained within a woven polyethylene jacket. The hydrophilic properties of hydrogel provide this device with the capacity to absorb fluid and expand. Hydrogel is a copolymer of polyacrylonitrile (non-hydrophilic) and polyacrylamide (hydrophilic); the ability to absorb and bind water is determined by the ratio of these polymers. The current design permits the pellets to absorb 80% of their weight in water, giving the PDN device the potential to restore or maintain disc height. The aim of the woven polyethylene jacket is to limit swelling and to minimize horizontal spreading (3).

The recommended technique involves the coronal placement of two parallel devices within the enucleated disc space, either by the posterior (hemilaminotomy) or lateral (transsoas) routes. The developers state that this device is not intended for use in cases of severe disc degeneration or where end plate defects are present (3).

Initial trials during the mid-1990s, with two implants placed side by side in a sagittal plane, demonstrated a high expulsion rate with 38% of subjects requiring revi-

sion (4). The PDN shape and surgical protocol were subsequently modified to minimize the extrusion rate, and further clinical trials are in progress. Encouraging results are claimed with the use of PDN (3–5), although in each paper details of the methodology are insufficient to permit critical review.

Other nuclear replacements implanted clinically include the Aquarelle (Stryker Howmedica, Mahwah, NJ), a polyvinyl alcohol material and the Newcleus (Sulzer Spine-Tech, Edina, MN), a polycarbonate urethane elastomer, but to date there are no published results of these devices.

Nucleus prostheses may be inserted through a relatively minimally invasive or potentially percutaneous approach. While this increases the appeal of the procedure, nucleus replacement does not address pathology related to the annulus or end plate, both of which may be important components of a painful degenerative process. Furthermore, nucleus devices are intended to work in conjunction with the annulus to restore the biomechanical function of the disc. To insert such a device, an annulus lesion must either be made or already exist. Although special dilators to minimize annulus damage have been used for the phase IV trials of the PDN, it is unclear whether the benefits of nucleus replacement will outweigh the effects of damage caused to the annulus.

### MECHANICAL DISC PROSTHESES

The prime aim of mechanical disc replacement is to restore the normal kinematics of the motion segment. The designs of two mechanical disc prostheses tested in clinical trials are based on the principle of low-friction polyethylene on metal articulations developed for total hip and knee arthroplasty. A third device, similarly designed on the basis of the success of prostheses developed for large synovial joints but with a metal/metal (chrome cobalt) interface and a posterior rotation axis, is being

tested in a multicenter clinical trial (6). In general these prostheses are intended to replace almost the entire disc, are inserted using an approach similar to an anterior lumbar interbody fusion, and rely on large spikes or fins plus bony ingrowth for stability against the vertebral end plates. Mechanical artificial discs lack elasticity and cannot replicate the normal compressive stiffness of the natural disc. Instead they depend on the restoration of a mobile lordosis to absorb compressive loads across the lumbar spine (7). Moreover their articulating surfaces provide little resistance to torsion, a function of the motion segment that is impaired by the necessary removal of most of the annulus.

Schellnack and Buttner-Janzen were responsible for the development of the first version of the Link SB Charité (Waldemar Link GmbH & Co., Hamburg) artificial disc in 1982 (8). Over the next five years there were two revisions of the design. Consisting of a biconvex polyethylene spacer articulating with two concave cobalt-chromium alloy end plates, the prosthesis allows rotation in all three planes. Changing centers of rotation are allowed by the sliding of the polyethylene core, similar to that which is achieved in mobile-bearing total knee replacements. First implanted in 1987, the latest model of the Link SB Charité has been used more extensively than any other disc prosthesis. Approximately 4,000 prostheses have been implanted (7); the report from the largest case series of 105 patients describes a satisfactory outcome with the procedure (8).

The ProDisc (Spine Solutions, New York, NY) was first described by Marnay in 1991 (9). It consists of a polyethylene cap articulating with two titanium alloy end plates. The cap over cup design of the metal-polyethylene-metal articulation permits motion in all three planes. Bertagnoli and Kumar reported on a series of 108 patients with follow-up ranging between 3 months to 2 years (10). In this, the only published paper on the outcome with the ProDisc, an overall success rate of 90.8% was claimed, increasing to 98% in patients considered to have "prime" indications.

### ELASTOMERIC DISC PROSTHESES

The attraction of elastomeric discs is their potential to replicate the elasticity of the normal human disc. Not only would it be feasible to restore the normal compressive stiffness of the natural disc, but also if firm attachments to the bony end plates could be achieved, it would provide resistance to torsion and shear.

With these goals in mind, Steffee designed the AcroFlex (DePuy, Acromed Corporation, Cleveland, OH) artificial disc using a polyolefin-based rubber core vulcanized between two titanium end plates. Not only did the rubber core provide range of motion, but it also enabled replication of normal disc elasticity. In theory, this design

should allow for better absorption of loads. However, this advantage of elastomers is offset by their potentially inferior wear characteristics as demonstrated by the relatively high rates of failure. In the original series of six patients, two were reported as failures due to debonding of the rubber core (11). A second-generation device, using a silicone core instead of rubber, was implanted in eight patients with one mechanical failure. All failures occurred at levels with increased stress, either due to adjacent fusion levels or scoliosis. The AcroFlex is now in its third generation of design, reverting back to the rubber core optimized with improved processing and bonding techniques, and refined indications for surgery. Although functional outcomes following implantation have been generally satisfactory, further trials with the third generation prosthesis were abandoned with the detection of early failure of the rubber core on thin-section computed tomography (CT) scans (12).

The thin-section CT scans used in the AcroFlex study also identified a significant number of patients with periprosthetic heterotopic ossification. Limiting range of motion may be another potential source of failure for any disc replacement. It is therefore recommended that future studies include the use of thin-section CT and relate this to range of motion on standing flexion and extension radiographs.

### BASIS FOR CURRENT INDICATIONS

For any spinal operation, including total disc arthroplasty, patient selection should be based on a careful consideration of many factors. A successful outcome is more likely to be achieved with the precise correlation of the patient's history, physical examination, and radiographic investigations, in conjunction with psychosocial and medical backgrounds. Bearing this in mind, indications were developed for a trial of the AcroFlex lumbar disc prosthesis (12). Only patients with one- or two-level symptomatic disc degeneration at either L4-5 or L5-S1 were included. Patients had to complain of disabling low back pain, with or without referral type leg symptoms that had been present for a minimum of 12 months and had failed to respond to nonoperative treatment. Furthermore, the symptomatic degenerative level had to be convincingly localized by provocative discography. For inclusion in the study discography had to demonstrate (a) internal disc disruption at the target level, (b) reproduction of the patient's typical pain at the target level, and (c) failure to reproduce typical pain at the control levels adjacent to the target level. Because of uncertainty about the long-term results only patients between the ages of 30 and 55 were considered (12).

The contraindications to disc replacement surgery are made up of technical and patient selection considerations. Patients should be excluded if there is a history of previ-

ous lumbar infection or an active infection elsewhere. Because disc replacement surgery does not address posterior element pathology, patients with spondylitic spondylolisthesis, significant facet arthritis, lateral recess stenosis, or central stenosis should be considered unsuitable. Technical considerations that impede or prevent disc arthroplasty include patients with a steep lumbosacral angle at the target level, osteopenia, previous abdominal radiation or vascular graft, and morbid abdominal obesity. Lastly, patient factors such as significant medical comorbidity, ongoing litigation or compensation issues, substance abuse, presence of three or more Waddell behavioral signs (13), or psychiatric illness may be the major factors influencing eventual outcomes. The presence of any of these factors should be regarded a contraindication to disc replacement surgery.

Despite the suggestion that in time disc replacement will be a solution for multilevel degeneration or degeneration adjacent to a fused segment, this has not been considered an ideal indication. Additionally, given the increased stresses placed on the prosthesis in a patient with structural scoliosis or adjacent-level fusion, such conditions are considered relative contraindications.

Bertagnoli and Kumar tried to correlate preoperative clinical findings to outcome with a view to formulating appropriate indications for disc replacement (10). They conducted a retrospective review of 108 patients who underwent total disc arthroplasty with the ProDisc prosthesis. The patients were separated into accordingly into four groups, those who were considered to have “prime”, “good”, “borderline”, or “poor” indications for surgery. Patients with a “prime” indication had a disc height greater than 4 mm, absence of facet joint arthritis, no adjacent-level degeneration, and intact posterior elements. Patients with adjacent-level fusions were considered to have “borderline” indications. While there appears to be a gradient of improved successful outcomes in patients with better indications, no statistical analyses were performed. However, it also seems that patients with “better indications” were those with minimal degeneration and they may well have achieved better outcomes no matter what form of treatment was employed.

## REPORTED CLINICAL RESULTS

In a critical assessment of the evidence related to lumbar disc replacement, Wai et al. (14) carried out a thorough search of both the Pubmed and Ovid Medline databases up to October 2002, and identified papers concerned with the current clinical use of disc prostheses. Their assessment, summarized in Table 40-1, recorded factors important to the outcome of disc replacement, namely: (a) restoration of disc function, (b) preservation of adjacent levels, (c) overall clinical function, and (d) complications. The follow-up for all papers reviewed

averaged just less than 2 years with the conclusions often based on patients followed up for a much shorter period.

Although a follow-up of 2 years is generally considered acceptable for publishing surgical results, it is quite inadequate when assessing the outcome of disc replacement surgery. This is particularly the case when assessing the safety of implants used for total disc replacement. Their large dimensions and location close to major vessels makes anterior low-lumbar revision surgery hazardous, particularly when this is performed for complications related to mechanical failure.

In their critical review, Wai et al. (14) found a wide discrepancy in the definitions of clinical outcome, many of which were poorly defined, with reported success rates ranging from 63% to 95% after disc replacement. Overall, these results are similar to those from case series reports for spinal fusion (15–21), and for common forms of nonoperative care (22–26). Certainly, randomized controlled trials, using validated and independent assessments of outcome and safety are necessary to establish the efficacy of disc replacement compared with the current standard of care. Clearly, because of the large influence on function of factors other than disc pathology, a major effect from disc replacement would be needed to reach statistically significant differences. The Swedish Lumbar Spine Study Group published a report of a randomized controlled trial on fusion for back pain (15). From the published data, Wai et al. (14) estimated that more than 500 subjects would be needed to determine a 10% improvement in outcome for a 2:1 study design with a power of 0.8.

Even though there may be no significant difference in clinical outcomes between fusion and disc replacement in the short term, the latter has the theoretical advantage of restoring the function of the motion segment, hence protecting the adjacent levels. Almost all of the published studies have described restoration of disc height and return of motion for both nuclear and total disc replacement surgeries (14). Although protection of adjacent disc levels is considered of prime importance to the rationale for disc replacement, only three studies have assessed this potential benefit. Cinotti et al. performed magnetic resonance imaging (MRI) on 10 patients from their original cohort of Link SB Charité III prostheses and found no adjacent level degeneration (27). As more than 75% of their study population has not been assessed, it is not valid to draw any conclusions from their report. In the report of their experience with the ProDisc, Bertagnoli and Kumar mention that 4.6% of patients developed radiographic evidence of adjacent-level degeneration within 3 to 24 months of implantation (10). With such a short follow-up and without a control group, it is unclear if this represents the natural history of disc degeneration or is significantly less than would have occurred had the patients undergone a lumbar fusion. Many investigations of

**TABLE 40-1.** Summary of published peer-reviewed clinical papers on disc replacement arthroplasty

Author/year	Disc	Sample size (no. of discs)	Months of follow-up (range, if stated)	Study quality	Restoration of normal mechanics	Preservation of adjacent levels	Clinical success	Complications
Enker, 1993 Griffith, 1994	Acroflex Charité SB III	6 93 (139)	40 12 (1–37)	— —	8° avg. ROM N/A	N/A N/A	66% success 65% improvement in back pain	33% implant failure 4.3% migration/ dislocation; 1% core failure

adjacent-level degeneration after fusion have used MRI or have longer follow-up times (28–31).

The work of Kumar et al. is the most similar in methodology to the study by Bertagnoli et al. but with a much longer follow-up period (32). They found an 8% incidence of radiographically determined adjacent-level disease in patients 5 years following lumbar fusion with a normal sagittal alignment. Furthermore, in an MRI study we carried out 10 years after anterior lumbar interbody fusion (28), the adjacent disc was found to be free of degeneration in 68% of cases. We examined the pattern of degeneration in the remainder of the lumbar spine, including the presence of skip lesions, comparing this with the reports of MRI findings in normal asymptomatic populations. Based on this comparison, we concluded that adjacent-level degeneration was determined more by constitutional factors than by the presence of a solid fusion.

Further challenging the ability of disc replacement to preserve the adjacent levels, a study by Zeegers found that 24% of patients required adjacent-level surgery within 2 years of having an SB Charité III prosthesis inserted (33). While this high incidence may represent a failure to adequately rule out adjacent-level pathology before performing the index procedure, it is much higher than any reported for lumbar fusion. In any event, there is clearly no evidence to date that disc replacement protects against adjacent level degeneration.

#### FOOD AND DRUG ADMINISTRATION STATUS

At the present time, the U.S. Food and Drug Administration (FDA) has not approved disc replacement devices for routine marketing, and currently the use of these devices is for investigational purposes only. To obtain approval for general use the manufacturer is required to demonstrate to the FDA's satisfaction that their prosthesis is as substantially equivalent (as safe and effective) to an already approved device. Specific guidelines concerning the indications, *in vivo* biomechanical testing, and clinical results of devices have been published for spinal implants (34).

Two separate multicenter, randomized controlled clinical trials are in progress in the United States under the FDA's Investigational Device Exemption. The SB Charité III is being compared with anterior interbody fusion using the Bagby and Kuslich (BAK) device, while the ProDisc is being tested against combined anterior and posterior fusion using pedicle screws and an interbody fusion construct (35). Both trials intend to recruit between 300 and 500 patients and the manufacturers hope to achieve FDA approval within the next few years. The initiation of a FDA-approved trial in the United States is pending. The PDN has been given approval by the Canadian Therapeutic Directorate to begin a clinical trial and three Canadian centers are recruiting patients for a prospective evaluation of the PDN (4).

It is expected that these trials will address short-term safety issues related to the prostheses and whether the clinical efficacy is similar to fusion at 2 years. As mentioned previously, these studies are unlikely to have sufficient power to detect a difference with fusion unless there is a large clinical effect. It is therefore essential that long-term follow-up of the studies be carried out to determine efficacy, the overall safety of the implants, and their ability to protect adjacent levels.

#### THE FUTURE OF DISC REPLACEMENT

It is the spectacular success of arthroplasty of the hip and knee that has continued to drive the development of artificial disc technology. Further enthusiasm has been generated by the demonstration that a number of prostheses have restored range of motion to the disc and by the clinical use of the Link SB Charité device for over 10 years. However, this measure of technical success and implant longevity does not necessarily mean that the future of disc replacement is certain. It is only if it can be shown in the long term to perform at least as well as fusion, without compromise from implant failure, heterotopic bone formation or excessive facet degeneration leading to stenosis, that the place of disc replacement will be finally assured.

From the reported results of case series described herein, it seems likely that current FDA trials will demonstrate short-term efficacy and safety, leading to approval of these devices for routine marketing. Because of anticipated demand, the expected FDA approval is likely to be followed by extensive and widespread clinical usage of these devices. Based on the experience associated with the release of other spinal implants as well as the knowledge gained from hip and knee arthroplasty, it will be only a matter of time before surgeons are confronted with problems created by implant failure. There is, however, one major advantage for the spinal surgeon compared with the hip or knee surgeon undertaking revision procedures for a failed prosthesis. Unlike surgery for the hip and knee, there is unlikely to be a great functional disadvantage in converting spinal arthroplasty to arthrodesis; moreover, it may be possible to circumvent the surgical site by retrieving the situation with a posterolateral fusion. However, when it is necessary to remove a large lumbar interbody device anteriorly, the proximity of the major vessels and other vital organs, the scarring from the original surgery, and the pathology associated with implant failure all combine to make the revision procedure extremely difficult and potentially disastrous (12).

Clearly the introduction of these devices into the community should be with caution. The current "gold standard" investigations for diagnosis of discogenic back pain, MRI, and discography have significant high false-positive rates. A large potential for misdiagnosis resulting in surgery for pain not arising from the disc exists; hence

the unsatisfactory outcomes often reported for treatment of discogenic back pain.

Combined anterior and posterior fusion has been promoted by many spinal surgeons for the management of back pain since it deals with many different potential pain sources, including not only the disc but also the ligaments and facet joints. In contrast, disc arthroplasty targets only the disc. It is, therefore, more vulnerable to the effects of misdiagnosis leading to the replacement of a nonpainful disc rather than dealing with the actual pain source. This is countered by the restoration of the functional spinal unit's range of motion. However, it is unclear whether the extra few degrees of range of motion offered by a disc replacement over fusion is functionally significant, especially given the motion available at adjacent levels and hip joints.

Future models of spinal arthroplasty will no doubt aim to replicate the elastic properties of the disc without incurring the problem of wear particles, and also will attempt to address facet joint pathology. It will take a great deal of time and carefully controlled long-term trials to determine whether or not these devices offer the best alternative for patients undergoing surgery for discogenic low back pain.

## CHAPTER 41

# Disc Herniation: Definition and Types

Tom Bendix

---

Disc herniation used to be considered as a local bulge on a disc surface, causing pressure on a nerve root. This was based largely on the fact that myelogram was the only way to establish the diagnosis. As myelogram is a highly invasive procedure, which also exposes the patient to significant radiation levels, it is considered ethically unacceptable in the examination of asymptomatic individuals. Today, computed tomography (CT) and magnetic resonance imaging (MRI) studies in asymptomatic individuals have shown that the presence of a local bulge on the disc surface certainly does not correlate convincingly with the classic symptoms of disc herniation (Fig. 41-1) (1–6).

Such studies have sparked a totally new era for this diagnosis. It is likely that disc herniation symptoms are predominantly initiated by nuclear tissue coming into physical contact with the nerve root, whereas a (local) bulge does not normally cause nerve damage (Fig. 41-1). Moreover, after a passed clinical cause the bulge consists of scar tissue, forming the morphologic “herniation” (7).

Several terms have been used to describe this condition: disc herniation, herniated nucleus pulposus (HNP), prolapse, and slipped disc are those most often used. Time has come, however, to redefine the condition as a syndrome characterized by nerve damage, primarily caused by irritation from nuclear tissue, giving rise to a production of a variety of cytokines and other inflammatory or autoimmune components (8–21), leading to secondary pressure hypersensitivity (22,23).

While lifetime prevalence of sciatica of any etiology is about 40% (24), no authors have been able to give a serious frequency of lifetime prevalence of lumbar disc herniation (LDH). This may be in agreement with the vague definitions described later in the chapter that the most frequent rough estimate is about 3% to 4%. The 1-year incidence has been estimated at 0.1% to 0.5% (25). Of patients with acute low back pain, only 1% have nerve-root symptoms (26). Age distribution has its peak close to 40, and male: female ratio is probably close to 1:1 for all

LDH, whereas for those operated upon it is 1.5:1 to 2:1 (5,27,28).

In this chapter only lumbar annular (not end plate) disc herniation is addressed.

The onset of annular rupture is usually the end point of gradual disc degeneration, which in turn seems more related to genetic issues than to physical loads (29). Of physical factors, flexion plays the greatest role, but even this factor is not impressive (30).

### DEFINITIONS

Considering the aforementioned poor correlation between clinical and imaging findings, different aspects of definitions have to be considered.

### Patho-Anatomic Types

In accordance with today’s knowledge (as discussed later in the chapter), the aspect of the nucleus being contained or not seems most relevant as the primary nerve damage is most likely associated with the inflammatory influence of free nucleus pulposus tissue on the nerve root. If nerve damage resulted primarily from pressure, it is not likely that so many silent disc herniations are seen in MRI studies. Pressure is, however, obviously important secondarily, as pressure on any inflamed structure causes pain. But as the primary lesion, pressure alone only rarely seems to be relevant (Fig. 41-2).

### Contained

The disc bulges locally, but the outermost layer is still intact. In most cases it is questionable whether this condition causes root damage, rather than referred discogenic pain. If the bulge compresses the dorsal ganglion of the intervertebral nerve root, however, it is likely that the presence of nuclear material directly touching the root

**FIG. 41-1.** The three disc herniations shown here are identical on computed tomography or magnetic resonance imaging. Clinically only the one with chemical irritation of the nerve root (**bottom, left**) produces symptoms. **Bottom right:** A healed, but now clinically silent herniation.

may not be necessary (31,32). This is substantiated by research demonstrating that the threshold for compression-induced neuronal firing is about half that for other parts of the nerve root (33). Likewise, if a chemically inactive bulge causes compression over such a wide area of the nerve root that the root suffers ischemia (33), this may also sensitize the nerve root without any chemically induced lesion (34–36) (Fig. 41-3).

It seems as if contained disc herniations or more diffuse disc herniation displacements (5,37,38) represent a

poorer prognosis as opposed to a more well-defined herniation, probably because the first condition is only a small part of a more substantial degeneration (Fig. 41-6). Some authors also divide “contained disc herniations” into “soft” and “hard” categories. Thus, pain from a primary contained disc herniation is most likely rather a “simple” discogenic pain, which causes back pain that dominates over optional leg pain. Such leg pain can be “radicular”/dermatomal in its perceived location (39), but will most often be diffuse in its distribution.

**FIG. 41-2.** The different types of disc herniations.

**FIG. 41-3.** The main basic pathology in disc herniation is inflammation. Pressure on the ganglion and ischemia (widespread compression) may also cause a primary lesion, but plays a greater role as secondary irritation when existing inflammation has caused nerve damage.

### **Complete = Protruded = Free**

The nuclear material has broken through the outermost layer of annulus fibrosus, and can be seen in the canal, and is therefore no longer contained. It is extruded from the fissure of the disc, whether or not it is in continuum with the central nuclear tissue. It is not quite clear from literature if a herniation that has passed the outermost annulus layer, but still remains subligamentous (40), is considered “free”. Those protruding through the ligament are called “transligamentous” (40).

### **Sequestered**

A free nucleus fragment, no longer in contact with the annular canal it originated from, is clinically meaningful in the interpretation of fluctuating symptoms, and during surgery.

### **“No-Bulge Herniation”**

It seems likely that some nucleus-tissue-induced nerve damage is caused by leakage of nuclear chemicals that do not physically form a bulge on the disc (Olmaker, personal communication). As with other nerve-root lesions, a mechanical component is needed to cause the leakage.

### **Radiologic Types**

Radiologically, LDH is defined as a localized bulge on a disc. Several researchers have tried to make a strict distinction between prolapse and disc protrusion by means of deciding how much of the entire intervertebral-disc circumference is taken up by the bulging “dome”. The reason why no consensus has ever been made is most likely that it has become clearer that the correlation between a certain “dome” and the clinical symptoms is small (1).

Another radiologic categorization refers to the location of the LDH on the circumference (Fig. 41-4).

**FIG. 41-4.** The location in the segment can be intraspinal (a), foraminal (b), or extraforaminal (c).

The intraspinal herniation is most often paramedian as shown on Fig. 41-4, but can be median as well. “Extraforaminal” herniation is also known as “extreme lateral”, and seems to cause a higher degree of pain than the other types (41).

### **Clinical Types**

The classic disc herniation starts after a period with only back pain, or back pain that dominates over leg pain/sciatica. When leg pain takes over and dominates, the course of a disc herniation begins (Fig. 41-5).

It may be argued that the clinical disc herniation begins with the initial back pain. However, when a period of (dominating) back pain of discogenic origin starts, it is only seldom that it is followed by a disc herniation. Moreover, dominating leg pain may follow shortly after the onset of back pain, or after months or years with back pain. Probably the short course corresponds to a single, and “clean” annular rupture, whereas a long-lasting “prodrome” may correspond to a herniation in a disc that is highly degenerated (Fig. 41-6).

**FIG. 41-5.** A typical course of a disc herniation. See text.

**FIG. 41-6.** The clinical course of a disc herniation in relation to the different stages of what happens in the disc. See text.

The distribution of leg pain usually follows the root leaving the spinal canal one level caudal to the herniation (Fig. 41-7). If the herniation is more centrally located, the root leaving two levels below will occasionally be affected. A central herniation may even damage the roots that exit several levels below, as seen in the “cauda equina syndrome” (see below). Or it may simply cause—or take part in—spinal stenosis, most often when the canal is already narrow at that level (see Chapters 1 and 48).

**FIG. 41-7.** The typical root irritations with paramedian lumbar disc herniation at various levels.

If the herniation is foraminal or extraforaminal, the nerve root taking off at the same level may be affected.

About 95% of lumbar herniations are located in the two lower discs, 5% at L3-4, and only very few above that level.

The symptoms of “cauda equina syndrome”, where several sacral roots are involved, include flatus incontinence, urinary incontinence, and groin hypoanesthesia. The influence on the vesica urticaia sphincter is most often retention. Urinary incontinence may either be seen because of retention in terms of overflow, or as a primary neurologic disturbance. Groin hypoanesthesia can be unilateral or bilateral.

#### NATURAL HISTORY

The natural course of LDH has certainly not been accurately stated (42). It varies with:

- different intensity of clinical symptoms including the degree of paresis
- coexisting pathology, particularly whether the actual disc is highly degenerated or not, but also recess or spinal stenosis, spondylolisthesis, and so forth (43)
- psychosocial factors (e.g., employment and higher social group correlates to a faster recovery) (44).

The course does not seem influenced by sex or age (44), the latter at least not with complete herniation (5).

It is problematic that the clinical courses described in various studies represent a variety of definitions of LDH, most likely including many without actual nuclear herniation. The literature makes no conclusions on an average course of the different phases.

Thus, the “about-average” natural history (described subsequently) is largely based on clinical experience, and a mixture of literature information (28,37,43,45,46). The onset of dominating leg pain is usually the period with the most intense pain. Commonly, the pain fades out to some extent after a few weeks and then tends to remain at about the same level for a total of approximately 1 to 3 months. Thereafter, the symptoms generally abate over another few months, and (almost) disappear in 50% to 70% of nonsurgical cases (28,37,46), and in about the same number of surgical cases in most reports (5,47,48), with as many as 80% to 90% in a few reports (28,49) (Fig 41-5). The remaining patients experience:

- long-lasting discogenic pain, which also tends to fade off, but over a period of some years (50,51)
- peripheral neurogenic leg pain due to root damage (52)
- domination of a central nervous system component of the pain (53).

Among these, psychosocial factors are associated with the majority of the pain (37).

Formation of a fibrous layer (54,55) is followed by a gradual reduction of the scar bulge (56) (Fig. 41-6). The rate of recurrent LDH is about 3% to 14% (54,57).

### History and Physical

Several relevant issues of the clinical examination will be presented, but not all. For further details on clinical usefulness of history and physical signs, test repeatability, and so forth see Andersson and Deyo (58), Hunt et al. (59), or Vroomen et al. (60).

From the history taking, one of the most important questions is probably whether leg pain or paraesthesia dominates over back pain or vice versa. The distribution of the leg pain—radicular or diffuse—does not allow a clear distinction between disc herniation or other causes of sciatica to be made, as diffuse sciatica has often been reported where herniation has subsequently been verified at surgery.

As paresis in gradual progress is an indication for acute surgery, this should be explored during history taking, as should possible cauda equina symptoms, where the sequence of symptoms most often is flatus incontinence, urinary retention, and groin hypoesthesia.

“Bowel strain” is also described to be reasonably indicative for herniation.

Whereas painful forward bending is highly correlated to herniation, there does not seem to be a consistent correlation with lying or sitting. Especially in the acute stage night pain is common, probably due to increased temperature and inflammation. Sitting has been thought to aggravate a herniation due to the increased intradiscal pressure (IDP), but is not often the most pain-free posture. A possible explanation could be that the advantage of more space around the herniation due to reduced lor-

dosis—or even kyphosis—caused by sitting (61) exceeds the disadvantage from a small increase in herniation size (62) (Fig. 41-8). Moreover, the increase in IDP is probably smaller than previously believed (63), and when sitting backwardly inclined with a backrest, the IDP is at least not higher than when standing (64).

Conversely, lumbar extension is generally omitted due to the reduction in the foramen size (65).

Of the physical signs, the sagittal lumbar curve in standing is also influenced by the same principle: the lumbar curvature is flattened or even kyphotic, automatically arranged by a posterior rotation of the pelvis. This is done to enable the described mechanism of optimizing the space for the nerve root. Such a kyphotic curve might also be obtained by forward bending of the trunk. However, in that case the addition of static back-muscle activity compresses the herniated disc to an uncomfortable level. Thus, erect posture with flattened or kyphotic loin, or a supported (e.g., hands on the thighs) forward bended posture is characteristic.

A scoliotic list seems only moderately correlated to operative findings (66–68). In particular, the Finneson hypothesis that a certain side location of the herniation and the nerve root should cause a specific list direction does not seem valid (67).

A painful forward bending may distinguish disc herniation from recess stenosis, where leg pain also may dominate over back pain, but where forward bending usually relieves the sciatica (69). A lateral shift—usually away from the side of the LDH—during forward bending is often seen in LDH, but does not provide much help in distinguishing between herniation or recess stenosis.

Side bending toward the opposite side of the pain usually relieves the pain (Fig. 41-8).

The straight leg-raising (SLR) test with radiating pain below knee level seems reasonably associated to disc herniation (38), although the test reliability—like that for the ranges of motion mentioned earlier—seems lower than commonly believed (59). With the surgical finding as the

**FIG. 41-8.** With reduction of the lordotic curvature, and with lateral bending, the size of the herniation increases, but the enlargement of the intervertebral foramen is even more pronounced.

“gold standard,” and without letting SLR influence the indication for surgery, the following was registered by Kosteljanetz et al. (48) (Fig. 41-9): Root compression, if present, was estimated to be caused by disc herniation in two-thirds of the patients in this study. This is the case for those patients with dominating leg pain of more than 6 weeks’ duration. It may be differently distributed in another group of patients, characterized otherwise.

The literature on SLR is confusing regarding the degree of leg angle and clinical symptoms. Some authors report that the smaller the SLR angle, the more intense the symptoms (70), whereas others do not find such correlation (71).

SLR is not very sensitizing to an extraforaminal herniation (41). The crossed SLR sign (lifting the symptom-free leg, increasing contralateral pain) seems highly correlated to LDH, especially to complete and large herniations (5,67,72).

For a herniation affecting nerve root L4—or L2-L3, which are rare—the “femoral-nerve stretch test” may be valid if carried out correctly: the patient is in a prone position and the 90° flexed knee is lifted causing hip extension. To avoid co-movements of the lumbar spine, the pelvis is fixated by pressing on the lower third of the sacral bone.

The springing test is a “segmental lordosing” pressure placed successively on all lumbar segments with the patient lying prone. If it is painful, it may indicate which segment of the leg pain originates from, and may also help to differentiate pain arising in areas such as the sacroiliac joint.

Obviously neurologic signs—altered sensibility, reflexes, muscle strength, and muscle atrophy—should be tested (refer to neurologic textbooks for more information).

Consideration of the piriformis muscle may be worthwhile. In many patients with disc herniation piriformis myositis may contribute to some of the buttock

and leg pain, especially for herniation at L5-S1, because the S1 root innervates this muscle. There has been some discussion whether leg pain is caused by “self-strangulation” in the major ischiadic foramen where swelling of the muscle causes compression of the sciatic nerve, or whether it is simply referred pain. Piriformis involvement can be tested with (a) palpating the muscle for tenderness or (b) placing the ipsilateral foot on the other knee, fixating the pelvis with the “heel of the hand” on the anterior superior iliac spine (ASIS), and then pushing the knee toward the contralateral side, and asking for stretch pain.

Dynamic testing *ad modum* McKenzie should be performed. With extension, an increase in radicular pain indicates an active herniation (73). As the herniation increases, and the foramen decreases (65), possible centralization of the pain with repeated extension indicates either that the healing has begun, or at least that the prognosis is good (74).

It seems likely that future tests may include blood samples elucidating whether or not an inflammatory process of the disc is present. Serum tested for glycosphingolipid is already optional, but its applicability in practice is still unclear (75).

## CHAPTER 42

# Disc Herniation: Imaging

Josef Assheuer and Klaus-Peter Schulitz

### PLAIN RADIOGRAPH

Following the Quebec Task Force on Spinal Disorders (1), a radiograph of the lumbar spine is of limited value in the first 7 weeks after onset of low back pain. Even with the pain radiating to the extremities with neurologic signs, radiography can delineate loss of disc height, vacuum phenomena, and calcification, as well as sclerosis of the end plates, osteophytes, and focal end plate defects. Those signs are not specific for herniation; they are hardly found in acute disc herniation.

A radiographic examination is not recommended when disc herniation is suspected. It is the main purpose of radiographic evaluation to exclude low back pain (LBP), which was specifically caused by tumors, infections, inflammatory spondylarthropathies, and fractures (2).

Functional radiographs can delineate instability. Some biomechanical studies (3) showed increased hypermobility after open discectomy at the level of operation. How-

ever, hypermobility can be found preoperatively at the same rate at the level of herniation as in adjacent levels (4–7). Postoperatively, no significant changes in hypermobility were found. Therefore, hypermobility does not seem to be a consequence of discectomy. Instability in the levels above or beneath the level of herniation is caused by increased stress in the moving segment caused by changes in motion pattern at these levels (4,5).

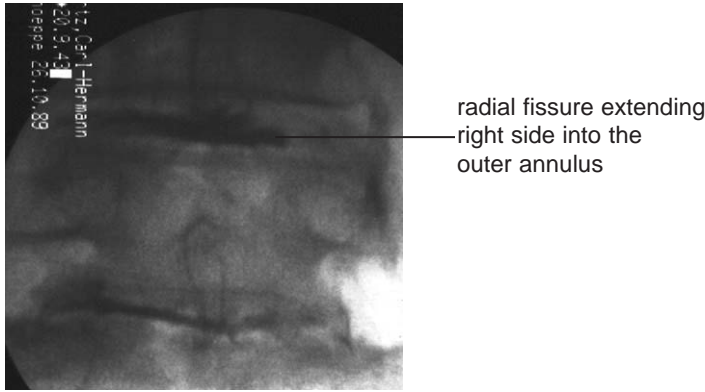

### MYELOGRAPHY

Myelogram delineates the cerebrospinal fluid (CSF) space of the thecal sac including the subarachnoidal space of the nerve roots. An indentation or occlusion of this space can be regarded as an indirect sign of disc herniation and must be differentiated from other space-occupying lesions (Fig. 42-1). Therefore, it is of minor importance for the diagnosis of herniation.

**FIG. 42-1.** **A:** The right dural poach of the nerve root L5 is not filled because of compression by a herniation (myelography antero-posterior view). **B:** The mass compressing the dural sac and poach of the L5 nerve root can not be identified. It is probably a herniation according to the position of the mass (myelography, right oblique view).

**FIG. 42-2.** Discography L4-5 antero-posterior view. The intradiscal injected contrast media extends in both levels into the outer annulus according to grade 4.

Nerve root entrapment beyond the termination of the nerve root sheath caused by lateral or foraminal disc herniation cannot be detected. High radiation exposure and invasive procedure as well as possible complications also have to be taken into account.

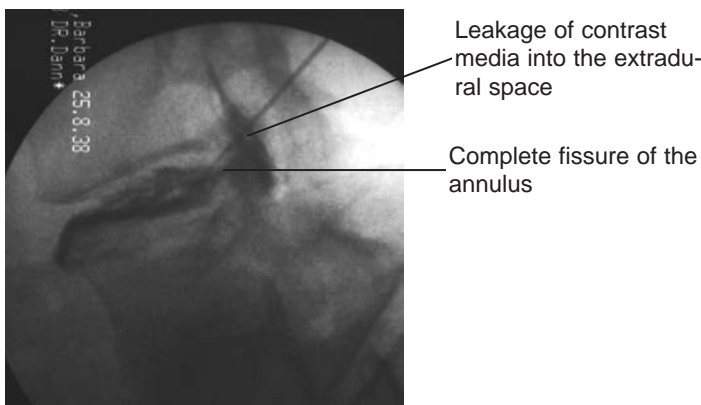

Myelography may be the only method to evaluate disc herniation and other stenosing diseases in patients having metal implants.

Functional myelography may be indicated to evaluate so-called dynamic entrapment in disc herniation in patients showing motion-dependent pain patterns. In future, functional myelography may be replaced by positional magnetic resonance imaging (MRI) (8,9).

**DISCOGRAPHY**

Discography mainly demonstrates the internal state of the disc and it is very useful to classify types of internal derangement. The contrast medium injected into the center of the disc pushes the disc matrix aside and forms pools. The locations and patterns of these pools are the criteria for the staging of disc degenera-

tion (10–12). Five different types of discograms are distinguished based on consistently identifiable features in the shape and extension of the radiopaque shadow (13,14). There are different classifications. According to the pathoanatomic classification of Adams et al. (13), type 1 does not show any signs of degeneration (cotton ball), type 2 is a mature disc with the nucleus starting to coalesce into fibrous lumps (lobular or sandwich), type 3 demonstrates a degenerated disc with fissures and clefts in the nucleus and inner annulus (irregular), type 4 is a degenerated disc with radial fissures extending into the outer edge of the annulus (fissured) (Fig. 42-2), and type 5 has complete radial fissures that allow injected fluids to escape (ruptured) (Fig. 42-3). Injection is done into at least two segments depending on the pain pattern. Herniation cannot be visualized directly but if type 4 and 5 are found, herniation is likely, especially if the contrast medium forms a pool beyond the intervertebral interspace (Figs. 42-3, 42-4). The leakage of the contrast medium beneath the posterior longitudinal ligament (PLL) is not a relevant sign for herniation. Therefore,

**FIG. 42-3.** Discography L4-5 reveals total degeneration of the disc with rupture of the annulus, allowing the intradiscal injected contrast media to escape into the epidural space according to grade 5.

**FIG. 42-4.** Discography L4-5. The rim of the herniated disc is marked by contrast media.

discography is not a relevant imaging modality to demonstrate herniation. Discography is widely used as a pain reproduction test to identify the segment causing the low back pain and sciatica. The reliability of this test is controversial because the referred pain depends to a high degree on the psychological profile of the patient (15–21).

**COMPUTED TOMOGRAPHY**

Computed tomography discriminates with high contrast between bone structures and soft tissue. High resolution computed tomography (HRCT) visualizes the subarachnoidal sac, nerve root sleeves, and ligamentum flavum (Fig. 42-5) (22). Disc material can well be detected inside and outside the spinal canal. However, CT does not differentiate between nuclear and annular tissue (Fig. 42-6). There is a high contrast between herniated disc material and epidural fat tissue (23,24). Contrast media after intravenous (i.v.) administration enhance vascular structures and delineate tissue with disturbances of the blood-tissue barrier. This is helpful in the diagnosis of vascular malformations and certain tumors such as meningiomas (25,26). Sometimes, after i.v. administration of contrast medium, a rim of enhancement is observed at the margins of the herniated disc material. This may be related to epidural veins or edema of the neighboring tissue (27,28). Swelling and displacement of ganglia and nerve roots can be visualized as well as the indentation of the dural sac (Fig. 42-7). However, swollen nerve roots and ganglia with high content of water may have the same Hounsfield Units (HU) as disc material and it may be difficult to distinguish one from the other.

**FIG. 42-5.** **A:** Computed tomography of the disc level L4-5. **B:** Computed tomography of the level L4-5 4 mm below Figure 42-5A. **C:** Computed tomography of the level L4-5 8 mm below Figure 42-5A.

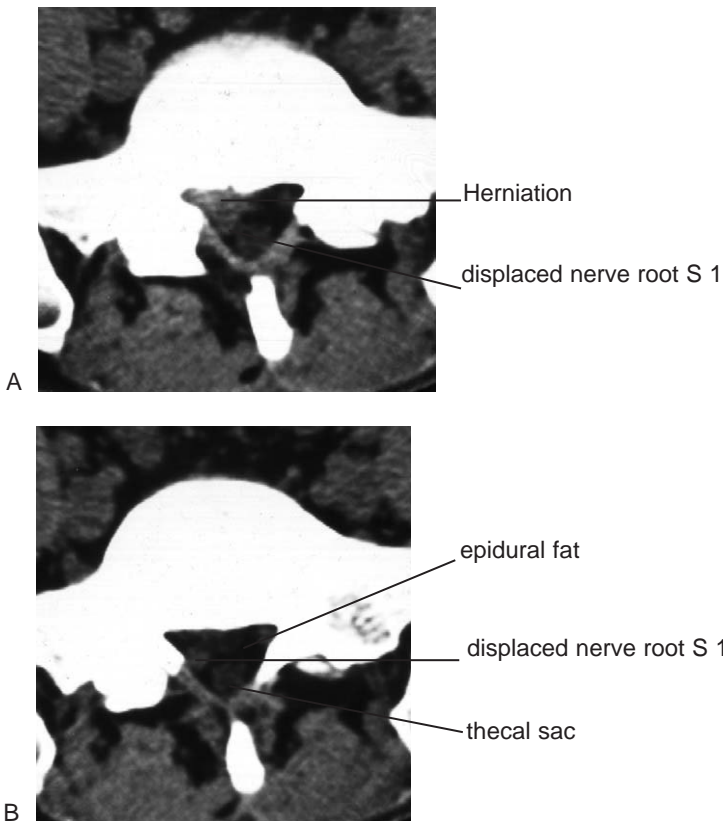

**FIG. 42-6.** By computed tomography herniation is delineated as focal extension of the disc. Differentiation between nucleus and annular tissue as well as between protrusion and extrusion is not possible.

Multiplanar reconstruction is helpful in these cases, especially with foraminal disc herniations (23,29).

Conjoined nerve roots occurring on the L5-S1 level are likely to have the same attenuation as disc material and may be misinterpreted as a disc herniation (30,31). An accurate analysis of successive CT slices demonstrates this anatomic variant. It can be seen how two nerve roots outside the dura join the same dural sheath cranially. Both nerve roots occasionally leave the spinal canal by the same neuroforamina (32). The process is unilateral. A rounded lateral recess is always found with it. Intrathecal administration of contrast media verifies the diagnosis,

showing the common dural recess (33). This anomaly was found in 2% of the cases within a CT study, and in 14% within an autopsy series (32).

Most hematomas of the lumbar spine are located epidurally or subdurally. They may be confounded with disc herniations. The epidural mass has indistinct margins and extends over the surface of a vertebral body, being largest at the mid-vertebral level. The hematomas are isodense with the thecal sac and are indistinguishable from the nerve root and ganglia. They may arise from a tear of the fragile epidural veins because of disc disruption. Computed tomography follow-ups show a regression of

**FIG. 42-7. A:** Computed tomography of the level L5-S1. A right side disc herniation displacing the right nerve root S1 dorsally. The nerve root is nearly indistinguishable from the herniated disc material. **B:** Computed tomography of the level L5-S1 3 mm beneath the level of Figure 42-11A. The displaced nerve root is delineated by the surrounding epidural fat of low density.

**FIG. 42-8. A:** Differentiation between scar tissue and possible reherniation is not possible (computed tomography native at the level L4-5). **B:** The enhancement of the intraspinal mass after intradiscal administration of contrast medium reveals reherniation and differentiation from scar tissue (computed tomography discography at the level of L4-5).

hematomas with the underlying disc herniation remaining (34–36). Epidural and subdural hematomas also may originate from hematologic disorders, hypertension, and atherosclerotic vascular diseases (36–38).

Because of their location, synovial cysts and synovial ganglia of degenerated facet joints may mimic disc fragments. They are broad-based to the zygapophyseal joint, mostly rounded, emerging into the central canal or subarticular recess. The mass may exhibit internal gas or a calcified rim (39–42). The thickened and protruding ligamentum flavum and capsule are isodense with the disc and may cause diagnostic problems. Injection of contrast media into the relevant facet joint shows the communication of the cyst with the joint space (43). Occasionally cysts can also emerge out of a degenerated disc and are difficult to differentiate from herniation. They may result from resorption or mucoid degeneration of an already existing herniation (44).

Perineural cysts (45), occurring beneath the perineurium at the level or beyond the dorsal root ganglion, and subarachnoid cysts (cystic nerve root sleeve dilatation or meningeal diverticulum) (46) located proximally to the nerve root ganglion, should not be misinterpreted as herniation. They can be distinguished from herniation when the pressure erosion of the surrounding bone is regarded and contrast medium is filled in after intrathecal administration (47,48).

Nerve sheath tumors may be confounded with lateral herniations and because of their locations are only Schwannomas (49).

The main question with postoperative backaches (failed back surgery syndrome) is to find out whether the nerve root compression results from reherniation or scar tissue, especially epidural fibrosis. Native CT is not suitable to answer this question (Fig. 42-8) (50). It shows

both scar tissue and reherniated disc material with identical density. The location of both processes does not permit discrimination either, because scar tissue normally extends epidurally and laterally to the posterior aspect of the operated disc (51,52). Therefore, CT discography is necessary to clarify this condition (Fig. 42-8). If postoperative spine hemorrhage and noninfectious inflammatory processes arise, they can be well visualized. Contrast enhancement of scar tissue depends on the time that passed between operation and CT examination with older scar enhancing less. Nevertheless, the diagnosis improves by 20% up to 3 years after operation (53,54).

#### **PATHOMORPHOLOGIC DEFINITIONS AND NOMENCLATURE OF DISC HERNIATION**

The grading of disc herniation mainly depends on the internal disarrangement of nucleus and annulus; the displacement of nuclear material is the most important feature.

Resnick and Niwayama (55) and other authors (56) propose the following schema for disc herniation:

*Annular bulge:* Annular fibers are intact and the disc protrudes beyond the intervertebral interspace around the end plate (Fig. 42-9).

*Protrusion:* Nuclear material protrudes through torn fibers of the annulus, with the outermost fibers remaining intact (Fig. 42-6).

*Extrusion:* The nuclear material penetrates all of the fibers of the annulus fibrosus and lies under the PLL (Fig. 42-10).

*Discal sequestration:* The nucleus material penetrates the posterior longitudinal ligament (PLL) and lies within the epidural space or the nucleus material does not

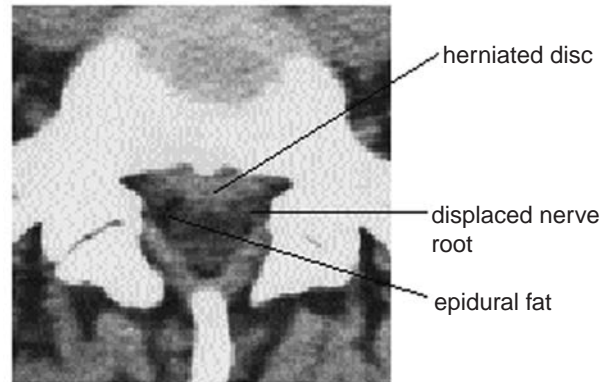

**FIG. 42-9.** Computed tomography at the border of the disc L3-4 to the vertebra L4. The disc exceeds symmetrically and uniformly the contour of the margin of the vertebra.

**FIG. 42-10.** Computed tomography of the level L5-S1. The extruded disc material is clearly depicted. Possible rupture of the posterior longitudinal ligament cannot be visualized.

**FIG. 42-11.** Computed tomography of the level L4-5 (bony window). A bony fragment has extruded together with disc material into the subligamentous space of a 15-year-old trampoliner jumper.

**FIG. 42-12.** Computed tomography of the level L5-S1. The herniation has displaced the left nerve root S1 dorsally. The epidural fat on the left side has nearly disappeared.

A

B

penetrate the PLL and migrates beneath the PLL cranially or caudally as a fragment and is separated from the remaining portion intervertebral disc.

The schema proposed by Herzog (57) is more related to practical experience concerning protrusion and extrusion.

Protrusion is a herniation of disc material and not only nuclear material. It results in a focal contour abnormality of the disc margin (Fig. 42-6).

Extrusion means penetration of the outer annulus of any disc material, including possible bony fragments (Figs. 42-10, 42-11). This material may remain beneath the PLL and is called subligamentous extrusion. If it penetrates through the PLL it is called transligamentous extrusion. Once the extruded material loses contact with the parent disc, it is called a sequestered disc fragment, which can be transligamentous or subligamentous.

Because CT examination cannot discriminate between nuclear and disc material or outer annular fibers and PLL (Fig. 42-10), the pathomorphologic schema should be used only with restrictions.

Bulging occurs when the disc symmetrically and uniformly exceeds the contour of the margin of the vertebra (Fig. 42-9) (22,58,59). The differentiation between protrusion and extrusion as well as subligamentous and transligamentous extrusion is uncertain (Fig. 42-10). A distinct focal extension of disc material of remarkable volume and clear lateral position is probably an extrusion. A protrusion normally has a broader base with regard to its extension (Fig. 42-12) (60). A sequester has to be assumed when there is clear loss of continuity of extruded disc material in successive slices. Reformatting of the axial slices into sagittal orientated views are helpful in demonstrating a sequestered extrusion. Therefore, a CT description of herniation is mainly restricted to the localization of the herniated material. This may be central, lateral, intraforaminal, and extraforaminal and can extend into cranial and caudal direction. The extent of herniated disc material is better visualized by CT discography (Fig. 42-13). The relation of disc herniation contact and displacement to the nerve root can be depicted.

### COMPUTED TOMOGRAPHY DISCOGRAPHY

To get more information about the pathoanatomy of the degenerative disc, discography may be followed by CT examination (12,61–64). When performing a CT immediately after discal injection, the annular fissures are mainly filled with contrast media. When a CT 4 to 6 hours after the injection is performed, mainly the nuclear material is stained. On the base of the discography grading (13,14), it may be useful for CT discography-staging to subdivide type 4 into a, b, and c, where in (a) the derangement extends to less than half of the cross-section

**FIG. 42-14.** CT-discography of L4-5. Patches of enhancement of contrast media in internal disc disruption. No herniation.

of the disc; (b) the unstained annulus amount is still one third of the disc radius; and (c) the contrast medium extends to the outer fibers of the annulus (Fig. 42-14). Leakage is possible in this case (Fig. 42-15). Type 5 is also subdivided into a, b, and c groups, where (a) means protrusion (Fig. 42-16); (b) subligamentous extrusion (Fig. 42-17); and (c) transligamentous extrusion (Fig. 42-18). Types 5 b and c include sequestration (63,65). Small and broad-based disc herniation can be defined (66). The amount of contrast-medium uptake in the herniated portion can be evaluated (67). Because of the high information value, CT discography is regarded as golden standard in evaluating disc degeneration and herniation for other imaging procedures.

**FIG. 42-15.** CT-discography of the level L5-S1. Axial view in the upper part of the image and sagittal reconstruction in the lower part. The leakage may mimicry straining of sequestered disc herniation.

**FIG. 42-16.** CT-discography of the level L4-5. The intradiscal applied contrast media extends with a broad base to the dorsal border of the disc according to type Va.

**FIG. 42-17. A:** Computed tomography of the level L5-S1. The herniation has uncertain defined limits. Distinction from nerve root is not possible. **B:** CT-discography of the level L5-S1 displayed in the soft-tissue window defines clearly the border of the extruded disc material. **C:** CT-discography of the level L5-S1 displayed in the bony window. The bony structures are better defined CT-discography.

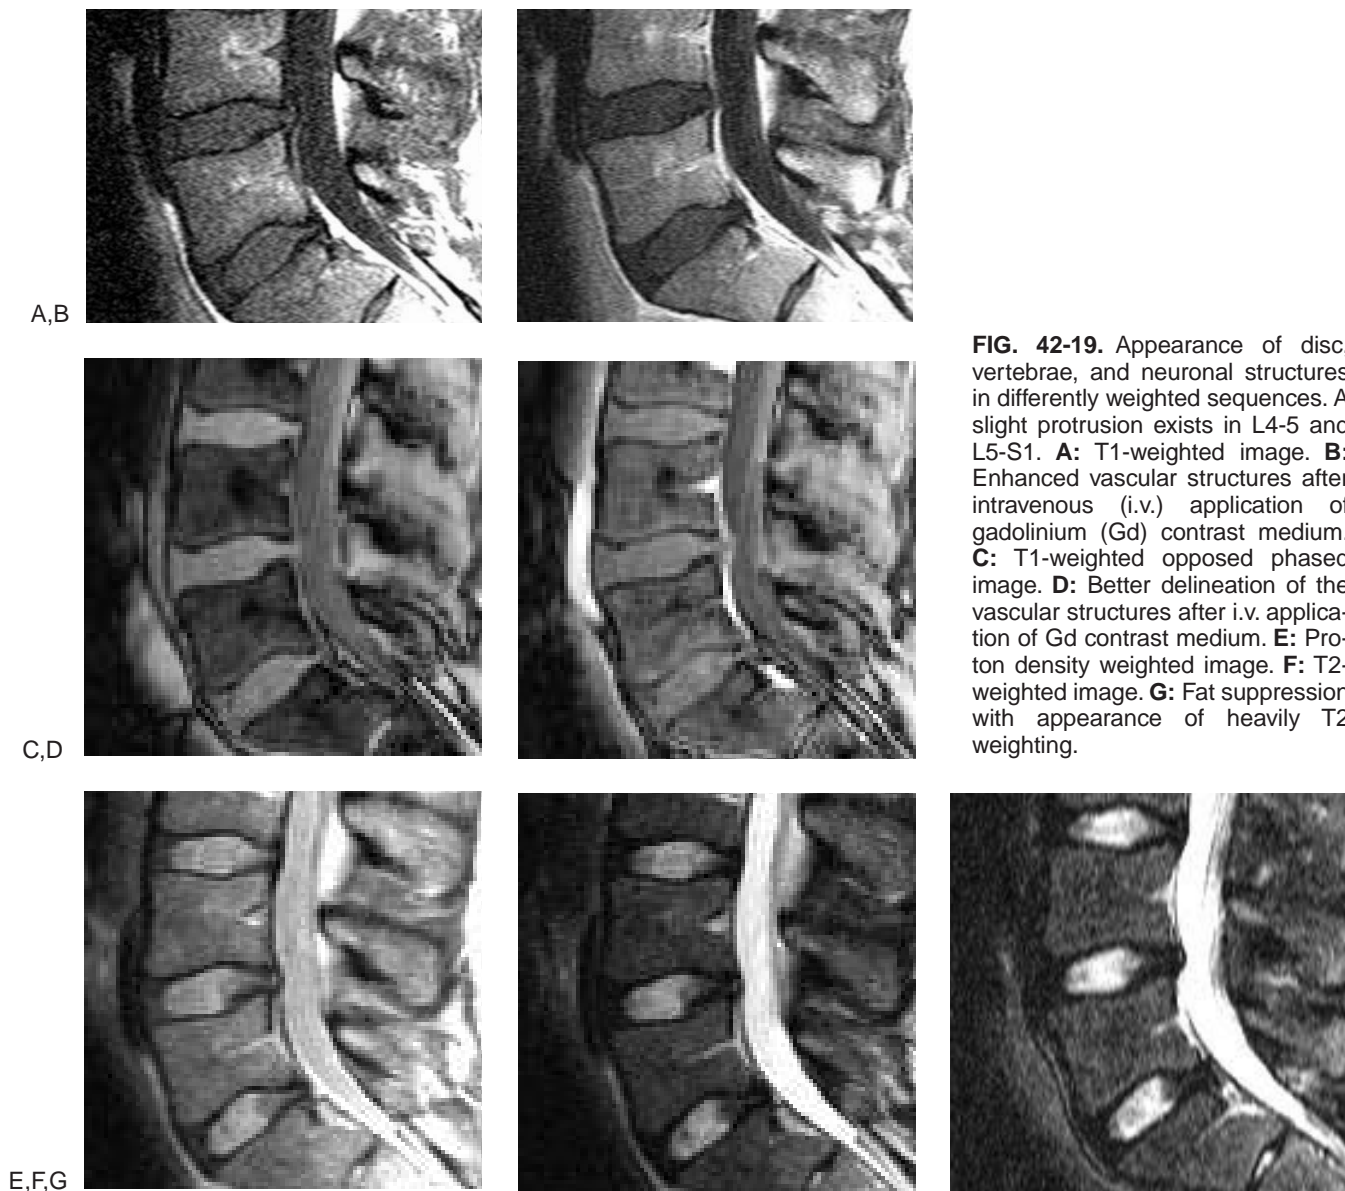

**FIG. 42-18.** CT-discography L4-5 displayed with soft-tissue window shows a transligamentous extrusion with staining of the disc material. The extruded annulus material has less uptake of contrast media.

## MAGNETIC RESONANCE IMAGING

Up to now, MRI has become the most frequently used method to depict disc herniation. In contrast to CT, MRI can directly produce slices in every chosen plane. In CT as in all X-ray modalities, the electron density is the contrast-determining parameter. In MRI there are at least three intrinsic parameters (proton density, spin-spin, and spin-lattice relaxation) with a multitude of extrinsic parameters (echo-time (TE), repetition-time (TR), inversion-time (TI), flip angle, field-strength, receiver-coils, etc.).

This allows to show the different spinal tissues with remarkable different signal intensities and results in high contrasts (Fig. 42-19). The nucleus, which is indistinguishable from the annulus in T1-weighted images, becomes very bright in strongly T2-weighted images. The

annulus, ligaments, and nerve roots with fiberlike structures are bright in gradient-echo sequences, out of phase, and T1-weighted and dark in T1- and T2-weighted SE-images. Epidural and intraforaminal fat appears very bright in T1-weighted images and less bright in T2-weighted images. It is dark with fat-suppression techniques. Cerebrospinal fluid has very low signal intensity on T1-weighted images and gets higher signal intensity with more T2 weighting. Because of identical values for T1 and T2 relaxation as for proton density, it is impossible to differentiate the outer annulus PLL complex. The resolution is equal to high-resolution CT. Inherent artifacts, mainly chemical shift (68) and pulsation, have to be considered because they can affect morphometric and signal intensity analysis. For signal intensities are no absolute values, ratios of the signal intensity of interest-

**FIG. 42-19.** Appearance of disc, vertebrae, and neuronal structures in differently weighted sequences. A slight protrusion exists in L4-5 and L5-S1. **A:** T1-weighted image. **B:** Enhanced vascular structures after intravenous (i.v.) application of gadolinium (Gd) contrast medium. **C:** T1-weighted opposed phased image. **D:** Better delineation of the vascular structures after i.v. application of Gd contrast medium. **E:** Proton density weighted image. **F:** T2-weighted image. **G:** Fat suppression with appearance of heavily T2 weighting.

ing tissue to the signal intensity of a reference tissue, are used to describe physiologic or pathologic changes; for example, the change of signal intensity of the aging or degenerated disc. Cerebrospinal fluid, adjacent vertebral marrow, or intensity of the nucleus of obviously normal disc segments mostly are taken as reference tissues (69–73). Because of the multitude of parameters that influence tissue contrast, there is no commonly accepted protocol for image-based investigation of the lumbar spine. T1- and T2-weighted images are included in most studies. The guidelines for quality control of the German Board of Medicine (Bundesärztekammer) list the spinal structures that have to be delineated and require in-plane resolution of  $1 \times 1.5$  mm with a slice thickness less than 4 mm (74).

Different classification systems are used to describe the degeneration process of the disc. The used parameters are the signal intensity of the nucleus, which decreases with growing age and degeneration, and the height of the intervertebral interspace. There is no commonly accepted procedure to determine stages of the intervertebral disc degeneration. Classification schemata, as proposed by Battié (69) and Pfirrmann (72), include the signal intensity of the nucleus, disc height, and morphologic description of the nucleus, and seem to be most appropriate to evaluate the degree of degeneration.

Herniated material may contain nuclear, annular, and end plate tissues. The classification schema of Brant-Zawadzki (60) for herniation, which is purely based on

morphologic criteria, is widely accepted. These authors give the following definitions:

*Normal:* No disc extension beyond the interspace

*Bulge:* Circumferential extension beyond the interspace (Fig. 42-20). If a spondylolisthesis occurs, the axial images can lead to misinterpretation of the disc fixed on the upper end plate, and the adjacent non-dislocated vertebra as protrusion (pseudoprotrusion) (Fig. 42-21).

*Herniation:* Any focal extension beyond the interspace.

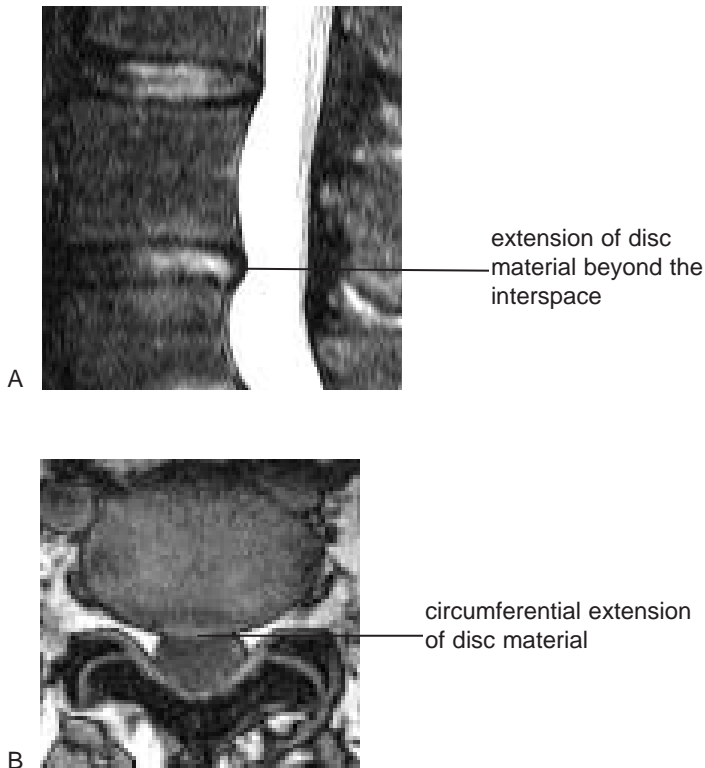

Subdivisions:

(a) *Protrusion:* Focal or asymmetric extension beyond interspace into the canal, base is broader than any other diameter of the protrusion (Fig. 42-22);

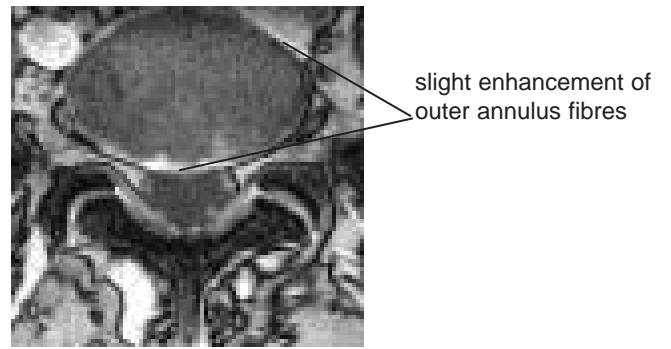

(b) *Extrusion:* Focal, obvious extension beyond interspace; the base against the parent disc is narrower than the diameter of the extruding material itself, or there is no connection to parent disc at all (Fig. 42-23).

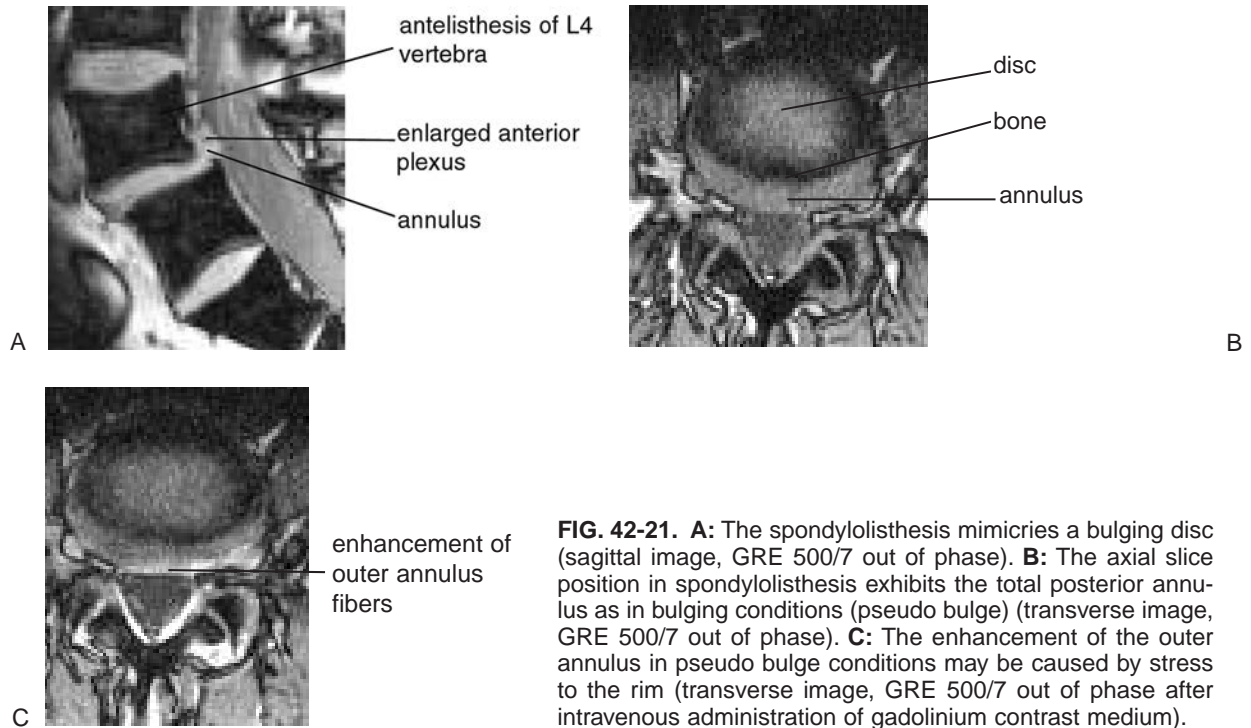

To eliminate a false-positive diagnosis it seems important not to use the global term “herniation,” but rather its subgroups.

The subdivisions of extrusion in transligamentous and subligamentous herniation as described by Herzog (57) are not included in the preceding schema, probably because of the difficulty of depicting the outer annulus PLL complex. An exact differentiation between these two subgroups can only be done when the rupture of this complex is clearly demonstrated (75,76). For the same reason, differentiation between protrusion and

**FIG. 42-20.** **A:** The bulging disc slightly dents the dural sac (sagittal image, STIR 2000/150/20). **B:** The convex shape of the disc is characteristic for bulging disc (transverse image, GRE 500/7 out of phase). **C:** We report the enhancement of the outer annulus fibers to the elevated tension of the annulus (transverse image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium).

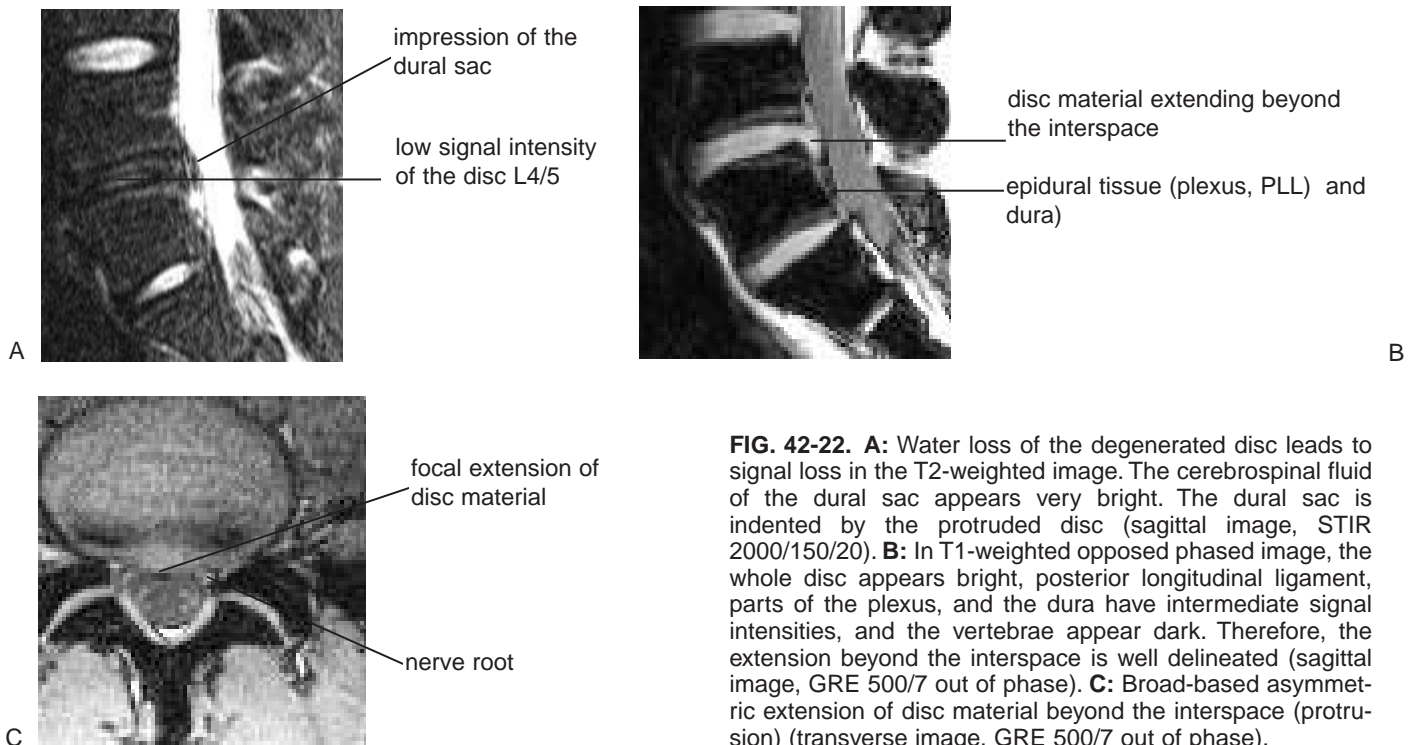

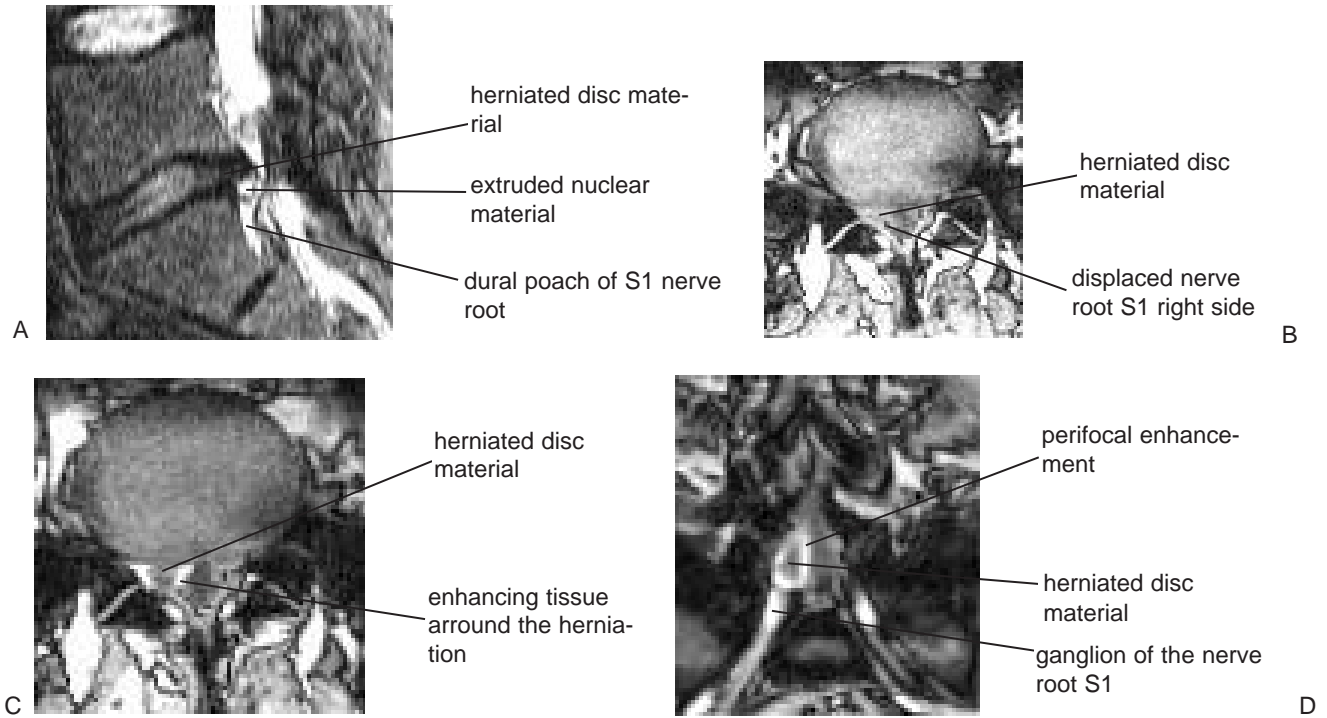

**FIG. 42-21.** **A:** The spondylolisthesis mimics a bulging disc (sagittal image, GRE 500/7 out of phase). **B:** The axial slice position in spondylolisthesis exhibits the total posterior annulus as in bulging conditions (pseudo bulge) (transverse image, GRE 500/7 out of phase). **C:** The enhancement of the outer annulus in pseudo bulge conditions may be caused by stress to the rim (transverse image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium).

extrusion may be difficult (60). Extrusion is more likely if the herniated material contains nuclear fragments with high signal intensity on T2-weighted images (Fig. 42-23). With older extrusions, the nuclear fragment tends to become dark by resorption and des-

iccation (76,77). There may be different opinions when defining a bulge or protruded disc (77). The divergence from the concentric contour cannot be clearly identified in every case. Foraminal and extraforaminal herniations are difficult to classify into protrusion and extru-

**FIG. 42-22.** **A:** Water loss of the degenerated disc leads to signal loss in the T2-weighted image. The cerebrospinal fluid of the dural sac appears very bright. The dural sac is indented by the protruded disc (sagittal image, STIR 2000/150/20). **B:** In T1-weighted opposed phased image, the whole disc appears bright, posterior longitudinal ligament, parts of the plexus, and the dura have intermediate signal intensities, and the vertebrae appear dark. Therefore, the extension beyond the interspace is well delineated (sagittal image, GRE 500/7 out of phase). **C:** Broad-based asymmetric extension of disc material beyond the interspace (protrusion) (transverse image, GRE 500/7 out of phase).

**FIG. 42-23. A:** Obvious compression of the dural poach of the nerve root S1 by herniated disc material. The herniated nuclear material has penetrated the outer fibers of the annulus (sagittal image, STIR 2000/150/20). **B:** The herniated disc obstructs the recessus S1 on the right side and displaces the nerve root (transverse image, GRE 500/7 out of phase). **C:** The uptake of contrast medium in the tissue adjacent to the herniation is caused by edema or hypervascularization (transverse image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium). **D:** Coronal image may be helpful in delineating extension and position of the herniation with regard to the neuronal and bony structures (coronal image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium).

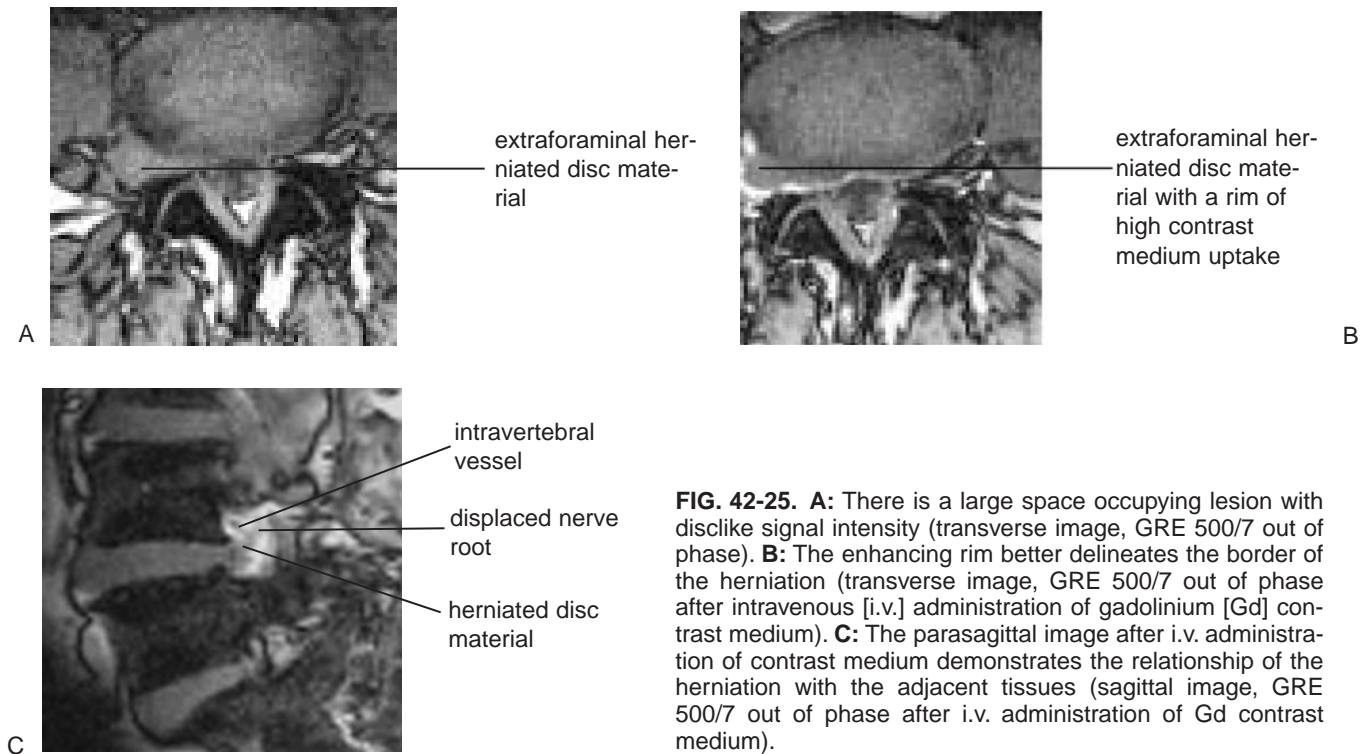

sion, especially when nuclear material inside the herniation cannot be depicted (Figs. 42-24, 42-25). Sequestered intervertebral discs are well delineated by sagittal images (Fig. 42-26)(78).

The relationship of herniation and the neurovascular structures is of major clinical importance. The contact of

the herniation with the nerve root and its possible deviation, mostly posteriorly, is well visualized in T1- and T2-weighted axial images. The term “nerve root compression” (79–81) does not seem to be adequate for these two conditions and is not convincingly presented in published images.

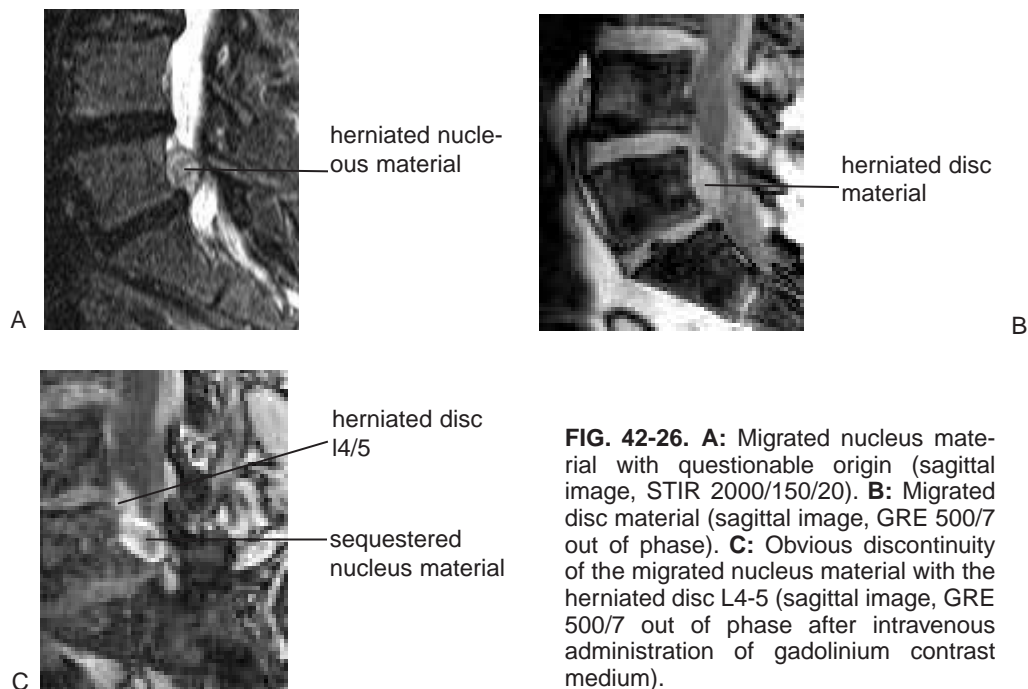

**FIG. 42-24. A:** The degenerated disc L4-5 extends laterally into the neuroforamina. Nerve root, intervertebral vessels, and intraforaminal fat cannot be differentiated by this sequence (sagittal image, GRE 500/7 out of phase). **B:** The coronal image after intravenous application of gadolinium (Gd)-contrast medium differentiates better between the affected nerve root and the intraforaminal herniation (coronal image, GRE 500/7 out of phase after intravenous administration of Gd contrast medium).

**FIG. 42-25. A:** There is a large space occupying lesion with disclike signal intensity (transverse image, GRE 500/7 out of phase). **B:** The enhancing rim better delineates the border of the herniation (transverse image, GRE 500/7 out of phase after intravenous [i.v.] administration of gadolinium [Gd] contrast medium). **C:** The parasagittal image after i.v. administration of contrast medium demonstrates the relationship of the herniation with the adjacent tissues (sagittal image, GRE 500/7 out of phase after i.v. administration of Gd contrast medium).

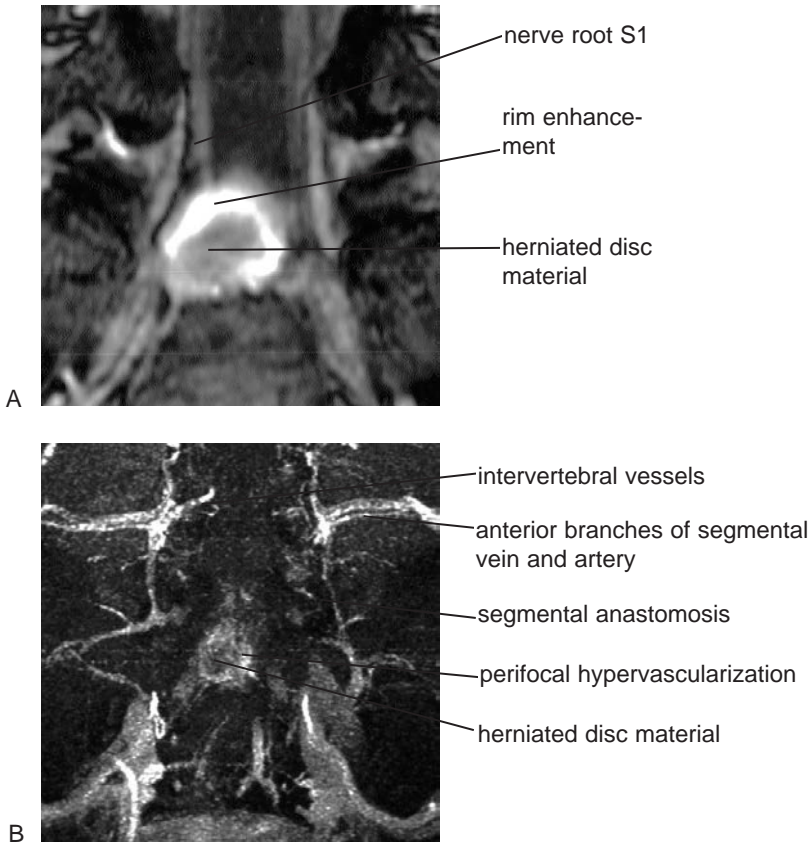

The effect of disc herniation on neurovascular structures may be visualized as swelling of the nerve root, possibly caused by edema. This effect is better demonstrated by enhancement after i.v. administration of gadolinium (Gd) contrast media (82–89). Enhancement is nearly always seen at the rim of the herniation (90,91). This is

caused by neurovascularization. Together with dynamic examination, MR angiography allows the separation of vascularization from edema (Fig. 42-27) (92–94). Also, the venous stasis of the anterior venous plexus caused by the herniation that obstructs the spinal canal can be visualized (83,95).

**FIG. 42-26. A:** Migrated nucleus material with questionable origin (sagittal image, STIR 2000/150/20). **B:** Migrated disc material (sagittal image, GRE 500/7 out of phase). **C:** Obvious discontinuity of the migrated nucleus material with the herniated disc L4-5 (sagittal image, GRE 500/7 out of phase after intravenous administration of gadolinium contrast medium).

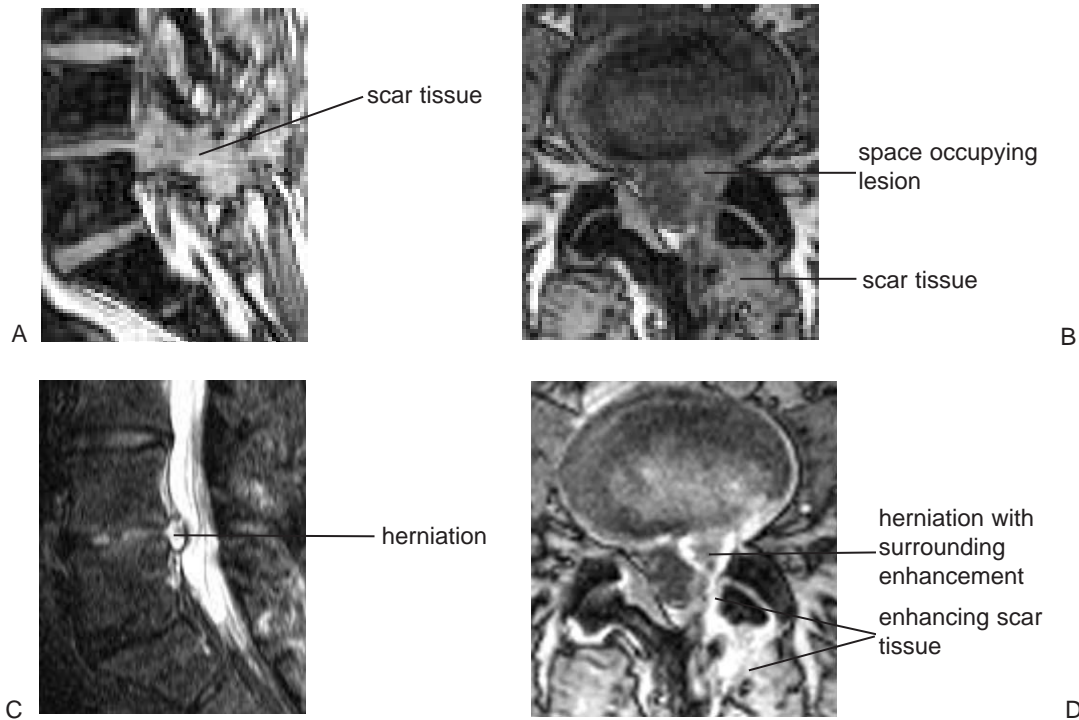

**FIG. 42-27. A:** The enhanced rim represents perifocal edema or vascularization (coronal image, GRE 500/7 out of phase after intra-venous administration of gadolinium contrast medium). **B:** The arterial phase of angiography demonstrates the hypercapillarization of the perifocal tissue.

**FIG. 42-28. A:** Scar tissue appears with lower signal intensity than the normal ligamentum flavum at the oppo-site side (transverse image, GRE 500/7 out of phase). **B:** Scar tissue has high uptake of contrast medium and bet-ter delineation of the affected nerve root.

**FIG. 42-29.** **A:** Recurrent low back pain 9 months after discectomy. Epidural scar tissue with suspicion of reherniation (sagittal image, GRE 500/7 out of phase). **B:** The reherniated nucleus appears very bright in T2-weighted images, indicating recent herniation (sagittal image, STIR 2000/150/20). **C:** Foreign mass on the left side compressing dural sac (transverse image, GRE 500/7 out of phase). **D:** After intravenous (i.v.) administration of gadolinium (Gd) contrast medium, the reherniation is demarked by a rim of high enhancement (transverse image, GRE 500/7 out of phase after i.v. administration of Gd contrast medium).

Shortly after discectomy, scar tissue appears dark in T1- and bright in T2-weighted images because of its high water content. It appears enhanced after i.v. administration of Gd-contrast media (Fig. 42-28) (96,97). Gradually, scar tissue becomes brighter in T1- and darker in T2-weighted images. The enhancement of contrast does not change much. Differentiation of recurrent herniation and scar tissue can be difficult when the herniated disc material also enhances by ingrowth of vascular structures. Normally, the herniated material does not enhance (Fig. 42-29). The usefulness of Gd-contrast media is doubtful when the high resolution fast spin-echo sequences are used along with proton density-weighted images (98).

T1-weighted images before and after Gd-contrast application are not sufficient to investigate the origin of reappearing pain in the early postoperative period. In such cases, retrodiscal infection has to be taken into account. T1-weighted out-of-phase sequences before and after Gd administration show the inflammatory tissue with high enhancement (Fig. 42-30). Possibly re-herni-

ated disc material appears brighter than any possible abscess (Fig. 42-31) (99).
